stimulation. For example, short bursts (1 s) of electrical stimulation of sympathetic nerves at low frequency (2–5 Hz) favor ATP release whereas longer periods of nerve stimulation (30 s or more) favor NA release.

Peptides, purine nucleotides, and NO (identified by localization of nitric oxide synthase (NOS)) are often found together with the classic neurotransmitters, NA and ACh. In fact, the majority of nerve fibers in the ANS, if not all, contain a mixture of different neurotransmitter substances that vary in proportion in different tissues and species and during development and disease. The widespread use of double and triple immunohistochemical labeling techniques has been critical to the demonstration of co-localization of potential cotransmitters within the same nerve fiber and has been invaluable when combined with electron microscopy. Different neurotransmitters within the same varicosity may be localized in the same or separate vesicular populations using post-embedding colloidal gold techniques. In the gastrointestinal tract, many neurons contain multiple transmitters. ATP is a cotransmitter with calcitonin gene-related peptide (CGRP) and substance P (SP) in many sensory–motor nerves and with NO and VIP in enteric NANC inhibitory nerves. Transmitters with seemingly diverse and opposing effector action are sometimes co-localized in the same neuron, but generally they act in the same way and usually synergistically.

The precise combinations of neurotransmitters (and neuromodulators) contained in individual neurons and their projections and central connections, termed their 'chemical coding' by Furness and Costa in 1997, has been defined in studies of the enteric nervous system and peripheral autonomic and sensory ganglia.

Neurotransmission at the sympathetic neuroeffector junctions: Evidence for co-release and roles of NA, ATP, and neuropeptide Y It is now recognized that the main neurotransmitters/neuromodulators in postganglionic sympathetic nerves are NA, ATP, and neuropeptide Y (NPY). These substances are co-released in varying proportions, depending on the tissue and species, and also on the parameters of stimulation. Short bursts at low frequency particularly favor the purinergic component whereas longer periods of nerve stimulation favor the adrenergic component, and NPY release is optimal with high-frequency intermittent bursts of stimulation. A considerable variability in the contribution of a purinergic component to sympathetic neurotransmission has been demonstrated in different blood vessels; for example, rabbit saphenous and mesenteric arteries have a substantial purinergic component, whereas in the rabbit ear artery, the purinergic component is relatively small. In intestinal submucosal arteries, the responses to sympathetic nerve stimulation are mediated solely by ATP, with NA acting as a prejunctional modulator via α_2-adrenoceptors. The initial electrophysiological postjunctional response to sympathetic nerve stimulation is a rapid, transient EJP, which is mediated by ATP. In some vessels, the EJP is followed by a slow depolarization, which is mediated by NA. Postjunctionally, the effects of ATP and NA released as sympathetic cotransmitters are generally synergistic. NA and ATP can depress sympathetic neurotransmission by prejunctional modulation, via α_2-adrenoceptors or predominantly via P1 receptors following extracellular breakdown to adenosine, but also via P2 receptors in some vessels. Prejunctional P2 receptor-mediated increase in NA release has also been reported.

In most tissues, including the vas deferens and many blood vessels, NPY does not act as a genuine neurotransmitter, having little direct postjunctional action, but rather acts as a neuromodulator, often by prejunctional attenuation of NA and ATP release

and/or postjunctional potentiation of responses to adrenergic and purinergic components of sympathetic nerve responses. In tissues in which NPY does have a direct vasoconstrictor effect, such as in blood vessels of the spleen and kidney and in coronary and cerebral arteries, the response is characteristically slow in onset and long lasting.

Other substances localized within sympathetic nerves include 5-hydroxytryptamine (5-HT), which is largely taken up by sympathetic nerves and released as a false transmitter. Opioid peptides are also widely distributed in sympathetic neurons where their functional role appears to be related to their prejunctional inhibitory effects on sympathetic neurotransmission.

Neurotransmission at the parasympathetic neuroeffector junctions: The atropine-resistant components of parasympathetic neurotransmission ACh, VIP, ATP, and NO are cotransmitters commonly synthesized in and released from parasympathetic nerves. As with sympathetic cotransmission, the relative functional importance of the cotransmitters in parasympathetic neurotransmission is variable in different tissues and species. For example, NO may be the main mediator of neurogenic vasodilation in cerebral vessels, whereas VIP may be of more importance during neurogenic vasodilation in the pancreas. The coordinated roles of VIP and ACh in parasympathetic neurotransmission were demonstrated in an elegant study of the cat exocrine salivary gland innervation. It showed that VIP and ACh were stored in separate vesicles in the same nerve terminal and were both released on transmural nerve stimulation, but with different stimulation parameters. ACh was released during low-frequency stimulation to increase salivary secretion from acinar cells and to elicit some minor dilatation of blood vessels in the gland. At high stimulation frequencies, VIP was released to produce marked dilatation of the blood vessels in the gland and to act as a neuromodulator postjunctionally on the acinar gland to enhance the actions of ACh and prejunctionally on the nerve varicosities to enhance the release of ACh. ACh was also found to have an inhibitory action on the release of VIP. VIP has since been shown to have a direct vasodilatory action in the submandibular gland in man. PACAP also seems to be present in VIP-containing parasympathetic nerves. NOS is often co-localized with ACh and VIP in parasympathetic nerves innervating blood vessels. Postganglionic nerves from pelvic ganglia containing VIP, ACh, and NOS project to the urethra, colon, and penis. The human bladder body receives a dense parasympathetic innervation comprised predominantly of ACh-containing nerves. In the rodent bladder, ATP is a major cotransmitter in these nerves. However, only a small purinergic component is present in human bladder, except in pathological conditions (discussed later).

Neurotransmission at sensory–motor neuroeffector junctions: The roles of SP, CGRP, and ATP The motor function of sensory nerves, whereby antidromic impulses down collateral fibers result in local release of sensory neurotransmitters, is widespread in autonomic effector systems and forms an important physiological component of autonomic control. To distinguish these nerves from the other subpopulation of afferent fibers that have an entirely sensory role and have terminals containing few vesicles and a predominance of mitochondria, they have been termed 'sensory–motor' nerves.

SP and CGRP are cotransmitters in many unmyelinated, primary afferent nerves. They often coexist in the same large granular vesicles in capsaicin-sensitive nerve terminals. The proportions of coexistence of SP and CGRP vary with species; for example, in the guinea pig, most sensory neurons containing CGRP also contain SP, but in the rat, about 50% of CGRP-containing neurons do not contain SP. In the vasculature, unlike CGRP, SP does not appear to act directly on receptors of the vascular smooth muscle but rather acts via occupation of receptors on endothelial cells lining the lumen to bring about NO release and consequent vasodilation. This action of neurally released SP may be particularly important in the microvasculature, but access of neurally released SP to the endothelium in large vessels is questionable; it is largely released from endothelial cells to act on receptors on endothelial cells to release NO, resulting in vasodilation. ATP is now also established as a cotransmitter with glutamate in small primary sensory nerves mediating mechanical and/or nociceptive signals.

Other neuropeptides and transmitters have been localized in sensory–motor nerves. For example, in the human urinary bladder, VIP, cholecystokinin (CCK), and dynorphin (DYN) are present, together with SP and CGRP, in the afferent projections to the lumbosacral spinal cord. In the guinea pig, dorsal root ganglion neurons containing SP, CGRP, CCK, and DYN project to the epidermis and small dermal blood vessels. NOS has been localized in populations of primary sensory neurons of trigeminal and dorsal root ganglia. Endothelin, a potent vasoconstrictor peptide with mitogenic actions, is also localized in neurons of these sensory ganglia, often co-localized with SP.

There are increasing examples in the literature of cross-talk between sensory–motor, sympathetic, and parasympathetic nerves. In the heart, SP has

excitatory effects on cardiac parasympathetic innervation, in contrast to CGRP, which is inhibitory.

Neurotransmission involving intrinsic neurons: Special reference to neurotransmitters localized in nerve cell bodies in the heart, bladder, intestine, and lung
Many intrinsic neurons localized within autonomic neuroeffector tissues are part of the postganglionic parasympathetic system, but there are also intrinsic neurons derived from neural crest tissue that is different from that which forms sympathetic and parasympathetic neurons, such as intrinsic neurons abundant in the gut and possibly subpopulations in the heart and airways.

The most extensive system of intrinsic neurons is in the myenteric and submucous plexuses of the gastrointestinal tract. These enteric neurons contain numerous neuroactive substances, of which the majority are involved in neurotransmission or neuromodulation at the ganglion level and/or have a trophic role; only a small percentage are involved in neuromuscular transmission. The chemical coding of enteric neurons has been examined in detail, particularly in the guinea pig. ATP, NO, and VIP mediate NANC inhibitory neurotransmission in the gut in varying proportions depending on the region. ACh and SP are cotransmitters in enteric excitatory neurons.

There are many intrinsic neurons in the heart, particularly in the right atrium. The neurochemical makeup of the intrinsic cardiac ganglia is heterogeneous and includes a variety of neurochemical markers. For example, subpopulations of atrial intrinsic neurons from newborn guinea pigs immunostain for NPY, 5-HT, heme oxygenase-2, and NOS, and these neurons probably also utilize ACh and ATP.

Most airway intrinsic neurons contain choline acetyltransferase, but NOS and VIP are also found in these neurons in humans. Intrinsic ganglia in the human urinary bladder wall contain a number of neuroactive substances (VIP, NOS, NPY, ATP, galanin, and occasionally tyrosine hydroxylase); in the bladder neck, a few intrinsic neurons contain enkephalin and SP. Intramural ganglia containing NPY and VIP have been identified in human urethra.

Autonomic Neuromodulation

Some substances stored and released from nerves do not have direct actions on effector muscle cells but alter the release and/or the actions of other transmitters; these substances are termed neuromodulators. Many other substances (e.g., circulating neurohormones; locally released agents such as prostanoids, bradykinin, histamine, and endothelin; and neurotransmitters from nearby nerves) are also neuromodulators in that they modify the process of neurotransmission. Many substances that are cotransmitters are also neuromodulators. The wide and variable cleft characteristic of autonomic neuroeffector junctions makes them particularly amenable to the mechanisms of neural control mentioned earlier.

Plasticity of the Autonomic Nervous System

There are some examples of altered expression of neurotransmitters/neuromodulators in autonomic nerves during development and aging; following trauma, surgery, and chronic exposure to drugs; and in disease. Neurons possess the genetic potential to produce many neurotransmitters. The particular combination and quantity that result are partly preprogrammed and partly determined by 'trophic' factors and hormones that trigger the expression or suppression of the appropriate genetic machinery. The plasticity of expression of neural substances cocoordinated to environmental cues allows rapid and precise matching of neurotransmission to altered demands. Several neurotransmitters/neuromodulators are themselves trophic molecules, with mitogenic or growth-promoting/-inhibiting properties.

Conclusions

A combination of the variety of neurotransmitters involved in autonomic neurotransmission and the interactions between sympathetic, parasympathetic, and sensory–motor nerves and those arising from intrinsic ganglia, via mechanisms of cotransmission and pre- and postjunctional neuromodulation, indicate the complexity of peripheral autonomic control and the variety of ways by which autonomic dysfunction can occur. Recent advances in the unraveling of these mechanisms, together with molecular identification of specific receptor subtypes and localization and characterization of their expression, and of the long-term effects of dysfunction, will bring advances toward the design of treatment regimes to combat autonomic failure.

Structural Associations

Immune cells occur in close proximity to neural processes at sites where these structures are abundant. Anatomical nerve–immune associations have been reported involving mast cells as well as other bone marrow-derived cells, such as eosinophils and plasma cells in the lamina propria. Further work has demonstrated similar morphologic mast cell–nerve associations in the liver, mesentery, urinary bladder, and skin. In the skin, observations of Egan and co-workers showed that especially unmyelinated axons were associated with mast cells, as well as Langerhans cells (LCs) in primate and murine skin. Many if not most epidermal LCs appeared to be closely associated anatomically with calcitonin gene-related peptide (CGRP)-containing nerves, as determined by confocal laser scanning microscopy. In addition, there is morphological evidence for neural modulation of immune activity *in vivo*. It has been demonstrated clearly that the regions in which lymphocytes reside receive direct sympathetic neural input, and substance P may interact with thymocytes, mast cells, and other cells in the thymus, affecting their development and function.

Nerve–Immune Systems: Interaction

The nervous and immune systems can communicate in a bidirectional fashion as a result of a common set of signal molecules and their receptors. It has been established that the central nervous system (CNS) can regulate immune functioning. For instance, immune responses can be classically conditioned involving a CNS learning paradigm. Accordingly, information can flow not only from the CNS to the immune system but also in the opposite direction. Immune cells can produce neuropeptides such as substance P and β-endorphin. In addition, cells of the immune system possess receptors for a host of hormones and neurotransmitters, including receptors for catecholamines, acetylcholine (ACh), adrenocorticotropic hormone (ACTH), opioid peptides, substance P, CGRP, somatostatin (SOM), and vasoactive intestinal peptide (VIP). These receptors have been shown to respond *in vivo* and/or *in vitro* to the neurotransmitter substances, and their manipulation can alter immune responses. Furthermore, the CNS shares receptors with the immune system for neuropeptides and neurotransmitters as well as for cytokines.

Immune regulation is mediated via a cascade of events requiring cell–cell interactions and subsequent release of their contents, such as cytokines and antibodies, to regulate these responses. Cells of the immune system and their products have been shown to influence peripheral and central neurotransmission, leading to the conceptualization of a bidirectional neuroimmune communication system.

Innate immunity and adaptive (acquired) immunity are the two major immune defense responses of the body. Microbe-associated molecular patterns (MAMPs) derived from bacteria are recognized by pattern recognition receptors such as Toll-like receptors (TLRs). Detection of microorganisms through MAMPs by TLRs is crucial in triggering protective immunity. Studies have shown an essential role for TLRs in the activation of innate and adaptive immunity in animals. Ligand recognition induces a host defense response, which includes the production or regulation of inflammatory cytokines, upregulation of co-stimulatory molecules, and induction of antimicrobial defenses. Dendritic cells (DCs) are key players in the orchestration of immune events. Their function is crucial in both the early innate responses and the subsequent adaptive response. Activation of DCs by TLR ligands is necessary for their maturation and consequent ability to initiate immune responses.

Peripheral neuropeptides can directly attract immature DCs and at the same time they may capture mature DCs at sites of neurogenic inflammation. Low neuropeptide concentrations can improve the motility of DCs to the source of the neuropeptides, primarily sensory nerve fibers, where they may undergo functional and phenotypical maturation, probably due to changes in signal transduction pathways of neuropeptide receptors in immature and mature DCs. These findings provide evidence for a connection between adaptive immunity and the nervous system. The adaptive immune response can be altered by the nervous system releasing neuropeptides at specific local sites of infection or challenge, which may then influence the direction of the T helper cell (Th1/Th2) response. For instance, CGRP can inhibit interferon-γ (IFN-γ) production markedly in a dose-dependent manner; substance P and VIP can suppress interleukin-4 (IL-4) production. Catecholamines may play an important role in regulating adaptive immune responses as Th1 cells express adrenergic receptors. Furthermore, adrenergic receptors on B cells suggest that the sympathetic nervous system may also

regulate antibody production in addition to natural killer (NK) cell activity.

Recent reports have identified neural pathways that regulate the peripheral immune response. For instance, two immunomodulatory peptides, VIP and the pituitary adenylate cyclase-activating polypeptide (PACAP), are present in and released from both nerves and immune cells. VIP/PACAP have a general anti-inflammatory effect, both in innate and adaptive immunity. In innate immunity, VIP/PACAP inhibit the production of proinflammatory cytokines and chemokines from macrophages, microglia, and DCs. In adaptive immunity, VIP/PACAP promote Th2-type responses, and reduce the proinflammatory Th1-type responses.

Cytokine-induced illness (behavioral changes) can be seen as a neuroimmune response to activation of innate immunity. The nervous system can regulate immune function and inflammation. The CNS alerts the immune system to environmental changes using the shared neuropeptide, neurotransmitter, and cytokine receptors on immune cells. Neuropeptides, neurohormones, and neurotransmitters of the CNS interact with the immune system, which, in turn, feeds back to the brain, inducing behavioral changes and changes in the immune system. Cytokines produced in the periphery can affect the brain, producing illness and activation of neuroendocrine and autonomic stress-related circuits. Recognition of stimuli such as viruses and bacteria by the immune systems results in transmission of information to the CNS, causing physiological responses, such as fever associated with illness behavior. In the abdomen these responses are a direct result of immune cell-derived proinflammatory cytokines signaling the CNS via the subdiaphragmatic vagus nerve.

Neuropeptides

Neuropeptides are produced primarily in the brain and nervous system, although every tissue in the body can produce and exchange neuropeptides. The immunological activity of neuropeptides is mostly mediated through specific receptors. The presence of specific receptors for substance P, SOM, CGRP, corticotropin-releasing hormone (CRH), melanocortin peptides, VIP, and related peptides has been reported on immune cells. For example, macrophages, DCs, T lymphocytes, and B lymphocytes all have the ability to express neurokinin type 1 (NK-1) receptors. The existence of these specific neuropeptide receptors on immune cells represents the framework for neuropeptides functioning as mediators of neuroimmune interactions.

Substance P, the most important neuropeptide of the tachykinin family, is widely distributed in the central, peripheral, and enteric nervous systems of many species. Substance P functions in the CNS as a neurotransmitter and its NK-1 receptors are localized in distinct areas of the brain important in affecting behavior and the neurochemical response to both psychological and somatic stress. It may also coordinate the response to stress by interacting with the hypothalamic–pituitary–adrenal (HPA) axis and the sympathetic nervous system. Neuronal substance P is stored in vesicles and released from sensory nerves in response to various stimuli, such as leukotrienes, prostaglandins, and histamine. Release of substance P is often accompanied by release of CGRP, since they are often co-localized in autonomic nerves.

The tachykinin family has recently been extended by the discovery of a third tachykinin gene preprotachykinin-C mRNA, encoding a tachykinin called hemokinin-1. An important observation that has been made is the fact that constitutive expression of hemokinin mRNA occurs preferentially in leukocytes and lymphoid tissue, not in the nervous system. Microglial cells, described as resident macrophages in the brain, are a potential source of hemokinin-1. There is the possibility that hemokinin-1 could play a significant role in communication between immune cells in the CNS, and between immune cells and neuronal cells expressing the NK-1 receptor.

Neuropeptides can influence the innate immune response, especially since NK-1 receptors have been found on macrophages and DCs. *In vivo* studies have demonstrated a role for the NK-1 receptor in the initiation of the host response against bacterial and viral pathogens. Upregulation of NK-1 receptor expression by *Salmonella* may significantly increase the substance P-mediated macrophage response, directly killing the bacteria. In addition, substance P can enhance IL-1, IL-6, and tumor necrosis factor (TNF) secretion by macrophages.

CGRP can also be found by itself in some motor and enteric neurons. CGRP inhibits T cell proliferation by inhibiting IL-2 production. In macrophages, it inhibits antigen presentation and other macrophage functions, including phagocytosis. It also stimulates production of a number of cytokines, such as IL-6, IL-10, and TNF. *In vivo* injection of CGRP was shown to inhibit the onset of delayed-type hypersensitivity reactions, supporting the role of CGRP in systemic regulation of immune activation. Endogenous CGRP may generally modulate immune function, presumably, in part, through an inhibitory effect on LC function in the skin. CGRP is capable of inhibiting both the induction and expression of

fundamental cellular immune functions. This suggests an interaction between the nervous system and immunological function. These observations imply the likelihood that the CNS may be capable of suppressing the initiation of immune responses, and is also effective in their modulation. Overall, there is substantial experimental evidence demonstrating that CGRP can influence the function and development of inflammatory and immune cells in local microenvironments by specific receptor-mediated mechanisms.

Although classically neuropeptides are released from autonomic and sensory nerves, there is increasing evidence that they may also be synthesized and released from immune cells such as macrophages and eosinophils, particularly in disease. The regulation of synthesis and secretion of these mediators is largely undetermined. Therefore any description of homeostasis, especially under conditions in which immune stimulation or inflammation is present, must by necessity remain incomplete until this knowledge is available.

Neurotrophins

Based on their expression profile, neurotrophins are good candidates for mediating immune–nerve cell interactions. Nerve growth factor (NGF) is the best characterized neurotrophic factor, but the term 'neurotrophin' includes brain-derived neurotrophic factor (BDNF), glial-derived nerve growth factor (GDNF), and neurotrophins 3/5. Neurotrophins influence the proliferation, differentiation, survival, and death of neuronal and nonneuronal cells. However, several nonneuronal functions have also been characterized. For instance, neurotrophic factors are essential for enteric nervous development. Especially GDNF has been identified to control the migration, morphogenesis, and differentiation from precursors to the enteric nervous system. Furthermore, neurotrophins can regulate neuropeptide expression, interact with immunoregulatory cells and epithelial cells, and control motility during inflammation. Neurotrophins also act as an important intermediate in inflammatory pain, contributing to both peripheral and central sensitization.

Neurotrophin receptors are widely expressed in the peripheral and the CNSs, as well as on cells of the immune system. Many immune cells express the high-affinity NGF tyrosine receptor kinase A (TrkA) receptor. This allows NGF to promote the release of inflammatory mediators. Several of these mediators, such as IL-1, IL-4, IL-5, TNF, and IFN, can, in turn, induce the release of NGF. Therefore, NGF seems to be a mediator with functions on both immune cells and nerve cells and is likely an important factor in integrating communication between the nervous and immune systems.

There is increasing evidence that NGF acts on cells of the immune system. NGF promotes differentiation, activation, and cytokine production of mast cells and macrophages, and activates eosinophils. It promotes survival of different cell types, such as mast cells, by their prevention of apoptosis. NGF is a chemoattractant, thereby causing an increase in the number of mast cells as well their degranulation. Furthermore, NGF influences activity of basophils, eosinophils, neutrophils, macrophages, and T cells and is also produced by a wide range of immune cells. Mast cells, T cells, B cells, eosinophils, lymphocytes, and epithelial cells can synthesize NGF.

NGF can have proinflammatory as well as anti-inflammatory effects, dependent on its location and concentration. In mice, nasal treatment with NGF induces airway hyper-responsiveness, measured by electrical field stimulation. NGF-transgenic mice, overexpressing NGF in Clara cells, develop hyper-reactivity in the absence of airway inflammation, suggesting that NGF by itself determines the induction of airway hyper-responsiveness. On the other hand, there is evidence indicating that the increased production of NGF in the CNS during brain diseases, such as multiple sclerosis, can suppress inflammation by switching the immune response to an anti-inflammatory, suppressive mechanism. The fact that NGF may under different circumstances be either proinflammatory or anti-inflammatory is an important example of the complexity of interactions between neuroactive molecules and the immune and inflammatory systems.

Mast Cells–Nerve Interaction

Histological studies reveal an intimate association between mast cells and neurons in both the peripheral and CNSs. Besides the anatomical link, mast cells also form a functional link between the immune and nervous systems. Neuronal mechanisms are involved in mast cell activation and mast cells act as principal transducers of information between peripheral nerves and local inflammatory events.

Direct bidirectional communication between mast cells and superior cervical neurites has been supported, in an *in vitro* co-culture model of murine sympathetic neurons cultured with rat basophilic leukemia (RBL-2H3) cells. Neurites show neurotrophic and neurotropic activity for RBL cells. Intimate synapse-like contact occurs followed by cessation of division, membrane electrophysiologic alterations, maturation

of granules in RBL cells, and accumulation of vesicles in neurons close to the point of contact. Activation of nerves with scorpion venom elicited degranulation of RBL cells via substance P, and substance P activation is initiated only at their point of contact. Co-cultures of bone marrow-derived mast cells (BMMCs) and neurites have demonstrated that expression of NK-1 receptors by mast cells lowers the threshold of activation induced by nerve stimulation.

Mast cells and nerves in many tissues are in constant contact with each other and share a number of activating signals, for some of which both cells express receptors (such as vanilloids). Additionally, both mast cells and nerves respond to stimulation by secretion of preformed mediators, many of which are produced by both cells (NGF, neuropeptides, and endothelin-1). Moreover, a large proportion of primary spinal afferent neurons, which contain CGRP and substance P, express the proteinase-activated receptor 2 (PAR-2). Proteases, such as tryptase from degranulated mast cells, have recently been shown to cleave PAR-2 on primary spinal afferent neurons, causing release of substance P, activation of the NK-1 receptor, and amplification of inflammation and thermal and mechanical hyperalgesia. This mechanism of protease-induced neurogenic inflammation may contribute to the proinflammatory effects of mast cells in human disease.

Many studies have shown that mast cell-derived mediators, such as histamine, serotonin, and cytokines, modulate nonadrenergic noncholinergic (NANC) neurotransmission. NANC nerve endings express receptors for histamine (H1 and H3) and serotonin (5-HT_{2A}), and histamine H1 receptor expression at least is upregulated on primary NANC nerves in inflammation. Mast cell mediators such as TNF can sensitize afferent C fibers by lowering their threshold, but can also cause direct release of substance P, neurokinin A, and CGRP from unmyelinated fibers.

In addition to IgE and antigen, cytokines, hormones, and neuropeptides can trigger mast cell secretion. The latter include SOM, neurotensin, PACAP, CGRP, and substance P. CRH, stem cell factor (SCF), and NGF can promote mast cell growth and can also trigger mast cell degranulation. SCF has also been reported to induce mast cells to become responsive to PACAP. Keratinocytes, LCs, fibroblasts, mast cells, and endothelial cells express functional neurokinin receptors, while G-proteins on mast cells can, in addition, be directly activated by substance P. Functional NK-1 receptors are expressed on murine mast cells in the presence of IL-4 and SCF, but are not constitutively expressed by human intestinal mast cells; this changes upon stimulation by IgE receptor cross-linking. This suggests that, *in vivo*, specific tissue conditions such as allergic inflammation may lead to mast cell expression of NK-1 receptors.

Nerve–mast cell interactions are engaged in both homeostatic and pathologic regulation. Synaptic cell adhesion molecule (SynCAM) is involved in most CNS synaptic associations. Furthermore, SynCAM was reported to mediate the attachment of mast cells to neurites by expression in both cell types. This homophilic binding not only results in this immune–nerve association, but also facilitates successful neurotransmission from neurite to mast cell.

Neurogenic Inflammation

Neurogenic inflammation involves a change in function of sensory neurons due to inflammatory mediators, inducing an enhanced release of neuropeptides from the sensory nerve endings. The effects produced by tachykinins and CGRP released from peripheral endings of capsaicin-sensitive primary sensory neurons are collectively referred to as neurogenic inflammation. There is also histological evidence for the presence of cytokines, especially IL-6, within both sensory and autonomic nerves. The release of these cytokines would cause local inflammation and indicates a direct link between neurogenic stimulation and the release of proinflammatory cytokines. Experimental research has shown a role for neurogenic inflammation in disease processes such as arthritis, colitis, bladder inflammation, and asthma.

The postganglionic sympathetic neuron may also play a role in neurogenic inflammation. In the presence of subdiaphragmatic vagotomy, the potency of nociceptor afferents to inhibit the sympathetically dependent bradykinin-induced plasma extravasation was significantly increased. These findings suggest that there is a vagal mechanism affecting neurogenic inflammation. Afferent signals to the brain can generate a reflex, causing an anti-inflammatory response, which is partly mediated by the efferent branch of the vagus nerve. This cholinergic anti-inflammatory pathway is mediated primarily by nicotinic ACh receptors expressed on tissue macrophages and blood monocytes. ACh can interact specifically with macrophage $\alpha 7$ subunits of nicotinic ACh receptors, leading to cellular deactivation and inhibition of cytokine release.

CNS and Stress

Several pathways have been shown to link the brain and the immune system: the autonomic nervous system, via direct neural influences, and the neuroendocrine humoral outflow, via the pituitary. The CNS can and does activate or even inhibit immune and

inflammatory events. Stress activation of the HPA axis has such a bimodal effect. CRH activates peripheral mast cells. Corticosterone may inhibit inflammatory events and catecholamines have complex effects. Hypnosis has been shown to inhibit the expression of skin reactivity to allergen in classical tests of allergic hypersensitivity, and it has been shown that classical Pavlovian conditioning could cause mast cell secretion.

In the CNS, mast cells may participate in the regulation of inflammatory responses through interactions with the HPA axis. In the dog, degranulation of CNS mast cells evokes HPA activation in response to histamine release and CRH. Control or peripheral administration of specific antigen results in corticosterone release from the adrenal glands. CRH is also thought to be involved peripherally in tissue responses to stress in the skin, respiratory tract, intestine, and bladder. Many, if not all, of the recorded changes have involved mast cells and neuronal activation, the latter being often mediated by neurotensin and/or substance P.

Central neuropeptides initiate a systemic stress response by activation of neuroendocrinological pathways such as the sympathetic nervous system, the hypothalamic–pituitary axis, and the renin–angiotensin system, with the release of the stress hormones (i.e., catecholamines, corticosteroids, growth hormone, glucagons, and renin). Immobilization stress increases colonic motility and many other physiologic parameters through release of CRH. Both mast cells and nerves are involved, and the effects have been shown to occur through neurotensin and substance P, mediated by cholinergic, adrenergic, and ganglionic pathways. These results provide support for an important link between the nervous and the immune systems in stress-mediated intestinal responses.

Active immune responses represent a source of systemic stress, which impacts the brain and modifies various neuroendocrine and behavioral functions. Therefore, the immune system has been conceived of as a potential contributor to stress-related behavioral abnormalities, such as clinical depression. It is suggested that immunologically induced changes in the brain activate neuropeptides, thereby sustaining an adaptive state of arousal that promotes appropriate behavioral adjustments during infectious illness.

Immune cells such as macrophages are involved in certain types of stress. The cold-water swim test results in the increase of peritoneal substance P and its receptor in peritoneal macrophages. Immune–nerve interaction has been shown to be involved in the skin during stress. Stress can inhibit hair growth *in vivo* and significantly increases the number of hair follicles containing apoptotic cells, activated perifollicular macrophage clusters, and degranulated mast cells, whereas it downregulates the number of intraepithelial lymphocytes. Substance P seems to be a key mediator of stress-induced hair growth inhibition *in vivo*. Increased numbers of substance P-immunoreactive sensory fibers, seen in the dermis of stressed mice, are a result of transient high levels of NGF, suggesting that NGF is a central element in the perifollicular neurogenic inflammation that develops during the murine skin response to stress.

Several inflammatory skin conditions, including atopic dermatitis and psoriasis, are exacerbated by stress. Recent evidence suggests that cross-talk between mast cells, neurons, and keratinocytes might be involved in such exacerbation. CRH and its receptor are present in the skin and their levels are increased following stress. Human mast cells synthesize and secrete CRH in response to IgE receptor cross-linking. Mast cells also express CRH receptors, activation of which leads to the selective release of cytokines and other proinflammatory mediators. CRH receptor antagonists could be used to inhibit stress-induced mast cell activation and provide new therapeutic options for chronic inflammatory conditions exacerbated by stress.

Summary

The brain and nervous system have a bidirectional communication with the immune system. There is a consistent finding of associations between nonmyelinated nerves and lymphocytes, mast cells, eosinophils, and LCs, at which locations bidirectional interaction clearly occurs. Furthermore, it has become apparent that many cells in these different systems possess the same receptors and can make the same molecules. Behavioral changes can be initiated as a result of peripheral inflammation (illness behavior) and fever can be caused by peripheral infections and inflammation as a result of communication with and through the nervous system. The brain routinely receives communication signals from peripheral immune events and can coordinate responses through the HPA axis and the sympathetic, parasympathetic, and NANC nervous systems. Hypoactivity or hyperactivity of these mechanisms could contribute to diseases characterized by either a decreased or an exaggerated inflammatory response. Much remains to be done, but scientific progress promises much greater complexity as well as understanding of these processes. What is clear, however, is that immune mechanisms cannot be ignored in dealing with a functional understanding of the nervous system or even behavior, and the reverse is also true.

Autonomic Neuroplasticity and Aging

T Cowen, University College London, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Autonomic neurons, in common with neurons from all parts of the nervous system, undergo extensive and continual adaptation in response to intrinsic and extrinsic stimuli. The nature of neural plasticity and the factors that influence it vary throughout life. Broadly, these changes fall into three stages: development, maturation and adulthood, and old age. During development, neurons undergo differentiation toward their adult phenotype. This process includes acquiring appropriate morphology, expression of neurotransmitters and receptors, and patterns of activity and signaling pathways adapted to particular functions and connectivity. Toward the end of this period, usually during the perinatal period in mammals, neurons that have not made appropriate connections with their target tissues (which may be other neurons or effector organs such as muscles and glands) die by programmed cell death. During maturation and adulthood, plasticity takes different forms. The broad outline of the phenotype acquired during development – morphology, neurotransmitter, and other functional characteristics – remains stable. However, neurons retain responsiveness to altered demand. During adulthood and aging, many autonomic neurons retain a remarkable capacity to adapt to changing circumstance. However, a minority of cells become subject to selective vulnerability, undergo atrophy, and may die, probably contributing to the functional losses of old age which include deficits in autonomic control of homeostasis. The molecular mechanisms that underlie autonomic neural plasticity are beginning to be understood. A recurring theme throughout the life span is the interaction between neurons and their target tissues, which has profound effects on many aspects of neural plasticity.

Plasticity in the Developing Autonomic Nervous System

Neuronal Growth

During embryonic development, differentiating neurons of the autonomic nervous system (ANS) migrate to appropriate peripheral locations, such as the pre- and paravertebral autonomic ganglia and the enteric nerve plexuses of the gut. From these locations, the neurons extend dendrites to form synapses with spinal autonomic neurons of the intermediolateral column. They also extend axons toward their peripheral targets which may be smooth muscle effectors in organs such as blood vessels, gut, or iris, or glands such as salivary, pineal, or sweat glands, or glands of the gastrointestinal tract. Guidance cues for migratory neurons and growing neurites are provided by bound molecules of the extracellular matrix (ECM) as well as by diffusible factors. In recent years, it has become increasingly clear that guidance, like other epigenetic processes in the nervous system, is regulated by a combination of positive and negative influences. In the case of neural guidance, bound and diffusible factors may act as chemoattractants or chemorepellents. Chemoattractants include the ECM glycoprotein laminin and the diffusible neurotrophic and other growth factors, while chemorepellents include members of the semaphorin family, netrins, and ECM glycoproteins. Some but not all of these molecules have been investigated in relation to autonomic neurons. The combination of attractive and repulsive signals ensures that growing neurites follow appropriate pathways, including established nerve fascicles, grow toward appropriate targets, and avoid inappropriate ones.

Around the time that neurons approach their target areas, the peripheral tissues start to synthesize a locally specific cocktail of factors, which attract the growing axons and stimulate synaptogenesis. Bound factors such as laminin stimulate growth of autonomic neurites, for example, through contact between receptors on axon terminals and laminin located in glial or smooth muscle basal laminae. Laminin binds to integrin receptors of the tyrosine kinase family, which initiate neuronal growth and survival signals through ERK/MAP-kinases and PI3-kinase. Diffusible growth-promoting factors produced by targets include the neurotrophin family of growth factors, nerve growth factor (NGF), and neurotrophin-3 (NT3) having the most clearly defined functions in the ANS. These molecules generate growth responses in sympathetic and other peripheral neurons by activating the Trk family of tyrosine kinase receptors, of which TrkA and TrkC are the receptors principally responsible for mediating the effects of NGF and NT3, respectively. The contribution of the nonspecific neurotrophin receptor, p75, remains controversial. Some suggest a synergistic role with Trk receptors in promoting growth and survival; others argue for an inhibitory role for p75 in neuronal growth and survival, probably acting in situations where Trk's are absent. A characteristic of these signaling systems is that they often act in combination, with bound and diffusible factors either working synergistically or providing a balance of positive and negative influences.

Locally Specific Phenotype

Target specificity of innervation is achieved by secretion by target tissues of locally specific combinations of factors, which stimulate particular patterns of neuronal growth as well as neuronal synthesis of particular neuropeptides. Growth of large, complex sympathetic neurons (supplying, e.g., the iris where fast physiological reflexes are required) correlates with high levels of synthesis of NGF. In contrast, smaller sympathetic neurons supplying sparse innervation to blood vessels (where much slower, less specific neuromuscular responses are required) are associated with low levels of NGF synthesis in the vessel wall (Figure 1). Target-derived factors also ensure the adoption by the neurons of a suitable neurotransmitter phenotype The mechanism underlying establishment of neurotransmitter phenotype has been investigated widely, particularly in the minority of sympathetic nerves of the ANS which utilize acetylcholine as a neurotransmitter. Target-derived molecules are clearly involved in this process; however, their identity remains elusive and may include the cytokines ciliary neurotrophic factor, leukemia inhibitory factor, or cardiotrophin-1 and/or the neurotrophic factor, glial cell-derived neurotrophic factor (GDNF).

Neuronal Survival

The nervous system at large generates more neurons during embryogenesis than are required in maturity.

Figure 1 The neurotrophic hypothesis. Target tissues support neuronal growth, survival, and phenotype through their production of neurotrophic and other factors which are taken up by neurons and retrogradely transported to the cell body where they initiate gene transcription. Neurons regulate the supply of these factors through their activity. Targets producing high levels of neurotrophic factors become innervated by large, complex neurons; conversely, targets producing lower levels of these factors become innervated by smaller ones. These different phenotypes are likely to be functionally adaptive. However, they appear to have pleiotropic effects on the survival trajectories of these neurons in old age (see text).

Fine-tuning of the numbers of surviving neurons to the physical size and physiological demands of peripheral organs occurs by ensuring that the cocktail of diffusible growth factors produced by the target tissue provides sufficient but not superfluous support for the innervating neurons. Neurons that reach their target compete for this scarce resource by growing axons bearing receptors which uptake the appropriate factors, generating further growth and survival signals. Those that fail to take up a sufficient supply undergo programmed cell death or apoptosis. This process was extensively investigated in sympathetic neurons of the ANS and only later understood to be important in many areas of the nervous system. This model of developmental regulation of neuron survival has become encapsulated in the 'neurotrophic theory' (Figure 1). An interesting recent addition to this concept concerns the emerging evidence that physiological activity of the target, which is at least partly a result of the activity of the innervating neurons, can itself stimulate synthesis or secretion of growth factors. This important observation suggests that neurons have the capacity to regulate their target-derived trophic support.

Similar groups of molecules contribute to the survival as well as to the growth of ANS neurons. Thus, target-derived NGF and NT3 signaling through Trk receptors regulate survival of numbers of sympathetic neurons appropriate to the particular target tissues during development while the survival of gut neurons is regulated partly by laminin, and subsequently by GDNF and NT3. Pruning of neuron numbers takes place at different periods of perinatal life depending on the target area. In general, it starts in the few days before birth and continues for a variable number of weeks after birth. The signaling pathways mediating developmental survival are similar to those driving neurite growth, that is, tyrosine kinase signaling through ERK/MAP-kinase and PI3-kinase. It seems most likely that downregulation of these pathways (i.e., by subthreshold levels of the ligand neurotrophins), particularly of PI3-kinase, is the key signal for neuronal death. The death signal involves a pro-apoptotic shift in the downstream effectors of tyrosine kinase signaling, which include expression of the BCL-2 and caspase families of proteins. Knockout studies in mice indicate that the p75 receptor, signaling through NFκB, is also involved in the developmental regulation of cell death in NGF-dependent autonomic and other neurons.

Plasticity in the Adult and Aging ANS

Neuronal Growth

Adult neurons retain the capacity to respond sensitively to extrinsic growth signals. Body organs continue to

grow beyond the period of naturally occurring postnatal neuronal cell death. Existing and relatively stable populations of neurons are therefore required to expand their axonal and dendritic connections by continued growth and synaptogenesis. *In vitro* studies have shown that adult neurons are at least as sensitive as early postnatal neurons in terms of their growth responsiveness to neurotrophins. Indeed, even those neurons that survive into old age retain growth responsiveness to neurotrophins; strong nerve sprouting has been observed *in vivo* in response to treatment with neurotrophic factors. However, there is an age-related reduction in the dose-response curve *in vivo* and *in vitro*.

That plasticity is a physiological feature of adult autonomic neurons is supported by several lines of evidence. Pregnancy and the estrous cycle are accompanied by substantial cyclical changes in the autonomic neurons innervating the uterus. Sympathetic nerve fibers undergo atrophy in late estrus and pregnancy, followed by regeneration. Pregnancy-induced neuronal atrophy may protect the fetus against vasoconstriction caused by homeostatic responses such as fight and flight. Multiple pregnancies may result in the death of some of the innervating sympathetic neurons. Transplantation studies and experimental enlargement of organs demonstrate further that neurons, particularly autonomic neurons, retain an extraordinary ability to expand their field of innervation. Partial obstruction of the bladder can result in a roughly tenfold increase in muscle mass to which the innervating autonomic neurons respond with an increase in size of around 80%. Removal of the obstruction results in reversion of neuron size to control values over a few weeks. Comparable manipulations in the gut and iris – both autonomically innervated tissues – have yielded similar results.

The same neurotrophic factors, which regulate growth of neurons during development, are retained by the adult target tissues, generally at unchanged levels. In the case of adult sympathetic neurons, these factors include NGF and NT3. Of these, NGF produces the substantially stronger growth response, although both factors are present in many of the target tissues of sympathetic neurons. TrkA and TrkC receptors are present on adult sympathetic neurons to mediate the growth responses. The increased target area resulting from the physiological or experimental expansion of organs described above is therefore likely to induce nerve growth by increasing the availability of neurotrophins in the vicinity of existing nerve terminals. The role of the nonspecific p75 receptor remains as controversial in the adult nervous system as it is at earlier stages of development. Some argue that p75 inhibits neuronal growth in adult rodent neurons while others consider that p75 supports the trophic role of NGF by heterodimerization with Trk. These apparently contradictory roles for this receptor may result from different expression ratios of p75 and Trk in different neurons and under different circumstances. Local availability of neurotrophins can affect the expression of both p75 and Trk receptors in the adult nervous system, thus providing a further level at which nerve growth can be regulated.

The signaling pathways involved in adult neuron growth are less well defined than those regulating survival. While inhibition of tyrosine kinase signaling largely inhibits extension of neurites from adult sympathetic neurons *in vitro*, there is less conclusive definition of the downstream pathways involved. This may be because neurite extension involves integrin-as well as neurotrophin-mediated activation of tyrosine kinase signaling, with resulting convergent activation of ERK/MAP-kinase and PI3-kinase.

During aging, some autonomic neurons undergo atrophy (shrinkage of their dendritic and axonal arbors and cell soma), while others continue to grow into old age. This phenomenon has been called 'selective vulnerability' and affects sympathetic neurons projecting to vascular targets and sweat and pineal glands. In contrast, neurons projecting to iris and submandibular gland show no evidence of atrophy. To the extent that the subpopulations of neurons innervating each target tissue exhibit specific patterns of growth or atrophy during aging, selective vulnerability involves interactions between particular target tissues and neurons. However, it has not proved possible to demonstrate that reduced levels of NGF availability from targets causes age-related atrophy of fibers.

Locally Specific Phenotype

Adult neurons retain locally specific morphology and neurochemical phenotype. Thus, subpopulations of adult sympathetic neurons, retrogradely traced from particular target tissues, exhibit different sizes which appear to relate to physiological function in the same way that developing neurons adapt to the physiological function of the end organ. In addition, adult neurons continue to express locally specific patterns of neuropeptides and transmitters. For example, neuropeptide Y expression is highest in superior cervical ganglion (SCG) neurons projecting to iris, lower in those projecting to the middle cerebral artery, and lowest in neurons projecting to the submandibular gland. There is evidence that these patterns of neurotransmitter expression remain plastic in adulthood. Transplantation in adult rats of sweat glands (normally innervated by cholinergic, vasoactive intestinal peptide (VIP)-expressing sympathetic neurons) into contact with catecholaminergic sympathetic neurons induces a shift to a cholinergic, VIP-expressing phenotype in those neurons, which extend processes to innervate the

transplanted tissue. There is no obvious loss of this form of plasticity in old age.

Neuronal Survival in Adulthood

While neurons retain growth responsiveness to extrinsic factors in adulthood and even in old age, the factors that determine survival, at least of sympathetic and other (sensory) peripheral neurons, appear to change dramatically during maturation and in aging. Between birth and 12 weeks of age, rodent sympathetic neurons, from being dependent for their survival on an extrinsic source of neurotrophin, become almost completely independent and able to survive in dissociated cell culture for many days and even weeks under serum- and NGF-free conditions (Figure 2). The loss of survival dependence on target-derived signals may be seen as an adaptation allowing adult neurons a degree of resistance against an axonal injury that separates the neuron from its target, thus allowing the neuron a period of respite in which to initiate regeneration.

The principal signaling pathway that mediates neuronal survival independence, as this phenomenon is called, is PI3-kinase. Pharmacological and/or genetic inhibition of this pathway at different points leads to the rapid death of cultured adult sympathetic neurons; inhibition of ERK/MAP-kinase is without significant effect. This suggests strongly that while neurons lose their dependence on signaling through Trk receptors to regulate their survival, the downstream PI3-kinase pathway remains a key determinant of neuronal resistance to cell death. It is feasible that autonomic and perhaps other neurons protect their survival in adulthood by cell-autonomous activation of PI3-kinase in a way that resembles a mechanism by which cancer cells avoid apoptosis.

Figure 2 Differential regulation of neuronal growth and survival during maturation. During postnatal maturation, sympathetic neurons lose their survival dependence on NGF. Growth, however, remains NGF dependent. (a) Sympathetic neurons become independent of NGF for their survival between embryonic day 18 (E18) and 12 weeks of age, as demonstrated by a dramatic increase in survival with age in dissociated, pure neuron cell cultures maintained over several days in the absence of serum and NGF. Note that by 12 weeks, approximately 60% of neurons survive for longer than 5 days *in vitro*, whereas no E18 neurons survive longer than 3 days. (b) Postnatal sympathetic neurons require NGF to initiate growth and to extend neurites *in vitro*. Note that neurons fail to grow in the absence of NGF; dose responsiveness is similar in 12-week-old and 7-day-old neurons.

It has recently become clear that production of neuronal progenitors, at least in the central nervous system (CNS), continues throughout life under the influence of a range of epigenetic factors, including physical exercise, brain activity, and injury. It is not clear, however, whether the ANS can continue to generate neuronal precursors in adulthood or whether plasticity mechanisms similar to those seen in development and maturation regulate the differentiation, survival, and integration of progenitor cells into the functioning adult nervous system.

Neuronal Survival in Old Age

Selective vulnerability to neuron cell death is a well-established characteristic of the aging nervous system as a whole, as well as of the ANS. The groups of neurons affected are similar to those which exhibit age-related atrophy (see the earlier section on neuronal growth). Among sympathetic neurons, only certain populations undergo cell death, while many survive into extreme old age. Roughly 50% of vascular-projecting neurons in the SCG are lost in aging rats, while neurons projecting to the iris are less significantly reduced in numbers. Autonomic neurons from the myenteric plexus of the gut are also vulnerable to age-related cell death, with roughly 50% of neurons lost from for small and large intestine of aging rats and guinea pigs (Figure 3). There is limited but less secure evidence that similar patterns of myenteric neuron loss occur in humans, at least from the large intestine.

In line with evidence that adult neurons become relatively independent of target-derived trophic support, it is probable that locally selective patterns of neuron death during aging are not the result of

Figure 3 Age- and diet-related loss of myenteric neurons from the rat small intestine. (a) Counts of myenteric neurons using the pan-neuronal marker, PGP 9.5. The histogram shows significant losses of total numbers of neurons, commencing at 12–13 months of age in *ad libitum*-fed (AL) animals, which reaches a peak of 51% at 24 months. There is a much smaller but statistically significant ($p < 0.05$) reduction seen in animals of the same age (24 months) but fed a calorie-restricted (CR) diet, demonstrating substantial protection by CR against age- and diet-related loss of myenteric neurons. Statistically significant differences are indicated by $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$. (b, c) Photomicrographs of young (6 months; b) and old (24 months AL; c) PGP-immunostained whole-mount preparations of rat myenteric plexus. Note the large spaces in the old ganglia indicating where neuron cell loss has occurred.

reduced availability of neurotrophins. Studies of different target areas show no evidence of altered levels of NGF or NT3 protein or mRNA in targets of aging sympathetic neurons, mirroring similar observations in targets of vulnerable NGF-dependent neurons in the CNS. The search for causes of age-related neurodegeneration is a high priority in aging research. A number of avenues are being explored including whether expression of the p75 or Trk receptors are selectively altered in subgroups of aging sympathetic neurons vulnerable to age-related cell loss. In the absence of changes in levels of extrinsic factors, these are likely to be cell-autonomously regulated. Subpopulations of neurons that exhibit age-related cell loss project to target areas that throughout life express relatively low levels of neurotrophic factors; conversely neurons that survive successfully into old age tend to project to targets expressing high levels of neurotrophic factors (see the above discussion on locally specific phenotype). These differential levels of neurotrophin synthesis are retained throughout life and are reflected in altered patterns of p75 and Trk receptor expression, which correlate directly with neurotrophin availability. It therefore seems likely that growth factor signaling is set during maturation at levels that are adapted to particular physiological requirements of subgroups of neurons. This maturational setting affects the capacity of neurons to survive into old age.

Oxidative and other forms of free radical damage are heavily implicated in neurodegenerative disease as well as in normal aging. It is now known that neurotrophic factors can influence antioxidant defense in neurons and that free radical levels increase in neurons, such as those of the myenteric plexus, prior to the onset of age-related cell loss. A working hypothesis, then, is that differential, lifelong patterns of neurotrophin signaling are established during early postnatal life, and become more or less fixed in maturity. These differential and adaptive levels of signaling then determine, among other things, neuronal capacity to resist prolonged exposure to free radical damage. The neurons with low levels of signaling succumb first (Figure 4).

An alternative way in which neurotrophin signaling might be altered in adulthood and old age concerns the recent discovery that the precursor pro-form of NGF, previously thought to be expressed within target cells prior to its cleavage by enzymes of the proconvertase family, is widely distributed in the adult nervous system, including in nonneural targets of autonomic nerves. ProNGF levels are elevated in the pregnant uterus, in association with the atrophy and degeneration of the innervating sympathetic neurons (see the earlier section on neuronal growth). ProNGF is also the predominant form of NGF present in the Alzheimer's diseased brain and in the spinal cord after injury – two situations known to

Figure 4 Model illustrating mechanisms regulating lifelong survival of autonomic neurons. During perinatal life, autonomic neurons become increasingly independent of target-derived NGF for their survival as a result of upregulation of intraneuronal PI3-kinase activity. The degree of upregulation is variable (see dashed and solid green lines), locally specific and adaptive, being set initially by the levels of the target-derived NGF (large and small arrows). Later in life (around puberty and after), PI3-kinase activity is maintained independently of NGF availability. Toward the end of the reproductive life span, exposure to reactive oxygen species (ROS) downregulates PI3-kinase activity, increasing vulnerability to age-related neuron cell death. AL feeding (see Figure 3) increases exposure to ROS and thereby accentuates this process, while CR provides protection.

be associated with widespread neuron cell death. ProNGF has been shown to induce apoptotic cell death in PC12 cells as well as SCG neurons from young animals. ProNGF signals via the receptor sortilin (first discovered as a member of the Vsp10 family of sorting receptors and later identified as the receptor for neurotensin) acting in combination with p75. At present, there is little evidence from the aging nervous system that proNGF contributes to age-related cell death. However, the sortilin receptor is expressed in the adult (including human) brain; therefore, this possibility cannot be ruled out.

Extrinsic Factors Affecting Neuron Survival

Factors that influence life span have been shown, unsurprisingly, to also affect neuron survival. The classical extender of life span in rodents, caloric restriction (CR), has remarkable effects in rescuing myenteric neurons of rats from age-related cell death. CR also reduces free radical levels in neurons, and appears to achieve this by influencing neurotrophic factor-mediated antioxidant defense. Exercise and the environmental stimuli to which laboratory rodents are exposed (including group vs single animal housing) may also affect health, life span, and, perhaps, cell survival. Further studies are required to quantify these phenomena and to explore the underlying mechanisms.

Conclusions

Autonomic neuronal plasticity is regulated by core mechanisms which are set up during development, modified and consolidated during maturation, and maintained into adulthood and old age. These mechanisms, which are adaptive, may have deleterious pleiotropic consequences for some groups of aging neurons, making them vulnerable to neurodegeneration. Neurodegeneration probably occurs initially as loss of terminal nerve fibers (axons and dendrites) and shrinkage of the cell soma and may progress ultimately to cell death. Interactions between neurons and their target tissues, including the provision of nerve growth and survival promoting factors by targets and the related expression of appropriate receptors in neurons, comprise an intimate and essential interaction at the core of plasticity responses throughout life. Intraneuronal signaling pathways have specific roles in regulating plasticity, including growth and survival responses, and, probably, maintenance of neurotransmitter phenotype and antioxidant defense. Extrinsic factors, including diet and other behaviorally regulated phenomena, have major effects on neural plasticity, probably by acting on intraneuronal signaling pathways.

Autonomic Neuroplasticity and Regeneration

P J Kingham and G Terenghi, University of Manchester, Manchester, UK

Introduction

Neuronal plasticity can be defined as the responsiveness of a neuron to its surroundings and how this changes following injury. The normal phenotype and function of a neuron depends on both the integrity of the neuron and also its connection with other neurons and end targets. During development of the nervous system, the terminals of neurons project to the same target and compete for limited quantities of neurotrophic growth factors, which then bind to surface receptors and are internalized and transported to the cell body to provide key signals for survival and differentiation. Disruption of these connections, through injury, initiates a sequence of molecular and cellular responses which act to promote regeneration and if successful reestablish contact with end targets. Therefore, the plastic changes which remodel the autonomic nervous system following injury involve a balance between cell death, due to trophic starvation, and regeneration of surviving neurons which switch from a differentiated to growing phenotype.

Cell Survival and Growth Factors in the Autonomic Nervous System

Nerve growth factor (NGF) is the classic target-derived neurotrophin synthesized by end targets. Sympathetic neurons were the first neurons to be identified as NGF responsive and their targets, vascular and smooth muscle, skin cells such as keratinocytes and melanocytes, and various endocrine tissues produce large quantities of the growth factor. NGF has two known receptors, TrkA and $p75^{NTR}$, which are both expressed by adult sympathetic neurons. TrkA is a transmembrane protein which serves as a receptor tyrosine kinase, and the neurotrophic properties of NGF are largely attributable to its effects on this receptor. $p75^{NTR}$ interaction with TrkA further modulates the responsiveness to NGF. The use of primary cell cultures of sympathetic neurons or the PC12 cell line has led to the identification of numerous intracellular signaling pathways activated by NGF. In brief, binding of NGF to TrkA initiates receptor dimerization leading to phosphorylation of integral tyrosine residues, which results in activation of kinase activity and subsequent phosphorylation of adaptor proteins which link to the mitogen-activated protein (MAP) kinase signaling cascade. Activation of these proteins contributes to altered expression of NGF-responsive genes via the mobilization of transcription factors from the cytoplasm to the nucleus. In addition to the local effect of NGF on the axon terminals, it is retrogradely transported from the end target to neuronal cell bodies within the sympathetic ganglia via postganglionic axons. This occurs through endocytosis of the ligand receptor complex and the formation of signaling endosomes. These vesicles then accumulate in the neuronal soma where high levels of phosphorylated TrkA activate the signaling events necessary for survival.

The importance of NGF signaling for cell survival is illustrated by studies of NGF–/– animals, which show almost complete loss of sympathetic nerves. Lesion to a sympathetic nerve isolates it from the end target source of NGF and leads to a reduction in neuron number. Nevertheless, adult sympathetic neurons do not die acutely after such a challenge but instead undergo a gradual cell death. This resistance to growth factor deprivation suggests that protective mechanisms can be activated following nerve injury. This involves changes both at the lesion site and within the cell bodies. Ultimately, this leads to activation of signaling cascades which act to mimic the effects of NGF and other growth factors which are important for the regulation of autonomic nerve survival.

Early Responses to Nerve Injury

Nerve injury causes damage to axonal membranes and interrupts the retrograde flow of signals from the normal innervation target. Before the ends can be resealed, Ca^{2+} enters the axoplasm and activates calcium-dependent proteases such as calpains, leading to extensive cytoskeletal remodeling. This may underlie new growth cone formation and may direct new intra-axonal protein synthesis, preventing the axons from simply withering away. Both myelinated and unmyelinated (sympathetic postganglionic nerves) axons are surrounded by Schwann cells. In the healthy nerve, Schwann cells appear quiescent and their function is tightly regulated by the axon they ensheath. When this interaction is lost, Schwann cells become highly active. Within hours of nerve injury, Schwann cells produce elevated levels of inflammatory cytokines such as tumor necrosis factor α and interleukin-1 which act to attract infiltrating macrophages, T-cells, and neutrophils. Both resident and recruited macrophages are critical for removal of nerve debris, which might impede the regeneration of axons.

Schwann cells proliferate in large numbers at the distal stump, forming a strand of cells called the band of Büngner, which provides an indispensable pathway for guiding regenerating axons to their end target. Perhaps more importantly, the Schwann cells release a number of neurotrophic factors to compensate for the decline occurring as a result of lost contact with the end target. Following nerve injury, Schwann cells produce increased levels of NGF which remain 10- to 15-fold elevated for at least 2 weeks. High levels of NGF are maintained by interactions between Schwann cells and invading macrophages. NGF may subsequently be taken up by the newly forming growth cones at the proximal stump. It is likely that the growth factor is dispersed diffusely in a gradient fashion around regenerating axons and therefore boosts axonal elongation. Brain-derived neurotrophic factor (BDNF) is another growth factor important for the survival of sympathetic neurons. Quiescent Schwann cells contain low levels of BDNF, which is upregulated following axotomy. In contrast to NGF, the response to denervation is slower and peak levels of BDNF are reached weeks following injury. Ciliary neurotrophic factor (CNTF) is a growth factor important for the survival of parasympathetic ciliary ganglion neurons. Schwann cells in intact nerves contain high levels of CNTF. Following injury, the levels decline and are reestablished only upon reinnervation, suggesting that contact with axons is necessary for the synthesis of CNTF in Schwann cells. Studies exploring the downstream targets of CNTF such as signal transducer and activator of transcription-3 (STAT-3) indicate that this could be an important mediator of early responses to nerve injury. Local release of CNTF by denervated Schwann cells activates the CNTF receptor on nearby axons, leading to phosphorylation of STAT-3 and its retrograde transport to the cell bodies of injured neurons. Therefore, the release of neurotrophic factors by Schwann cells at the injury site can help maintain a viable population of neurons which can switch to a growth phenotype, enabling their axons to regenerate across the lesion and back to the periphery.

Signaling Pathways and Changes in Gene Expression in the Injured Neuron

Chromatolysis, a histological change involving the rough endoplasmic reticulum and nucleus, was first noted in axotomized cell bodies many years ago. It was suggested that this process reflected a change in the types of proteins the neurons were synthesizing. It is now well accepted that nerve injury induces changes in intracellular signaling pathways which result in the induction of transcription factors and gene activation leading to upregulation of growth-associated molecules and a switch from neurotransmission. The recent development of microarray technology has led to the identification of large numbers of neuronal genes regulated by nerve injury. With regard to the autonomic nervous system, these changes have been best studied in the sympathetic, superior cervical ganglion (SCG). This is partly due to the difficulties of injuring selectively parasympathetic axons, given that most of the peripheral neuron cell bodies lie in widely dispersed ganglia closely associated with, or in the end target. Additionally, *in vitro* SCG explants provide an intact ganglion maintaining the association between neurons and nonneuronal cells and allow the subsequent investigation of the role of individual regeneration-induced genes. Indeed, it has been shown that upregulation of leukemia inhibitory factor (LIF) in the satellite cells of the ganglion within 6 h of axotomy mediates the expression of many of the induced genes. Studies are now underway to elucidate the role of the gene products produced during regeneration, a selection of which are discussed below.

Transcription Factors

These proteins play a major role in coupling extracellular signals to altered gene expression in the neuron and contribute to the underlying neuroplasticity of the autonomic nervous system. STATs are transcription factors which are phosphorylated by janus (JAK) kinases in response to cytokine activation of cell surface receptor tyrosine kinases. Activated STATs dimerize and translocate to the nucleus where they activate transcription of cytokine-responsive genes. To date, at least three JAK kinases and six STAT proteins have been shown to participate in this complex signaling pathway. Axotomy of SCG results in the rapid and sustained activation of STAT-1α and STAT-3 proteins in neuronal cell bodies. This activation is dependent on LIF release from satellite cells. The signaling cascade may also in part be mediated by reduced trophic support since NGF and other growth factors have been shown to reduce STAT expression. The STAT pathway may be particularly important for the regulation of neuropeptide expression in the SCG (see below).

Nuclear factor kappa B (NF-κB) is another transcription factor that plays a key role in the regulation of genes involved in nervous system function. NF-κB is a heterodimeric protein, principally composed of a 50 kDa subunit and a 65 kDa subunit. Typically, NF-κB is sequestered in the cytoplasm by the specific inhibitory protein IkB. The phosphorylation and subsequent proteasomal degradation of IkB releases

NF-κB and permits its translocation into the nucleus in which it can bind DNA and regulates transcription. NF-κB is constitutively activated in sympathetic neuron cultures maintained in the presence of NGF and withdrawal of the growth factor downregulates NF-κB activity. This correlates with increased apoptosis and therefore NF-κB might play a role in the survival of sympathetic neurons.

Like NF-κB, activating protein-1 (AP-1) transcription factors are dimeric molecules and comprise two major protein families: the Jun family and the Fos/activating transcription factor (ATF) family. Activation of the transcription factor c-Jun through phosphorylation by the MAP kinase, c-Jun N-terminal kinase (JNK), has been implicated in neuronal stress responses. Neurons contain low basal levels of the c-jun protein and axonal damage results in dramatic increases in expression levels, most likely as a consequence of decreased trophic support. The relative role of c-jun in neuronal cell death and regeneration is still unknown. In sympathetic neuron culture, c-jun is activated following NGF withdrawal and correlates positively with the onset of apoptosis. In contrast, *in vivo* studies of peripheral nerves have shown that deletion of c-jun hinders the expression of genes and proteins associated with axonal regeneration and reduces the speed of target reinnervation. The activity of other transcription factors such as NF-κB and ATF-3 can suppress the c-Jun-dependent transcription of cell death genes. Microarray data from axotomized SCG indicate that all three transcription factors are upregulated, suggesting a complex interaction for the balance of neuronal cell death and regeneration.

Cell Survival Proteins

The expression of a number of genes encoding anti-apoptotic proteins are increased in axotomized SCG. These proteins may contribute to the survival of injured neurons in response to growth factor deprivation. Heat shock proteins (HSPs) are a group of molecules expressed after cellular stress such as nerve injury. It has been suggested that these proteins serve a protective role by stabilizing other protein structures that are sensitive to denaturation and to help them to retain or to restore their native, functional conformations. The production of HSP70 mRNA is increased rapidly following SCG injury, and although protein studies have not been performed, it is likely that the ganglion cells expressing high HSP70 levels show a greater resistance to apoptosis. In mixed peripheral nerves, HSP70 protein remains elevated for days and positively correlates with surviving neurons. One particular stress a neuron encounters following axotomy is an increase in oxidative free radicals. Elevated expression levels of superoxide dismutase following sympathetic axotomy may protect against cell death. Of the pathways leading to apoptosis, mitochondria play a central role releasing a number of proapoptotic molecules resulting in the activation of caspases and fragmentation of DNA. Studies of cultured sympathetic neurons indicate that the translocation of Bax protein, from cytoplasm to mitochondria, is a critical and irreversible step in the cell death pathway following trophic factor deprivation. However, the extent to which the same pathway is used *in vivo* is still not clear. Nevertheless, the observation that Bax inhibitor-1 expression is increased in the SCG following axotomy suggests a protective response.

Neural Transmission Molecules

Noradrenaline (NA) is the principal neurotransmitter of peripheral sympathetic neurons and is stored in vesicles, which are formed in the cell body and then transported into the axon, toward the nerve terminal, by fast axonal transport. Here the neurotransmitter is released upon the arrival of a nerve impulse. Both large (80–100 nm diameter) and small (40–50 nm diameter) vesicles exist, which in addition to NA contain varying types of peptides (see below). ATP is also an important co-transmitter with NA. The phenotype of sympathetic neurons is highly plastic both *in vitro* and *in vivo*. For example, dissociated neurons exposed to medium conditioned by nonneuronal cells can upregulate choline acetyltransferase activity and develop cholinergic characteristics. Likewise, the sympathetic axons innervating rat sweat glands are initially noradrenergic but as the sweat gland matures, NA levels fall and cholinergic properties are acquired. This indicates that sympathetic neurons are highly responsive to extracellular factors. This plasticity is especially apparent in neuropeptide expression levels following nerve injury.

Neuropeptide Y (NPY) is a 36-amino-acid peptide, which is highly concentrated in the large vesicles of sympathetic postganglionic neurons and is co-released with NA. Following axotomy, NPY levels are increased both *in vivo* and in SCG explants. This occurs in response to as yet unidentified factors released from injured nonneuronal cells in the ganglion. In contrast to the high number of adult sympathetic neurons positive for NPY, other neuropeptides such as galanin and vasoactive intestinal polypeptide (VIP) are rarely expressed in healthy neurons. Both are significantly increased in response to axotomy as the result of LIF release in the ganglion. In the case of VIP, it has been shown that LIF promotes the binding of transcription factors to a cyclic AMP responsive element located within the 5′-flanking region of the

VIP gene. Other cytokines such as interleukin-1 can also potentiate the number of VIP-positive sympathetic neurons. In contrast, administration of NGF partially suppresses the increases in galanin and VIP positive neurons following axotomy. This suggests that under physiological conditions, NGF may play a role in controlling the neuropeptide phenotype of sympathetic neurons. Recent microarray data have identified two additional upregulated neuropeptides, cholecystokinin (CCK) and PTHrP, which had not previously been observed in sympathetic neurons. It is tempting to speculate that in addition to their classic transmitter role, neuropeptides are involved in the growth response during sympathetic nerve regeneration. The observation that galanin knockout mice display retarded regeneration of the sciatic nerve indicates this may be the case. Furthermore, VIP increases the neurite extension of sympathetic neuroblasts and the survival of cultured sympathetic neurons deprived of NGF. In addition to affecting neurons, VIP can also act on Schwann cells to increase the expression of extracellular matrix (ECM) molecules necessary for promoting regeneration.

Regulators of Neurite Outgrowth

Although sprouting at the lesion site occurs within hours of injury, it takes several days before axonal outgrowth emerges from the proximal stump. During this time, there is upregulation of many proteins necessary for remodeling the growth cone of regenerating axons. Organized cytoskeletal structures in association with activated intracellular signal transduction pathways determine the shape and motility of growth cones. Many years ago, it was noted that while molecules involved in the synthesis of neurotransmitters such as tyrosine hydroxylase were decreased, important structural proteins including actin and tubulin were increased, indicating an active remodeling process. GAP-43 is a small acidic protein, which is highly associated with outgrowth of neurites during development. Following injury to the adult nerve, GAP-43 is synthesized in the cell body and transported to the regenerating tip where it accumulates at high levels in the growth cones. The N-terminal of GAP-43 binds to the plasma membrane of the growth cone and the C-terminal with the cytoskeletal components of the axon. Calmodulin, an important mediator of signal transduction, is also attached to GAP-43. Phosphorylation of GAP-43 by protein kinase C releases calmodulin and leads to growth cone extension. In contrast, activation of G-proteins at the N-terminal end can lead to inhibition of growth cone extension. Thus, GAP-43 plays an important role in signaling and controls the spreading, branching, and adhesion of the growth cone.

The extension and path finding of growth cones are mediated by substrates such as ECM molecules with which they interact. The basal lamina is the ECM to which regenerating axons attach preferentially. The most potent adhesion molecule for promoting axonal outgrowth in this matrix is laminin, which binds with integrin receptors on the axon surface. An integrin is a heterodimer protein composed of α and β chains, and peripheral nerve injury results in the upregulation of the $\alpha6$, $\alpha7$, and $\beta1$ integrin subunits. Neuronal jun-deficient mice do not show an upregulation of $\alpha7$ integrin after injury, which contributes to the poor regenerative response seen in these animals. In addition, the expression of the fibronectin gene is significantly increased following axotomy of sympathetic neurons, and this may contribute to Schwann cell migration to the regenerating front. Therefore, the increased expression of cell adhesion molecules is likely to lead to activation of intracellular signal transduction pathways and remodeling of the cytoskeleton, facilitating the growth of regenerating axons. This is in part mediated by the nonreceptor tyrosine kinase, pp60c-src, which is also upregulated following nerve injury, and concentrates within the growth cone. Pp60c-src directly links a complex of integrins, vinculin and actin filaments, which can control cytoskeletal transformations. Transient activation of this complex, by phosphorylation events, enables growth cone motility. In addition, phosphorylation of tubulins by other members of the c-src family of tyrosine kinases suppresses the formation of microtubules creating a highly plastic environment in the regenerating axon.

Since regrowth is necessary for functional recovery following axotomy, it is interesting to note that microarray data often produce 'hits' for molecules that are known to regulate neurite outgrowth. For instance, axotomy of the SCG leads to increased expression of the arginase 1 gene, an enzyme involved in polyamine synthesis. Arginine is hydrolyzed to ornithine, which is then converted to the diamine putrescine and then the polyamines spermidine and spermine. Levels of these molecules increase in axotomized ganglia. Pharmacological blockade of polyamine synthesis inhibits the regenerative response, while administration of exogenous polyamines promotes neurite outgrowth and functional recovery following injury to *in vivo* SCG neurons. In contrast, the levels of inhibitors of regeneration such as the proteinase activated receptor or thrombin receptor fall in response to axotomy. Together, these changes lead to the promotion of outgrowth and an enhanced regenerative response.

Conclusions

The aim of this article is to highlight how autonomic nerves respond to nerve injury and produce a regenerative response. The recent use of microarray technology combined with classic protein biochemistry studies have helped to elucidate many of the signaling pathways involved and demonstrate the highly plastic nature of the peripheral nervous system. Activation of mechanisms that compensate for neurotrophic factor deprivation aim to maintain sufficient neuronal numbers which can then switch from a differentiated to growing phenotype and subsequently reinnervate the end target. Further investigation of these endogenous responses to injury should lead to a new generation of therapies to enhance nerve repair.

Autonomic Neuroplasticity: Development

P G Smith, University of Kansas Medical Center, Kansas City, KS, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The concept that the nervous system can undergo substantial reorganization has been appreciated for over a century. In 1909, in *Modern Problems in Psychiatry,* Ernesto Lugaro used the term 'plasticity' in the context of the nervous system to convey the idea that chemical interactions responsible for the developmental patterning of the nervous system also provide adaptive mechanisms for behavioral modification and nervous system repair.

While plasticity can occur throughout the nervous system, the autonomic nervous system arguably has been most instructive in revealing the underlying principles. One reason is that the peripheral autonomic nervous system provides a particularly tractable system for studying neuroplasticity. Because its principal neurons are located outside of the central nervous system, it is relatively easy to isolate and remove relatively pure neuronal populations, either for cell culture under regimented conditions or to examine the effects of extirpation or transposition. A second reason is that sympathetic neurons are responsive to the prototypic neurotrophic factor, nerve growth factor (NGF); thus the role of target-derived proteins and autonomic neuronal survival and growth has been recognized and manipulated in this system for over half a century. Moreover, this system has proved not only to be highly complex, with multiple factors controlling development, but also very amenable to investigations using genetic manipulation to elucidate the role of various genes and proteins. Accordingly, the autonomic nervous system has served as a primary model system for advancing our knowledge of cellular and molecular processes regulating nervous system development. Perturbations to these processes have allowed us to more fully appreciate the repertoire of responses that comprise developmental neuroplasticity.

The process of nervous system development is itself inherently plastic. During development, undifferentiated cells undergo variable degrees of migration and cell division, giving rise to pools of precursor cells which provide the anatomical substrate of the nervous system. Precursor cells differentiate, taking on specific properties and becoming responsive to chemical cues in their environment, and eventually elaborate axons which find their way to appropriate targets. Neuron numbers are further refined through apoptosis in response to limitations in available target-derived survival factors, thus matching neuronal numbers to target mass and cell type. Target innervation density is then established through the actions of both propulsive and repulsive signals, and retrogradely transported proteins contribute to final determination of transmitter phenotype. In the perinatal period, hormonal factors play increasingly important roles in refining nerve–target relationships. Perturbations to any of these dynamic processes can lead to significant alterations in nervous system properties, which are appropriately defined as 'developmental neuroplasticity.'

Developmental autonomic neuroplasticity is defined here broadly to include pre- and postnatal developmental processes associated with sympathetic and parasympathetic nervous system formation and those perturbations that affect structure, phenotype, and function. These include (1) molecular signaling events regulating autonomic neuronal ontogeny and the impact of their disruption through genetic manipulation and transpositioning or removing individual structures, (2) the establishment and maintenance of autonomic projections to peripheral targets, and (3) establishment, maintenance, and alterations of neurochemical phenotype during development or in response to injury.

Autonomic Gangliogenesis

A defining event in the ontogeny of the autonomic nervous system is the formation of motor ganglia. These consist of aggregates of sympathetic and parasympathetic postganglionic neurons, located in the periphery, which receive excitatory cholinergic synaptic input from preganglionic neurons located in the central nervous system. Autonomic postganglionic neurons derive from the neural crest, a transient structure that originates from cells migrating rostrocaudally from the neural tube shortly after closure. Neural crest precursor cells give rise to a variety of cell types, including melanocytes, peripheral glia, cartilage, smooth muscle, adrenomedullary chromaffin cells, and sensory and autonomic neurons. Those destined to become autonomic ganglion neurons of the peripheral nervous system migrate ventrally through the rostral somitic mesoderm to populate sympathetic and parasympathetic ganglia. Any perturbation that disrupts normal ganglion formation will severely impact autonomic nervous system organization and function.

The generation of autonomic neuronal precursors is complex, involving a variety of transcription factors and signaling proteins (Figure 1, Table 1). A pool of

Figure 1 Schematic diagram indicating processes involved in the ontogeny of the autonomic nervous system, and the roles of some regulatory proteins. Neural crest gives rise to progenitor cells which differentiate into mammalian achaete–scute homolog-1 (MASH1)-expressing autonomic neuronal precursors under the influence of members of the bone morphogenetic protein (BMP) family. Neuronal identity appears to be determined within a BMP gradient, with sympathetic neurons differentiating within high concentrations and parasympathetic neurons differentiating within low concentrations. Parasympathetic neurons require expression of members of the Phox2 family of transcription factors, which are also required for sympathetic neurons, in addition to Hand2 and Gata2. Coalescence of precursors into ganglia requires artemin acting on the GFRα3/c-Ret receptor complex and neuregulin acting on ErbB receptors for sympathetic ganglia, and glial cell-derived neurotrophic factor (GDNF) and neurturin acting on GFRα1 or GFRα2 complexed with c-Ret. Sympathetic axon outgrowth requires both artemin and neurotrophin-3 (NT3), which acts on the TrkA receptor, whereas parasympathetic axon outgrowth may be dependent on GDNF or related proteins. Target-derived factors regulate target innervation: in sympathetic neurons, nerve growth factor (NGF) acting on TrkA can promote neuronal survival and increase innervation density, whereas proNGF and brain-derived neurotrophic factor (BDNF) acting selectively on the $p75^{NTR}$ diminish target innervation density. GDNF regulates innervation density of some parasympathetic targets. Target-derived factors can also influence neuronal neurochemical phenotype.

Table 1 Factors regulating autonomic nervous system development, and effects of mutations of regulatory genes

Factor	*Role in development*	*Effect of deletion*
MASH1, CASH1	Transcription factors specifying autonomic neuron identity	Autonomic neurons fail to form
Bone morphogenetic protein	Regulates formation of autonomic precursors, and differentiation of sympathetic and parasympathetic neurons	Sympathetic and parasympathetic neurons fail to form
Phox2a/b	Transcription factors required for catecholaminergic phenotype	Sympathetic and parasympathetic neurons fail to develop
Hand2, Gata2	Transcription factors specifying sympathetic fate	Absence of sympathetic neurons
Neuregulin, ErbB2/3	Promote sympathetic precursor migration	Inappropriate sympathetic trunk ganglion formation
Hepatocyte growth factor	Neuroblast survival and differentiation	Reduction in sympathetic ganglion neurons
Semaphorin 3A	Neural crest cell migration	Abnormal sympathetic ganglion formation
Neurotrophin-3	Sympathetic axon outgrowth	Impaired axon extension, fewer surviving sympathetic neurons due to inaccessibility to target-derived trophic factors; impaired cholinergic sympathetic phenotype
Glial cell-derived neurotrophic factor, c-Ret, GFRα1/2	Parasympathetic neuron survival, neuroblast migration; axon guidance	Reduced numbers of parasympathetic postganglionic neurons, impaired axon outgrowth
Nerve growth factor	Target-derived protein regulating sympathetic neuronal survival in early postnatal development, and target innervation density	Augmented cell death of sympathetic neurons; absent or diminished sympathetic innervation of some targets
Artermin, c-Ret, GFRα3	Sympathetic neuroblast migration; rostral sympathetic ganglion formation; sympathetic axon outgrowth	Misplaced superior cervical ganglion; impaired sympathetic axon outgrowth
Neurturin	Maintenance of parasympathetic target innervation	Reduced parasympathetic innervation

autonomic neuron progenitor cells differentiates from neural crest precursors under the influence of local expression of bone morphogenetic proteins (BMPs). Differentiation of both sympathetic and parasympathetic precursor cells is dependent upon their expression of the mouse or chick achaete–scute homolog transcription factors, MASH1 or CASH1, respectively, and animals lacking these proteins fail to form autonomic neurons. The transcription factors Phox2a and Phox2b are also involved in expression of catecholaminergic properties, which are characteristic of both sympathetic and parasympathetic neuronal precursors. Phox transcription factors are required for early survival of both sympathetic and parasympathetic autonomic neuron precursors. Sympathetic neuronal precursors are further dependent upon the Hand2 and Gata2 transcription factors.

Autonomic neuronal precursors migrate ventrally toward their ultimate destination, guided by local signaling proteins which, for truncal sympathetic neurons, include neuregulin and Sema3A, acting on the ErbB and neuropilin 1 receptors, respectively. Artermin, acting on the c-Ret and GFRα3 receptors, appears to play an important role in sympathetic ganglion coalescence and in providing chemotactic signals responsible for rostral migration of superior cervical ganglion precursor neurons. The factors regulating parasympathetic neuron migration are less understood, but evidence indicates that in some cranial parasympathetic ganglia, precursors are dependent initially upon glial cell-derived neurotrophic factor (GDNF) via the c-Ret and GFRα1 receptors for ganglion cell proliferation and migration, and subsequently on neurturin and the GFRα2 receptor for neuronal survival and ganglion development.

During normal development, different regions of the neural crest give rise to specific structures. In chick–quail chimeras, for example, rostral parasympathetic ganglion neurons derive from mesencephalic neural crest, whereas sympathetic ganglion neurons derive from the truncal neural crest extending below somite 4. However, premigratory precursor cells apparently are not committed to specific fates. Thus, neural crest cells from the vagal region that would normally give rise to enteric ganglion cells, when transplanted caudally, give rise to apparently normal sympathetic ganglion neurons and adrenomedullary cells. This suggests that neural crest derivatives at this stage remain multipotent and substantially plastic, and differentiation into mature neural crest derivatives is determined largely by peri- and postmigratory environments.

While most migrating neural crest cells become irrevocably committed during the process of migration and gangliogenesis, it is now clear that a small population of precursor cells remains undifferentiated

and may give rise to nascent neurons and glia throughout development and maturity. These presumptive stem cells may serve as a source of cells that can contribute to continued plasticity in the developing and adult organism.

Plasticity of Autonomic Neuroeffector Pathways

Axon Outgrowth

Following migration and coalescence of ganglion cells, connectivity between the central nervous system and peripheral targets must be established. Autonomic neurons elaborate axons in the prenatal and early postnatal periods. Preganglionic axons traverse the anterior region of the somitic mesoderm. Somitic mesoderm appears to play a critical role in preganglionic axon guidance, and removal or transpositioning of somites leads to major alterations in axon trajectory. Preganglionic axons project to the region of their intended ganglion, even if the ganglion has been removed. Once having entered the ganglion, preganglionic axons synapse with the postganglionic neurons; while some synapses are present in the prenatal period, the first postnatal week is characterized by dramatic synaptogenesis and establishment of a functional pathway, at least in the sympathetic inferior cervical ganglion of the rat. Ganglion neurons are initially polyinnervated by convergent inputs from multiple preganglionic neurons, and normal reductions through axon pruning taking place postnatally.

Autonomic postganglionic neurons elaborate axons shortly after exiting the cell cycle, and postganglionic axons first reach their intended targets in the late postnatal period in rodents; substantial increases in numbers of target projecting neurons occur through the first 2–3 postnatal weeks. In the case of sympathetic axonal outgrowth, this appears to be regulated predominantly by two locally produced proteins. Artemin, a member of the GDNF family of trophic factors, is produced by vascular smooth muscle cells in early development, and sympathetic axons at this developmental stage express the artemin receptors c-Ret and GFRα3. Neurotrophin 3 is also produced locally and activates sympathetic TrkA receptors, and is required for normal postganglionic axon outgrowth. The association of these growth factors with vascular smooth muscle is believed to account for the fact that sympathetic pathways associate closely with blood vessels as they course to their target destinations. Parasympathetic axon outgrowth is dependent upon GDNF and its receptors c-Ret and GFRα1. Disruptions of these growth factors or their receptors have serious consequences; without sufficient axon outgrowth, not only are targets hypoinnervated, but neurons are also in turn deprived of required target-derived survival factors and hence undergo abnormally extensive cell death, leading to fewer ganglion neurons. In some cases, diminished postganglionic axon outgrowth affects the mature neurochemical phenotype because of deprivation of target-derived proteins that influence neurotransmitter properties.

One feature of the postganglionic sympathetic system is a dramatic ability to reorganize in response to injury in the postnatal period. For example, innervation of the orbit normally derives exclusively from the ipsilateral superior cervical ganglion, and damage to this pathway in the adult results in sustained denervation and impairment, known clinically as Horner's syndrome. In this syndrome, the pupil is abnormally constricted (loss of excitatory sympathetic innervation to the pupil dilator muscle) and the upper eyelid fails to retract normally (ptosis, due to loss of excitatory sympathetic innervation to the superior tarsal smooth muscle which elevates the eyelid). However, in the neonatal rat, removal of one superior cervical ganglion results in sprouting of spared intracranial vascular sympathetic axons from the contralateral intact ganglion, which take atypical pathways to reach the orbital targets. Despite having significant phenotypic differences from normal resident innervation, such as expression of neuropeptide Y, as is typical of vascular sympathetic neurons but not normal resident tarsal muscle innervation, this aberrant pathway largely restores functional control of the target (**Figure 2**). The ability to establish contralateral orbital innervation is lost completely during the first postnatal month, largely through differentiation of smooth muscle-like myofibroblasts that define their trajectory to the orbit; this coincides with the time course reported for the loss of artemin expression during development in similar cell types, implicating a developmental reduction in artemin expression as a cause of the postnatal diminution in pathway plasticity.

Neuronal Survival: The Neurotrophic Hypothesis

Once the terminal axon reaches the target, a critical process takes place in which the relationship between target and neuron is established and refined, thus ensuring that the neuroeffector pathway is effective and appropriate. This process relies on target-derived proteins that can modify both neuronal survival and terminal axon growth.

The prototypical neurotrophin NGF has long been associated with sympathetic postganglionic axon sprouting *in vitro*, so it is not surprising that this protein would be considered to be the primary candidate for controlling sympathetic innervation. An abundance of

Figure 2 Plasticity in postganglionic pathway formation in the rat. The right superior cervical ganglion was removed from the rat in the top panel on postnatal day (PND) 30, whereas the same ganglion was removed from the rat in the bottom panel on PND 3. The photographs are of the awake rats at 3 months of age. Following PND 30 ganglionectomy, contraction of the superior tarsal muscle in the right eyelid is impaired, leading to ptosis and reduced palpebral fissure width. In the rat receiving ganglionectomy on PND 3, there is minimal evidence of impaired contraction; recovery is due to the formation of an atypical pathway deriving from intact contralateral neurons that normally project to cranial blood vessels to the denervated orbital targets.

information supports the idea that NGF (and many other trophic proteins in different contexts) is required for neuronal survival. Sympathetic neurons are produced in overabundance during development, and a relatively large proportion (in some cases >50%) undergoes developmental cell death in the perinatal period, leading to the ganglion cell numbers ultimately observed in the adult. Those neurons that do survive are believed to be the ones that have obtained access to adequate amounts of a target-derived survival protein (trophic factor, from the Greek term *trophos*, meaning 'to nourish'). However, trophic proteins are believed to be produced in limited quantities. In those sympathetic axons that reach the target first and have access to the greatest amounts of NGF, which binds to the NGF-selective receptor TrkA and is transported retrogradely to the cell body as receptor–ligand complex, programmed cell death (apoptosis) is prevented. Axons that cannot compete for adequate neurotrophic factor because they are misguided or arrive after target innervation has already achieved optimal density ultimately are eliminated through programmed cell death. The principle that an oversupply of developing neurons competes for target-limited trophic factor, thus matching neuronal numbers to target needs, represents the essence of the 'neurotrophic hypothesis.' While less is known about the trophic requirements of parasympathetic neurons, members of the GDNF family of ligands appear to serve similar roles. Modulating the amount of trophic factor available can induce considerable plasticity in the numbers of postganglionic neurons; addition of exogenous NGF or upregulation of its synthesis in peripheral tissues, such as epidermis, results in increased numbers of surviving sympathetic ganglionic neurons. Similarly, depletion of endogenous NGF during development, inactivation of the NGF gene, or null mutations of the TrkA gene encoding the NGF receptor all result in marked reductions in numbers of sympathetic ganglion neurons. A comparable situation has been shown to be the case for cranial parasympathetic neurons, the survival of which is reliant first upon GDNF and subsequently upon neurturin, acting, respectively, on GFRα1 and GFRα2 complexed with the coreceptor c-Ret.

Regulation of Target Innervation

The establishment of effective neuroeffector transmission is dependent upon the presence of appropriate numbers of terminal autonomic axons within the target tissue. Visceral targets show a wide range in the numbers of sympathetic and parasympathetic fibers present per unit tissue mass (innervation density). In light of NGF's well-documented role, not only in inducing sympathetic neuronal survival but also in eliciting robust outgrowth *in vitro*, it is not surprising that this neurotrophin would be a logical candidate for regulating sympathetic innervation density in peripheral targets. Indeed, early studies of several different targets revealed a positive correlation between levels of NGF mRNA or protein and the relative densities of sympathetic innervation. In keeping with this idea, mice with null mutations for NGF or TrkA fail to develop normal target innervation. Conversely, conditions favoring increased target levels of NGF can lead to increased target innervation. For example, spontaneously hypertensive rats display abnormally elevated levels of NGF in the mesenteric vasculature, and these vessels are also hyperinnervated by

sympathetic axons. Further, in keeping with the central tenet of the neurotrophic hypothesis, that neurons compete for limited amounts of trophic factors, neonatal destruction by capsaicin of sensory nociceptor nerves (which express TrkA and compete for target NGF) results in sympathetic axon hyperinnervation; this presumably occurs because reduced competition makes more NGF available to sympathetic axons. Accordingly, alterations in target NGF levels can result in significant plasticity in target innervation density.

While there is little doubt that NGF plays an important role in sympathetic target innervation, recent lines of investigation show that the relationship is far more complex. As indicated earlier, NGF is required for neuronal survival; therefore, loss of innervation in the absence of NGF or TrkA could be due solely to cell death rather than to an absence of local growth-promoting properties. Indeed, using mouse mutants lacking genes for both NGF and the apoptotic factor Bax (thus circumventing cell death that would normally occur in the absence of NGF), Ginty and colleagues found that the dependency on NGF for development of target innervation was highly variable, with innervation of some targets being drastically reduced (e.g., salivary glands, heart) while others were unaffected (trachea). This supports the idea that growth-promoting factors other than NGF contribute to target sympathetic innervation.

A second complicating factor is that, in addition to propulsive effects of proteins such as NGF and GDNF, autonomic target innervation appears to be controlled by proteins that are repulsive in nature. For example, sympathetic neurons are responsive to semaphorins and can be repulsed from targets expressing high levels of these proteins. Moreover, neurotrophins show surprising complexity. In addition to the TrkA receptor mediating sympathetic neuron survival and axon outgrowth, the pan-neurotrophin receptor $p75^{NTR}$ can facilitate ligand binding to TrkA, but can also mediate repulsive cues. Brain-derived neurotrophic factor (BDNF), a neurotrophin closely related to NGF, shows little affinity for TrkA but binds avidly to $p75^{NTR}$. When $p75^{NTR}$ is selectively activated, this inhibits sympathetic axonal outgrowth and contributes to sympathetic axon pruning (and in some cases can cause cell death). Importantly, in addition to BDNF, the precursor form of NGF, proNGF, shows relatively little affinity for TrkA but strongly binds $p75^{NTR}$, and, like BDNF, can be repulsive and pro-apoptotic to sympathetic neurons. Thus the extent to which NGF regulates target innervation density will depend upon which form predominates.

The balance between TrkA and $p75^{NTR}$ activation has important implications for developmental plasticity of sympathetic innervation. Some targets, such as those of the female reproductive tract, undergo considerable innervation plasticity in the postnatal period. For example, uterine innervation changes through puberty and beyond, under the influence of the gonadal steroid hormone estrogen; in fact, changes in estrogen lead to reductions in myometrial sympathetic innervation at the estrus stage of each estrous cycle. Available evidence shows that estrogen increases uterine expression of BDNF, and that fluctuations in this hormone underlie physiological axon pruning that takes place during puberty and throughout the reproductive cycle.

Neurochemical Plasticity

Neural crest progenitor neurons give rise to a richly diversified range of peripheral autonomic neurons. Fully differentiated parasympathetic neurons typically express a cholinergic phenotype, which includes choline acetyltransferase and vesicular acetylcholine transporter (VAChT), a nitrergic phenotype (neuronal nitric oxide synthase), and the neuropeptide vasoactive intestinal polypeptide (VIP). Most mature sympathetic neurons are noradrenergic, expressing the proteins tyrosine hydroxylase (TH), dopamine β-hydroxylase (DBH), vesicular monoamine transporter-2 (VMAT2), and the norepinephrine transporter; a significant proportion of noradrenergic sympathetic nerves, mainly those innervating blood vessels, also contain neuropeptide Y. About 5% of mature sympathetic neurons, which project to eccrine sweat glands and periosteum, are cholinergic. Neural crest progenitor cells also give rise to autonomic ganglionic small intensely fluorescent (SIF) cells, which are dopaminergic (express TH but not DBH), and adrenomedullary chromaffin cells (synthesize epinephrine and contain phenylethanolamine *N*-methyltransferase (PNMT), in addition to TH and DBH).

The differentiation of parasympathetic and sympathetic neurons appears to be regulated by way of a BMP gradient; progenitors most proximate to BMP-producing tissues (e.g., dorsal aorta) acquire a noradrenergic phenotype, while those exposed to lower concentrations become cholinergic parasympathetic neurons. Differentiation of both types of neurons requires MASH1 and Phox2a/b transcription factors, and noradrenergic neurons additionally require the Hand2 and Gata2 transcription factors. Differentiation of neural crest progenitors into adrenomedullary chromaffin cells is, in part, under control of the local environment; corticosteroid derived from the surrounding adrenal cortex is required for PNMT expression. Local factors have also been implicated in phenotype acquisition and maintenance in SIF cells,

which are located proximate to blood vessels and may require endothelial factors for differentiation.

The common origins of both sympathetic and parasympathetic neurons underlie sustained similarities throughout development and presage responses observed with certain perturbations. Experimental observations in neural crest-derived precursor cells reveal that the biochemical machinery necessary for acetylcholine synthesis is present well before commitment to final cell fate. Similarly, catecholaminergic properties have also been described as a feature of autonomic neuron progenitors prior to expression of other pan-neuronal properties.

Transmitter Phenotype 'Switching'

While genetic programming and instructive signals during precursor migration and gangliogenesis appear to play a major role in determining autonomic neuronal phenotype, target-derived proteins are also important in determining or refining mature neuronal phenotype. The best studied example of this is the transition from an adrenergic to a cholinergic phenotype in some sympathetic neurons. Early studies showed that neonatal sympathetic neurons cultured under certain conditions (e.g., in culture medium conditioned by cardiac myocytes) lose their noradrenergic phenotype, and this is replaced over time by cholinergic properties. In an extensive series of experiments, Story Landis and colleagues extended these findings *in vivo* by showing that sweat glands, which are innervated by cholinergic sympathetic axons in the adult, are actually innervated by axons with a catecholaminergic phenotype at postnatal day 4; however, these catecholaminergic properties (dense core vesicles, catecholamine histofluorescence, and TH immunoreactivity) are downregulated over the next 10 days and are replaced by cholinergic properties (VIP immunoreactivity and cholinesterase activity). An impressive body of evidence has been accrued to support the idea that these neurons undergo a 'phenotype shift' from catecholaminergic to cholinergic. Evidence in favor of this hypothesis includes several findings: (1) destruction of catecholaminergic fibers by neonatal administration of selective neurotoxins 6-hydroxydopamine, guanethidine, or antisera to NGF prior to the shift prevents sweat gland cholinergic innervation, even though cholinergic nerves should be unaffected by these treatments, (2) transplantation of the sweat glands to ectopic sites where sympathetic nerves normally do not show a cholinergic phenotype (trunk hairy skin, ocular anterior chamber co-cultures with the superior cervical ganglion) induces cholinergic properties, (3) replacement of sweat glands with a target that normally is not innervated by cholinergic sympathetic axons (salivary gland) prevents cholinergic properties from appearing in the resident innervation, and (4) mouse mutants that fail to develop sweat glands also fail to develop cholinergic fibers to the footpad. Further studies have shown that the shift is facilitated by an interactive loop with the target, in which noradrenergic transmission accelerates acquisition of cholinergic properties, and that a similar phenotypic shift occurs to sympathetic innervation to the periosteum; periosteal cells induce a VIP and VAChT phenotype in resident innervation and also when transplanted to ectopic sites. The factors responsible for this shift have not been definitively identified, but members of the gp130 cytokine family, which includes leukemia inhibitory factor and cardiotropin, promote cholinergic properties in cultured neurons and are strong candidates.

Recent studies imply that the establishment of cholinergic traits in sympathetic neurons is more complex. Using antibodies with high sensitivity to VAChT, it appears that cholinergic properties are demonstrable in subpopulations of sympathetic neurons prior to target innervation, and that sweat gland-innervating fibers can express VAChT at an age supposedly preceding the phenotype shift. Thus, the extent to which cholinergic properties are conferred *de novo* by the target or are instead an intrinsic property of sympathetic neurons undergoing normal development *in vivo* remains uncertain. Nonetheless, it is clear that some targets produce factors that are capable of inducing neurochemical phenotype plasticity in developing sympathetic neurons.

Another factor that can influence neurochemical phenotype is injury. Normally, VIP-immunoreactive neurons are only rarely encountered in the superior cervical ganglion. Following axotomy, however, VIP is dramatically upregulated *in situ* or under culture conditions. This implies that the factors normally responsible for providing a stable neurochemical phenotype can be affected by injury.

Autophagy and Neuronal Death

Autophagy and Its Role in the Mediation of Autophagic Cell Death

Autophagy

Although this article is primarily concerned with neurons, and the implication of autophagy in their death, it will be necessary to draw general principles from studies on other cell types, because autophagy is a general phenomenon occurring in virtually all types of cell, and the most convincing molecular analyses of its role in cell death have been done in nonneuronal cell lines.

Autophagy is the mechanism by which cells degrade parts of their own cytoplasm using the lysosomal machinery. There are several types of autophagy, including microautophagy, the direct capture of tiny portions of cytosol by invagination of lysosomal membranes; chaperone-mediated autophagy, a specific mechanism for degrading cytosolic proteins containing a particular pentapeptide consensus motif; pexophagy, the specific autophagocytosis of peroxisomes; and macroautophagy, which involves the engulfment of sizeable regions of cytoplasm, including organelles, in double-membrane vesicles called autophagosomes. Macroautophagy is the best-studied type of autophagy, and the only type that has been studied in detail in relation to cell death. This article will therefore deal primarily with macroautophagy.

Macroautophagy (Figure 1) is initiated by the formation of autophagosomes (about 400–800 nm in diameter) from cup-shaped double-membranous structures called isolation membranes or phagophores, which engulf cytosolic components, including organelles. The isolation membrane then closes to form the autophagosome. The origin of the isolation membrane is still a matter of debate. There is evidence that it may arise from various sources including smooth endoplasmic reticulum and the *trans*-Golgi network, but recent research on yeast indicates that a major source of its membrane is an independent punctate structure called the 'pre-autophagosomal structure.' The autophagosome fuses with a lysosome to form an autolysosome, where the enclosed material is broken down. The term 'autophagic vacuole' includes both autophagosomes and autolysosomes.

Autophagy (including macroautophagy) is involved in the normal turnover of cell contents and is enhanced by cellular stresses, against which it provides protection, for example, by replenishing the pool of free amino acids in the case of amino acid depletion, or by eliminating damaged proteins. Also, by reducing the size of stressed cells, autophagy reduces their metabolic burden. Thus, in many situations, autophagy promotes the health and survival of cells.

Autophagic Cell Death: Origins of the Concept

Despite the life-promoting roles of autophagy, macroautophagy has also been associated with cell death, and the term 'autophagic (or type 2) cell death' is used as a morphological classification for dying cells containing numerous autolysosomes. This occurs frequently during embryonic development and is probably the most common type of cell death in insect metamorphosis, but (macro)autophagic features are also associated with many cases of pathological cell death including heart failure, excitotoxicity, and neurodegenerative diseases.

Historically, the development of electron microscopy permitted the discovery of (macro)autophagy in the early 1960s, and this was soon followed by numerous ultrastructural studies from the mid-1960s onward, showing an abundance of autolysosomes in dying cells in many situations, including most cases of metamorphosis. Nevertheless, even as late as the 1990s, only a few authors considered that the autophagy was instrumental in the cell death.

The reasons for this reluctance were multiple. One was that autophagy had from the moment of its discovery been understood to play physiological roles in healthy cells, for example, the provision of breakdown products for reuse and the elimination of abnormal proteins, and several authors interpreted its presence in the dying neurons to reflect an unsuccessful survival-promoting mechanism for eliminating damaged regions of cytoplasm. Many other authors were influenced by the (then) widely accepted 'suicide bag hypothesis' of De Duve, discoverer of the lysosome, according to which cell death is achieved by the release of hydrolases from the lysosomes; the status of this hypothesis is still controversial. Then, as the suicide bag hypothesis gradually fell out of favor in the 1970s and 1980s, the simultaneous rise in popularity of a somewhat rigid dichotomy according to which all cell death had to be apoptosis or necrosis did not encourage openness to alternative mechanisms of cell death. Indeed, proponents of the apoptosis–necrosis dichotomy maintained that

Figure 1 Macroautophagy. An isolation membrane (formed from smooth endoplasmic reticulum, the *trans*-Golgi network, or the 'pre-autophagosomal structure') enwraps cytosolic components and closes to form the two-membraned autophagosome, which then fuses with a lysosome or late endosome to give an autolysosome, in which the engulfed contents and the inner autophagosomal membrane (shown in green) are degraded.

autophagic dying cells were in fact undergoing apoptosis and that the autolysosomes were either a protective reaction or an irrelevant epiphenomenon. And, finally, it has to be admitted that a death-mediating role for the autophagy had not been proved, and in several cases very strong autophagy can occur without neuronal death.

The idea of autophagy-mediated cell death was, however, supported in the 1980s by experiments on neuronal death in the target-deprived isthmo-optic nucleus in chick embryos. (The isthmo-optic nucleus is the source of efferents from the brain to the retina in birds.) This neuronal death was characterized by abundant autolysosomes that ultimately filled most of the cytoplasm, and also by the loss of DNA from the nucleus to neighboring lysosomes. The fact that a cell's own DNA was being degraded by autophagy went against the view that the autophagy was a survival-promoting reaction to cellular stress.

Prevention of Autophagic Cell Death by Pharmacological Inhibitors of Autophagy

Nevertheless, a death-promoting role for autophagy gained only limited acceptance until it could be proved that inhibiting it prevented cell death. Initial evidence for this was provided in the 1990s by the death-preventing effects of 3-methyladenine (3-MA), an inhibitor of the formation of autophagic vacuoles that has been described as 'specific' but only in the limited sense that it does not alter the overall level of protein synthesis. Sandvig and van Beurs first showed, in 1992, that cell death, in this case toxin induced, could be prevented by 10 mM 3-MA. Subsequently, similar doses of 3-MA were shown to prevent (partially or completely) or delay cell death with autophagic characteristics in many situations including sympathetic neurons deprived of nerve growth factor, telencephalic neurons exposed to chloroquine, and cerebellar granule neurons deprived of serum and potassium. In all cases, the dying cells were shown to contain numerous autophagic vacuoles, and their rescue by 3-MA was accompanied by a reduction in their content of autophagic vacuoles. The suppression by 3-MA of autophagy is probably due to its inhibition of class III phosphatidylinositol 3-kinase (PI3-K), but it was uncertain whether this is also the basis of its protection against autophagic cell death, because its pharmacological profile is poorly characterized and it probably affects other enzymes. It was therefore important to test whether better-characterized inhibitors of PI3-K (LY294002 and wortmannin) could have similar protective effects. In many situations, these inhibitors are proapoptotic, because they inhibit the powerfully protective class I PI3-K pathway, so a protective effect due to inhibition of class III PI3-K (and hence autophagy) can easily be masked; but in serum-deprived PC12 cells, LY294002, wortmannin, and 3-MA have all been shown to be protective, apparently through the blockade of autophagy.

Prevention of Autophagic Cell Death by Interference with Autophagy Genes

However, even the better-characterized PI3-K inhibitors affect other cellular processes as well as autophagy, and definitive evidence for the death-mediating role of autophagy was provided only recently, by studies involving RNA interference of specific autophagy genes.

Our understanding of the control mechanisms of autophagy (particularly macroautophagy) depends to a great extent on intensive studies on autophagy in yeast, where about 30 genes controlling the initiation and execution of autophagy have been identified during the last decade. Until recently, these were grouped into three main gene families (apg, aut, and cvt), according to the genetic screens in which they were detected, but the functional distinctions between these families do not appear to be very clear-cut, and in the current terminology all the genes are grouped into the single 'atg' (autophagy gene) family (atg1–atg29 at the time of writing, but new members continue to be discovered). A detailed description of how these genes control autophagy would be beyond the scope of this chapter, but it is highly relevant to our present concerns that many of the yeast genes have vertebrate (including mammalian) homologs, and that certain of them, including atg5, atg6 (beclin 1), and atg7, are essential for the formation of autophagosomes.

This fact was used in two key papers in 2004 in which macroautophagy was blocked by RNA interference of atg5, atg6 (beclin 1), and atg7 (as well as by pharmacological inhibitors of autophagy) in cell lines whose apoptotic machinery had been deactivated genetically or pharmacologically. In both papers, pure autophagic cell death occurred and both the autophagy and the accompanying cell death were prevented by the RNA interference (and by the pharmacological inhibitors). Although a role for the autophagy genes in processes other than autophagy cannot be entirely ruled out, the fact that silencing each of the three genes prevented the autophagic cell death is strong evidence that the (macro)autophagy is not merely an epiphenomenon, or a defensive reaction, but is actually involved in mediating the cell death.

The Importance of Autophagy-Mediated Cell Death in Relation to Apoptosis

Autophagic cell death, as judged morphologically, seems to be the commonest type of cell death in physiological situations of massive cell death leading to the destruction of a tissue, as in many cases of metamorphosis and in some radical cases of mammalian embryonic tissue remodeling, whereas apoptosis appears to be the usual mechanism where sporadic dying cells occur in a tissue destined to survive. Thus, if autophagy could be assumed to mediate cell death in all cases of morphologically identified autophagic cell death, one could conclude that the autophagic death mechanism was of almost equal importance to the apoptotic mechanism.

Unfortunately, this is currently uncertain. While the reliability of 3-MA in protecting against many different cases of autophagic cell death does suggest that the autophagic death mechanism is of widespread importance, the more specific studies with RNA interference (or antisense) are still few in number, and situations have been reported in which massive autophagy can occur in cells without them dying. Moreover, there is evidence that a lysosomal, presumably autophagic, mechanism can initiate caspase activation and apoptosis. This is clearly different from autophagic cell death, which in many cases has been shown to be caspase independent, but does mean that morphological evidence for autophagy cannot be taken as proof of autophagy-mediated cell death. Thus, although the existence of an autophagic death mechanism is now difficult to deny, its generality and importance are still matters of debate.

Indeed, it has recently been argued that autophagy may mediate cell death only in very artificial situations where apoptosis has been deactivated (as in the two RNA interference studies mentioned above). Even if this were true, it would not detract from the importance of autophagic cell death in many pathological situations, where apoptosis may indeed have been deactivated either genetically (as in cancers that have become resistant to apoptosis-promoting chemotherapy) or pharmacologically (as in anticaspase neuroprotective protocols). But it has recently been shown that downregulation of atg5 by antisense technology protected against interferon-γ-induced autophagic cell death in HeLa cells whose apoptotic machinery had not been inhibited. Moreover, pharmacological blockade of autophagy by inhibition of PI3-kinase actually enhances the apoptotic machinery by increasing caspase-3 activation, but it can still prevent or delay cell death.

Thus, the autophagic death mechanism can be effective without the artificial deactivation of apoptosis, but its generality and importance are still not entirely clear.

Autophagy in Neuronal Death and Neurodegeneration

Autophagy in Neuronal Death

Although our mechanistic understanding of autophagic cell death has come largely from studies of

Table 1 Reports of neuroprotection by 3-MA

Situation	*Autophagic morphology?*	*Protection by 3-MA?*	*Caspase-dependent?*	*Reference*
Cerebellar granule neurons deprived of serum and potassium	Yes	Partial protection	Partially	Kaasik et al. (2005)
Cerebellar granule neurons in low potassium	Yes	Yes	Yes	Canu et al. (2005)
Telencephalic neuronal cultures exposed to chloroquine	Yes	Yes	No	Zaidi et al. (2001)
Sympathetic neurons treated with cytosine arabinoside	Yes	Cell death delayed	No	Xue et al. (1999)
Sympathetic neurons deprived of NGF	Yes	Cell death delayed	No	Xue et al. (1999)

nonneuronal cells, there is considerable morphological evidence for autophagic 'neuronal' death in all the main situations where neurons die: in natural development, in various pathological situations, and in experimental models, as is discussed below. In addition, there are a few studies showing the prevention of autophagic neuronal death by 3-MA (see Table 1).

Autophagic Neuronal Death during Development

Reports of autophagic neuronal death occurring naturally during development are relatively few, and most concerned anuran metamorphosis, including the death of the Rohon–Beard neurons, a transient population of sensory neurons that undergoes 100% cell death. In mammals, one is able to find only one relevant report; it concerned autophagic neuronal death in the developing cerebral cortex. This paucity of reports suggests that autophagic cell death plays only a relatively minor role in naturally occurring neuronal death in mammals (and other higher vertebrates). This fits with the generalization made above, that autophagic cell death occurs most commonly in physiological situations of massive cell death leading to the destruction of a tissue. However, caution is required, because in many studies isolated autophagic dying cells may have been mistaken for phagocytes, which they resemble morphologically and in their expression of autophagic markers.

Failure in competition for retrograde neurotrophic support is believed to be a major cause of naturally occurring neuronal death, and numerous studies of neuronal death in development have involved axotomy or other means of depriving neurons of retrograde support. In some cases, the resulting neuronal death was autophagic, but in many others it was clearly not. The reasons for the differences are unclear, but one factor may be the developmental stage. This was first indicated by an elegant study by Decker in 1978 on motor neuronal death in larval frogs. He found that very early axotomy caused a pyknotic (apoptosis-like) morphology, whereas very late axotomy caused classic chromatolysis. But axotomy at an intermediate stage caused the 'genesis of numerous secondary lysosomes in degenerating cells' – in other words, cell death with an autophagic morphology.

Studies on the isthmo-optic nucleus of chick embryos showed an age dependence that was similar to the above but not quite so clear cut. Early deprivation of retrograde support by blocking axonal transport in the isthmo-optic axons led to isthmo-optic neuronal death with a mixed morphology that was both pyknotic and autophagic, whereas later transport blockade caused a purer form of autophagic cell death with only minimal pyknosis (Figure 2). This neuronal death was also characterized by strong endocytic activity, a phenomenon that has since been observed in several subsequent studies of stressed, but not necessarily dying, neurons. Isthmo-optic neuron death could also be provoked by de-afferentation, but this caused no signs of autophagy, and when combined with blockade of retrograde support it decreased the autophagic characteristics of the dying neurons.

Neuronal Autophagy in Acute Neurological Conditions

The neuronal cell death in virtually all acute neurological conditions (e.g., stroke, traumatic brain injury, and neonatal asphyxia) shares a common mechanism: excitotoxicity, excessive depolarization that is usually due to the excessive activation of glutamate receptors, especially the *N*-methyl-D-aspartate (NMDA) subtype. Excitotoxic neuronal death is generally considered to be necrosis (most commonly) or apoptosis or a combination of the two, and, until recently, the presence of enhanced autophagy in these conditions was largely ignored. However, over the last few years, morphological evidence for intense autophagy and an increase in the autophagosomal marker LC3-II have been reported in several experimental models of cerebral hypoxia–ischemia, and an increase in the autophagy gene beclin 1 has been reported in a model of traumatic brain injury. NMDA receptor activation has likewise

Figure 2 Electron micrographs of two autophagic dying neurons in the isthmo-optic nucleus of 14-day-old chick embryos. The death of both neurons was provoked by an injection of colchicine in their axonal target territory, which blocked axoplasmic transport, depriving them of retrograde support. (a) Early stage of neuronal death. Several vacuoles are found in the cytoplasm of the soma and main dendrite. The nucleoplasm and cytoplasm are somewhat denser than in a healthy neuron. (b) Advanced stage of neuronal death. The vacuoles are larger and more numerous, many containing membranous whorls. The arrows indicate vacuoles labeled with intravascularly injected horseradish peroxidase (in this and several other cases autophagic dying neurons have been shown to be strongly endocytic). Scale bar = 2 μm. From Hornung JP, Koppel H, and Clarke PGH (1989) Endocytosis and autophagy in dying neurons: An ultrastructural study in chick embryos. *Journal of Comparative Neurology* 283: 425–437.

been shown to induce autophagic neuronal death, in organotypic hippocampal cultures. This neuronal death was also characterized by strong endocytosis of exogenous horseradish peroxidase (Figure 3). However, it is currently unknown whether the autophagy in acute neurological conditions and excitotoxicity mediates cell death.

Autophagy in Neurodegenerative Diseases

In contrast to acute neurological conditions, neurodegenerative diseases involve progressive neuronal degeneration over periods of many months or years. Changes in the endosomal–lysosomal system, including increased macroautophagy, have been reported in virtually all neurodegenerative diseases including Alzheimer's, Huntington's, and Parkinson's diseases, prion diseases, and amyotrophic lateral sclerosis. The causes and roles of the increased macroautophagy are difficult to establish in human diseases, but additional information from experimental models provides some preliminary hypotheses. From models of Alzheimer's, Huntington's, and Parkinson's diseases, there is evidence that the macroautophagy may in many cases be involved in clearing protein aggregates from affected neurons, and hence be protective, but may also lead to autophagic neuronal death.

In Huntington's disease, the autophagy seems to be primarily protective. This disease involves massive neuronal death in the striatum as a result of the presence of an expanded polyglutamine repeat in the Huntington gene product. The dying neurons have a strongly autophagic morphology, and the autophagy appears to be a defense mechanism because the experimental enhancement of autophagy in fly and mouse models of Huntington's disease reduces the accumulation of polyglutamines as well as the neuronal death, whereas inhibition of autophagy has the opposite effect on both.

In Parkinson's disease, the situation is more ambiguous. The best-known neuropathological characteristics of this disease are the degeneration of dopaminergic neurons of the substantia nigra, and the presence of cytoplasmic inclusions called Lewy bodies in these neurons before they die. Lewy bodies contain ubiquitinated aggregates of α-synuclein and other proteins. There are reports that this neuronal death can have an autophagic morphology. Some cases of early-onset Parkinson's disease involve a mutation in the α-synuclein gene. In cultured PC12 cells, overexpression of mutant but not wild-type α-synuclein causes an impairment in the ubiquitin–proteasome system and the presence of ubiquitinated protein aggregates, an accumulation of autophagic vacuoles, and increased nonapoptotic autophagic cell death. Thus, although the increased autophagy may be an attempt to protect the cells by clearing the protein aggregates, it may also be involved in mediating the neuronal death.

Alzheimer's disease is characterized by the presence of (extracellular) β-amyloid plaques and filamentous tangles, primarily in the hippocampus and cerebral cortex. Both are currently believed to be involved in the degenerative changes in these brain regions. Pronounced macroautophagy has been demonstrated in the affected neurons, and β-amyloid has been shown to be generated by the proteolytic cleavage of β-amyloid precursor protein. In a mouse model of the

Figure 3 Autophagic degenerating neurons in the CA1 region of organotypic hippocampal cultures after 2 h (a) or 8 h (b) of exposure to 100 μM NMDA. (a) Thick white arrows, membranous whorls (autolysosomes); black arrows, endosomes labeled with horseradish peroxidase; N, nucleus. (b) Clumps of peroxide labeling within a large vacuole; stars, putative unlabeled endosomes. Scale bar = 1 μM. Reproduced from Borsello T, Croquelois K, Hornung JP, and Clarke PGH (2003) *N*-methyl-D-aspartate-triggered neuronal death in organotypic hippocampal cultures is endocytic, autophagic and mediated by the c-Jun N-terminal kinase pathway. *European Journal of Neuroscience* 18: 473–485, with permission from Blackwell Publishing.

disease, a similar neuronal macroautophagy occurs, and this happens rather early, before the extracellular β-amyloid deposits, but the maturation of autophagosomes to autolysosomes appears to be impaired. At later stages, there is a further accumulation of autophagosomes, and these are rich in β-amyloid. Inducing or inhibiting macroautophagy elicits parallel changes in macroautophagy and β-amyloid production, suggesting that in this case the macrophagy may contribute to the disease process, but not necessarily through autophagic cell death.

Neuronal Autophagy in Lysosomal Storage Diseases

Lysosomal storage diseases are caused by mutations in the genes encoding various lysosomal hydrolases, leading to the accumulation (or 'storage') of partially digested substances in lysosomes. Different lysosomal storage diseases cause degenerative and other changes in different organs of the body, including in some cases the brain (e.g., in Tay–Sachs disease and Niemann–Pick C disease). Whereas most neurodegenerative diseases involve increased lysosomal digestion, lysosomal storage diseases are caused by a 'decrease' in one particular component of lysosomal digestion, but this can lead to complex changes in many different cellular signaling pathways. Since the genetic mutation directly affects the lysosomal system, autophagic digestion must presumably be affected. There have been few studies of autophagy in neuronal death in these diseases, but in a mouse model of Niemann–Pick C disease there was massive degeneration of cerebellar Purkinje cells, which had features consistent with autophagic cell death.

Aversive Emotions: Genetic Mechanisms of Serotonin

S E Ahmari, M D Alter, and R Hen, Columbia University, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Anxiety and fear responses are necessary components of adaptive behavior. Fear of predators and normal vigilant behavior are essential for survival in the wild. It is when these responses are uncontrollable that they stop being protective, instead becoming maladaptive and pathological, ultimately impairing an individual's ability to function in the world.

Though a complete understanding of the neurobiological mechanisms underlying normal and pathological fear and anxiety remains a future goal and motivator for research, a role for serotonin, also known as 5-hydroxytryptamine (5-HT), in these emotions has been firmly established. Both clinical evidence, ranging from empirical data (serotonin reuptake inhibitors have been found effective in treating a wide range of anxiety disorders; see Table 1) to human genetic studies, and animal experiments have supported a role for this neurotransmitter in both normal anxiety and pathological disease states. For example, there is evidence from human linkage analyses implicating monoamine oxidase A (MAO-A; a molecule which plays a key role in the degradation of serotonin) in the pathophysiology of panic disorder, and also suggesting a role for the serotonin transporter and two serotonin receptors (5-HT1B and 5-HT2A) in obsessive–compulsive disorder (OCD). It is likewise clear that neurotransmitters other than serotonin play a role in the development of anxiety and fear responses. However, though the story is ultimately likely to be very complex, with particular neurotransmitters and receptors being important at different times in development and with gene–environment interactions and epigenetics playing important roles in the ultimate determination of behavioral phenotypes, focusing on the role of serotonin will serve as a starting point for discussion. One way of shedding light on the role of this neurotransmitter in fear and anxiety is through examination of the combination of the effects of serotonin-related genetic factors and early life stress on development and the impact of these factors on the development of anxiety disorders in later life.

Relationship between Fear and Anxiety

Though there is a close relationship between fear and anxiety, and animal models of fear conditioning have allowed us to gain important insights into the neural circuits underlying anxiety, it is apparent that there is a distinction between these responses despite substantial overlap in involved brain regions. Past models have differentiated fear as being a response to real threats and anxiety as being an abnormal response to a perceived threat in the absence of immediate danger to the organism. Alternatively, one can understand fear as being stimulus specific (akin to 'phobia' in humans), whereas anxiety is more generalized. Despite this distinction, it seems apparent that there is substantial overlap in the neural circuitry of fear and anxiety. For example, rodent studies of fear conditioning have clearly demonstrated the involvement of cortical and thalamic projections to the lateral nucleus of the amygdala, where substantial intra-amygdala processing occurs. Projections then arise from the central nucleus of the amygdala to areas of the brain stem, hypothalamus, and hippocampus, leading to fear responses. However, there is evidence that different amygdala output tracts may differentially subserve fear versus anxiety responses. For example, by using bright light exposure and corticotropin-releasing hormone-enhanced startle paradigms to model anxiety in comparison to stimulus-specific fear conditioning, Davis and colleagues demonstrated differential involvement of the bed nucleus of the stria terminalis in anxiety versus the central nucleus of the amygdala in fear, despite very similar output projections to the hypothalamus and brain stem. Human neuroimaging studies of perception of fearful faces (trait anxiety) and fear conditioning have clearly demonstrated involvement of the amygdala, hippocampus, and thalamus; similarly, neuroimaging studies of anxiety disorders have also implicated the amygdala (post-traumatic stress disorder (PTSD), phobia, OCD, panic disorder), prefrontal cortex (PTSD, generalized anxiety disorder (GAD), OCD, phobia), hippocampus (PTSD, phobia, panic disorder), and striatum (OCD, phobia). The remainder of this article will focus on the relationship between serotonin and the development of anxiety responses in both animals and humans, with the understanding that there is likely a close relationship between anxiety and fear responses, particularly in disorders such as PTSD.

Early Life Stress and Mental Health

A multitude of research studies associate early life stress with the development of mental health problems. Morbidity and mortality from a wide array of medical and mental illnesses are increased in abused children. Even less severe forms of early-life

stress have been associated with an increase in adverse outcomes. For example, children brought up in families characterized by a lack of parental warmth or either over- or underregulation of children's behavior are more likely to have a host of medical or psychiatric problems. One could speculate that such children might start to have aberrations in the regulation of normal anxiety and fear responses early in development, which ultimately puts them at greater risk for development of disordered mood in later life.

Still, not all children exposed to these stressful environments have adverse outcomes. A particularly interesting line of research has demonstrated that at least a portion of these effects is mediated by genetic variability of the serotonin system. In a landmark study, Caspi and colleagues demonstrated that boys with a hypofunctioning polymorphism in the MAO-A gene are at increased risk for adolescent and adult antisocial behavior if they were abused during childhood. Since MAO-A is one of the primary enzymes responsible for the breakdown of serotonin in the central nervous system, this finding demonstrates a potential interaction between serotonin genetics and adolescent and adult psychopathology. Similarly, in a separate study in the same prospective cohort but utilizing both boys and girls, individuals homozygous (s/s) or heterozygous (l/s) for the short allele of a hypofunctioning polymorphism in the serotonin transporter (SERT) gene were found to have a markedly increased risk for depression if subjected to child abuse, but individuals homozygous for the normal functioning long allele (l/l) had no increase in depression when exposed to abuse. Many studies have since examined the relationship between SERT and MAO polymorphisms and various forms of psychopathology, demonstrating associations in OCD, panic disorder, specific and social phobia, GAD, and anxious personality traits.

When examining the multiple studies demonstrating the detrimental effects of early life stress and genetic variance on mental health, the logical next question is, how are these detrimental effects being mediated? An attractive hypothesis is that early life represents a particularly sensitive period for the development of neural circuits and that disruption of the normal processes of establishing these circuits makes a person more vulnerable to the development of psychopathology.

Sensitive Periods of Development: A Role for Serotonin?

A sensitive period is a general term that applies whenever experience has a particularly strong and lasting effect over a limited time (Figure 1). A classic example is that of filial imprinting, which occurs shortly after birth as a young animal learns to recognize and bond with its parent. An important characteristic of sensitive periods is that the effects of experience are not readily amenable to change after the sensitive period has occurred. For example, once an animal has undergone imprinting, the attachment to the parent will be strong and persistent; moreover, attachment to an alternative parental figure will be much more difficult to achieve. This is thought to occur because, though sensitive periods are marked by behaviors such as attachment to a parent or speaking a language, they are actually a property of underlying neural circuits. The properties of the neural circuits are shaped by experience during the sensitive period, and once formed, they may be modulated but do not easily change their basic structure. Furthermore, because behaviors, complex behaviors like language or anxiety responses in particular, represent the coordination of many neural circuits, the true effect of the persistence of circuit-level changes occurring during a sensitive period will tend to be underestimated.

Sensitive periods are of particular interest to researchers and clinicians because they represent periods in development during which certain capacities are readily shaped or altered by experience and therefore may serve as key points during which interventions may have a lasting impact on the development of normal versus abnormal brain circuits.

Figure 1 Sensitive period. The immature brain goes through a sensitive period of development during which it is particularly sensitive to environmental and genetic factors. Changes that occur during this period are persistent and are reflected as differences in adult behavior.

Research on the serotonin system underscores an important role of serotonin in the development of anxiety. Many regions innervated by the serotonin system, including the amygdala, hippocampus, anterior and posterior cingulate, and prefrontal cortex, have been suggested to play a role in anxiety and anxiety-like behavior. Studying the genetics of the serotonin system has helped to outline circuits important in anxiety and to further suggest that serotonin affects these circuits during sensitive periods of their development. This work has repeatedly pointed to early life as a sensitive period of development and the amygdala and hippocampus as regions of importance. Together, these lines of research are lending insight into how a molecule traditionally believed to be involved only in synaptic transmission can have multiple roles in shaping brain development and complex behavioral responses.

Serotonin Has Multiple Roles

Initially isolated from serum in 1949 and detected in the mammalian brain in 1953, serotonin is traditionally viewed as a modulatory neurotransmitter. Serotonergic neurons cluster in the brain stem, primarily in the dorsal and median raphe nuclei, and send projections throughout the brain and spinal cord. Dorsal raphe neurons preferentially send projections to the basal ganglia (striatum, substantia nigra); in addition, they typically have small fusiform boutons, diffusely branching fibers, and likely more release of extrasynaptic serotonin. In contrast, neurons in the median raphe nuclei mainly project to components of the limbic system (hippocampus, amygdala) and have large, spherical varicosities with extensive repeated synapses. Notably, there is significant overlap in projection areas from these two sets of nuclei, and single serotonergic neurons have been found to innervate multiple regions in a synaptically connected circuit.

Through its diverse projections, the serotonin system plays a role in modulating sleep, appetite, memory/cognitive function, impulsivity, sexual behavior, motor function, and limbic/affective responsiveness. In addition to this traditional understanding of serotonin as a neuromodulator, increasing evidence demonstrates that neurotransmitters, including serotonin, have important roles in development. Serotonin in particular has been closely studied in this regard. Pharmacologic studies have demonstrated that serotonin can modulate a number of developmental events, including cell division, neuronal migration, cell differentiation, and synaptogenesis.

At first glance, it appears unlikely that one neurotransmitter could have such diverse modulatory functions and also play a role in the regulation of complex neural circuit formation. However, the serotonin system seems ideally suited for this position as it is itself quite complex and diverse; it therefore appears perfectly capable of carrying out multiple tasks. This complexity is clearly demonstrated by the multitude of receptors through which serotonin exerts its effects. Fifteen distinct genes encode for serotonin receptors; these are further classified into five families on the basis of their second messenger systems. Splice variants and posttranslational processing expand the

repertoire of viable receptor products to 30. In addition, receptors are located throughout the body and brain, and their expression is both temporally and spatially dynamic. Depending on the receptor type, its location, and the developmental stage of the organism, stimulation of serotonin receptors can be excitatory or inhibitory. Thus, combinations of variables can lead to vastly different downstream effects from this single neurotransmitter, which may be particularly important in the development of anxiety disorders, including abnormal fear responses.

Disruption of Serotonin Homeostasis during Development Leads to Anxiety

Adding further to the complexity of the serotonin receptor system, serotonin synthesis, reuptake, and degradation are further levels at which serotonin function is regulated. Disruption at each of these dynamically regulated levels of serotonin synthesis has been demonstrated to have long-standing effects on anxiety behavior. These effects appear to be mediated at least in part through changes that occur during development.

Excessive extracellular serotonin during development is associated with increased anxiety. Deletion of the MAO-A or SERT gene in mice leads to an accumulation of extracellular serotonin in the brain. MAO-A is the principal enzyme responsible for degradation of monoamines in early postnatal life. MAO-B compensates for the deletion later in life, but mice lacking MAO-A have a ninefold increase in brain serotonin levels during the first postnatal week. SERT is another molecule responsible for the removal of serotonin from the synaptic cleft. In the absence of SERT, serotonin continues to be released but is unable to be removed and accumulates in the synaptic cleft, leading to significant alterations in receptor binding and downstream effects. Knockout mice with deletions of either MAO-A or SERT genes have marked alterations in behavior characterized by increased anxiety and aggressiveness.

Despite this clear anxiety behavioral phenotype, putative anxiety circuits have not been carefully examined in these mice. Notably, SERT and MAO-A knockout mice have been found to have defects in the formation of brain circuits involved in sensory processing. It is interesting that both these mutations lead to abnormal development of thalamocortical axons important in the formation of barrel receptive fields and retinal axons important in visual processing. This abnormal development has been shown to be mediated by the serotonin 5-HT1B receptor. Double knockouts of MAO-A and 5-HT1B or triple knockouts of MAO-A, SERT, and 5-HT1B resulted in normal axonal development. It is tempting to speculate that excessive serotonin might mediate abnormal development of anxiety circuits in a manner similar to the serotonin-dependent disruption of thalamocortical and retinal circuits in these mice. Disruption of anxiety circuits during a developmental sensitive period would help to explain the persistence of anxiety-like behavior in these mice throughout their life span.

Serotonin levels which are abnormally low can also lead to the development of abnormal behaviors. For example, Pet-1 is a transcription factor that regulates transcription of several genes important in serotonergic function. In mice, knockout of Pet-1 leads to an 80% reduction in brain serotonin levels. It is interesting that although the levels of serotonin in these mice move in directions opposite those in the MAO-A and SERT knockout mice, at a behavioral level Pet-1 knockout mice resemble MAO-A and SERT knockout mice, with increased anxiety and aggressive behavior.

The recent identification of a neuronal-specific form of tryptophan hydroxylase provides another example of the effects of reduced serotonin in the developing brain. Functionally significant polymorphisms in the gene that encodes for this neuron-specific form, TPH2, have been found in humans and mice. In mice, the hypofunctioning allele is found in the BALB strain, which is known for its significantly increased baseline levels of anxiety. However, this allele is not found in the less anxious strain, C57. There is good evidence that these behavioral effects of decreased serotonin may be mediated through effects on developmental processes. For example, in rodents, pharmacologic depletion of serotonin in the mother or embryo results in alterations in neurogenesis, neuronal migration, and dendritic maturation.

Taken together, the evidence from mouse models shows that disruption of serotonergic homeostasis in either direction can have clear effects on anxiety behavior. There is also good evidence that serotonergic dysregulation can have developmental effects on circuit formation, neurogenesis, neuronal migration, and dendritic maturation. Putting these observations together lends credence to the idea that serotonin's effects on development, at least in part, underlie serotonin's effects on behavior.

Anxiety Phenotype Develops in Early Life

In the above models, it is not clear when particular gene deletions are mediating their effects. For example, germline deletions of MAO-A and SERT result in changes in serotonin levels throughout the life of an

animal, thus making it difficult to determine when these changes might be most influential. To address this issue of timing, researchers have used fluoxetine, a selective inhibitor of serotonin transporter activity, to mimic the effects of disrupting the SERT gene during a restricted time. In one particular study, newborn mice were given fluoxetine for only the first 3 weeks of life. In this way, serotonin levels were altered only during a limited time of postnatal development. Nonetheless, throughout the life span, these mice were behaviorally indistinguishable from the SERT knockout mice with respect to exploration in novel environments, one measure of anxiety behavior.

Mice deficient in the 5-HT1A receptor have been demonstrated to have increased anxiety-related behavior. In an elegant study to address the timing of this effect, Gross and colleagues showed that genetic replacement of the serotonin 5-HT1A receptor during only the first 3 weeks of life was able to completely rescue normal anxiety behavior in mice deficient in 5-HT1A. On the other hand, replacement of the 5-HT1A receptor throughout life with the exception of the first 3 weeks did not restore normal behavior. Mice deficient in 5-HT1A receptor during only the first 3 weeks of life continued to display the characteristic 5-HT1A knockout anxiety phenotype that is similar to the anxiety phenotype of MAO-A and SERT knockout mice. There is also substantial evidence that experience has potent effects during this same period. Rats exposed to high levels of maternal care during the first 3 weeks of life have decreased levels of anxiety relative to rats that receive low levels of maternal care. Similarly, lengthy maternal separation during the same period results in increased anxiety-related behavior.

In humans and other primates, this developmentally sensitive period appears to be somewhat longer, with research suggesting a time course beginning during the third trimester of pregnancy and extending to periadolescence. Nonetheless, as discussed previously, early life appears to be a particularly potent period for the effects of experience and genetic variation.

Early Life: What Is Happening at the Circuit Level?

It is important to consider what is occurring in the brain during the developmentally sensitive period of early life. Numerous studies have demonstrated that different brain regions develop and mature at different rates and different times. In a general sense, phylogenetically primitive regions such as the hippocampus or amygdala develop earlier than the phylogenetically more advanced regions such as the human frontal cortex. It is therefore important to consider not only timing but location in order to understand the effects of experience on development.

Figure 2 Development of rat hippocampus. Development of the rat hippocampus proceeds in a stepwise fashion in which late prenatal neurogenesis is followed by early postnatal dendritic outgrowth and spine development. These postnatal changes are coincident with the sensitive period for the development of an anxiety phenotype. E, embryonic; P, postnatal; *, birth. Adapted from Ben-Ari Y (2001) Developing networks play a similar melody. *Trends in Neurosciences* 24(6): 353–360, with permission from Elsevier.

The rat hippocampus has been particularly well studied in regard to its developmental time course, and as discussed previously, the hippocampus has also been well demonstrated to be involved in anxiety and anxiety-related behavior. Within the first 3 weeks, there is a dramatic rise and fall of dendritic growth and dendritic spine formation in the rat hippocampus that is fundamental to the formation of synapses and circuits (Figure 2). During this same time, other events occur that are likewise important for the development of brain circuits. In the rat hippocampus, there is a dramatic increase in the spontaneous synchronous firing of neurons that is a hallmark of developing neuronal networks. The timing of this spontaneous network activity directly precedes the emergence of hippocampal-dependent functions such as context-dependent learning.

In concordance with the broadened period of vulnerability, in humans these processes are proposed to occur over an extended period beginning earlier, in the third trimester of fetal development, and continuing later, throughout much of childhood. In summary, the period during which animals are most vulnerable to experience and genetic variability is the same period during which brain circuits important in anxiety are developing.

Anxiety Circuits Disrupted?

We have seen that early life represents a period of increased vulnerability to the effects of both experience and genetic variation. Furthermore, it is clear that this period is an important time in brain development and circuit formation. But what about the final piece of the hypothesis? Do changes in serotonin

function during early postnatal life affect circuit formation in the anxiety system? The developmentally sensitive period for the establishment of an anxiety phenotype that persists into adulthood is highly suggestive of an effect at the circuit level.

Examination of 5-HT1A knockout mice, which display more anxiety-related behaviors than do wild-type mice, lends support to this hypothesis. Lesion studies in these mice have specifically implicated the hippocampal circuit in anxiety-related behaviors. In humans, a functional polymorphism in the 5-HT1A gene promoter is associated with increased anxiety-related personality traits, as well as an increased incidence of a subtype of panic disorder characterized by the additional presence of agoraphobia.

Also in support of the hypothesis that changes in serotonin system gene expression can modulate anxiety and fear circuits, Hariri and colleagues have shown that in humans, a polymorphism in the SERT gene is associated with particularly robust changes in the sensitivity of the amygdala to fearful or threatening stimuli. Individuals with the hypo-functioning SERT allele (s/s) had a fivefold increase in amygdala activation in response to fearful stimuli. Another group of researchers also demonstrated this increased amygdala activation and further suggested changes in neural circuitry by demonstrating that individuals with at least one copy of the short allele had increased coupling of amygdala and prefrontal cortex activity. Because of the likely relation between fear and anxiety, this change in fear responsiveness may underlie an increased risk for anxiety disorders in these individuals. It is important to note that these differences in regional brain activation were much more readily apparent than were overt behavioral differences in these individuals, underscoring the point that a change in neural circuit function does not necessarily result in a behavioral phenotype in the case of an animal model, or in an anxiety disorder in the case of humans.

Sensitive Period Revisited: Gene–Environment Interactions

Current evidence suggests that anxiety circuits appear to be subject to a sensitive period of development. Gene knockout studies and phenotypic characterization of individuals with functional polymorphisms have highlighted several genes of the serotonin system that affect the developmental course of circuits involved in anxiety. Evidence for this is both direct, as with functional neuroimaging of individuals with SERT polymorphisms, and indirect, as evidenced by the lifelong persistence of anxiety phenotypes based on genetic variation and early experience.

The existence of a sensitive period in the development of neural circuits involved in anxiety becomes particularly interesting when the myriad influences are examined for their combined effects. These effects can be antagonistic, as seen when the 5-HT1B receptor is removed in the MAO-A and SERT knockout mice. Removal of this receptor blocks the detrimental effects of increased serotonin on the formation of thalamocortical and retinal circuits. The combined effects can also be additive, exemplified by an exacerbation of the anxiety phenotype in SERT knockout mice when BDNF, another molecule important in circuit formation, is also removed.

It is important to note that these combined effects are not limited to gene–gene interactions. As discussed at length above, the normal functioning (l/l) allele of the SERT polymorphism appears to be protective against many of the behavioral consequences of early life stress in humans and in primates, whereas those that are homozygous (s/s) or heterozygous (l/s) for the hypo-functioning short allele have less resilience in the face of early life adverse events.

Conclusions, Future Directions, and Resilience

Understanding that psychopathology, particularly anxiety responses, can represent developmentally mediated changes in neural circuits is not an end but rather a beginning. It affords an opportunity to more carefully dissect not only the factors involved in psychopathology, but also the resilience factors that protect individuals with circuit-level dysfunction from developing illness.

Understanding brain function and pathology as an intermingling of individual circuits, each subject to its own developmental trajectory, also serves as a framework to probe for deeper understanding of the process of brain development. Defining circuits for a particular research focus opens the door for a careful dissection of genetic and environmental influences on neural function that is not available when using the gross outcome measures of behavior or disease.

Furthermore, it is possible that dysfunction in neural circuit formation may represent a more fundamental dysfunction of molecular circuits. This certainly may be the case in the 5-HT1A knockout mouse, in which the 5-HT1A receptor represents a critical regulator of negative feedback on serotonin function. Understanding dysfunction of molecular circuits would not only enhance understanding of the fundamentals of brain function but may also provide a yet more sensitive phenotypic marker of risk of psychopathology and a potential marker for treatment responsiveness.

Ultimately, however, attempts must be made to relate neural changes to behaviors or cognitive functions. Having defined changes in molecular or neural circuits, one then has a carefully defined subset of individuals to probe for subtle differences in higher-order functions. It is through this iterative process that progress in understanding brain function and behavioral pathology can be made.

Aversive Emotions: Molecular Basis of Unconditioned Fear

J B Rosen, University of Delaware, Newark, DE, USA

© 2009 Elsevier Ltd. All rights reserved.

Interest in the scientific study of emotions in psychology, biology, and neuroscience has waxed and waned for many years. In the latter part of the nineteenth century, Darwin brought emotion to the forefront of biology with a functionally and biologically grounded analysis of emotional expression. Darwin considered that emotion and the expressions of emotional behavior developed because of their importance in intra- and interspecies communication that promotes survival. Many emotions were considered innate and developed through evolutionary and functional mechanisms, just as body morphology evolved through environmental pressures. However, the scientific study of emotions has always been hampered by the subjectivity of emotional experience and therefore was not as prominent a field of study in psychology and neuroscience as other fields of behaviorism and cognition were throughout much of the twentieth century. In the last few decades, the study of the neurobiology and molecular biology of emotions, particular aversive emotions such as fear, has recently become tractable in both animals and humans because of the ability to measure behavioral and neural emotional responses, and it consequently has become a major field of neuroscientific study in the twenty-first century.

Great strides in our knowledge of the neuroscience of fear stems from the use of simple conditioning paradigms that measure fear with species-specific defensive responses to elucidate a fundamental and detailed understanding of the neuroanatomy of fear that can then be followed by the study of the molecular biology within these neuroanatomical circuits of fear. Combining a number of learning procedures, particularly Pavlovian fear conditioning paradigms in rodents that produce robust learning and memory of fear, with neuroscience techniques has been very successful in developing an understanding of neurobehavioral systems in the brain that are crucial for learning, memory, and the expression of the emotion fear. On the heels of the study of learned fear, in recent years the neuroscientific study of unconditioned fear has begun and is now accumulating data that suggest the neural and molecular mechanisms of unconditioned fear may have similarities to, but also important differences from, those of conditioned fear.

Conditioned and Unconditioned Fear

Fear conditioning paradigms in animals have a long history in psychological research and theory. Pavlov not only paired a bell with the arrival of food to induce conditioned or learned appetitive responses to the bell, but also paired bells and other neutral stimuli to unconditioned aversive events, such as shocks, to induce aversive responses to these formerly neutral, but now conditioned, stimuli. Thus, just as stimuli contingently paired with food become predictive signals for the arrival of food, stimuli contingently paired with shock develop into predictive signals for the arrival of the shock. Pavlovian fear conditioning therefore is an adaptively important process that helps organisms survive and is one of the most rapid types of learning in many animal species, with significant learning in a single trial and typically reaching asymptote within a handful of trials. Although Pavlovian conditioning by pairing lights, tones, contexts, and shocks is a fairly simple paradigm to perform, the associative process is not merely a transfer of the ability to elicit behavioral responses from one stimulus to another but is, instead, cognitive in nature and involves animals making predictions, representations, and relations between events, situations, and circumstances. Pavlovian learning and memory processes have immense biological significance by increasing the survivability of animals in a world where the predictive value of stimuli changes.

Because Pavlovian fear conditioning is learning about predictive relationships between conditioned and unconditioned stimuli, and not about learning new behavioral responses, innate, functionally adaptive species-specific defensive responses are typically displayed during fear and experimentally are used as measures of conditioned fear. These include autonomic changes in heart rate and blood pressure, and increases in behavioral responses such as freezing and reflexes such as startle. All these measures are considered preparatory responses to the anticipated aversive stimulus that are induced by presentation of the conditioned stimulus and are, thus, thought to be indicative of a state of fear.

Whereas learning to be afraid of stimuli that we encounter is adaptive and has great significance for survival, the ability to be innately fearful of some stimuli has similar significance and may be important for encounters and circumstances that organisms typically do not survive (and therefore cannot learn

from). It is suggested that in humans fear of heights, the dark, and small animals may be examples of unconditioned fears. Unconditioned fear may also be a basis for some anxiety disorders, particularly some specific phobias. However, it is very difficult, if not impossible, to determine whether these fears are innate or are due to learning. However, this may be resolved in laboratory animals that have been bred for generations in a laboratory environment with no contact with putative unconditioned fear stimuli. Although there are a number of different types of unconditioned fear stimuli or situations that have been studied, such as neophobia and brightly lit environments, this article focuses on fear of predators and predator odors. It has been know since 1913 that laboratory rats display unconditioned fear responses to cats, and unconditioned fear to predators and predator odors have been studied most extensively.

The use of ecologically and biologically based stimuli, such as exposure to predators and odors from predators, allows for the controlled, scientific study of unconditioned fear. Use of these innate fear-inducing stimuli exploits the evolutionarily shaped unconditioned fear of predators and predator odors. The physiological and behavioral responses to these predators and predator odors are similar to those evoked by conditioned fear stimuli (e.g., cardiovascular changes, freezing, startle, and vigilance), indicating that the same species-specific defensive responses are used during unconditioned fear states. What distinguishes unconditioned from conditioned fear is that it is unnecessary to initially induce unconditioned fear with a painful stimulus and, significantly, that unconditioned fear appears without learning or prior exposure to the unconditioned stimulus. Also, fear responses in rats to repeated exposure to live predators (e.g., cat) and some predator odors (e.g., ferret fur odor or trimethylthiazoline, a synthetic fox odor) do not habituate. This does not mean that learning cannot occur with exposure to predators and predator odors. Robust conditioned flavor avoidance is supported by synthetic fox odor. Learning of cue and contextual fear can be supported by exposure to a live cat and some predator odors (e.g., cat fur), but this is difficult to demonstrate with other predator odors (e.g., synthetic fox odor, ferret fur odor, and cat feces), except in specific types of environments. However, sensitization can be produced by exposure to these predators and predator odors that may last for at least 3 weeks. These learning effects of predators and predator odors (both nonassociative sensitization and associative conditioning) may recruit different neural circuits from those necessary for unconditioned fear responses.

Neuroanatomical Circuits of Unconditioned Fear

Before discussing the molecular biology of unconditioned fear, I delineate the neural circuits where molecular changes are to be found. If we were to envision the neurocircuitry of unconditioned fear, it would probably be similar to that subserving conditioned fear. Pavlovian fear conditioning in rodents has been very important for delineating specific neuroanatomical circuits of fear conditioning (**Figure 1**). Numerous studies have demonstrated that the lateral, basal, and central nuclei of the amygdala are all necessary for fear conditioning. The lateral nucleus is particularly important as a site of stimulus integration because it receives information from association cortices and from sensory and pain-relay nuclei of the thalamus. The basal nucleus also integrates afferents from the lateral nucleus and other brain regions. The central nucleus receives input from the lateral and basal nuclei and is the major output pathway to many subcortical regions that mediate numerous fear-related responses and behaviors.

Whereas the neuroanatomy of conditioned fear is fairly well established, the neuroanatomy of unconditioned fear is just beginning to be dissected. Early studies of exposure to a cat or cat fur supported the view that conditioned and unconditioned neural circuits are the same by showing that fear behavior diminished in rats with large lesions or inactivation of the amygdala. However, more recent studies with smaller lesions of discrete nuclei of the amygdala found that the lateral, basal, and central nuclei of the amygdala are not necessary for the display of

Figure 1 An amygdala fear circuit for fear conditioning. Input from thalamus and cortex with information about conditioned and unconditioned stimuli enters the lateral nucleus of the amygdala (La). The lateral nucleus projects to the basal (B) and central (Ce) nuclei of the amygdala. Output from the Ce nucleus projects to midbrain and brain stem areas to generate different kinds of conditioned fear behavior. This circuit is hypothesized to be important for fear conditioning, but not for unconditioned predator fear. However, it is recruited for associative and nonassociative fear induced by unconditioned predator fear.

unconditioned fear to various predator odors. A different neural fear circuit running through the medial hypothalamus may underlie innate defensive behavior to predators and predator odors (Figure 2). The core of this medial hypothalamic defense circuit includes the anterior hypothalamic nucleus (AHN), dorsomedial part of the ventromedial hypothalamic nucleus (VMHdm), and the dorsal premammillary nucleus (PMd). These nuclei are highly interactive, where the AHN has strong reciprocal connections with the VMHdm and PMd, and the VMHdm sends efferents to the PMd. This system also lies as an interface between sensory inputs and motor outputs, similar to the way that the amygdala does. The circuit is thought to play a major role in the somatomotor integration and initiation of aversively motivated behavior. For example, rats with PMd lesions display significantly reduced unconditioned freezing and escape during exposure to a live cat or cat fur odor. Also, lesion or inactivation of major inputs to this system (the medial nucleus of the amygdala or bed nucleus of the stria terminalis) also reduces freezing to predator odors.

The AHN and VMHdm have substantial olfactory afferents from main and accessory olfactory systems via the medial and accessory basal nuclei of the amygdala and the bed nucleus of the stria terminalis. VMHdm afferents from posterior intralaminal thalamus supply auditory inputs, paralleling thalamic auditory afferents of the lateral nucleus of the amygdala. Indirect input from the lateral nucleus of the amygdala by way of hippocampus and ventral subiculum provides processed visual information to the AHN. The VMHdm also receives substantial visceral and nociceptive information from the parabrachial nucleus in the brain stem. Efferents from the hypothalamic nuclei to the amygdala, septum, bed nucleus of the stria terminalis, and medial prefrontal cortex are able to influence processing in numerous regions of the telencephalon. Finally, the three core hypothalamic nuclei of the circuit each have substantial projections to the periaqueductal gray and other brain stem areas to generate and control a variety of fearlike behaviors.

Figure 2 A medial hypothalamic fear circuit for unconditioned predator and predator odor fear. The anterior hypothalamic nucleus (AHN), the dorsomedial ventromedial hypothalamic nucleus (VMHdm), and the dorsal premammillary nucleus (PMd) make up the core of this circuit. Input into this system comes for numerous areas. Inputs from the bed nucleus of the stria terminalis (BNST), medial nucleus of the amygdala (Me), lateral septum (LS), ventral subiculum (VS), CA1 region of hippocampus (CA1), and several regions of the medial prefrontal cortex (PFC), posterior intralaminar nucleus of thalamus (PIL), and parabrachial nucleus (PB) are shown, but other inputs also exist. All core nuclei of the medial hypothalamic circuit project to brain stem regions (particularly strong to the periaqueductal gray) that control and generate fear responses.

Although the fear circuits for conditioned and unconditioned fear may be different, continued research will surely find a functional overlap between these circuits. Neuroanatomical studies demonstrate that the lateral nucleus of the amygdala receives projections from the VMHdm. The prefrontal cortex has been shown to project to both amygdala nuclei and the AHN and PMd. It has been known for many years that electrical and chemical stimulation of the ventromedial hypothalamus elicits fear behavior and that this is modulated by stimulation of the amygdala. Furthermore, lesions of the bed nucleus of the stria terminalis disrupt contextually fear-conditioned freezing and lesions of the medial nucleus of the amygdala interfere with fear-potentiated startle. Probably there is much interaction between fear conditioning and unconditioned fear circuits during both associative and nonassociative learning to unconditioned predator stimuli that will be elucidated in the coming years.

Molecular Biology of Unconditioned Fear

The study of the molecular and cellular mechanisms of unconditioned fear to predators and predator odors is in its infancy and sketchy at best, but it will eventually include the expression of molecules at all levels of neural transmission, signaling transduction, and gene expression. To data, the data demonstrate altered expression and participation of molecules at the levels of gene expression, neurotransmitters, and receptors following the exposure of rodents to these unconditioned fear stimuli.

Inducible Transcription Factors (Immediate-Early Genes)

The neural circuitry of unconditioned fear to predators and predator odors suggested by brain-lesion techniques is corroborated by measures of immediate-early

genes that are highly responsive to environmental stimulation. Changes in the expression of immediate-early gene mRNA or protein levels, such as c-fos and egr-1, not only can be used as markers for transient neural activity, but, because these genes are inducible transcription factors, they provide a pattern of gene expression in these brain regions that may regulate some of the long-lasting changes in behavior (e.g., nonassociative sensitization, and associative conditioning) induced by exposure to predator stimuli.

Exposing rats to cats induces c-fos mRNA in regions of the medial hypothalamic defensive circuit, including the ventromedial hypothalamus, dorsal premammillary nucleus, bed nucleus of the stria terminalis, and lateral septum. Significantly, c-fos in these regions does not increase with restraint or hypoxia, other common stress-inducing manipulations. Furthermore, c-fos in the medial nucleus of the amygdala is increased with both cat exposure and restraint stress. Other studies of fear conditioning also demonstrate that c-fos increased in the medial nucleus of the amygdala, indicating that the activation of the medial nucleus of the amygdala is not specific for unconditioned fear to predators or predator odors but is activated during many types of fear or stress.

Studies investigating exposure to predator odors (cat and ferret fur and synthetic fox odor) induce similar patterns of c-fos mRNA and Fos protein expression as seen with exposure to a live cat, but more brain regions have been examined. Thus, these predator odors are found to induce c-fos mRNA or Fos protein in the main olfactory bulbs, paraventricular nucleus of the hypothalamus, locus coeruleus, cuniform nucleus, and all divisions of the periaqueductal gray (the brain region important for the fear behaviors freezing and escape). Interestingly, the subnuclei of the amygdala (lateral and basal nuclei), regions critical for all types of fear conditioning (i.e., auditory, visual, olfactory, and contextual fear conditioning induced by shock), do not display increased c-fos expression following live predator or predator odors. In addition, the expression of another immediate-early gene, egr-1, also is not induced in the lateral and basal nuclei of the amygdala of rats exposed to a live cat. These data begin to delineate and corroborate lesion studies showing differences in brain circuits for conditioned and unconditioned fear.

The expression of these inducible transcription factor genes not only provides patterns of neural activation during behavior, but also suggests that these changes may alter long-term responses to predators and predator odors and, in the wild, may facilitate the survival of the animal. To date, few studies have examined the role of inducible transcription factors in unconditioned fear. However, these are some data demonstrating that the reduction of translation of egr-1 in the lateral nucleus of the amygdala interferes with fear conditioning but not with unconditioned fear to synthetic fox odor. Further research will elucidate the importance of inducible transcription factors in unconditioned and conditioned fear.

Phosphorylated Cyclic AMP Responsive Element-Binding Protein

Expression of other inducible transcription factors has not been investigated. However, there are a couple of studies examined the phosphorylation of cyclic AMP responsive element-binding protein (CREB) induced by cat exposure. CREB is a constitutive factor that on phosphorylation (pCREB) becomes an active transcription factor that has been shown to be involved in many forms of learning and memory, including fear conditioning within the amygdala. pCREB had been found to increase in the lateral, basal, central, and medial nuclei of the amygdala, as well as in the periaqueductal gray of rats following exposure to a live cat. This is interesting because live-cat exposure induces a long-lasting sensitization that can be demonstrated in a number of anxiety tests. Of further interest is that pCREB does not increase in the ventromedial hypothalamus, a nucleus of the medial hypothalamic defense circuit. Taken together with the findings that the inducible transcription factors, c-fos and egr-1, are not induced in the lateral and basal nuclei of the amygdala by a live cat, cat odor, ferret odor, or synthetic fox odor but are induced in the ventromedial hypothalamus, the data suggest that unconditioned predator fear and predator-induced sensitization engage different neural circuits. Circuits for predator-induced sensitization appear to be similar to those necessary for shock-induced fear conditioning.

Extracellular Neurotransmitter Signaling

Dopamine

The effect of unconditioned predator fear on the dopamine system has been studied more than other neurotransmitter systems. Dopamine release and turnover in the prefrontal cortex and amygdala (subnuclei of the amygdala were not specified), which are known to increase in response to stress, also increase with exposure to synthetic fox odor. Dopamine neurons in the ventral tegmental area that project to the prefrontal cortex and amygdala are activated by synthetic fox odor, whereas dopamine neurons in the substantia nigra do not. Unconditioned fear induced by synthetic fox odor also interferes in a non-match-to-sample short-term working memory task that is dependent on prefrontal cortex processing. Dopamine in other regions, such as hypothalamus, striatum, and nucleus

accumbens, has also been shown to increase with exposure to predator odors but not as consistently as the increase in the prefrontal cortex. Pharmacologically, dopamine D1 receptor agonist infused in the prefrontal cortex of mice increases fear and anxious behavior to predator and predator odor exposure. These data suggest that unconditioned predator and predator odor exposure, similar to other fear- and stress-inducing stimuli, enhance dopamine neurotransmission in the prefrontal cortex and interfere with working memory tasks that are dependent on the prefrontal cortex.

Serotonin

In general, pharmacological serotonin 5-$HT1_A$ receptor agonism and blockade of serotonin reuptake reduce fear and anxious behavioral responses in rats and mice to predators and predator odors. In mice, there appears to be differential effects of 5-$HT1_A$ receptor agonists to reduce predator risk-assessment behavior, and 5-$HT2_A$ receptor antagonism to reduce flight or escape behavior. Mutant mice with a knockout of the serotonin transporter were shown to have increased vulnerability to predator-induced sensitization, as shown by the increase anxiety-like behavior in the elevated-plus maze and a light–dark box test after exposure to a cat. The increased vulnerability to unconditioned fear in these mice may be similar to the enhanced vulnerability to stress in humans with the short allele of the serotonin transporter.

Norepinephrine

Norepinephrine plays a role in vigilance and conditioned fear, and therefore it should also modulate unconditioned fear. Norepinephrine was shown to increase in the hippocampus in mice exposed to a cat and in the bed nucleus of the stria terminalis of rats exposed to synthetic fox odor. Complementary to increases in norepinephrine, the blockade of norepinephrine neurotransmission in the bed nucleus of the stria terminalis with a local infusion of clonidine decreased unconditioned fear-related freezing responses to synthetic fox odor. Furthermore, in a drug schedule of intermittent methylphenidate treatment for 3 weeks that sensitized dopamine and norepinephrine systems, rats given yohimbine, which facilitates norepineprhine neurotransmission, displayed increased avoidance of a predator odor. Together, these studies confirm that norepinephrine neurotransmission is important for unconditioned fear to predators and predator odors.

γ-Aminobutyric Acid

γ-Aminobutyric acid (GABA) levels have been shown to increase in the amygdala and nucleus accumbens with exposure to a predator or predator odor. These increases are probably compensatory because the facilitation of $GABA_A$ neurotransmission with the administration of systemic benzodiazepine agonist reduces defensive threat/attack and risk-assessment behaviors to cat and cat odors in mice. Unconditioned freezing in rats to synthetic fox odor is blocked by local infusion of muscimol, a $GABA_A$ agonist, into the bed nucleus of the stria terminalis or medial nucleus of the amygdala. Interestingly, muscimol infusion into the basal nucleus of the amygdala of rats only delays freezing in response to synthetic fox odor for a few minutes, but freezing reaches levels-seen in vehicle-treated rats. Furthermore, in a study investigating fear behavior of sheep in response to a predator (a dog), an infusion of bicuculline, a $GABA_A$ antagonist into the sheep's central nucleus of the amygdala had only a marginal effect on predator-elicited fear, but sensitized predator fear when measured 2 days after the initial exposure to the dog. These data suggest that the basal and central nuclei of the amygdala play only a minor modulatory role in unconditioned fear to predators, but may have a more substantial role in long-lasting fear sensitization induced by predator fear.

Glutamate

Both competitive and noncompetitive antagonism of *N*-methyl-D-aspartate (NMDA) receptors has effects on fear induced by exposure to a predator and to predator odor. In rat pups, CGP 43487 given at postnatal day 5 reduces freezing elicited by exposure to an adult male rat at postnatal days 13 and 20 but not at postnatal day 30. In adult rats, CPP and AP7 do not affect rat defensive behavior to cat exposure, but they significantly interfere with long-lasting enhancement of fear on a number of anxiety tests. This is reminiscent of the role of NMDA receptors in long-term potentiation, in which NMDA receptors are involved in long-term synaptic plasticity by not short-term potentiation. The role of NMDA glutamate receptors in the amygdala appears to be involved in the long-lasting fear sensitization induced by predator exposure, possibly by strengthened synaptic transmission in amygdala–periaqueductal gray circuits. Glutamate has also been shown in increase in the rat nucleus accumbens in response to synthetic fox odor. Other brain regions have not been examined yet.

Corticotropin-Releasing Hormone and Corticosterone

Corticotropin-releasing hormone (CRH) and corticosterone are part of the hypothalamic–pituitary–adrenal axis. This system is important for the regulation of glucose metabolism to provide fuel for diverse behavioral and physiological demands,

including fear. Blood plasma corticosterone levels are increased by exposure to predator and predator odors. Exogenous CRH induces fear and anxiety-like behavior. Both CRH and corticosterone are involved in the consolidation of fear conditioning, and the amygdala is a major locus of action. Chronic high levels of corticosterone enhance memory of learned and unconditioned fear, and they also induce CRH expression in the central nucleus of the amygdala and the bed nucleus of the stria terminalis. Corticosterone enhancement of unconditioned startle appears to be through CRH in the bed nucleus of the stria terminalis but not the amygdala. However, exposure to predator and predator odor increases CRH release in the amygdala. In sheep exposed to a dog (a fear stimulus in sheep), CRH release in the amygdala occurs in two waves. The first wave lasts for only a few minutes and is independent of corticosterone, whereas the second wave of CRH release is corticosterone dependent. Interestingly, repeated exposure to the dog potentiates fear to the dog and enhances only the corticosterone-dependent CRH release in the amygdala. Furthermore, infusion of a CRH antagonist into the amygdala had little effect on unconditioned fear behavior to the dog, but interfered with the potentiation of fear to subsequent dog exposure. These data suggest that CRH in the amygdala is not critical for unconditioned predator fear but that corticosterone-regulated CRH in the amygdala is important for nonassociative sensitization to predator stimuli. Whether corticosterone-induced enhancement of CRH in the bed nucleus of the stria terminalis is involved in sensitization to predators, as it is in sensitization to cocaine, awaits further research.

Cholesystokinin

Cholesystokinin (CCK) is known to induce anxiety-like feelings in humans. In rats, it appears to play a role in unconditioned predator fear and sensitization induced by predator exposure. CCK is increased in the basal nucleus of the amygdala in mice exposed to synthetic fox odor compared to mice not exposed to this odor, but only after a light–dark box anxiety test. Blockade of CCK-2 receptors, but not CCK-1 receptors, decreases fearfulness in rats during exposure to a cat and decreases cat-exposure-induced sensitization demonstrated in the elevated plus maze. An interesting difference in response to cat exposure has been found in PVG hooded and Sprague-Dawley rats, in which PVG hooded rats freeze more during exposure to a cat than do Sprague-Dawley rats. PVG hooded rats also have a greater abundance of CCK-2 receptors than and several genetic variations in the code for CCK-2 receptors different from those of Sprague-Dawley rats. The importance of these differences for unconditioned fear is not known at present, but it is interesting to note that Sprague-Dawley and Long-Evans rats display robust freezing to synthetic fox odor, whereas Wistar rats do not. There are also mouse strain differences in response to predator odors. Whether these are related to CCK or other neurotransmitter systems is not known.

Conclusion

Investigation of the molecular basis of unconditioned fear, particularly fear of predators and predator odors, has seen substantial progress in the last few years. As shown by lesion and expression of immediate early genes, a neural circuit for unconditioned predator fear through the medial hypothalamus is emerging that may be distinct from an amygdala circuit for fear conditioning. However, there appears to be an overlap of these circuits and recruitment of the amygdala fear-conditioning circuit for associative and nonassociative conditioning to predator stimuli. Although inducible transcription factors seem to be expressed in the unconditioned fear circuit during exposure to predator stimuli, nonasssociative sensitization of fear induced by predator exposure appears to induce pCREB, a phosphorylated constitutive transcription factor known to be involved in fear conditioning and other types of learning, in amygdala nuclei of the fear-conditioning circuit. A number of neurotransmitter systems also seem to be involved in unconditioned fear and sensitization induced by predator exposure. The list of neurotransmitter systems involved will certainly grow. Investigation of signal transduction pathways has not started, but will probably contribute to our understanding of unconditioned fear in the coming years. Continued research with ethologically based fear stimuli should provide more neuroanatomical and molecular detail of unconditioned fear and should have a substantial influence on our understanding of normal fear and related anxiety disorders.

Introduction

This article describes attempts to identify experimentally the neural correlates of the contents of conscious experience in humans. In general usage, the term 'conscious' can be used in both a transitive and intransitive sense. For example, it is possible to be conscious (as opposed to being unconscious, asleep, or in some other state). But it is also possible, when awake, to be conscious of a particular thing (as opposed to not being conscious of that thing, or conscious of some other thing at that particular moment). This distinction means that any experimental account of the neural correlates of consciousness must at a minimum specify the neural structures and processes associated with each sense of the word conscious.

The Waking State

The contents of consciousness are accessible and can be reported by individuals who are in the waking state. Changes in the level of consciousness, such as those induced artificially by anesthesia or pathologically by brain damage leading to coma, lead to individuals' being rendered unconscious and unable to report the contents of their consciousness. Sensory processing is altered, leading to an absence of conscious representation. Neural structures mediating level of consciousness are therefore surmised to facilitate the representation of conscious contents. Understanding how sensory processing is altered during changes in the level of consciousness can therefore help understand how the contents of consciousness are represented in the human brain.

Sensory processing is profoundly altered by changes in level of consciousness resulting from different causes. Typically, responses can still be obtained from the primary sensory cortices, but responses of association and the higher cortices are reduced or absent. For example, primary auditory cortex activation can still be elicited during sleep, during anesthesia, or after brain damage leading to coma. Similarly, less dramatic modifications of level of consciousness associated with meditation modify activity only in areas of the posterior sensory cortex, apart from primary visual cortex.

Anesthesia represents perhaps the most common deliberate manipulation of the level of consciousness, and it is crucial for surgical practice. Although there is increasing knowledge about the molecular and cellular targets of anesthetic agents, their effects on sensory processing in the human brain at a systems level remain poorly understood. Inhalational agents modulate brain stem nuclei and (by inference) their ascending modulatory efferent pathways. For example, isoflurane and halothane cause relative reductions in regional cerebral glucose metabolism in midbrain reticular formation, and propofol-induced depression of thalamic and reticular blood flow are closely linked. Similarly, halothane and enflurane or isoflurane depress spontaneous single-unit firing in the reticular formation of cat. However, brain stem responses to sensory stimulation (e.g., auditory evoked potentials) appear intact.

In the auditory cortex, most investigations of the effects of anesthesia on sensory processing have focused on auditory stimulation and are consistent with the general position outlined previously. In contrast, very little is known about processing in the other sensory cortices under anesthesia. For the visual system, a dose-dependent reduction in activation of the primary visual cortex is observed with thiopental, but that study did not measure the depth of anesthesia so we cannot correlate such findings with the level of consciousness. Subanesthetic isoflurane affects task-induced activation in the parieto-frontal (but not visual) cortices during performance of a visual search task. Visual evoked potentials can still be obtained during anesthesia, although somewhat unreliably in the operative environment, indicating some preservation of cortical processing. Similarly, little is known about brain areas involved in tactile processing in the unconscious human, despite the obvious clinical requirement to eliminate somatosensory sensation during surgical procedures. The clinical utility of monitoring somatosensory evoked potentials indicates that cortical processing can persist, although presumably without awareness. Two neuroimaging studies have examined localized cortical responses to somatosensory stimuli. Both showed diminished responses in the primary somatosensory cortex to electrical or vibrotactile stimulation but showed preserved responses in either the thalamus or secondary somatosensory cortex. This suggests impaired thalamocortical information transfer during anesthesia, but it is somewhat inconsistent with observations from other techniques. For example, intraoperative intrinsic signals from human somatosensory cortices to vibrotactile stimuli delivered during anesthesia are topographically specific to the stimulated digit. The reasons for this inconsistency are unclear, but it may suggest that some

somatosensory cortical responsiveness is retained during anesthesia.

Taken together, these studies suggest that the waking state (compared to the anesthetized state) is associated with significant modifications in the responsiveness of sensory cortices to stimulation, particularly affecting secondary and association cortices. One unifying model for the actions of anesthetic agents is that the interruption of the dynamic connectivity between the thalamus and cortex represents a common mechanism underlying the observed changes in sensory processing and unconsciousness. Because changes in thalamocortical connectivity can also be observed in persistent vegetative state and resolve on recovery, it is conceivable that a single underlying mechanism underlies all changes in sensory processing associated with modification of the level of consciousness.

Rarely, awareness during anesthesia is reported subsequent to the administration of an anesthetic. The neural substrates of such experience remain poorly understood due to its rarity. A single case has recently been reported of an individual in a minimally conscious state who could not report her experiences overtly; however, when the patient was asked to imagine one of two different experiences, brain imaging revealed different patterns of brain activation. One possible explanation of these findings is that the individual was able to formulate an intention to follow the instructions given by the experimenter, implying concomitant awareness. How this can arise in an apparently comatose patient unable to report by any overt means and its implications for understanding the mechanisms of coma and changes in level of consciousness more generally remain to be explored.

Conscious Access: Neural Correlates of Perceptual Awareness

When people are awake, a characteristic feature of awareness is that its contents can be reported. We have subjective conscious access to the contents of our consciousness. But it is equally apparent that much of our mental life remains unconscious and inaccessible to report. Experimental enquiry must therefore distinguish what is special concerning the neural activity specifically associated with the contents of conscious experience, in contrast to other activity that merely reflects the unconscious correlates of perception or behavior. The principal methodological approach of the work reviewed next is thus to contrast the neural activity evoked by conscious versus unconscious processing, using a number of experimental paradigms.

Spontaneous Variation in the Contents of Consciousness

Bistable Stimulation

When a physical stimulus allows two different perceptual interpretations, awareness typically fluctuates spontaneously between the two possible perceptual interpretation. For example, binocular rivalry occurs when two different images are presented, one to each eye separately. Conscious experience fluctuates spontaneously, each monocular view being in turn visible for a few seconds while the other is suppressed. Because these fluctuations in awareness occur without any change in the physical stimulus, binocular rivalry (and other forms of bistable perception) form a useful model system with which to distinguish the neural correlates of these changes in the contents of consciousness from brain activity related solely to physical stimulus characteristics.

Investigations of the neural correlates of bistable stimulus perception identified two distinct patterns of findings. First, brain activity time-locked to perceptual transitions can be identified in the prefrontal and parietal cortices for both binocular rivalry and a wide variety of bistable stimuli. Moreover, the involvement of these cortical areas is independent of any requirement to make overt reports of the perceptual transitions. Similar areas are also active during spontaneous changes in the contents of consciousness in very different paradigms, during the emergence of a figure when the subject views either fragmented figures or stereo pop-out stimuli. Activation in these areas of the parietal and prefrontal cortices is associated with selective attention. More recently, activation of different parietal and prefrontal loci, thought to be involved in working memory, have been associated with the maintenance of a stable bistable percept. Although these studies do not identify whether these different psychological processes are specifically associated with such prefrontal and parietal activation, they offer a rich line of future investigation.

A second major pattern of findings associated with studies of bistable perception is that fluctuations in brain activity specifically associated with the particular contents of consciousness can be identified in the ventral visual cortex. Strikingly, such fluctuations can be identified at all levels of the human geniculostriate pathway, from the lateral geniculate nucleus (LGN) to V1 to category-specific areas such as the fusiform face area. Indeed, the local pattern of activity in cortically evoked responses carries sufficient information that automated algorithms can be used to blindly decode and accurately predict the fluctuations in perceptual experience that the observer reports. Significantly, response fluctuations that are

further along the ventral visual pathway are generally larger than those observed at earlier stages, and at later stages in processing they are equal in magnitude to responses evoked to physical (nonrivalrous) stimulus alteration. This pattern of findings has been interpreted as suggesting that, at anatomically early stages of the ventral visual pathway, both seen and perceptually suppressed images are physically represented, but that competition between the two is increasingly resolved at higher stages of the visual system. Such findings are broadly consistent with event-related potential (ERP) measurements in humans and single-unit recordings in monkeys.

The involvement of both ventral visual cortical structures (representing the current contents of consciousness) and the frontoparietal structures (whose activity is either time-locked to perceptual transitions or associated with perceptual maintenance) suggests the involvement of a distributed network in perceptual rivalry. Consistent with such a hypothesis, large-scale changes in intra- and interhemispheric neuronal synchronization can be observed during rivalrous fluctuations. One model that might account for these data is that distributed object representations in the ventral visual pathway compete for perceptual dominance, biased by top-down signals reflecting working memory and attention from the frontal and parietal cortices. In the context of bistability, a conscious percept is thus represented by both an activated representation of the perceptual content and activity in the frontal and parietal cortices. Such a hypothesis is consistent with emerging theoretical models of consciousness that posit the involvement of both sensory representations and a global workspace, the latter tentatively identified with the frontal and parietal cortices.

Near-Threshold Stimuli

A detection threshold can be defined for any type of sensory stimulus, for example, by presenting it in temporal proximity to a mask or by physically degrading it in some fashion. At detection threshold, only a proportion of stimuli presented to observers will be detected, whereas the others fail to reach awareness. This spontaneous trial-to-trial variability in awareness of stimulation can be used to determine the neural correlates of stimulus awareness without confounding by changes in physical stimulus characteristics. Alternatively, brain responses to different types of fully masked and invisible stimuli can be used to determine neural correlates of unconscious processing.

Fully invisible stimuli can nevertheless evoke modest but reliable activation throughout the visual cortex. For example, activity specific to the orientation of a simple visual grating can be decoded from the primary visual cortex activity even when the stimulus is completely invisible to the observer. Similarly, when a simple target such as an achromatic disc is briefly flashed, robust activity is elicited in the corresponding retinotopic location of V1 (plus V2 and V3), even when the target is rendered completely invisible by a surrounding mask. Invisible images of tools evoke both activity in the primary visual cortex and category-specific activity in visually responsive dorsal stream structures. Invisible motion can activate the V5/middle temporal (MT) visual motion area. At higher levels of the visual system, activation selective for the presence (although undetected and invisible to the observer) of a word or for invisible faces and objects can also be observed. When an object or word is not noticed during the attentional blink, unconscious activation of the ventral visual pathway corresponding to the object identity or semantic processing can be observed. Unconscious sensory activation by complex visual stimuli is not confined to the cortical visual pathways but extends to subcortical structures. For example, the amygdala can be activated by fearful-face stimuli that have been rendered invisible through masking, in response to the emotional content of invisible words or during the suppression in binocular rivalry.

Complementing these studies in normal observers, unconscious activation of the visual cortex can also be identified in patients with visual extinction resulting from damage to the right parietal cortex. Areas of both the primary and extrastriate visual cortex that are activated by a seen left-visual-field stimulus are also activated by an unseen and extinguished left-visual-field stimulus. The unconscious processing of an extinguished face stimulus extends even to the face-selective cortex in the fusiform face area. Taken together, these findings indicate that, even without awareness, extensive processing of visual stimuli can take place in the normal visual cortex, including the generation of category-specific responses.

Invisible stimuli evoke activity associated with their mere presence and/or identity; it is equally clear that, when stimuli become visible, this is associated with an increase in activity in the corresponding category-specific areas of the visual cortex. For example, simple detection of a low-contrast grating stimulus is associated with retinotopically specific enhancement of activity in the primary visual cortex. Visually presented objects can be made difficult to identify by degrading them, and in such circumstances occipitotemporal activity shows a close correlation with recognition performance. At higher levels of the ventral visual cortex, successful detection of a face stimulus during the attentional blink is associated with significantly higher

activity in the fusiform face area. Such successful detection of visually presented stimuli in the attentional blink is associated with event-related potentials that occur relatively late in stimulus processing (after several hundred milliseconds), suggesting that such activation may be associated with a late wave of activation that spreads through a distributed network of the cortical association areas. A similar pattern of enhanced activation in category-specific areas of the visual system is seen in other paradigms comparing conscious and unconscious perceptions. For example, the introduction of a flicker between successively presented visual images makes it particularly difficult to detect large-scale changes between the images. When such a change is successfully perceived, however, enhanced activity in regions of the visual cortex with category specificity for the detected change can be observed that may precede conscious detection of the change.

Successful conscious detection of stimuli is associated not just with changes in activation of the ventral visual cortex but also with changes in coupling between the early retinotopic cortex and higher visual areas. When the interval between a target and a nonoverlapping metacontrast mask is varied over a few hundred milliseconds, observers report that visibility of the target first declines before rising again, in a U-shaped function. Strikingly, the degree of coupling (or effective connectivity) between the early retinotopic cortex and higher visual areas shows a pattern of changes with target–mask stimulus onset asynchrony (SOA) that closely parallel this behavioral function, suggesting that effective connectivity may play a role in determining visibility.

As for bistable stimuli, conscious detection of stimuli close to the threshold involves not just the sensory cortices but areas of the frontal and parietal cortices. For example, successful detection of a change is associated with parietofrontal activation that may reflect the successful deployment of attention. At the detection threshold, differences in parietal and prefrontal activity emerge following electrical activity associated with conscious perception at approximately 100 ms. Parietal cortical activation is also associated with conscious recognition of visual verbal stimuli. Successful identification of an object evokes event-related negativity and is associated with occipital responses and modulation of the parieto-occipital alpha rhythm. Finally, conscious detection of flicker is associated with the activation of the frontal and parietal cortices, indicating that these areas are important not just for awareness of spatially extended objects but also for conscious detection of temporally distinct visual events.

Hallucinations

A hallucination is a false sensory perception in the absence of an external stimulus, and it is often associated with drug use, sleep deprivation, and neurological or psychiatric disease. During visual hallucinations, brain activation can be observed in object-selective regions of the ventral visual pathway whose selectivity corresponds to the content of the hallucination. During auditory hallucinations in schizophrenia, the subcortical nuclei and limbic structures and the primary auditory cortex are activated. Finally, hallucination of a supernumerary limb after stroke is associated with activation of the medial prefrontal cortex in the supplementary motor area. Hallucinations are therefore associated with the activation of either the sensory or motor cortex whose modality and neuronal specificities corresponds closely to that of the hallucinatory perceptual content.

Modifying the Contents of Consciousness

Changes in the contents of consciousness can be driven by spontaneous fluctuations. They can also be systematically altered by either top-down signals (e.g., directing attention toward or away from some aspect of a stimulus) or by altering the spatial or temporal context in which a stimulus is presented.

Attention

When subjects are engaged in a demanding task, irrelevant but highly salient stimuli outside the immediate focus of attention can go entirely unnoticed. This is known as inattentional blindness, and it suggests that consciousness may depend on attention. Consistent with this hypothesis, brain activity evoked by irrelevant sensory stimulation in the ventral occipital and temporal cortices is reduced when attention is withdrawn. Moreover, when inattentional blindness results for unattended words, then brain activity no longer differentiates between such meaningful words and random letters. This suggests that attention is required both for brain activity associated with the higher processing of sensory stimuli and for their subsequent representation as the contents of consciousness. However, although attention may be necessary for conscious representation, it is not sufficient. Varying the availability of attentional resources changes the activity evoked in the primary visual cortex by even completely invisible stimuli. Thus, attention can act on invisible stimuli and need not change their visibility as a consequence.

Illusions

An illusion occurs when real external stimuli are misperceived and represented in consciousness in an

incorrect fashion. The content of the illusory perception typically depends on the spatial and temporal context in which it occurs. For example, sensory aftereffects are illusory sensory perceptions in the absence of sensory stimulation that occur following an extended period of adaptation to a sensory stimulus. Aftereffects contingent on prior adaptation to color or motion activate V4 or V5/MT, respectively, and the time course of such activation reflects phenomenal experience. Perception of illusory or implied motion in a static visual stimulus results in the activation of V5/MT, and the perception of motion at unstimulated regions of the visual field on the path of apparent motion is associated with retinotopically specific activation of V1 mediated by feedback from V5/MT. Perception of illusory contours activates areas of the early retinotopic extrastriate cortex. Similarly, when a moving grating is divided by a large gap, observers report seeing a moving phantom in the gap and there is enhanced activity in the locations in the early retinotopic visual cortex corresponding to the illusory percept. The primary visual cortex represents the perceived angular size of an object rather than its actual size on the retina. Finally, when a uniformly illuminated surface is placed eccentrically on a dynamic textured background, after a few seconds, it is perceived to disappear and be replaced by the background texture. This texture filling-in is associated with the reduction of activity in the primary visual cortex associated with the representation of the now-invisible surface.

Common to all these experimental paradigms are changes in phenomenal experience without corresponding changes in physical stimulus. Perceptual illusions can also be used to manipulate feelings of ownership of a rubber hand. When participants feel that the hand is theirs, then activity in the premotor cortex reflects this conscious perception of ownership. Thus, both perceptual and motor illusions lead to a specific modification of brain activity. Altered brain activity is observed in areas of the brain known to contain neurons whose stimulus specificities encompass the attribute represented in consciousness.

Imagery

Conscious perception can be created by the act of imagination. In patients with implanted electrodes for presurgical epilepsy mapping, single neurons in the human medial temporal lobe that fire selectively when particular visual stimuli are presented are also activated when the individual imagines the same stimuli. Similarly, neuronal populations elsewhere in the ventral visual pathway with stimulus specificity for faces or places are activated during imagery of these categories of object. These findings are consistent with the notion that activity in functionally specialized neuronal populations in sensory cortices is associated with the representation of an object or image in consciousness.

Summary and Outstanding Problems

Findings from a wide variety of neuroimaging experiments are remarkably consistent in reaching the following conclusions. First, sensory stimuli that remain unconscious can nevertheless undergo extensive processing in the sensory cortices. Second, compared to stimuli that remain unconscious, consciously perceived stimuli elicit greater levels of activity in functionally specialized areas of the sensory cortex corresponding to the attributes represented in consciousness. Finally, consciously perceived stimuli also elicit activity in specific areas of the prefrontal and parietal cortices that may be associated with higher-level cognitive processes such as attention and working memory.

This article has focused exclusively on studies of awareness employing a single method, functional neuroimaging. In practice, findings from a single technique are never considered in isolation and identifying experimentally the neural correlates of the contents of conscious experience in humans depends on considering converging evidence from multiple methodologies. It is therefore appropriate to consider some of the important limitations of neuroimaging methodologies in order to understand the potential contribution of these data in the context of findings from other experimental techniques.

Causality

All the work discussed in this article has attempted to correlate changes in brain activity with changes in the contents of consciousness. Such correlational studies cannot determine whether such neural activity plays a causal role in determining the contents of consciousness. In particular, they cannot show whether the areas that have been identified in association with particular contents of consciousness are either necessary or sufficient for such conscious experiences to occur. The identification of necessary and sufficient brain activity requires explicit experimental manipulation of that activity. If manipulation of brain activity changes consciousness, then a causal role for that brain activity can be inferred. Manipulations of brain activity can be performed with direct electrical stimulation, using transcranial magnetic stimulation and as a consequence of brain lesions (although in humans this depends on the presence of pathological conditions and is not under direct experimental control!).

Report

The studies discussed in this article seek to relate neural activity to visual awareness, and in doing so they must distinguish the neural correlates of such activity from the merely unconscious concomitants, such as unconscious perception or behavior. Typically, keeping unconscious aspects of perception or behavior constant can allow this distinction to be made. For example, many of the studies reviewed here employed physically identical stimuli that elicited different conscious percepts. However, with very few exceptions, such studies also required that participants report whether they were aware of the stimulus. Because different behaviors are required to make different reports of awareness, it is possible that this might confound the interpretation of such studies. For example, when masked words are consciously identified and then named (as opposed to when they are not consciously identified and not named), then activity is observed in the frontoparietal cortex. However, such activity may reflect the (unconscious) processes associated with generating verbal output rather than the neural correlates of awareness. Although the differences in behavior elicited by the various reports of awareness are typically much more subtle, and, for example, frontal and parietal activsergenity associated with awareness can be observed in the absence of report or when performance confounds are controlled, further study of the unconscious correlates of behavior associated with report is indicated.

Conclusion

The most parsimonious account of currently available data is that the current contents of visual consciousness consist of a representation in the primary visual cortex and ventral visual pathway corresponding to the attributes represented in consciousness, together with activity in specific parietal (and perhaps) prefrontal structures. Future work must seek to more closely delineate the qualitative and quantitative differences between sensory representations of stimuli that either reach consciousness or remain unconscious, determine whether the frontal and parietal cortices play a causal role in representing the contents of consciousness, and more closely define the relationship between particular higher cognitive processes involved in awareness and corresponding patterns of brain activation.

Axon Guidance by Glia

A Faissner, Ruhr-University, Bochum, Germany

Evidence for Conducive Functions of Astroglia

Astroglial Cells Constitute Axonal Growth Pathways *In Vivo*

Astrocyte-derived basal laminae Astrocyte surfaces were originally recognized as a favorable substrate for axon outgrowth. Müller cells, for example, produce a specialized structure toward the inner surface of the retina, the glial endfeet. Retinal ganglion cell axons elongate along the endfeet-derived basal lamina that contains characteristic extracellular matrix (ECM) components such as laminin-1, collagen IV, heparan sulfate proteoglycan (HSPG), and nidogen. The response of axonal growth cones to laminin-1 is regulated by integrins, heterodimeric receptors of the ECM.

Astrocyte monolayers Astrocyte monolayers constitute an excellent growth substrate for axons *in vitro*. For example, type I protoplasmic astrocytes with extended surfaces prepared from embryonic or perinatal central nervous system (CNS) tissues are more efficient than those obtained from later postnatal stages. Primary astrocytes are more efficient soon after plating and tend to lose beneficial properties with time. Subtypes may exist that are less supportive for axon extension. The neurite growth-promoting properties are also regulated by the spatial arrangement of astrocytes.

Astrocytes in three dimensions It has been observed that astrocytes that still support axon growth when used as monolayers may have inhibitory properties when assembled in tissuelike structures. For example, dorsal root ganglion axons confronting astrocytes lodged in three dimensions in a cellulose acetate tube will grow readily into tubes filled with embryonic but not with aged or matured astrocytes. The model in this regard mimics the dorsal root entry zone, a reputed stop area for centripetal axons in the adult. In this context, the astrocyte–meningeal cell interface may construct a growth barrier.

Multiple Control Mechanisms Regulate the Astrocyte-Dependent Establishment of Cortical Connections via the Corpus Callosum

The Corpus Callosum and the Glial Sling

Anatomy of the corpus callosum and the blueprint hypothesis The corpus callosum connects the left with the right hemisphere in the developing nervous system. In the mouse, it consists of approximately 3 million myelinated fibers that link corresponding regions of the cortices. More that 50 human genetic aberrations have been described that lead to some form of dysgenesis of the corpus callosum. Two populations of midline glia, the indusium griseum and the glial wedge, are necessary for the adequate guidance of axons in this process. The emerging glial structures construct a transient bridge of astrocytes that connects the left with the right hemisphere of the developing telencephalon. This glial bridge, also called the glial sling, supports the reciprocal growth of cortical axons, and the experimental interruption of the sling leads to the formation of acallosal mice. In this situation, the cortical connecting axons role up on either side of the cerebral midline and form the bundles of Probst, longitudinal fascicles of misdirected axons. Growth promotion of cortical axons can be restored by the implantation of nitrocellulose filters that are covered with embryonic astrocytes-derived membranes. The blueprint hypothesis of axon growth states that channels walled by astrocyte surfaces might provide a mechanical growth and guidance substrate for growth cones. Molecular specializations of both growth cone and astrocyte surfaces are presumably implicated in the regulation of these interactions.

Molecular bases of neuron–glia interactions The mechanistic concept of axon guidance has been modified and geared toward an interpretation which emphasizes molecular signals in the growth environment, the readout by specific growth cone-based receptors, and integration of these influences by signal transduction cascades which eventually modulate growth cone movements (Table 1). Thus, a conduit function of astroglia based on the chemorepellent slit-2 has been proposed as an additional guidance principle in the corpus callosum. The molecular analysis of the signaling system involved in corpus callosum formation has progressed and additional gene families have been identified. Thus, the wnt5 protein is expressed by cells of the glial wedge and plays a role in guidance of connecting axons on the contralateral side of the developing corpus callosum formation. Wnt5a-dependent guidance in this context is mediated by the protein tyrosine kinase Ryk that is required in the axon.

Cell Adhesion Molecules Play a Pivotal Role in Neural Cell Interactions

General Definition of Cell Adhesion Molecules

Cell adhesion molecules (CAMs) were first identified during the study of sponge aggregation and

Table 1 Families of adhesion molecules involved in axon guidance

Adhesion molecules	*Features*	*Functions*
Ig superfamily (IgSf)	At least one immunoglobulin (Ig-like) domain, often in combination with fibronectin type III domains	Ca-independent adhesion, either in the homophilic or in the heterophilic mode
L1CAM, NCAM	First IgSf members found in the nervous system	Axon growth and guidance, synapse formation, and plasticity; human L1CAM mutated in the human MASA syndrome that is associated with mental retardation
TAG-1	GPI-linked member of the IgSf	Axon fasciculation
Cadherin superfamily	Characterized by at least one cadherin domain	Primarily homophilic, Ca^{2+}-dependent adhesion; roles in sorting out of cells, synapse formation
N-cadherin	Classical cadherin	Neuron–neuron and neuron–astrocyte adhesion; elimination leads to premature death and cardiovascular malformations
Laminin-1	Founding member of the laminin gene family that comprises more than ten members; laminins are heteromultimers formed by α, β, and γ chains; several genes for each subunit have been distinguished	Excellent axon growth promoting substrate and, for this reason, obligatory cell substrate constituent in many cell culture protocols; as a component of basal lamina, laminin-1 promotes axon growth in the peripheral nervous system; the outgrowth promotion is read out via integrins
Integrins	Large family of heterodimeric receptors formed by α and β subunits; many genes for either type of subunit have been described	Integrins are receptors of extracellular matrix constituents; a subgroup interacts with the sequence RGD in target molecules; more than 20 Itg receptors have been identified
Netrin-1, -2	Homologies to the γ_1 subunit of laminin-1	Netrins are released by midline glia and build up a chemotactic gradient that attracts axons from commissural neurons

subsequently discovered in mammals. One distinguishes Ca^{2+}-dependent and Ca^{2+}-independent adhesion mechanisms that are served by separate gene families, the immunoglobulin (Ig) and the cadherin gene superfamilies. CAMs interact either in the homophilic mode with identical members of a gene family or in the heterophilic mode with distinct partners that may or may not belong to the same gene family.

The Cadherins and Ca^{2+}-Dependent Adhesion

N-cadherin was the first classical cadherin discovered in the CNS and it mediates neuron–neuron and neuron–astrocyte interactions. Classical cadherins contain five cadherin repeat motifs, calcium binding sites, and a transmembrane domain that result in an overall molecular mass of approximately 100 kDa. Subgroups of cadherin-related neuronal receptors and of protocadherins as characterized by the cadherin domain have been discovered, many of which are expressed in the CNS. There, expression patterns correlate with neuroanatomical networks, and current concepts propose a functional role in wiring and synaptogenesis within these systems. This interpretation is consistent with the fact that classical cadherins function in a homophilic, calcium-dependent manner. The constitutive cadherin domain motif has also been found in so-called unconventional cadherin-like molecules that play a role in epithelial cell junction formation or in *Drosophila* tumors (e.g., the gene *fat*). The cytoplasmic domain of classical cadherins interacts with specialized linker proteins called catenins. These are required for the functional activity of cadherins, and the component β-catenin is involved in signal transduction to the cell nucleus and is an important mediator of the wnt signaling pathway, which links cadherins to differentiation processes and to cancer pathology.

Immunoglobulin Superfamily

The Ig superfamily constitutes the other dominating family of CAMs in the nervous system. Its characteristic feature is the Ig domain that consists of 90–100 amino acids arranged in seven antiparallel β-pleated sheets that fold into a globular structure. In many molecules, the Ig loop is combined with one or several fibronectin type III (FNIII) domains, followed by a transmembrane domain. Some IgCAMs are connected to the membrane by a glycosylphosphatidylinositol (GPI) anchor that confers augmented mobility within the membrane plane. GPI-linked proteins are thought to be associated with transmembrane glycoproteins that convey signal transduction processes – for example, the neurexin family member Caspr/paranodin in the case of the IgCAM contactin. On the mechanistic level, Ig superfamily members mediate calcium-independent adhesion processes that may be either homophilic or heterophilic. Several neuronal adhesion molecules with pronounced expression

on axonal surfaces, such as L1CAM or TAG-1/axonin-1 CAM, have been grouped as AxCAMs, highlighting their prominent role in axon fasciculation.

IgCAM Interactions Launch Signal Transduction

Functional participation of IgCAMs in neurite outgrowth requires the activation of downstream signaling mechanisms, including the variation of intracellular calcium in the growth cone. The transduction mechanisms elicited by IgCAMs converge with those launched via N-cadherin and necessitate the basic fibroblast growth factor (bFGF) receptor that *cis* interacts with these CAMs within the membrane. Selected isoforms of NCAM are expressed by astrocytes *in vitro* and mediate neuron–astrocyte adhesion. With regard to heterophilic interactions, the small isoform of the receptor protein tyrosine phosphatase (RPTP)-β/ζ is expressed by astrocytes, a transmembrane protein that interacts with the neuronal adhesion molecule contactin, and other CAMs of the Ig superfamily. These examples illustrate the functional involvement of IgCAMs in conducive neuron–astrocyte interactions. Mutations of the human L1CAM lead to mental retardation, hypotrophy of the corticospinal tract, and hydrocephalus, emphasizing the importance of the Ig superfamily for development of CNS structures.

Integrins as Extracellular Matrix Receptors

The integrins constitute the third prominent gene family of membrane-based CAMs. These consist of α and β subunits that assemble to heterodimers and mediate the interactions of neural cells with ECM components. In some cases, interactions between integrins and Ig superfamily members have been reported, and the activation of integrins involves signal transduction pathways with small GTP-binding proteins such as *ras*.

Evidence for Segregating Functions of Glia

Gene Families That Mediate Axon Growth Inhibition Counterbalance Adhesion Molecule Gene Families

Growth cone collapse The investigation of neural cell interactions resulted in the identification of the Ig and cadherin superfamilies and of growth- and motility-promoting ECM constituents. However, in the 1980s it became clear that in addition to growth promotion, growth inhibitory molecules also contribute to the regulation of cell migration and growth cone movement (Table 2). The phenomenon of growth cone collapse had been described in the context of the interaction of sympathetic with retinal neurites, or when growth cones were confronted with myelin fractions or membrane preparations obtained from inhibitory territories. These interactions invariably resulted in collapse and retraction of the growth cone that remained paralyzed for 30–60 min *in vitro* prior to resuming growth and exploratory behavior. It was quickly realized that this inhibitory effect might equally affect guidance and inhibition of regeneration.

Eph kinases and ephrins The systematic investigation of the visual projection led to the identification of RAG (retinal axon guidance molecule), a GPI-linked protein with a gradient-like distribution in the tectum that proved homologous to a gene family subsequently renamed ephrins. One distinguishes the GPI-linked ephrins A, which interact with complementary EphA-type tyrosine kinases, from the transmembrane ephrins B, which recognize the EphB-type tyrosine kinases. Both groups contain a large number of both ephrin- and Eph-type kinase genes, and a certain degree of freedom in the mutual combinations has been noted. A remarkable trait of the Eph kinases and the corresponding ligands is that the molecules are expressed in reciprocal gradients, which is similar to the concept that Sperry developed in his chemoaffinity hypothesis that posited a chemical cell surface expressed code of positional information. Manipulation of expression levels of Eph genes resulted in a graded repositioning of axonal projections in the visual system. These studies provided impressive support both for the Sperry hypothesis and for the notion that the Eph–ephrin signaling system is an important contributor to the code. Whether the members of the pairs are expressed in neuronal and glial lineages, respectively, remains to be established.

Semaphorins and neuropilins Another gene family mediating growth cone collapse is the semaphorins, which comprise an increasing number of members and have been described in *Drosophila*, chicken, mouse, and human. A constitutive structural feature of these proteins is the sema domain of 500 amino acids that is shared by all family members. Semaphorin-dependent growth cone collapse is mediated by the plexin receptors, which can be categorized into subtypes A–D. In some cases, the plexins interact in the membrane in *cis* with the neuropilins NP1 or NP2 that act as coreceptors in these cases. The semaphorin IIIa dimer, for example, interacts with plexin A1 and neuropilin 1 to launch growth cone collapse using a signal transduction pathway that

Table 2 Gene families involved in repulsion and inhibition

Inhibitory molecules	*Features*	*Functions*
Semaphorins	Characterized by the semaphorin domain; seven structural classes reported in vertebrates and invertebrates	Sema3 molecules inhibit axon growth from several classes of neurons.
Plexins and neuropilins	Transmembrane semaphorin receptors of the growth cone	Detect and mediate Sema-dependent axon growth and guidance.
Ephrins	Family of genes that is divided into the GPI-linked ephrin A and the transmembrane located ephrin B molecules	Ephrins are the long sought-after ligands of the Eph kinases, originally described as orphan receptors.
Eph kinases	Tyrosine kinases located in the membranes of growth cones; one distinguishes Eph-A and Eph-B kinases; Eph kinases activated by interaction with complementary ephrin-A or -B ligands	In the CNS, activation of Eph kinases by ephrins in certain (but not all) combinations leads to growth cone collapse. Eph kinases and ephrins construct complementary gradients in the nervous system that encode positional information, for example, in the visual system.
Nogo proteins	Nogo proteins A–C have been described; they belong to the inhibitory components of myelin that are involved in the prevention of regeneration (in addition to MAG and OMgp)	Nogo proteins activate the Nogo receptor NgR that interacts with the low-affinity NGF receptor p75. Activation of these receptors results in growth cone collapse.
Chondroitinsulfate proteoglycans (CSPGs)	Composed of a core glycoprotein and at least one chondroitin sulfate carbohydrate chain; CSPGs include the lectican family, NG2, and phosphacan	CSPGs are found enriched in glial boundaries during development and in glial scars of the lesioned CNS. They are associated with axon growth inhibition. Axon growth stimulatory chondroitin sulfates have also been described.
Tenascin-C and tenascin-R	Composed of egf-type repeats and fibronectin-type 3 modules and represent the best-characterized glycoproteins of the neural extracellular matrix; tenascins assemble to multimers and are distributed in discrete patterns	Tenascins are inhibitory in certain situations and are capable of forming boundaries *in vivo* and *in vitro*. On the other hand, stimulation of axonal growth has also been reported. These molecules are thus best suited to mediate the ambivalent influences of astrocytes on axon growth and guidance.

involves small GTP-binding proteins, such as Rho and Rac1. The contributions of these inhibitory molecules in the context of neuron interactions with astrocytes remain to be worked out in detail.

Nogo and myelin-based inhibitors By comparison, more is known about the myelin sheath-derived inducers of growth cone collapse that are believed to underlie myelin-dependent inhibition of regeneration. These include the Nogo glycoproteins, with Nogo-A as the principal myelin-based inhibitor of growth, a member of the larger Reticulin gene family. Nogo-A contains a region called Nogo-66, a looplike structure which induces growth cone collapse by interacting with the complementary Nogo receptor NgR. NgR is GPI anchored to the growth cone membrane and part of a receptor complex that also contains the low-affinity NGF receptor p75. Interestingly, two other myelin components inhibitory to axon growth have been detected – the Ig superfamily member MAG (myelin-associated glycoprotein) and OMGP (oligodendrocyte–myelin glycoprotein). Both are also able to activate the Nogo receptor complex, which suggests a common downstream pathway of myelin-dependent inhibition. This pathway involves the downstream activation of RhoA family-type proteins that play a major role in growth cone collapse (Table 3).

Glial Boundaries between Developmental Compartments of the Central Nervous System

Rhombomeres of the hindbrain The brain stem is subdivided into rhombomeres, and the paraxial mesoderm is substructured into somites. The rhombomeres in the hindbrain emerge beginning with the six somite (6s) stage and can be identified as a series of eight swellings along the neuraxis which are separated by grooves at stage 16s. The axons of motor neurons located in pairs of rhombomeres are destined to innervate specific branchial arches and leave the even but not the odd-numbered rhombomeres at defined exit points. The motor nuclei of the cranial nerves and their motor tracts are confined to subsets of rhombomeres along the rostrocaudal axis. Cells of neighboring compartments do not mingle, and intercellular communication by gap junctions is limited to cells within a given compartment. The apparent segmentation of the hindbrain correlates with

Table 3 Gene families involved in choice decisions at the midline

Floor plate-based signals	*Growth cone-based receptors*	*Functions and comments*
Netrin-1, -2 (laminin gene SF; unc-6 in the nematode)	Dcc ('deleted in colorectal cancer', IgSF)	Netrin attracts commissural neurons toward the floor plate. The gene products unc-5 and unc-6 were found to control circumferential axon growth in the nematode.
Sonic hedgehog (Shh)	Patched and smoothened	Shh is a morphogen with fate-instructing functions in early development (e.g., induces the floor plate). It serves as chemoattractant at this stage.
Slit-1, -2, -3 (extracellular matrix components)	Robo-1, -2, -3 (IgSF members)	Slit builds a chemorepellent gradient to drive axons away from the floor plate after crossing. When the robo receptor is mutated, the axons circle incessantly back and forth across the midline ('roundabout' mutation in *Drosophila*). There are several *slit* and *robo* genes in mammals.
Sema3a	Neuropilin and plexin-A, -B, and -C receptors	Acts as chemorepellent that prevents return to the floor plate after crossing.
Ephrin B2	EphB kinases	The Eph–ephrin connection mediates membrane-based reciprocal avoidance behaviors in certain combinations.
NrCAM (IgSF member)	Tag-1/axonin-1 (IgSF member)	The NrCAM–Tag-1 interactions are required to enable the growth cone to cross the midline.

distinct expression patterns of transcription factors of the homeobox gene family that code positional identities in *Drosophila* and vertebrates. The limits of expression of these genes in the mouse spinal cord progress in a caudorostral direction and are strictly coherent with boundaries of rhombomeric pairs in ascending order. Also, other genes are expressed in register with rhombomere boundaries, such as various members of the Eph tyrosine kinase and complementary ephrin ligand gene families and zinc finger transcriptional activators such as *Krox-20*. The Hox code can be altered by treatment with retinoic acid, which caudalizes the spinal cord, including cranial nerve nuclei. These findings concur to qualify the rhombomeres as true compartments with homeotic identity.

The prosomeric model of the prosencephalon Analogous patterns of transcription factors at more rostral positions of the neuraxis have prompted the view that compartments may also exist in diencephalic or telencephalic structures. A detailed analysis of the distribution of numerous transcription factors, such as Otx2, Emx1, Emx2, and Gbx2, in the developing rostral CNS has founded the view that one compartment yields the mesencephalon and six prosomeres preconfigure the diencephalon and the telencephalon with its cortical hemispheres. A more detailed assessment of compartments of the CNS is beyond the scope of this article and is available elsewhere. Interestingly, early axonal pathways often follow the boundaries between transcription factor expression territories. This is also true for interrhombomeric boundaries, where the extension of axonal fiber pathways has been documented.

Specialized cells in the compartment interface Closer inspection of the cellular populations in boundary regions revealed a reduced interkinetic nuclear migration of neuroepithelial cells and an increased intercellular space. IgCAMs such as NCAM that are expressed in rhombomeres may mediate intercellular adhesion in this context. The boundary cells exhibit an unusual fan-shaped array and abut with their endfeet on both the pial and the ventricular surfaces. In zebra fish, a so-called glial curtain has been proposed to separate individual rhombomeres. It has been envisaged that the specialized boundary cells construct a privileged pathway for outgrowing axons. An instructive influence of glial cordones on axon pathways is supported by transplantation experiments in which fiber tracts follow ectopic boundaries. The mechanism and molecular bases of hypothesized boundary functions for axon guidance are unknown, and differential adhesion or local inhibition concepts are being discussed.

Midline Glia as a Signaling Center for Growth Cone Guidance Decisions

Genetic control of the midline in *Drosophila* In *Drosophila*, the midline of the ladderlike nervous system involves the so-called midline glia, which is controlled by a battery of genes. Upstream, *single-minded* regulates the fate determination of midline cells in general. Glial cells emerge under the regulatory influence of *spitz*, a homolog of transforming growth factor-α, and the transcription factor *pointed*, which intervenes in the expression of *gcm* (glial cell missing), an additional gene required for the generation of glial cells in *Drosophila*. Homologs of *gcm*

have been described, but they seem to play a different role in vertebrates. Elimination of the midline glia prevents the separation of commissural fibers and eliminates the longitudinal connections of the characteristic ladderlike nervous system. The commissural fibers of the system begin to extend between three pairs of midline glia cells and the pair of MP1 neurons. Separation of the commissural fiber systems involves migration of the midline glia in the correct direction. A genetic screen has led to the identification of a number of additional genes which control this migratory behavior, one of which, called *klötzchen*, seems to implicate the spectrin cytoskeleton of midline glia. In all cases, deficits in midline glia migration lead to errors in the separation of the connecting commissural fiber systems.

The midline glia in the optic nerve chiasm A comparable class of boundaries associated with glial cell types has been described in the midline of the developing nervous systems of vertebrates. Thus, glial cells separate the left and right axonal projection systems at the optic chiasm. Advancing axons are attracted by netrin, interact with this glial population, and are directed either to the ipsilateral or to the contralateral cortex, as required in the context of binocular vision. Several candidate molecules have been considered to be involved in the directional growth cone choice. Among these are the glycoprotein L1, the hyaluronate receptor CD44, and chondroitin sulfate proteoglycan(s), as visualized by the expression of chondroitin sulfate epitopes in boundary glia. Chondroitin sulfate proteoglycans (CSPGs) are thought to indicate inhibitory territories in the developing nervous system that are also secured by ephrins.

The floor plate of the vertebrate neural tube Analogous situations are also observed in the floor and roof plates of the developing spinal cord (Figure 1). In the latter case, the dorsal midline cells express keratan sulfate and chondroitin sulfate epitopes linked to proteoglycan core proteins. Thereby, the CSPGs outline a boundary region that is not traversed by the commissural axons. When chondroitin/keratan sulfate-expressing proteoglycans are exposed as patterned substrates alternating with the glycoprotein laminin-1, various cultured neurons and their processes avoid the proteoglycan-rich regions and grow out on the laminin-1 substrates.

In the ventral half of the spinal cord, commissural axons of the dorsal horn are attracted toward the floor plate that releases the chemoattractant netrin-1. Netrin-1 binds to the growth cone-based receptor deleted in colorectal cancer (*dcc*) of the Ig superfamily. This mechanism is highly conserved because it has already evolved in the nematode *Caenorhabditis elegans*, in which unc-5 guides circumferential axons via the unc-6 receptor – homologs of netrin-1 and dcc, respectively. Sonic hedgehog (*Shh*) represents a second chemoattractant that acts in a similar direction. When the axons reach the midline, the commissural fibers interact with the floor plate via an adhesive mechanism that involves the Ig superfamily members NrCAM as expressed in the midline and TAG-1/axonin-1 as heterophilic ligand in the growth cone membrane. The GPI-linked axonin-1/TAG-1 protein is downregulated after the crossing has occurred and L1CAM appears on the longitudinally oriented fibers. Concerted interactions of these Ig superfamily members thus seem to be required to regulate the crossing step. Subsequently, the axons lose responsiveness to the attractant netrin-1 and develop

Figure 1 Axon guidance at the midline of the developing spinal cord. The figure shows the developing spinal cord of the rat at approximately embryonic day 13. At this stage, axons emanating from the commissural neurons migrate toward the ventral midline. There, axons contact the floor plate, midline glia (outlined in green) that defines an axon growth choice point. The growth cone migration and its behavior at the midline can be monitored *in vitro* with the so-called 'open book' preparation (right). Many genes are involved in growth cone guidance at the midline, some of which are listed in Table 3.

a sensitivity to the chemorepulsive signaling protein slit. This glycoprotein is released by midline glia and induces growth cone repulsion mediated by the Ig superfamily receptor roundabout (*robo*). *Robo* as well as *slit* were originally discovered in *Drosophila*, in which axons fail to stay on the ipsilateral side after crossing the midline, leading to the characteristic picture of incessantly circling axons. Several *slit* and *robo* genes have since been identified in mammals. A further inhibitory system is provided by semaphorins of the sema3 class and the complementary plexin and neuropilin receptor complexes NP1 and NP2, which mediate growth cone collapse. In addition, evidence has been presented that Eph kinase–ephrin interactions are also involved in the midline choice decision of the growing corticospinal projection. Thus, ephrin B3 is a constituent of the midline and prevents recrossing of these axons when they enter the gray matter after having migrated to the contralateral side of the spinal cord. Subsequently, the wnt proteins are involved in stimulating neurite outgrowth and regulating anterior–posterior guidance of commissural axons. These proteins utilize at least three signal transduction pathways and are implicated in many aspects of axon growth and interneuronal wiring (Table 3).

The Ambivalent Properties of Astrocytes Are Reflected by Extracellular Matrix Components That Embody Both Axon Inhibitory and Stimulatory Properties

Glycoproteins of the Extracellular Matrix

The pericellular space is organized by a superstructure of interacting glycoproteins and proteoglycans of the ECM. Astrocytes *in vitro* produce many of the ECM glycoproteins originally described in other tissues, namely fibronectin, laminin-1, vitronectin, thrombospondin, and tenascin-C. Laminin-1 is a functional component of astroglial endfeet in limiting membranes, for example, in the developing retina, and forms an excellent growth substrate for axon extension of many neuronal cell types. The chemodiffusible chemoattractants netrin-1 and netrin-2, which guide outgrowing commissural axons toward the floor plate of the midline in the spinal cord, are structurally related genes. Fibronectin has been found in association with blood vessels, a structure in which astrocytes contribute to the formation of the blood–brain barrier which isolates the CNS from the bloodstream.

The Tenascin Gene Family

Tenascin-C is transiently expressed by immature astrocytes in the developing CNS in which its distribution follows functional neuroanatomical subdivisions. For example, in the barrel field it delineates the emerging barrel field structure in layer IV. The glycoproteins of the tenascin gene family are characterized by structural motifs common to tenascin-C (Tnc), tenascin-R (Tnr), tenascin-X (Tnx), tenascin-Y (Tny), and tenascin-W (Tnw). A cysteine-rich N-terminus is followed by a series of egf-type repeats, fibronectin type III modules, and, finally, homologies to fibrinogen-β and -γ at the C-terminus. Different from this organization, a tenascin-like pair-rule gene in *Drosophila* contains the characteristic egf-type repeats but is devoid of other structural elements. The egf-type repeats of tenascins display a characteristic arrangement of cysteines that has also been found in the ECM protein reelin and is distinct from the one in the egf-type repeat modules of Notch or the laminin genes. The N-terminus links monomers in Tnr to trimers and in Tnc to hexamers under nonreducing conditions. As viewed with the electron microscope, the hexamer appears as a typical six-armed structure that has been designated hexabrachion and seems to be conserved during evolution. Two isoforms which are distinguished by one FNIII motif have been described in Tnr, a gene which is expressed in oligodendrocytes at later stages of development.

Multiple Isoforms of Tnc

Tnc possesses an alternative splice site between the fifth and the sixth FNIII module, where as many as six and nine additional FNIII repeats can be inserted in mouse and human Tnc, respectively. Up to 30 alternatively spliced variants in this region of Tnc have been revealed, approximately 50% of the theoretically possible 64 isoforms assuming a binary combinatorial code. In the human, theoretically 512 or 2^9 splice variants are conceivable on the ground of 9 potential alternatively spliced modules. Therefore, Tnc seems suited to specify pericellular microenvironments or to distinguish glial sublineages. Tnc is associated with numerous pathological conditions, including glial tumors.

Tnc Is a Multimodular and Multifunctional ECM Component

The characteristic hallmark of Tnc is its antiadhesive property for many cell types. In situations that expose a Tnc-rich environment alternating with laminin-1, the glycoprotein deflects growth cones and neuronal cell bodies, consistent with its boundary-like distribution in several CNS territories. On the other hand, homogeneous substrates containing Tnc promote neurite outgrowth of most neuronal cell types studied to date. Neurite outgrowth promotion could be mapped to the distal splice site that surrounds

Figure 2 Structure–function relationship of tenascin-C. The glycoprotein of the extracellular matrix (ECM) tenascin-C is characterized by a modular structure with fibronectin type III domains (boxes), some of which are alternatively spliced (pink boxes). On the N-terminal end, the sequence comprises egf-type repeats (yellow elipses). Many functions have been ascribed to tenascin-C that are mediated by distinct receptors and/or ligands. The corresponding binding sites are underlined and complementary receptors are indicated. $\alpha_n\beta_m$ pairs of letters indicate specific integrin heterodimers.

cassette D. A site interfering with the motility of oligodendrocyte precursors was located to the FNIII module pair TNfn78, whereas the antiadhesive qualities could be mapped to other domains (Figure 2). Several Tnc receptors have been described, including the Ig superfamily member contactin, which mediates Tnc-dependent stimulation of neurite outgrowth, and the integrins $\alpha_v\beta_3$, $\alpha_7\beta_1$, $\alpha_8\beta_1$, and $\alpha_9\beta_1$. In the ECM, Tnc interacts with the proteoglycans phosphacan and neurocan. A number of studies on the Tnc −/− mutants suggest altered responses to stress, behavioral modifications, and deficits in the stem cell compartments of several organs, including the brain, during development, in the adult, and in response to lesion. These observations and the strong association of Tnc with human pathology in CNS cancer, hippocampal sclerosis, and various types of lesion warrant further studies of this versatile multifunctional glycoprotein. The antiadhesive glycoproteins of the CNS also comprise the thrombospondins, which have been found to mediate an astrocyte-derived signal for synaptic maturation.

Proteoglycans of the Extracellular Matrix

Key features of proteoglycans and heparan sulfate proteoglycans Proteoglycans represent the second class of ECM components expressed in the CNS. These components are defined as glycoproteins that carry at least one covalently linked glycosaminoglycan chain. One can distinguish HSPGs, which are mainly membrane bound, from CSPGs and keratan sulfate proteoglycans (KSPGs) of the nervous system, which are preferentially recovered from saline detergent-free extracts.

Two important HSPG subfamilies are the membrane-based syndecans and the GPI-linked glypicans. Central roles of the HSPGs may reside in the support of signaling processes in the context of tissue development. Thus, bFGF binds to a specific motif in heparan sulfate carbohydrate chains that expose the factor to its (the FGF receptor is a membrane bound tyrosine kinase) receptor. Similar mechanisms have been proposed for wnt signaling that plays important roles in axon growth and synapse formation.

CSPGs and KSPGs of the central nervous system With regard to CSPGs, the members of the lectican family – brevican, neurocan, versican, and aggrecan – have been identified in the CNS. These CSPGs possess a binding site for hyaluronic acid, a lectin-type sequence, and further distinct structural motifs. Versican is expressed by mature oligodendrocytes, whereas neurocan and aggrecan have been detected in neurons. The core glycoproteins may carry the HNK-1 epitope, a carbohydrate structure also expressed by neural recognition molecules, or other N-linked carbohydrates, for example, of the Lewis X-type, which are

recognized by specific monoclonal antibodies. Further CSPGs that have been described in the CNS with the help of specific monoclonal antibodies include CAT 301 and NG2, a marker of oligodendrocytes. CAT 301 upregulation during early embryonic development of the spinal cord depends on activation of the NMDA receptor, suggesting a role in plasticity. The possible roles of CSPGs in synaptic reorganization have been highlighted by the finding that injection of chondroitinase ABC, which degrades the particular glycosaminoglycans of CSPGs, restores plasticity of the adult visual cortex.

Inhibition of axon outgrowth by CSPGs On the functional level, many studies support the view that CSPGs inhibit axon outgrowth in an otherwise supportive environment. Thus, DRG axons extend profusely on a laminin-1-coated substrate but strictly avoid territories that have been replenished with CSPG preparations. Comparable findings have been obtained with defined CSPGs such as neurocan and versican and a variety of cell types, including neural crest, which led to the conclusion that CSPGs play a central role in axon growth inhibition and guidance. These observations motivated the analysis of CSPGs in the context of regeneration inhibition. Numerous studies concur that CSPGs are strongly upregulated by reactive astrocytes in a broad spectrum of lesion paradigms. Therefore, these components are considered an important inhibitory compartment that plays a pivotal role in the lack of regeneration of the CNS. This interpretation has gained support by the observation that injection of chondroitinase ABC into the lesioned spinal cord enhances plasticity and reactive sprouting and hence entails some improvement of the afferent sensory function. Several possibilities are conceivable to explain the mechanistic aspects of the inhibitory properties of CSPGs, and it is plausible that these components bind growth cone collapse, inducing molecules such as semaphorins to particular structural sequences in the glycosaminoglycan chains. On the other hand, CSPGs have been found associated with axon growth and regeneration in the peripheral nerve, which emphasizes that overall matrix composition and the lineage and age of the neurons involved need to be considered.

Phosphacan and Receptor Tyrosine Phosphatases of the Central Nervous System

The CSPG phosphacan/DSD-1-PG DSD-1-PG/phosphacan is one of the more abundant soluble CSPGs in postnatal mouse brain and is homologous to the secreted proteoglycan phosphacan from rat tissues. The GAGs of phosphacan are composed of chondroitin sulfate (CS)-A and CS-C motifs, a keratan sulfate chain, and the DSD-1-epitope. This unique structure was discovered with the MAb 473HD, requires the sulfation of the carbohydrate backbone, and contains CS-D dimers and dermatansulfate. The DSD-1-epitope displays neurite outgrowth promoting properties, which possibly involves its capacity to bind pleitrophin. Phosphacan is a splice variant and corresponds to the complete extracellular region of the largest isoform of the transmembrane receptor protein tyrosine phosphatase-β (RPTP-ζ/β). RPTP-ζ/β proteins occur as large or short receptors which possess a transmembrane domain and two cytoplasmic tyrosine phosphatase modules. The additional phosphacan short isoform (PSI) that corresponds to the N-terminal sequence has been described in the mouse, and several isoform variants have been found in *Xenopus*.

Receptor protein tyrosine phosphatases in neuron–glia interactions The different isoforms of RPTP-ζ/β are developmentally regulated, and astrocytes from various parts of the CNS express the short RPTP-ζ/β receptor. RPTP-ζ/β_{long} is expressed in the ventricular zone of the developing and the subventricular zone of the adult CNS and also by oligodendrocyte precursors. Neuronal expression has also been observed which may partially be due to PSI that is strongly expressed by cortical neurons. The spatiotemporal expression patterns of RPTP-ζ/β isoforms during development, maintenance, and pathology of the CNS have been correlated with cell–cell signaling, cellular proliferation, migration, differentiation, axon outgrowth, synaptogenesis, synaptic function, and tissue regeneration. Based on the prominent glial expression of phosphacan and RPTP-ζ/β receptors, the proteins have been considered as possible mediators of neuron–glia interactions. In the adult CNS, phosphacan occurs in the perineuronal nets of parvalbumin-expressing neurons, surrounding axon terminals and glial endfeet but not the synaptic clefts. It has been hypothesized that CSPGs associate with hyaluronic acid in these structures to build a neural ECM comparable to that in connective tissue. CSPGs in the perineuronal ECM may constitute an important element in limiting synaptic plasticity. On the functional plane, phosphacan interacts with the Ig superfamily members contactin/F3/F11, axonin-1/TAG-1, NrCAM, and NgCAM and hence might intervene in both homophilic and heterophilic interactions. Therefore, it is plausible to assume that IgSF constituents represent neuronal ligands of RPTP-ζ/β receptors expressed in glial membranes and serve as molecular mediators at the interface between these two cellular lineages. Interestingly, both RPTP-ζ/β

and the IgCAMs are linked to signal transduction pathways and hence will act back on the expressing cells in the context of reciprocal signaling mechanisms. In particular, the phosphotyrosine–phosphatase modules of RPTP-ζ/β may antagonize tyrosine kinase-based activities. ECM ligands of phosphacan include tenascin-C and tenascin-R. The integration into ECM superstructures might explain to some extent why the elimination of the phosphacan gene does not yield serious developmental deficits in mice.

Axon Guidance: Building Pathways with Molecular Cues in Vertebrate Sensory Systems

F Wang, Duke University Medical Center, Durham, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The functions and signaling mechanisms of many important axon guidance molecules may be described individually, but here we attempt to take a more systematic view to describe how various chemotropic guidance cues and adhesion molecules work together to help build precise connections in sensory systems, from the periphery to the brain. We focus on the cell surface/secreted molecules that regulate important pathfinding events in the vertebrates, especially in the mammalian sensory systems. Among the sensory systems, the pathfinding mechanisms are best understood in the visual and the olfactory systems, and to a lesser extent in the somatosensory system. The auditory and the gustatory systems, however, have not been very well characterized.

Building the Visual System

In vertebrate animals, visual stimuli are transmitted by retinal ganglion cells (RGCs) from the retina to subcortical relay stations and eventually to the primary visual cortex. The underlying pathway is formed during development by axons navigating through complex environments, involving decisions at multiple steps, in a remarkably stereotypical and precise manner.

Pathfinding and Topographic Mapping by RGCs

RGC axons project from the retina to the superior colliculus (SC) in mammals, or to the optic tectum (OT) in amphibians and avians, before reaching the lateral geniculate nucleus (LGN) of the thalamus. Significant progress has been made in revealing how RGC axons are guided to make several important choices: where to exit the retina, where to form the optic nerve, to cross or not to cross at the optic chiasm, and how to map the visual field topographically onto the SC and the LGN.

Finding and exiting the optic disk The first step in building the visual pathway is for the RGC axons to exit the retina and project into the optic nerve. RGC axons travel in radial routes inwardly toward the fovea of the retina, where the optic disk is located. Studies in zebra fish have revealed that RGCs express the chemokine receptor CXCR4, while the optic disk expresses the ligand stromal cell-derived factor-1 (SDF-1), and that SDF-1 attracts RGCs toward the optic disk (Figure 1(a)). In addition, cell adhesion molecules and bone morphogenetic protein (BMP) receptor type I, chondroitin sulfate proteoglycan (CSPG), and Sonic hedgehog (SHH) molecules have also been implicated in directing this process. Once the RGC axons reach the optic disk, they require netrin-1 to project into the optic nerve head (Figure 1(b)). In netrin-1 and DCC (deleted in colorectal cancer) mutant mouse embryos, many RGC axons fail to exit the eye and instead they project aberrantly into other regions of the retina, resulting in the hypoplasia of the optic nerve.

Forming the optic nerve and growing toward the optic chiasm After the RGC axons exit the eye, their growth along the optic nerve is guided in part by Slit proteins (Slit1 and Slit2). Slit1 and Slit2 are repellent molecules for RGC axons and are expressed in overlapping and complementary domains surrounding the optic nerve and adjacent to the optic chiasm (Figures 1(b) and 1(c)). In this way, Slit1 and Slit2 help establish repulsive barriers for a narrow corridor that channels retinal axons toward the optic chiasm. In the absence of both Slit1 and Slit2, retinal axons are defasciculated and project ectopically into the preoptic area. Slits also help to prevent RGC axons from growing back toward the other eye after they reach the chiasm. In zebra fish, mutations in the Slit receptor gene *Robo2* lead to random projections of RGC axons and complete disruption of optic nerve formation. The responses and sensitivities of RGC axons to Slit proteins appear to be regulated by heparan sulfotransferases.

Crossing or not crossing at the optic chiasm At the optic chiasm, RGC axons have to decide whether to stay on the ipsilateral side or to cross the midline to the contralateral side. The percentage of RGC axons crossing at the optic chiasm differs among different species. Fish and birds have no binocular vision and all of their axons cross the midline. In higher mammals, RGCs located in the nasal retina project their axons to the contralateral side, while axons from RGCs of the temporal retina stay ipsilaterally. In mammalian species with less binocular vision, such as mice, only a small subpopulation of RGCs in the ventrotemporal (VT) region of the retina will project their axons ipsilaterally. Studies in *Xenopus* and mice

Figure 1 Molecules guide retinal ganglion cells at the optic disk, optic nerve, and optic chiasm. (a) Expressed stromal cell-derived factor-1 (SDF-1) attracts the chemokine (CXCR4)-expressing retinal ganglion cells toward the optic disk. (b) Netrin-1 attracts retinal ganglion cells into the optic nerve. Slit proteins prevent retinal ganglion cell axons from straying away. (c) Slits channel retinal ganglion cell axons toward the optic chiasm. EphrinB prevents EphB1-expressing retinal ganglion cells from crossing the optic chiasm.

have demonstrated that the repulsive ligand ephrinB is expressed at the optic chiasm. EphrinB prevents the crossing of ipsilaterally projecting RGC axons which express the receptor EphB1 (Figure 1(c)). In EphB1 null mice, ipsilateral projections are dramatically reduced and almost all RGC axons cross the midline. The expression of EphB1 in these noncrossing RGCs is likely to be regulated by the zinc-finger transcription factor Zic2 and the Lim-homeodomain factor Islet2.

Topographic mapping in the optic tectum/superior colliculus Leaving the optic chiasm, RGC axons project to several subcortical regions. The most prominent midbrain target is the optic tectum of fish, amphibians, and avians, or the SC of mammals. In the OT/SC, RGC axons form an ordered map of the visual field, the positions on the retina being topographically mapped onto the OT/SC along two orthogonally oriented axes: the temporal–nasal (T–N) axis of the retina maps along the anterior–posterior (A–P) axis of the OT/SC (Figure 2, upper panel), whereas the dorsal–ventral (D–V) axis of the retina maps along the lateral–medial (L–M) axis of the OT/SC (Figure 2, lower panel). The T–N to A–P mapping is primarily governed by the repulsive guidance of the EphA–ephrinA interactions. The EphA expressions in RGCs have a high-to-low gradient along the T–N axis, whereas the ephrinA expressions in the OT/SC show a low-to-high gradient along the A–P axis. These two countergradients together control either the sites of RGC axon termination in fish and amphibians, or the locations of interstitial collateral sprouting in avians and mammals (Figure 2, upper panel). The D–V to L–M mapping is achieved by functions of two sets of guidance cues, ephrinB and Wnt. EphrinB is expressed in a high-to-low gradient along the M–L axis in the OT/SC, while EphB is expressed in a low-to-high gradient along the V–D axis in the retina. High-level EphB signaling results in repulsion, while low-level signaling leads to attraction. EphB–ephrinB signaling results in a net attraction of all RGC axons to the medial part of the OT/SC. This is balanced by Wnt protein signaling. Wnt3 causes repulsion of RGC axons through the Ryk receptor, but attraction is through the Frizzled (Fzl) receptor. Wnt3 is expressed in a high-to-low gradient along the M–L axis in the OT/SC. Ryk is expressed in a low-to-high gradient along the V–D axis in the retina, while Fzl expression is equal along the V–D axis. The net result is that Wnt3 causes RGC axons to project toward the lateral part of the OT/SC. The combination of ephrinB and Wnt signaling is required for topographic mapping of RGC axons from the retina to the OT/SC (Figure 2, lower panel). This projection can also be refined by

Figure 2 Topographic mapping of retinal ganglion cell projection in the superior colliculus, showing the temporal–nasal (T, N), the anterior–posterior (A, P), the dorsal–ventral (D, V), and the lateral–medial (L, M) axes. Schematic representations of graded receptors (EphA, EphB, Fzl, Ryk) and ligands (Wnt3 protein, ephrinA, ephrinB) that guide retinocollicular topographic mapping.

spontaneous correlated neural activity during a brief critical period.

Topographic mapping and segregation into eye-specific layers in LGN The lateral geniculate nucleus of the thalamus is the other main target of RGCs and is the relay station for visual input to the cortex. RGC axons again form ordered projections that map the visual field onto the LGN. Molecular mechanisms similar to those that govern the retinotopic map in the OT/SC also regulate the retinogeniculate projections. Gradients of ephrins in the LGN and countergradients of Ephs in RGCs regulate the topographic mapping in the LGN. Moreover, in mammals, input from the two eyes segregates into stereotyped eye-specific layers in the LGN. The precise pattern of segregation requires the function of EphrinAs, whereas the segregation of the eye input *per se* depends on neural activity.

From LGN to the Visual Cortex

The next connection in the visual pathway in mammals is for LGN neurons to relay the visual input that they receive from RGCs to the visual cortex. Compared with the pathfinding of RGCs, our understanding of the molecular mechanisms that guide the LGN neurons projections is quite limited. Here we summarize the current findings in this field, focusing on the guidance cues that are supported by *in vivo* evidence from mutant mice.

Getting to the cortex via thalamocortical projections LGN neurons follow precise pathways to relay information from the thalamus to the visual cortex. Their axons first project ventrally through the ventral thalamus. As they approach the dorsal border of the hypothalamus, they make a sharp turn and extend dorsolaterally through a narrow corridor, called the internal capsule (IC), into the ventral telencephalon. All thalamocortical axons (TCAs) likewise follow this path. Slit1 and Slit2 present in the hypothalamus prevent the TCAs from entering into the hypothalamus and also push TCAs away from the midline and toward the IC. Projecting into the IC requires recently identified 'corridor cells,' which express the membrane-bound form of neuregulin (Nrg1-CRD) that helps to attract and/or permit the growth of thalamic axons into the IC (Figure 3). Further extension of these axons to the cortex depends on the secreted form of neuregulin, containing an immunoglobulin-like (Ig) domain (Nrg1-Ig), which is expressed in the pallium and acts as a long-range chemoattractant (Figure 3). TCAs express the receptor Erb4 for both isoforms of neuregulin. Thalamocortical projection is severely disrupted in either the neuregulin or the Erb4 knockout mice in manners consistent with the roles of corridor cells and neuregulin in attracting TCAs. In addition, netrin-1 restricts the width of the internal capsule, and the semaphorin Sema6A is involved in the guidance of some TCAs.

Innervating and mapping in the visual cortex The molecular guidance cues that direct either the LGN axons toward the visual cortex or the subsequent axon branch projections into layer IV of the cortex are unknown at present. In terms of cellular events, axons initially accumulate and wait below the developing visual cortex in a zone called the subplate, which contains the first postmitotic neurons of the cerebral cortex, the subplate neurons. Subplate

Figure 3 Thalamocortical axon projections are guided in part by neuregulin isoforms. Thalamocortical axons which express ErB2, the receptor for neuregulin, project through a narrow corridor toward cortex. The corridor is made attractive by the presence of a membrane-bound form of neuregulin (Nrg-CRD). In addition, a secreted form of neuregulin containing an immunoglobulin-like (Ig) domain (Nrg-Ig) acts as a long-range attractant for these axons.

neurons have been shown to play important roles in controlling where LGN axons wait and where they project, but the identities of the guidance molecules expressed by subplate neurons are unknown. LGN axons also form topographic maps of the visual field in the visual cortex. Here again, interactions between gradients of EphA/ephrinA direct the formation of the map, but they are not the only factors. Moreover, activity-dependent processes are likely to play a major role in shaping the visual connectivity in the cortex.

Building the Olfactory System

Odorants are detected by olfactory sensory neurons (OSNs) residing in the nose of mammals. OSNs project their axons to the olfactory bulb (OB), the first relay station in the olfactory pathway, and form a sensory map that encodes the quality of odorous chemicals. Mitral (and tufted) cells in the olfactory bulb project to multiple olfactory centers via the lateral olfactory tract (LOT). In the following sections, we review receptors and cues that have been shown to play important roles in guiding the OSN projection and the formation of LOT.

Formation of an Olfactory Sensory Map in the Olfactory Bulb

In the nasal epithelium of mammals, each OSN expresses only one odorant receptor (OR) from a family of about 1000 genes that all encode seven-transmembrane proteins. All neurons expressing the same OR, although randomly distributed in a broad circumferential zone along the dorsoventral axis in the epithelium, project convergently to a pair of glomeruli, each located at a stereotyped position on one side of the olfactory bulb. In this way, the identity of a chemical group (or groups) that is recognized by a given OR is mapped onto two anatomically conserved locations in the bulb (Figure 4). How do neurons expressing a specific OR find their target with such precision?

ORs play important roles in OSN targeting. Since the choice to express a given OR is tightly linked to the choice of the axonal projection site in the olfactory bulb, a model in which ORs dictate OSN axon targeting was proposed and supported by several lines of evidence. mRNAs of ORs are found in the OSN axons. OR proteins are concentrated not only in dendrites (to detect odorants) but also on axon termini in the glomeruli. Swapping either the entire coding sequence or the DNA sequence for a few amino acids of one OR with those of another resulted in altered OSN axonal convergence points in the bulb.

How might ORs influence where OSNs form the glomeruli? Two recent studies have shed a light on this puzzle. The first study strongly suggests that ORs signal through G-proteins to regulate intracellular cyclic adenosine monophosphate (cAMP) levels and that different cAMP concentrations determine the differential expressions of axon guidance molecules along the A–P axis. All OSNs express the olfactory-specific G-protein, G_{olf}, throughout their life span. In addition, they express the generic α subunit of G-proteins, G_s, at younger stages. ORs are coupled to these stimulatory G-proteins through a conserved DRY (Asp-Arg-Tyr) motif in their cytoplasmic loop after the third transmembrane domain. Mutating this G-protein binding site on a given OR, I7, caused the mutant ($I7_{DRY}$) OSNs to project diffusely in a broad domain in the olfactory bulb and failure to form glomeruli. This lack of axonal convergence can be partially reverted by expressing either a constitutively active G_s or a constitutively active cAMP response element-binding protein (CREB) in $I7_{DRY}$ neurons. Interestingly, co-expressing a dominant-negative protein kinase A (PKA) with the wild-type I7 results in these neurons projecting to a drastically anteriorly shifted position. In contrast, putting either a constitutively active G_s or a constitutively active PKA into

Figure 4 Formation of the olfactory sensory map is guided by odorant receptors (ORs). (a) ORs activate G-protein (G_s)signaling/cAMP signaling to guide the projection of olfactory sensory neurons along the anterior–posterior (A–P) axis and dorsal–ventral (D–V) axis to a small domain in the olfactory bulb. (b) Odorant receptors activate olfactory-specific G-protein (G_{olf}) signaling to induce calcium entry and neuronal depolarizations. These neuronal activities in turn regulate the expression of axon sorting molecules that help sort olfactory sensory axons into distinct glomeruli. AC, adenylate cyclase; CNG, cyclic nucleotide gated channel; cAMP, cyclic adenosine monophosphate; CREB, cAMP response element-binding protein; PKA, protein kinase A.

I7-OSNs, causes them to converge at a much more posterior location in the olfactory bulb. These results led the authors to propose a model in which ORs instruct OSN targeting indirectly via OR-derived cAMP signals (most likely by activating G_s) and that different amounts of cAMP regulate the expression of A–P axon guidance molecules, probably through activating CREB (Figure 4(a)). Indeed, the authors have found that expression of the neuropilin-1 receptor positively correlates with the cAMP level, and that neuropilin-1 is expressed in a low-to-high A–P gradient in the glomeruli layer of the olfactory bulb. However, this model also implies that each OR can determine a unique level of cAMP, a hypothesis that remains to be tested. Moreover, since cAMP has been shown to have profound effects on growth cone turning responses, it is conceivable that OR-derived cAMP also control OSN growth cones navigation locally.

Another study used transgenic mice in which the majority of OSNs express one particular OR. This has led to the discovery that ORs also control the expression of the homophilic adhesive molecules (such as the Ig domain containing Kirrel2/Kirrel3 proteins) and the repulsive molecules (such as ephrinA5/EphA5) in an OR-specific and activity-dependent manner (Figure 4(b)). Different ORs, through OR-evoked activity, determine the 'on' or 'off' expression of certain cell adhesion or repulsion molecules, such that different classes of OSNs have distinct combinatorial adhesive/repulsive codes. Once OSNs project to a narrow domain in the olfactory bulb, the adhesive/repulsive molecules then control the sorting of olfactory axons expressing different ORs into different glomeruli within that domain, by both homophilic and mutual repulsive interactions. At the present, it is not known how ORs control the expression of these sorting molecules through OR-dependent neuronal activity. Neural activity may be spontaneous and random, as spontaneous activity is known to be required for the formation of the olfactory map. Spontaneous and odor-evoked activities are also required for the maintenance of the olfactory sensory map.

From the Olfactory Bulb to Higher Olfactory Centers

Mitral and tufted (M/T) cells are the projection neurons in the olfactory bulb; they send axons through the lateral olfactory tract onto several structures of the olfactory cortex. M/T axons are known to wait in the LOT (for about 2 days in the mouse) before sending collateral branches to the olfactory cortex. M/T cells with dendrites that receive input from one particular glomerulus project collaterals to multiple cortical areas in a highly distributed and complex, but not random, manner. Because the organizational

Figure 5 Peripheral projections of somatosensory neurons are guided in part by neurotrophins and semaphorins. Schematic representation of axonal projections of dorsal root ganglion (DRG) neurons. The molecules that guide the central axons into different layers of the spinal cord are unknown and are depicted as '?' in the drawing. Two classes of molecules, neurotrophins (including nerve growth factors, brain-derived neurotrophic factor, neurotrophins 3, 4, and 5, and glial-derived neuronal factors) and semaphorins, direct the peripheral axon outgrowth of sensory neurons by acting as chemoattractants and surround-repellents, respectively. Neurotrophins also promote the innervation, axon arborization, and sensory ending formation of DRG neurons in the target organs such as skin and muscle.

principle of the M/T projections in olfactory cortices is unclear, studies of this pathfinding process have largely focused on the formation of the LOT.

M/T cell projection to and along the LOT requires both short-range and long-range guidance cues. The short-ranged cues are believed to be at the surface of specialized cells called LOT cells. These cues help guide the M/T axons into the LOT and promote their elongation, although their molecular identities are unknown. M/T axonal projections in the LOT are also guided by long-range chemorepulsive molecules expressed in the septum, such that the axons avoid innervating septum regions *in vivo*. Slit1 and Slit2 together account for the repulsive ligands expressed in septum that repel M/T axons expressing Robo receptors. In Slit1 and Slit2 double-mutant embryos, M/T projection is completely disorganized, with many axons entering the septum region.

Building the Somatosensory System

The vertebrate somatic sensory system transmits to the brain information about physical stimuli that the body experiences. The stimuli can be painful, thermal, mechanical, or proprioceptive. Each of these modalities is detected by distinct types of primary sensory neurons and is processed by different central pathways. Although it is generally true that the body surface is topographically mapped onto subcortical processing centers and ultimately to the somatosensory cortex, surprisingly little is known about the molecular mechanisms that control the establishment of the somatosensory map and the neural circuit for each distinct modality.

The cell bodies of somatosensory neurons reside in a series of ganglia located outside the spinal cord (dorsal root ganglia) or the hindbrain (trigeminal ganglia), with the exception of the facial proprioceptive neurons, the cell bodies of which reside in the trigeminal mesencephalic nuclei inside the brain stem. Each sensory neuron grows two major branches stemming from a unipolar axon: a peripheral axon that innervates a specific body target, such as skin, viscera, or muscles, and a central axon that projects into the spinal cord or brain stem and forms specific synapses (Figure 5). Therefore, each neuron has two pathfinding tasks, one to the periphery and the other to the central nervous system (CNS), and the two processes must be coordinated such that the body is faithfully mapped onto the brain. The molecular mechanisms that guide the central axons of sensory neurons are largely unknown at present, but significant progress has been made in understanding the guidance of peripheral somatic sensory axons.

Peripheral Growth and Projection of Somatic Sensory Neurons Are Guided by Neurotrophins and Semaphorins

The growth of peripheral sensory axons follows stereotyped trajectories; this process is partly guided by neurotrophins (NTs) and semaphorins (Figure 5). NTs (including nerve growth factor, brain-derived neurotrophic factor, NT3, NT4, NT5, and glial-derived neuronal factor) are expressed and secreted by peripheral target tissues. They exert many biological effects on sensory neurons, acting not only as survival and differentiation factors, but also as chemoattractive factors for sensory axons. Both *in vitro* and

in vivo experiments have demonstrated that the chemotropic effects of NTs (for promoting axon elongation and target innervation) can be separated from their chemotrophic (survival) effects. For example, nerve growth factor-soaked beads, when embedded *in vivo* in embryos, can attract sensory axons growing toward them. The peripheral axons grow in fascicles, forming nerve bundles. This fasciculation is regulated by class III secreted semaphorins, which are expressed in a pattern surrounding the axon pathways, and sensory neurons express receptors that recognize these repellents (i.e., neuropilins 1 and 2 and plexins A3 and A4). Mice deficient in any of these receptors or semaphorin3A have severely defasciculated sensory axons. Besides NTs and semaphorins, little is known about the peripheral target selection and innervation process of sensory axons.

Summary

In summary, we have briefly reviewed the axon guidance molecules that work in concert to orchestrate the pathfinding processes that lead to the formation of visual, olfactory, and somatosensory systems. A general scheme is emerging, in that sensory neurons form topographic maps in their projections to the brain, such that sensory information is transformed into distinct spatial activities for the brain to process. These maps are guided first roughly by molecular gradients, and then by refinement with neuronal activity-dependent axon sorting. En route to their targets, neurons are guided to project through stereotyped pathways. These pathways are laid down by a combination of attractive and repulsive cues that usually result in a narrow channel for axons to navigate.

Axon Guidance: Guidance Cues and Guidepost Cells

Guidepost cells, also called landmark cells, were originally used to refer to specific cells in the developing insect limb that help peripheral nerve cells find their central targets. As vividly depicted by their name, these cells provide local cues to guide pioneer neurons to navigate through an unfamiliar territory in embryonic tissues. In combination with other cellular mechanisms, such as selective adhesion, they ensure the proper development of stereotypic neural connections that underlie complex behavior.

Although they have been historically studied in insects, guidepost cells have been demonstrated in many organisms as well as in both peripheral and central nerve systems. In fact, they now take a broader meaning and more appropriately refer to the intermediate targets in the course of neural development. In addition to guiding axons, they provide local guidance cues to control many other processes during nerve development. This article reviews the historical studies in insect cells, their role in midline crossing, and their emerging function in synapse formation.

Historical Studies of Guidepost Cells in Grasshoppers

The concept of 'guidepost cells' was first suggested by Australian biologist Michael Bate in his seminal study of peripheral pioneer neurons in grasshopper *Locusta migratoria*. In insects, peripheral sensory neurons are produced by a small number of epidermal cells at the body surface. Most of these cells invade their central targets by hopping along the preexisting nerve fibers that are established by pioneer neurons early in development. So how do pioneer neurons connect to the central nervous system (CNS) in the first place? To understand this, Bate followed them in the developing antenna and limbs by both light and electron microscopy. He discovered that these neurons, also with cell bodies born at the edge of each appendage, have to extend their axons through the entire length of the antenna or the limb to reach the CNS. Interestingly, through the course of their journey, not all axons follow a linear path, the shortest route. Instead, some of them, especially those in the limb, take an indirect route and change growth directions several times before reaching the central target. Based on this observation, Bate concluded that the connection path is determined by the interaction of the pioneer axons and the extrinsic cues in the limb. He suggested that these cues are provided by a group of cells, 'the signpost,' that "occur consistently at intervals along the developing appendage and seem to provide a series of stepping stones between the tip of the limb and its base."

The use of 'guidepost cells' or 'landmark cells' was adopted in subsequent studies of peripheral pioneer neurons in grasshopper limb buds, in which the simple nerve connection and the easy access for experimental manipulation provided an attractive system to further test this idea. Using newly developed staining techniques, many more cells have been found that can potentially serve as guidepost functions in the insect limb. They have some characteristic features, which were later used as major criteria to define guidepost cells in other systems: (1) they are located along the route of pioneer axonal path; (2) they are contacted by the growth cone of pioneer axons; (3) they are separated from each other but within reach of growth cone filopodia; (4) they are distinct from neighboring cells because they can be labeled by specific antisera on the surface, and they do not line up to form a continuous path for pioneer growth cones to follow; and (5) they form a special connection with axons because dye can pass from pioneer neurons to these cells. These physical and morphological attributes lead to a 'guidepost hypothesis,' which suggests that the placement of a series of distinctive cells is used to guide pioneer neurons along their trajectory from a distance.

The hypothesis was later tested in a cell ablation experiment, in which the putative guidepost cells that can be recognized immunologically were selectively killed with high-intensity light. The removal of guidepost cells in the developing grasshopper limb buds caused the pioneer neurons to wander away from their normal axonal pathway, and often resulted in the formation of multiple branches. Therefore, cells in the embryonic tissues are present to guide pioneer neurons during early development.

Guidepost Cells and Guidance Cues in Axon Guidance

Following the initial studies in the grasshopper, guidepost cells have also been described in several other invertebrates, including leech, moth, and fruit fly. Although the use of the term has been limited to these simple systems, the cellular studies of axonal pathfinding in grasshoppers have provided two important concepts that have simplified our understanding of

how complex neural pathways are connected. First, they have revealed that the long and sometimes irregular axonal trajectories can be broken down into short segments, and at each segment axonal growth is regulated by local cues at choice points. These choice points contain a cluster of individual cells as the guidepost cells in insects or often a group of functionally specialized cells, which are referred to as intermediate targets in vertebrates. Second, they have shown that complex neural networks are established in two phases, by pioneer neurons that enter the axon-free environment in early development and by later born neurons that face a more complex environment filled with intertwined nerve fibers from early projecting neurons. Whereas the pioneer neurons are guided by local guidance cues, those later developing axons can follow preexisting nerve fibers by selective fasciculation, a cellular mechanism that has also been well studied in grasshoppers.

How do guidepost cells regulate the growth of axons? What are the guidance cues they provide to change the growth direction of developing axons? Ramon y Cajal proposed a century ago that diffusible chemicals in the embryonic environment could guide axonal growth over a long range, just like the chemotaxis of single motile cells. They do so by attracting growth cones, the motile sensors at the leading edge of a neuron that have exquisite sensitivity to detect chemical cues in the embryonic tissues. *In vitro* studies of cultured neurons initially demonstrated the existence of factors secreted by intermediate targets of axons. In the past 15 years, many molecules have been identified by genetic screening and biochemical purification to serve as guidance cues. They include several families of highly conserved extracellular molecules – Netrins, Semaphorins, Slits, and Ephrins – as well as classic neurotrophins and morphogens.

The biochemical and biophysical properties of guidance cues separate them into two classes, diffusible and contact mediated, although their distinction has become less clear in recent studies. Diffusible cues are secreted by cells from a long distance and can either attract axons toward the target or repel axons away from it. Contact-mediated cues are often associated with extracellular matrix or cell surface and regulate the adhesiveness of the growth environment, so they either provide a permissive surface on which axons grow or create an unfavorable region that axons tend to avoid. As shown by embryological, tissue culture, and genetic studies, these molecules are present in developing nervous system and work together to control the growth and guidance of axons during their long journey to their eventual synaptic partners. The following sections review recent studies of midline guidance in both invertebrates and vertebrates and use it as an example to demonstrate now a simple change in axon growth direction is regulated by guidance cues at a specific choice point.

Guidepost Cells at the Midline

The midline in the animal CNS is important for establishing neural pathways used for bilateral communication. In the insect nerve cord or the vertebrate spinal cord, a group of neurons called commissures extend their axons across the midline. Once crossed, the axons turn rostrally, join the longitudinal nerve tracks, and eventually synapse on the contralateral side of the brain.

Cells in the ventral midline have been found to serve as intermediate targets to guide the commissural axons to cross the midline. In flies, there are several midline glial cells that are important for controlling the cross because mutations affecting their formation greatly reduce the fidelity of the growth of commissures crossing the midline. In the vertebrate spinal cord, the main action occurs at the floor plate, a region that contains several layers of neuroepithelial cells with distinct morphological and immunological features at the ventral midline. They are derived from the initial neural fold, but their properties are induced by a molecule, Sonic hedgehog, secreted from the notochord that lies ventrally below them. In mouse mutants of Danforth's short tail or Gli2 (a zinc-finger transcription factor) in which the floor plate is missing, commissural axons grow abnormally when they reach the ventral midline. The same has been documented in zebra fish, in which mutations affecting floor plates also result in the misguidance of spinal commissural axons. Therefore, the ventral midline cells provide a unique system for understanding axon guidance at a choice point.

Attracting to the Midline

The initial characterization in grasshoppers demonstrated that a single filopodium of the sensory growth cone makes a direct contact with guidepost cells and leads the axon in the correct direction. The distance between each pair of guidepost stops is less than 100 μm, which might be sufficient for filopodia to search in space and find the guidepost cells by differential adhesion. However, for commissural neurons, especially those from vertebrates, their targets are hundreds of micrometers away. How do they know where to find the intermediate target?

The ventral midline cells appear to secrete diffusible molecules that attract commissural growth cones

to cross midline. The presence of diffusible factors was first demonstrated in the study of vertebrate commissural neurons in culture. When the floor plate from chick or rodent embryos was cultured adjacent to the dorsal spinal cord explant in three-dimensional collagen gels, commissural axons in the explant grew out toward the floor plate. Subsequent biochemical purification identified a family of secreted protein Netrins that can stimulate commissural axon outgrowth and attract them toward COS cell aggregates that produce the protein. Netrins are secreted by the floor plate cells and bind DCC, a cell surface receptor that is exclusively expressed on commissural neuron axons. Genetic analyses in mice, fruit flies, as well as *Caenorhabditis elegans* have established that this ligand and receptor pair is required for midline attraction because mutations in these two genes lead to the failure of commissural axons growing toward the midline. However, interestingly, in the mouse netrin-1 mutant spinal cord, some axons still reach the floor plate. This is due to the presence of another molecule, Sonic hedgehog, also secreted from the floor plate.

How do soluble factors attract axons over a long distance? Target-derived factors have been thought to form a diffusible gradient that guides the growth cone, a theory proposed by Ramon y Cajal after the discovery of growth cones. Recent studies of netrin expression in chicks demonstrated that proteins secreted in the spinal cord do form a dorsal–ventral gradient, with the highest amount concentrated at the floor plate. In addition, growth cones in culture can respond to netrin gradients and turn toward the source that provides the protein. Therefore, chemoattraction provides a simple mechanism to explain the guidance of embryonic axons toward their targets.

Repelling Away from the Midline

After commissural axons are attracted to the midline, most of them do not stay there but instead leave the midline and project to the contralateral side of the spinal cord. A remarkably conservative and reproducible feature is that they cross the midline only once. How is this achieved?

The guidepost cells that provide attraction at the ventral midline also secrete another family of extracellular molecule, Slits. These molecules bind and activate cell surface receptor Robos on the commissural axons and repel them away from the midline after crossing. This was first demonstrated in a genetic screen in flies, in which a mutation in Slit caused all the commissural neurons to collapse at the midline. Interestingly however, the initial study of the Robo receptor revealed a very different phenotype. With only Robo eliminated, commissural axons freely cross and recross the midline and wrap around it to give the roundabout phenotype that is very different from Slit. This is because there are multiple Robo isoforms in flies. When another receptor Robo2 is also deleted in flies, the same Slit phenotype is observed, suggesting that both Robo1 and Robo2 can signal commissural axons to leave the midline, whereas only Robo1 is needed to prevent recrossing. Therefore, slits provide a negative guidance cue to commissural axons and directly activate Robo receptors to drive them away from the midline, thus preventing axon from recrossing. The same molecular mechanism is also used in vertebrates. When all three Slit genes are deleted from the mouse spinal cord, a considerable amount of commissurals are stalled near the floor plate.

In addition to preventing commissural axons from recrossing, the Slit proteins secreted by the midline cells serve as a guide to determine how far each interneuron axon should extend and which fascicle to join. Three Robo 1 homologs are differentially expressed on axonal fascicles, with Robo only on the medial fascicle, Robo and Robo3 on the intermediate ones, and all three (Robo, Robo2, and Robo3) on the most lateral one. The amount of Robo expressed on their surface provides a combinatorial code to determine the position of longitudinal fascicles. When the receptor level is perturbed by overexpression or knockdown, the fascicle positions along the lateral axis either shift away or move closer to the midline accordingly.

Slits are expressed in the midline at the same time as the attractive factor netrins. How do the commissural axons avoid being repelled from the midline before crossing? In flies, this is accomplished by an intracellular protein Comm, which appears to interact with Robo receptors and keeps them away from the growth cone membrane before crossing. In post-crossing axons, Comm expression is downregulated and thereby surface Robos are increased to respond to the repulsive signal from slits. Interestingly, no Comm homolog has been found in vertebrates, but a third Robo-like receptor, Robo3/Rig1, which is expressed also only on the precrossing axons, appears to serve the same function. In the Robo3/Rig1 mouse mutant, commissural neurons reach the ventral side of the spinal cord but stay away from the floor plate, mimicking the defect initially found for the Comm mutation in flies.

Adhesion at the Midline

The initial study of pioneer neuron guidance in grasshoppers suggests that cell adhesion may play an important role in controlling growth direction by

guidepost cells. Studies in the past 20 years have identified many cell adhesion molecules that form homophilic or heterophilic dimers on the cell surface. In the vertebrate floor plate, several immunoglobulin superfamily cell adhesion molecules – axonin-I, NrCAM, and NgCAM – have been shown to be involved in proper control of the behavior of commissural axons at the floor plate. If their functions are perturbed by antibodies in chick embryos, the axons reach the floor plate but fail to cross the midline and turn to the ipsilateral side of the spinal cord.

Another cell surface molecule, Fasciclin II (FasII), provides a permissive substrate for the later born neurons to join the fascicle and extend along the longitudinal axis after crossing. In fly FasII mutants, these bundles do not form tightly, even though they can turn and move away from the midline, as repelled by slits.

Guidepost Function in Synapse Formation

The concept of guidepost cells has also been used in a different developmental context. During the development of neural circuits, axons are guided to different regions of the nervous system, where they contact their synaptic partners. Synaptic target selection and synapse formation are also critical steps to achieve the precise assembly of neuronal circuits. Several studies have shown that distinct populations of guidepost cells are important at the level of synaptogenesis. The following sections summarize the discoveries of these studies.

Caja-Retzius Cells and Certain GABAergic Interneurons as Guidepost in Hippocampus

In hippocampus, the cell bodies of pyramidal neurons are located in the basal region and send out dendrites toward the pial surface. Distinct subcellular domains of pyramidal dendrites are innervated by two populations of afferents. Distal portions of pyramidal dendrites receive input from the ipsilateral entorhinal afferents, whereas the proximal dendrites form synapses with the commissural fibers. This layer structure is established during development with the help of two populations of guidepost cells. Caja-Retzius cells and a set of GABAergic interneurons are early developing neurons found in the two afferent layers. They synapse with the entorhinal afferents and the commissural axons, respectively. These synapses are transient in nature since some of the Caja-Retzius cells and GABAergic interneurons die later. The disappearance of transient synapses is accompanied by synaptogenesis of afferents with the pyramidal dendrites as the synapses are transferred from the guidepost cells to mature synaptic targets.

The significance of the guidepost cells in the development of hippocampal circuit was demonstrated by cell lesion experiments. When the Caja-Retzius cells are ablated, the laminar innervation of the entorhinal axons is impaired. It is interesting to note that the ingrowth of entorhinal axons into the hippocampus precedes the extension of pyramidal dendrites. It is conceivable that the early existence of the Caja-Retzius cells is important to hold the presynaptic terminal in place before the true postsynaptic target arrives. Since in the absence of the Caja-Retzius cells laminar projection of the entorhinal axons is impaired, this suggests that early synaptogenesis might be important for the stabilization of axon arbors. Indeed, several *in vivo* time-lapse studies have shown that synapse formation in the CNS is very dynamic, with constant synapse formation and disassembly, and branch addition and retraction. The presence of synapses on axon branches increases the stability of the branches. Therefore, the laminar distribution of the guidepost cells provides a scaffold for the presynaptic terminals on the afferent fibers, which consequently stabilizes the axonal arborization and achieves laminar innervation.

Subplate Neurons as Guidepost in the Maturation of Visual Cortical Circuit

In the mature visual system of vertebrate animals, thalamic inputs directly innervate primary visual cortex layer 4 neurons. Functional organization of the visual cortex, such as ocular dominance columns and orientation columns, emerges through specific synaptic circuit formation. Interestingly, thalamic inputs first form synapses with another population of neurons, the subplate neurons, before connecting to the layer 4 neurons. At this early time, subplate axons innervate the layer 4 neurons and relay the information from thalamus to the cortex. Later, during the critical period of cortical activity-dependent plasticity, the subplate neurons gradually die through programmed cell death. In the meantime, adult circuit forms in which thalamic inputs directly synapse onto layer 4 neurons.

Ablation of subplate neurons results in the failure of segregation of the thalamic inputs into ocular dominance columns and the formation of orientation columns. This strongly suggests that subplate neurons are essential for synaptic remodeling and maturation of neural circuit. In support of this notion, one study showed that subplate ablation prevents the upregulation of $GABA_A$ receptor expression and perturb the maturation of inhibitory circuits in the layer 4 neurons. Collectively, subplate neurons act as a relay station at early stages of cortical development and are indispensable for patterning mature synaptic circuits.

Vulval Epithelial Cells as Guidepost in the Development of the Egg-Laying Synaptic Circuit

In *C. elegans*, egg-laying behavior is controlled by a pair of motor neuron HSNs. The cell bodies of HSNs are situated just posterior to the vulva, with its axon guided ventrally and then anteriorly. The HSN axons defasciculate dorsally from the ventral nerve cords near the vulval opening and innervate the vulval muscles by forming a cluster of neuromuscular junctions onto the muscle arms. The HSN axons also form synapses onto the VC motor neurons in this region, which in turn innervate muscles. Genetic and developmental analysis revealed that the surrounding vulval epithelial cells play an important guidepost role in the formation of this egg-laying neural circuit. In the absence of these epithelial cells, HSNs form ectopic synapses, which are located more anteriorly than normal. Molecularly, an immunoglobulin superfamily protein, SYG-2, was found to perform the guidepost function. SYG-2 is expressed transiently by the guidepost epithelial cells at early stages of HSN synapse formation. SYG-2 directly binds its receptor on HSN, another immunoglobulin superfamily protein, SYG-1, and clusters SYG-1 at the segment of HSN axon near the vulva. SYG-1 induces accumulation of synaptic vesicles/presynaptic active zone components and directs the location and target selection of HSN presynaptic specialization. In the absence of functional SYG-1 or SYG-2, HSN has a reduced number of synapses formed at its normal location. Instead, the majority of synapses are formed onto adjacent body wall muscles, inappropriate synaptic targets, at anterior ectopic locations. Developmentally, the axons of HSN reach the synaptic region prior to the outgrowth of the postsynaptic VC dendrites. Presynaptic terminals can be observed in this segment of the HSN axons before the VC dendrites reach the same region. The transient synapses of HSN are likely to form directly onto the guidepost cells before being 'handed over' to the late maturing postsynaptic targets. The guidepost vulval epithelial cells have several important functions in the development of the egg-laying organ. These cells attract the migrating sex myoblast, which gives rise to the vulval muscles. They also stimulate the branching of the VC motor neurons. Therefore, guidepost cells not only spatially and temporally control the maturation of the egg-laying neurons and muscles but also regulate the assembly of the neural circuits at the synapse formation level.

The three types of synaptic guidepost cells mentioned previously are probably examples of similar cell types that have not been discovered. Guidepost cells seem to be particularly important in synapse formation where there is temporal discrepancy between axonal and dendritic development. It is conceivable that guidepost cells stabilize axons by forming transient synapses, which disappear upon the arrival of true postsynaptic dendrites.

Conclusion

The function of guidepost cells in axon guidance is well established. They are frequently the sources of axon guidance molecules that attract or repel axon growth cones. The emerging roles of guidepost cells in synapse formation and neural circuit maturation reveal previously unknown complexity during synaptic circuit assembly.

Axon Guidance: Morphogens as Chemoattractants and Chemorepellants

Introduction

The growth cones of developing neurons are guided to their targets by attractive and repulsive cues in the extracellular environment. Receptors on the growth cones recognize these cues and transduce signals that ultimately lead to changes in the direction of growth. Several families of molecules acting as guidance cues have been identified, including Netrins, Slits, Ephrins, and Semaphorins. In addition to these families, secreted signaling molecules from families of classical morphogens, known for their roles in controlling cell fates in a concentration-dependent manner, can act as axon guidance molecules. Sonic hedgehog (Shh) of the hedgehog family, bone morphogenetic protein 7 (BMP7) of the transforming growth factor-beta (TGF-β) family, and members of the Wnt family have all been found to function in the guidance of specific classes of neurons.

For each of the three morphogen families, the receptors and canonical signaling pathways through which they control cell fate are well studied and involve transcriptional regulation as their output. However, some members of these families can also signal through noncanonical pathways and control processes such as cell movements and cell polarity. The roles of these families in axon guidance, plus the finding that they likely act directly on the growth cone, argue for the activation of noncanonical signaling pathways that lead to cytoskeletal rearrangement.

Shh as a Chemoattractant for Commissural Neurons

Commissural neurons residing in the dorsal region of the spinal cord adjacent to the roof plate project axons through the floor plate at the ventral midline (Figure 1(a)). These commissural axons initially extend away from the roof plate and take a ventral and circumferential pathway through the dorsal spinal cord. Midway to the ventral midline, the axons change course and project ventrally and medially to the floor plate. After crossing the floor plate, they then make an abrupt turn and project anteriorly on the contralateral side of the spinal cord.

Commissural axons are guided to the ventral midline by Netrin-1, a chemoattractant secreted by cells of the floor plate and the adjacent periventricular zone. In *Netrin-1*$^{-/-}$ mutant mice, as well as in mice mutant for the Netrin receptor deleted in colorectal cancer (DCC), many commissural axons project abnormally, often failing to enter the ventral region of the spinal cord. However, some commissural axons in these mutants do manage to reach the floor plate, suggesting the existence of one or more additional factors in the floor plate. Indeed, the floor plate of *Netrin-1*$^{-/-}$ mice is still effective in reorienting commissural axons when juxtaposed to spinal cord explants, indicating the presence of another chemoattractant.

Shh was implicated as the additional factor since it is secreted by the floor plate and is known to have long-range effects within the spinal cord. In addition, Shh can cause rapid changes in the growth cone behavior of cultured retinal ganglion cells. An initial indication that Shh might be the missing floor plate factor was garnered by demonstrating the ability of Shh-expressing COS cells to reorient commissural axons in spinal cord explants. This reorienting effect of Shh is mediated through the Shh signaling component Smoothened (Smo), since the Smo inhibitor cyclopamine abolishes the effect.

Assessing the axon guidance role of Shh *in vivo* is more challenging because of its role in early patterning of the spinal cord. Shh acts as a morphogen to generate distinct neuronal cell types within the ventral spinal cord in a concentration-dependent manner. Although Shh is not directly required for generation of the dorsally located commissural neurons, these neurons do project their axons ventrally through regions that are patterned by Shh. This rules out the analysis of mice mutant for Shh, Smo, or the Shh receptor patched (Ptc) since other guidance cues in the ventral spinal cord of these mutants might be altered. However, using the Cre/loxP recombinase system and the *Wnt-1* promoter to drive expression of Cre recombinase, Smo can be selectively removed in commissural neurons developing within an otherwise normally patterned spinal cord. In these conditionally mutant mice, commissural axons project abnormally into the ventral spinal cord, sometimes failing to make the medioventral turn toward the floor plate and instead projecting along the edge of the spinal cord. Thus, Shh appears to be acting as a chemoattractant for commissural neurons. Ultimately, the commissural axons in these conditional Smo mutants do reach the ventral midline and form

Figure 1 Morphogens as axon guidance molecules. Schematic of the axon projections of neurons in the developing mammalian spinal cord (a) and the ventral nerve cords (VNC) of *Drosophila* (b) and nematode (c). The floor plate (green) secretes Netrin-1 (+), which acts as a chemoattractant for commissural axons expressing the Netrin receptor DCC. The floor plate also secretes Shh, which functions in concert with Netrin-1 to attract commissural axons expressing the Shh signaling component Smo. The roof plate (orange) secretes BMP7 (−), which repels the initial growth cones of commissural neurons away from the dorsal midline, probably as a heterodimer with GDF7. The specific BMP receptors in commissural neurons mediating the repulsive response are not known. After crossing the floor plate, growth cones of commissural neurons turn anteriorly in response to an increasing posterior-to-anterior (P-to-A) gradient of Wnt4, plus a decreasing gradient of Shh, secreted by floor plate cells. Fz3 and HIP are thought to mediate the responses to Wnt4 and Shh, respectively. In *Drosophila*, the major axon tracts (gray) consist of the bilaterally symmetric longitudinal connectives running in the anterior/posterior axis and, connecting the two sides in each segment, an anterior and posterior commissure. Like the vertebrate floor plate, the midline glia (green) secrete Netrins (+) which attract commissural axons expressing the DCC homolog Fra. Commissural axons that project through the anterior commissure, all of which express the Drl receptor, are repelled from the posterior commissures of their segment of origin and the adjacent anterior segment by Wnt5 (−). In the nematode, migrating cells that end up at the ventral midline (green) secrete the Netrin homolog UNC-6 (+), as does the VNC (gray). Axons expressing UNC-40, the nematode DCC homolog, are attracted to the VNC. Wnt proteins CWN-1 and EGL-20 (−) are expressed by cells in the tail and act to repel PVM and other anteriorly projecting neurons expressing the Fz receptors MIG-1 and MOM-5. The Drl/Ryk homolog, LIN-18, acts redundantly in Wnt-mediated repulsion.

a normal-looking commissure, arguing that Netrin-1, in the absence of Shh, is sufficient to attract commissural axons to the floor plate. If Shh is the only additional guidance factor secreted by the floor plate, the expectation is that *Smo* mutant commissural neurons should not be able to reach the floor plate in a *Netrin-1*$^{-/-}$ mutant background.

Although a loss-of-function phenotype is the gold standard for demonstrating that a gene is required for a particular process, a phenotype does not necessarily reveal the underlying mechanism. For example, rather than acting directly on the growth cones of commissural neurons, Shh could be activating a retrograde signal within the neurons that regulates the expression of genes encoding other guidance receptors. The definitive test for a guidance molecule's direct action on growth cones is the *in vitro* growth cone turning assay. Here, the spatial and temporal application of a factor can be precisely controlled by pulsing it through a pipette, creating a gradient of purified protein to which isolated cultured neurons can respond. Importantly, in this context Shh has the ability to rapidly attract growth cones and this attraction is abolished by cyclopamine. Thus, Shh, signaling through Smo, can indeed act as a chemoattractant.

Shh as a Chemorepellant for Postcrossing Commissural Neurons

After crossing the midline, commissural axons turn anteriorly along the contralateral side of the floor plate. RNA interference (RNAi) experiments in chick embryos have implicated Shh in this guidance event. When Shh levels are reduced by injection of Shh dsRNA, commissural axons tend to either stall at the floor plate exit point or project posteriorly. A decreasing posterior-to-anterior gradient of Shh suggests that in this case Shh is acting as a chemorepellant, a notion supported by its ability to repel postcrossing commissural axons in spinal cord explants. Importantly, this repulsion is not mediated by Smo and Ptc, since neither is expressed by commissural neurons by the time they have crossed the midline. Furthermore, cyclopamine has no effect on turning behavior. Instead of Ptc, another Shh receptor, hedgehog interacting protein (HIP), has been implicated. Lowering HIP function by RNAi knockdown results in the same turning defects observed when Shh is downregulated.

A model has thus emerged that depending on the receptor employed, Shh can act as either a chemoattractant or a chemorepellant. However, in contrast

to Shh chemoattraction, it is not known whether HIP-mediated repulsion by Shh is a result of direct action on the growth cone rather than the transcriptional control of other guidance receptors, such as those involved in Wnt-mediated attraction of post-crossing commissural axons.

BMP7 as a Chemorepellant for Commissural Neurons

The early phase of commissural axon growth within the dorsal spinal cord is unaltered in either *Netrin-1*$^{-/-}$ mutants or mice lacking a floor plate, suggesting the existence of additional non-floor plate-derived factors in their guidance. The proximity of commissural neurons to the roof plate and the stereotyped projections of their axons away from the dorsal midline suggests a role of the roof plate in repulsion (Figure 1(a)). This idea is supported by experiments showing that when juxtaposed to a spinal cord explant, the roof plate can reorient commissural axons away from the side facing the roof plate. Furthermore, the reorienting activity can be mimicked by COS cells expressing BMP7, one of the BMPs secreted by the roof plate.

BMP7 functions most efficiently in the axon reorienting assay by forming heterodimers with GDF7, another BMP family member expressed by roof plate cells but which on its own has no axon reorienting activity. In *BMP7*$^{-/-}$ mutant mice, there is a significant increase over wild type in the number of commissural axons that initially project medially and dorsally instead of laterally and ventrally. Similar numbers are seen in *GDF7*$^{-/-}$ mutants. However, in each case, these defects are corrected such that later in development the projection pattern of commissural neurons resembles that of wild type. Thus, in addition to BMP7 and GDF7, other cues must be operating–repulsive ones from the roof plate and/or attractive ones from more lateral positions in the dorsal spinal cord. The former possibility is bolstered by the finding that roof plates from *BMP7*$^{-/-}$ *GDF7*$^{-/-}$ double mutants, although compromised in their ability to redirect commissural axons within spinal cord explants, still retain some residual axon-reorienting activity.

Similar to the patterning role of Shh in the ventral spinal cord, BMP family members function early in development to generate specific dorsal cell types. In fact, GDF7 is required to generate a specific subclass of commissural neurons, raising the question of whether the observed guidance effects of BMP7 are direct or indirect. Although the guidance role of BMP7 has not been cleanly separated from its inductive role, as was done for Shh using the conditional *Smo* mutation, several lines of evidence argue against an indirect mechanism involving changes in cell fate. First, *BMP7*$^{-/-}$ mutants show no obvious defects in dorsal spinal cord patterning, presumably due to redundancy with one or more of the other roof plate BMPs. Second, commissural neurons in spinal cord explants from *BMP7*$^{-/-}$ mutants are able to reorient to the same extent as those from wild type in response to a wild-type roof plate, suggesting that these neurons retain at least some of their wild-type properties, including the expression of an appropriate BMP receptor complex capable of transducing the BMP7 signal. Finally, although *in vitro* growth cone turning assays to test for repulsion have not been carried out, BMP7 alone, as well as BMP7:GDF7 heterodimers, is capable of causing rapid growth cone collapse of commissural neurons *in vitro*. Collectively, these studies advance the case for a direct role on the growth cone in axon guidance.

Wnt Proteins as Chemorepellants

Wnt5 in *Drosophila*

In addition to specifying cell fates, Wnt proteins play diverse signaling roles in the developing nervous system. These include presynaptic axon remodeling during vertebrate synaptogenesis, the maturation of the *Drosophila* neuromuscular junction, and the polarity of neurons along the anterior–posterior axis in the nematode *Caenorhabditis elegans*. As first shown in *Drosophila*, Wnt family members have also turned out to function as axon guidance molecules.

As in vertebrates, the large number of commissural neurons in the *Drosophila* embryonic ventral nerve cord (the fly counterpart to the spinal cord) project their axons across the midline to the contralateral side (Figure 1(b)). Analogous to the vertebrate floor plate, specialized cells at the midline, the midline glia, divide the two halves of the ventral nerve cord and play a critical role in axon guidance. Like the floor plate, midline glia secrete Netrins that act as chemoattractants for commissural axons expressing Frazzled (Fra), the fly homolog of the Netrin receptor DCC.

Once attracted to the midline, commissural axons do not cross randomly. Instead, in each segment they reproducibly choose one of two distinct tracts that connect the two sides, either the anterior or the posterior commissure. This choice of whether to project anteriorly or posteriorly into the appropriate commissure is controlled by one of the seven fly members of the Wnt family, Wnt5, and a receptor to which it binds, derailed (Drl). The Drl receptor is expressed on the growth cones and axons of all neurons that

project through the anterior commissure. In *drl* mutants, many of the anterior commissure axons abnormally project through the posterior commissure; conversely, when misexpressed by posterior commissure neurons, Drl switches their axonal projections to the anterior commissure. Drl is therefore not only required by anterior commissure neurons for their guidance but also sufficient to dictate the choice of the anterior commissure for crossing axons.

In *wnt5* mutants, as in *drl* mutants, anterior commissure axons project abnormally through the posterior commissure. Since Wnt5 is expressed by cells associated with the posterior commissure (and the Drl receptor by anterior commissure neurons), it is functioning as a chemorepellant to keep Drl-expressing axons from entering the posterior commissure. Such a repulsive activity was illustrated *in vivo* by misexpressing Wnt5 in the midline glia. In these embryos, anterior commissure axons are prevented from crossing the midline in a Drl-dependent manner, overriding Netrin-mediated attraction.

Although Drl binds Wnt5 and is required for Wnt5 function in guidance, it is not yet clear whether Drl transduces the Wnt5 signal within growth cones or whether it acts as a coreceptor with a member of the other family of Wnt receptors, the Frizzled (Fz) proteins. Fz receptors are good candidates for transducing such a signal since they have been shown not only to mediate canonical Wnt signaling resulting in transcriptional regulation but also to mediate noncanonical signaling involved in controlling cell movements. In support of the coreceptor hypothesis, the mammalian homolog of Drl, Ryk, can bind to the cysteine-rich domain of Fz proteins when the two are co-expressed in tissue culture cells, suggesting the ability of Fz and Ryk to form a complex. Regardless of which receptor(s) transduces the signal, it is clear that Wnt5 controls the guidance of anterior commissure axons and that the Drl receptor is essential for Wnt5 signaling.

However, does Wnt5 act directly or indirectly in these guidance events? The difficulty in purifying active Wnt proteins has hindered efforts to test Wnt5 for repellant activity in an *in vitro* growth cone turning assay. However, a key observation *in vivo* does suggest a direct role in guidance: Drl can dictate commissure choice in a Wnt5-dependent manner when misexpressed on growth cones shortly before they make the choice. This makes it less likely that a retrograde signal, followed by a round of transcription and translation, is required.

Mammalian Wnts

Wnt proteins, acting through the Ryk receptor, also control axon guidance events in the developing mammalian nervous system. Similar to Drl expression on anterior commissure axons in *Drosophila*, Ryk is expressed on axons that project across the midline within the corpus callosum. In $Ryk^{-/-}$ mutant mice, callosal axons reach and cross the midline but often fail to project away from it on the contralateral side. The Wnt ligand in this case appears to be Wnt5a, which together with Wnt5b is most closely related to *Drosophila* Wnt5. Wnt5a binds to Ryk and is expressed by midline glia known to be required for proper guidance of the callosal axons. The spatial and temporal expression pattern of Wnt5a suggests that it is acting as a chemorepellant to guide Ryk-expressing axons away from the midline, a notion supported by the finding that Wnt5a can repel cortical axons in explants from wild-type, but not $Ryk^{-/-}$, brains.

Like callosal axons, axons of corticospinal neurons also express Ryk. These axons project posteriorly from the brain through a dorsal region of the spinal cord that exhibits an increasing posterior-to-anterior gradient of a number of Wnts, including Wnt1 and Wnt5a. Anti-Ryk antibodies block both the posterior growth of corticospinal axons *in vivo* and the repellant activity of Wnts on cortical axons in cultured explants, providing good evidence that Ryk is required for posterior guidance by interpreting the Wnt gradient as a chemorepellant one. The striking similarities between mammalian Wnt-mediated corticospinal axon guidance and *Drosophila* Wnt5-mediated commissure choice argue for a deep-rooted conservation of function: both fly Wnt5 and mammalian Wnts are acting as chemorepellants that signal via the Drl/Ryk receptor to control guidance in the anterior–posterior axis.

Wnts in the Nematode

In the nematode *C. elegans*, the conserved cue Netrin (UNC-6 in nematode) guides axons to the ventral nerve cord at the midline (**Figure 1(c)**). Once they enter the ventral nerve cord, growth cones choose to project either anteriorly or posteriorly. For example, the axon of the posterior ventral microtubule cell (PVM) enters the nerve cord and projects anteriorly toward the head. Two Wnts, CWN-1 and EGL-20, are expressed in the posterior end of the embryo and act redundantly as chemorepellants to guide the PVM axon, as well as others, anteriorly. In *cwn-1:egl-20* double mutants, the PVM axon often projects posteriorly and this guidance defect is enhanced by misexpression of EGL-20 anteriorly. In contrast to *Drosophila* and mouse, Wnt repulsion of the PVM axon is mediated primarily through two Fz receptors, with LIN-18, the nematode homolog of Drl/Ryk, acting redundantly, presumably through a parallel pathway.

Wnt Proteins as Chemoattractants

After crossing the floor plate of the spinal cord, commissural axons turn anteriorly toward the brain (Figure 1a). Observations of cultured spinal cord explants provided the first indication that this guidance event might be controlled by a chemoattractant. Near the posterior cut end of spinal cord explants, commissural axons project anteriorly in a normal fashion, but near the anterior cut end, they either stall or project randomly along the anterior–posterior axis. This suggests that an increasing posterior-to-anterior gradient of a diffusible chemoattractant, which slowly escapes from the cut ends of explants, guides commissural axons anteriorly. A candidate molecule approach led to the Wnt family, particularly Wnt4, whose mRNA levels exhibit an increasing posterior-to-anterior gradient in the floor plate. Wnt4-expressing COS cells juxtaposed to the anterior cut end of explants can redirect postcrossing axons anteriorly, in effect rescuing the projection defects near the cut end. Further support for this guidance event being mediated by a Wnt protein comes from the analysis of mice deficient for Fz3, one of the Wnt receptors expressed by commissural neurons. In these mice, commissural growth cones emerge from the floor plate and tend to project randomly along the anterior–posterior axis of the spinal cord.

Similar to Wnt function in *Drosophila* and nematode, Wnt4 appears to control anterior–posterior guidance. However, in contrast to the repellant activity of Wnts in the guidance of *Drosophila* commissural axons, the nematode PVM axon, and of mammalian callosal and corticospinal axons, Wnt4 is acting as a chemoattractant in the guidance of postcrossing commissural axons. Notably, this guidance event does not involve Ryk since commissural neurons do not express the receptor. Instead, it seems that a member of the Fz family of Wnt receptors, acting in the absence of Ryk, mediates the guidance. A model similar to that for Shh has been proposed in which Wnts can act as either chemoattractants or chemorepellants depending on whether a Fz or Ryk receptor is involved. However, the relative roles of these receptors in Wnt-mediated guidance in nematode suggest that the situation may turn out to be more complicated.

Conclusion

Hedgehog, TGF-β, and Wnt family members not only have roles in cell fate specification and early embryonic patterning but also act as axon guidance molecules. For Shh and BMPs, morphogen gradients initially used to specify cell types in the spinal cord are reused later in development to attract or repel axons. There is evidence that Shh, BMP7, and Wnt proteins act directly on the growth cone rather than through canonical signaling pathways to the nucleus. The current challenge, and one which is faced generally in studies of guidance molecules, is to identify the signaling pathways engaged by the receptors and to understand how these signals are integrated within the growth cone to achieve changes in direction of growth.

Introduction

In its simplest biological application, the term polarity is used to describe the existence of an asymmetric process, whether this refers to the shape of an organism, an organ or a single cell; directed movement; the distribution of molecules and organelles; and intracellular vectorial flows, centrifugal and centripetal. The relevance of understanding the cellular and molecular basis of polarity lies in the fact that most basic biological functions are a consequence of asymmetry. For instance, during development, the formation of the main body axes, that is, rostral–caudal and ventral–dorsal, is the consequence of the establishment of polarized domains. Polarized activities also control the proper three-dimensional organization of organs and tissues and the coordinated orientation of cells in two dimensions in certain tissues, a process called planar polarity. At the single-cell level, to cite only a few examples, polarity is important for asymmetric cell division, which generates cellular diversity; for the migratory movement of cells in response to external stimuli; for the differential uptake and release of ligands; and for the reception and propagation of electrical signals through dendrites and axons in neurons.

A polarized neuron is characterized by a very particular molecular and supramolecular organization of axons and dendrites, that is, a differential distribution of both cytoplasmic and membrane components. Most simply seen, the capacity of axons to transmit signals over long distances is due to the segregation of voltage-gated sodium channels and synaptic vesicles to this domain. Dendrites, on the other hand, are capable of receiving incoming information owing to the presence of neurotransmitter receptors. At the cytoplasmic level, the microtubule binding protein MAP2 is specifically distributed in dendrites, and axons are enriched in tau. Moreover, microtubules in axons are always oriented with their plus end toward the periphery, whereas in dendrites they exhibit a mixed polarity. Neurons, however, establish a clearly polarized phenotype very early in development, before they have acquired the capacity to transmit and receive electrical signals.

Neuronal polarization becomes visible shortly after the last mitosis, through the sprouting of a number of extensions which, due to the lack of a clear axonal or dendritic identity, are called 'minor neurites.' In the typical case of neurons generated in the ventricular or subventricular zones, these initial extensions constitute the cell's migratory force for reaching its final position in the cortex. It is of great importance to understand how neurons establish their polarity. Defects in this early process will have severe consequences in the way the brain is organized into different layers, nuclei, and areas, leading to brain dysfunction. Moreover, failures in the definition of axons and dendrites at later stages will lead to defective wiring of the brain. This article describes the morphological events and mechanisms leading to the regulated generation of the primordial neurites and how they differentiate into precursors of functional axons and dendrites. The anatomical changes occurring during the development of polarity have been well described for a variety of neurons *in situ*. However, the molecular, biochemical, and cellular biological knowledge on how a neurite initially forms from the round cell body and how this neurite later acquires axonal or dendritic characteristics mainly relies on studies performed in hippocampal neurons taken from rat embryos, which spontaneously polarize under *in vitro* conditions. After a short description of the morphological phases of neuronal polarization *in situ*, this article describes how neuronal polarization is understood as a result of the large number of studies performed in hippocampal neurons in culture.

From Round to Polar: Morphological Steps

Developmental Stages *In Situ*

In situ, cortical pyramidal neurons are generated in the proliferative layer of the dorsal telencephalon and follow mainly a radial path toward the pial surface, where they occupy the most superficial layer of the developing cortical plate and populate the cortex in an inside first, outside last sequence, generating the six-layered cortex. In the mouse neocortex, neurogenesis is initiated at embryonic day (E) 10, peaks at E15, and finishes around birth. Initially, ventricular zone neuroepithelial cells give rise, through symmetric proliferative divisions, to neurons and radial glia cells (E10–E12). While the newly generated neurons begin to differentiate, radial glia cells continue to divide either symmetrically, into two neurons, or asymmetrically, into one neuron and one radial glia cell. In addition, new neurons arise from symmetric

neurogenic divisions of basal precursors in the subventricular zone. Irrespective of the place and mode by which they are generated, neurons start to migrate toward upper cortical layers through a four-phase process. In phase 1, ventricular zone-derived neurons acquire a bipolar morphology, with one neurite facing toward the ventricle and one neurite toward the opposite, pial surface and migrating to the subventricular zone. In phase 2, neurons pause for approximately 24 h, forming more neurites, making the cells appear multipolar. In phase 3, a subpopulation of neurons extend a process toward the ventricle. Finally, in phase 4, cells migrate, after again acquiring a bipolar shape with a pia-directed leading process, to their final destination, where neurons attain their final shape and polarity. Thus, neuronal polarization begins at the place where neurons are generated, through the sprouting of initial asymmetric neurites. In addition, *in vivo* morphological progression studies indicate that the first 'role' that polarization plays is to support neuronal migration – quite different from the electrical transmission role of polarity in the mature neuron.

Figure 1 Establishment of polarity in dissociated hippocampal neurons. (a) This model proposes that neuronal polarization starts at the stage 2–3 transition. Positive and negative feedback regulation leads to the disruption of stage-2 symmetry. Red circles with arrows represent molecular signaling cascades that form positive feedback loops in the growth cone and promote neurite extension. Blue arrows represent a negative signal that is generated at each growth cone, propagates throughout the cell, and modulates the positive feedback loops in other neurites. The growth cone with highest positive feedback (produced probably by the environment) generates a strong negative signal, precluding other neurites from growing; meanwhile the neurite with the highest positive feedback grows as an axon. (b) The second model proposes an intrinsic polarization that is established at the immediate postmitotic stage and maintained through differentiation. Modified from Dotti CG, Sullivan CA, and Banker GA (1988) The establishment of polarity by hippocampal neurons in culture. *Journal of Neuroscience* 8: 1454–1468. From De Anda FC, Pollarolo G, Da Silva JS, Camoletto PG, Feiguin F, and Dotti CG (2005) Centrosome localization determines neuronal polarity. *Nature* 436: 704–708.

Developmental Stages *In Vitro*

Although the initial development of neurons is described well *in situ* on a morphological basis, most data describing functional and molecular aspects underlying the establishment of polarity are derived from a more easily accessible *in vitro* model system, that is, isolated rat hippocampal neurons developing in low-density culture. An early study on the polarization of these neurons demonstrated that polarization occurs in a most stereotyped and reproducible manner: Shortly after dissociation from the brain, embryonic hippocampal neurons are round (named stage 1 of development). Within the next 24 h, the round cells sprout four to six morphologically and ultrastructurally identical neurites (called stage 2). Finally, one of these neurites elongates more rapidly than the others, becoming the cell's axon. This is, according to this study, the first stage of polarity and represents developmental stage 3. A most important implication of that model and subsequent work was that polarity is established at the transition between stages 2 and 3 (see Figure 1(a)). A different perspective has arisen from more recent work showing that the neurite that appears first from the cell body of the new neuron later becomes the axon. The data from this recent work are consistent with the view that the immediate postmitotic neuron corresponds to stage 0, which represents a round neuron with a polarized cytoplasm marking the site of axonal outgrowth. The stage after the neuron grows the first sprout from that site is named stage 1. Stage-2 and stage-3 neurons in the new model correspond to stages 2 and 3 in the earlier classification (Figures 1(a) and 1(b)). The data from the newer work suggest that the establishment of polarity occurs immediately after mitosis, at the transition between stage 0 and stage 1 (see Figure 1(b)). Figure 2(a) illustrates the progression of polarity in actual neurons. The important difference in these two concepts of when polarity is first established is that they imply different mechanistic principles. Thus, from the earlier model, the random choice of a neurite for an axonal destiny implies that polarized growth is a stochastic process, in which the cross-talk between one neurite and the

Figure 2 (a) Intracellular polarization through different stages of neuronal differentiation as proposed in the model in Figure1(b). Neurons were fixed after different times in culture and stained for tubulin (blue), F-actin (red), and endosomes (green). (b) A neuronal sprout containing unstable F-actin with microtubules entering the sprout. Left panel, actin (red), middle panel, tubulin (blue), and right panel, merging of tubulin (blue) and actin (red) signals.

most appropriate environmental cue decides final outcome (i.e., axonal outgrowth). On the contrary, the temporal hierarchy described by the second model, suggesting that the first neurite has greater likelihood of becoming an axon, does not permit environmental influence, implying that the neurite that later grows into an axon is intrinsically predisposed. As will be shown, a number of early and recent observations indicate that the models overlap and that the establishment of neuronal polarity is, in the end, the con sequence of an initial intrinsically mediated predisposition later confirmed through extrinsic signaling.

From Round to Polar: Creating a Positional 'Lead'

Irrespective of the primary cause determining which neurite later becomes axon, the fact is that before this occurs, neurites must form from the round cell body of an immediately postmitotic neuron. This we consider as a most critical stage of neuronal polarization as it is the precondition for the later development of neurites into either axons or dendrites.

The sphere is the most economical cell architecture. Thus, the occurrence of the earliest morphological change leading to the appearance of the first neurite sprout is necessarily the product of energy-consuming activities that, on the one hand, disrupt the natural sphere-sustaining activities and, on the other hand, activate expansive forces. The site where sphere-sustaining forces are disrupted and consequently where neurite-inducing forces act must be tightly oriented in space. As described in the *in situ* polarization process, the place where the first neurite emerges is a most critical event as it determines the fidelity of migration. Therefore, the following section describes the most conspicuous intracellular constituents behind the disruption of the postmitotic neuron sphere as well as those involved in generating the primordial neurite and the way in which these activities are restricted in space.

Disrupting the neuronal sphere will require, among many other activities, changes in the dynamics of microtubules and actin filaments. In the quiescent, nonmotile stage, actin filaments are organized in a tight meshwork that surrounds the entire cell, directly underneath the plasma membrane. The action of a spatially restricted signal, whether a centrifugal action from the inside of the cell (e.g., microtubules or transported membrane) or a centripetal force from an environmental signal acting on the plasma membrane, will affect the stability of the tight actin meshwork, producing a localized change in this structure. Commonly, this change is the destabilization of the tight actin structure, leading to the formation of an actin cortex 'pore' allowing for the penetration of microtubules and thus increasing their chances to directly contact the plasma membrane at a spatially restricted place (Figure 2(b)). In fact, when the tight actin cortical organization is broken, highly motile actin-containing structures appear on the surface of cells: filopodia and lamellipodia, rich in highly dynamic actin and microtubules. In a neuron these

structures precede the formation of a neurite. Neurites therefore arise as a consequence of the destabilization of the actin cortex, the polymerization and stabilization of microtubules, and the directed membrane delivery via these microtubule tracks from the center of the cell. Microtubule polymerization can work in addition as one of the centrifugal forces inducing a localized change in the cortical actin, to trigger the escape of microtubules to the periphery to make the neurite. Microtubules polymerize in a polarized fashion from the minus to the plus end. While the minus end is either embedded in the microtubule organizing center (MTOC) or protected by minus end-binding proteins, the plus end dynamically explores the cytoplasm, and its dynamics and localization (e.g., its connection with the cell cortex) are regulated by a number of plus end-binding proteins, such as cytoplasmic linker protein-170 (CLIP-170), CLIP-115, lissencephaly 1 (Lis1), and end-binding protein 1. These proteins, which collectively are called plus end tracking proteins, are key players during neuronal migration, and their dysfunction leads to migration defects and thus severe brain malformations. It is interesting that *Lis1* haploinsufficiency results in reduced filamentous actin at the leading edge of migrating neurons. To summarize, changes in the dynamics of the actin and microtubule skeleton are major events leading to the disruption of the sphere and in turn to neurite production. However, attention should be drawn to many other events, such as localized endocytosis, local translation of messenger RNAs, calcium release, and mitochondria trafficking, without which the microtubule–actin tandem would not be able to act as a mechanical force.

How does the neuron position the microtubule–actin sphere-breaking/neurite-generating activities so that a neurite is made at the right place? This is a most critical issue as *in situ* the primary neurites must arise from a precise pole in order to more efficiently interact with the cues required to guide the neuron's migration. The precise place where microtubule–actin-based activities occur can be theoretically determined by two mechanisms. The first most economically profits from the asymmetric organization of the cytoplasm of a recently generated neuron. In fact, one immediate consequence of cytokinesis is the occurrence of an asymmetrically positioned centrosome, the organelle from which microtubules are nucleated, in the daughter cells (**Figure 3(a)**). The asymmetric positioning of this organelle adds to the separation 'force,' which will result in stronger contact of microtubules with the nearby actin cortex and thus the plasma membrane (**Figure 3(b)**). Since an asymmetrically positioned centrosome is thought to play a role in other polar processes, such as the orientation of the migratory axis of motile cells, it can certainly be important in controlling the emergence of neurites in neurons.

The second mechanism that can spatially restrict the activity of cytoskeletal forces depends on the localization of certain molecules to a restricted place on the membrane. In parallel to studies on bud site selection on yeast, where the membrane of the future bud site is marked and recruits a cascade of molecules that regulate trafficking and the cytoskeleton, such a hypothetical membrane mark could also be a determining feature in neuronal polarity (**Figure 3(c)**). Good candidate molecules to exert such a role are the proteins that regulate polarity during asymmetric cell division, such as the partitioning-defective proteins (Pars). Indeed, Par3 and Par6 are described as apically localized in neuroepithelial and radial glia cells. Their sorting to one of the two cells during division provides that cell with precursor properties, while the other cell becomes a neuron. Therefore, it is quite possible that small membrane patches containing Par3/6 are sufficient to bestow asymmetry to the nascent neuron, irrespective of where the centrosome is positioned. In this scenario, one can envision that these or similar molecules are responsible for 'weakness' on the cortical actin or the plasma membrane, in turn allowing microtubules to enter and support neurite expression. Whether an asymmetric, centrosome-mastered cytoplasm creates a major positional lead for polarity or whether molecular 'polarizers,' working independently or in tandem with centrosome-emerging forces establish initial asymmetry should be tested (**Figures 3(b)–3(d)**).

Irrespective of their degree of participation or hierarchical positioning in the polarity cascade in the postmitotic neuron (i.e., whether a molecular polarizer determines the positioning of the centrosome or vice versa), both these mechanisms support the idea of a mitotically determined process, strongly indicating that the decision of polar growth axis is intrinsically controlled.

From Round to Polar: Making a Neurite Become an Axon

Once sphere-breaking, neurite-inducing forces have been positioned in the sphere, a morphological deformation will result that eventually will become a neurite. Later, from the first or another neurite (depending on the model, **Figure 1(a)** or **1(b)**), the axon will form.

The growth of all neurites, independent of whether they become the axon or a dendrite, is dependent on the directed activity of the microtubule–actin

Figure 3 Ways neuronal asymmetry might be produced and might induce sprout formation. (a) The intracellular polarization of neurons coincides with the first sprout. Neurons were fixed after 1–3 h, and the centrosome was labeled in red and the nucleus in blue. (b) Forces originating from the asymmetric centrosome provide directionality and could regulate where the sphere is disrupted. (c) Disruption of symmetry might be explained by a membrane 'mark' that directs neuronal sprouting. (d) Another possibility is that inherited membrane asymmetries signal the inside of the cell to produce and maintain a cytoplasmic polarization.

cytoskeleton and selective membrane transport. The number of neurites will depend on the intrinsic program of the neuron: monopolar, bipolar, or multipolar. In fact, microtubules irradiate from the centrosome/MTOC in all directions of the sphere and are transported into all neurites. Actin is also similarly responsible for the presence of filopodia and lamellipodia in all neurites, and all neurites contain membrane carriers and mitochondria. Obviously, suppression of microtubule polymerization or membrane trafficking or stabilization of actin dynamics results in the lack of neurite outgrowth. The important issue, however, is which mechanisms neurons use to select only one of these neurites for fast growth, so that it later becomes the axon. One possible mechanism is through the simple 'passive' accumulation of 'neurite-making forces' in the place where the initial breakage was made. In this scenario, the neurite formed first will eventually become the axon because it is the place where these forces acted for the longest period and, consequently, where the growth threshold signal is surpassed first. Since the decision on the place on the sphere where the first neurite forms is defined by the positioning of the centrosome, which in turn is a consequence of the plane of cleavage of the last mitosis, this hierarchical, 'quantitative' mechanism implies, necessarily, that the decision of axon destiny is an intrinsic, mitotically predisposed process (Figure 4(a)).

The alternative mechanism is a 'qualitative' one, mediated by the 'sorting' to a single neurite, not necessarily the first, of molecules (called 'polarizers') with the specific capacity to affect microtubule–actin–membrane dynamics. This model of axon selection is illustrated in Figure 4(b). In line with such a predicted mechanism, it has been reported that certain molecules, such as the ganglioside converting enzyme PMGS or the small guanosine triphosphatases (GTPases) Rap1B and Cdc42, are preferentially transported to one neurite before it becomes the axon. Clearly, the polarization of such molecules to the tip (growth cone) of a single neurite can induce a special rate of growth (axonal) by selectively affecting the stability of the actin filaments or microtubules or by increasing membrane fusion or, most likely, by affecting all them in line or in parallel. Consistently, both PMGS and Rap1B signal to the pleiotropic PI3K, whose phosphorylating activity impinges on members of the actin and microtubule regulating proteins. Other molecules whose polarization before axonal growth can induce this growth are the Rho GTPases, a family of proteins with a very well elucidated role in the control of actin cytoskeleton dynamics. Studies of neurite elongation have shown that in general, RhoA inhibits and Cdc42 and Rac1 promote neurite elongation. RhoA activation induces stress fibers in starved fibroblast and leads to a more rigid actin cytoskeleton, whereas Cdc42 induces filopodia and Rac, membrane ruffles. If these actions apply to neurons, one would predict that Rho activity is low and Cdc42 and Rac1 activity are high in the growing

Figure 4 Sorting or cytoplasmic flow could select one neurite for sustained growth. (a) A quantitative mechanism would imply the delivery of 'polarizers' to all neurites, but with a preference for the one that began to grow first. (b) A second 'quantitative' model suggests a sorting process selectively sorting to the axon.

axon. In line with this, inhibition of RhoA has been reported to lead to the outgrowth of multiple axons, and the inhibition of Rac or Cdc42 inhibits axonal outgrowth. As mentioned already, Cdc42 has been found to be accumulated before axonal outgrowth in a single growth cone. From the latter mechanism arises a most basic question: what determines the sorting of the polarizers? One possibility is that it is the consequence of the time–hierarchy quantitative process described in the first place. This would not only reconcile quantitative and qualitative mechanisms but would also stress that the establishment of neuronal polarity is absolutely intrinsically defined. In this scenario, the extracellular environment would play a role in sustaining and guiding the already formed axon. The observation that the activity of PMGS increases locally on the addition of growth factors, an event also observed with the insulin-like growth factor receptor, is additional evidence of the importance of extracellular stimuli in growth sustenance. Moreover, there is abundant literature on the role of different types of extracellular ligands on the induction of axonal or dendritic growth.

A valid conclusion from all these findings is that a quantitative and centrifugal intracellular mechanism confers preferential, but not exclusive, growth capacity on a single neurite, with the extracellular environment playing a critical role in confirming such a predisposition. Thus, neuronal polarity is the result of the synchronous and sequential effect of intrinsic and extrinsic inputs.

Sustaining Polarized Growth

The sudden growth of the 'selected' neurite is a most important aspect of neuronal polarization, signaling to the cell that the normal one-axon, several-dendrites phenotype is finally established. A corollary

is that axonal fate is active whereas dendritic fate is passive (lack of sudden growth destines the remaining neurites of the cell to become dendrites). Obviously, final dendritic architecture requires more processes than a growth rate different from that of axons, and therefore dendritic destiny will be an active process as well. Science is only beginning to understand the mechanisms that lead to dendritic determination once the axon is formed, but the mechanisms responsible for rapid growth of the newly formed axon are fairly well understood. One important, well-described mechanism required for rapid growth is the destabilization of the actin skeleton in the growth cone of the selected neurite. Thus, neurons treated with the actin depolymerizing drug cytochalasin D extend, not one, but several rapidly growing neurites with axonlike characteristics. More important, local administration of this drug to any growth cone provides that selected neurite with axonal growth capacity. Another critical component behind rapid growth is the stability of microtubules. Indeed, the axon contains a higher proportion of acetylated, and thus more stable, tubulin, and a dephosphorylated version of microtubule binding protein tau, with a differential capacity to regulate microtubule dynamics depending on its phosphorylation state, is present in a distal–proximal gradient in axons.

The process of induction of rapid growth and of its maintenance requires the contribution of certain sustaining molecules, probably the same as the aforementioned 'polarizers.' Thus, for instance, the Par proteins described earlier are essential for axonal growth. The role of Par in axonal growth is mediated via kinases, such as the atypical protein kinase C ζ and PI3K, with a profound effect on cytoskeleton dynamics. Recently, it has been shown that the inhibition of the serine–threonine kinase GSK-3 leads to the outgrowth of supernumerous axons and thus is involved in regulating polarity. GSK-3 is interesting since among its many substrates are several microtubule-binding proteins, such as APC, tau, and Map1B. Its activity could therefore control polarization via the regulation of microtubule stability, microtubule bundling, and the dynamics at microtubule ends. In fact, phosphorylation of Crmp-2, a microtubule-binding protein whose ectopic overexpression leads to the outgrowth of extra axons, by GSK-3 reduces its microtubule-binding activity. On the other hand, GSK-3-mediated phosphorylation of APC changes the capacity of APC to bind and stabilize microtubules, influencing neuronal polarity and axon outgrowth.

Thus, any molecule with a critical role in the modulation of one or more of the critical determinants of the neurite-producing forces, whether microtubules, actin, membrane fusion/retrieval, or other events leading to large structural changes, will, to a greater or lesser degree, have an effect on neuronal polarity.

Conclusions and Summary

- *In situ* excitatory pyramidal neurons polarize in the ventricular and subventricular zone immediately after the last neurogenic division by sprouting two opposite neurites, which support migration.
- *In vitro* hippocampal neurons polarize immediately after mitosis: The neurite grown first eventually becomes the axon. Whether the first neurite *in situ* likewise becomes the axon still needs to be confirmed.
- The position from which the first neurite sprouts is marked by the presence of the centrosome and membrane organelles. It remains to be established firmly whether such spatial correlation alone determines the formation of the first sprout or whether a preexisting neurite-forming signal is needed.
- The first neurite grows as the axon because it is in the spot receiving growth information for the longest amount of time. It remains to be established whether the sorting of specific molecules primes such polarized delivery.
- A second neurite can become the axon if the first is lost. It remains to be established whether the selection of the new axon follows the same principles that govern the selection of the first.
- Dendrites begin to differentiate only after axonal destiny is conferred on one neurite.

Axonal and Dendritic Transport by Dyneins and Kinesins in Neurons

L S B Goldstein, University of California San Diego School of Medicine, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Size Problems in Neurons

Neurons are usually the largest and most highly polarized cells in multicellular organisms. In addition to the cell body, neurons have a dendritic compartment and an axonal compartment. Focusing on the axon, some simple size calculations reveal just how substantial the burden of their size is. Consider a 1 m motor neuron in a human adult. The 1 m axon can have a diameter ranging from a few tenths of a micrometer up to several micrometers as a consequence of variability in growth in diameter. The diameter of the cell body is on the order of 20–30 μm. Thus, the axon can be as much as or more than a thousand times the volume of the cell body. In addition to extraordinary volume, neurons must move materials such as synaptic proteins and vesicles synthesized in the cell body an enormous distance to reach the synapse where they have essential functions. Since diffusion is inadequate to support distant synapses and large axons and dendrites supplied with appropriate materials, neurons use a supply system composed of microtubule tracks and two types of microtubule-dependent molecular motor proteins, called kinesins and dyneins. These supply systems physically move the required large amounts of material from the cell body to the synapse and also keep the axon and dendrite supplied with ion channels, cytoskeletal proteins, membrane proteins, organelles, and many other components needed for axonal function and viability. In addition, although neurons use electrical signaling in the form of the action potential to communicate with targets and to drive electrical networks, a great many growth factors are moved to and then secreted at axonal termini to signal forward to targets. Simultaneously, targets release growth factors, which must complex with receptors and then be moved back to cell bodies to send chemical signals. Collectively these movements define axonal and dendritic transport. Axonal transport is better understood and consists of fast and slow components. In the case of movement from cell body to synapse, axonal transport is called anterograde, whereas from synapse to cell body, it is called retrograde. Dendrites have comparable burdens but also have a more complicated organization of cytoskeletal elements and a more highly branched structure with shorter processes than the axon. As a result, less is known about transport in dendrites although most work suggests that similar systems and principles are at work.

Microtubule Organization

Microtubules have structural, kinetic, and biochemical polarity (Figure 1). 'Minus' ends in nonpolarized cells are anchored at the centrosome whereas 'plus' ends radiate out toward the cell periphery. In axons, minus ends point toward the cell body, and plus ends point toward the synapse. Dendrites are more complex, with microtubules generally having a mixed polarity orientation in proximal dendrites but having plus end distal organization in the distal dendrites that have been studied. As discussed below, molecular motor proteins have defined directions of movement with respect to microtubules. Thus, a motor protein that walks from minus to plus along a microtubule is likely to play a role in anterograde transport in axons whereas its role in dendrites may be more complex. Similarly, motors that move from plus to minus along the microtubule will have retrograde functions in the axon and, again, more complex roles in the dendrites. In fact, because of the complex organization of microtubules in dendrites, principles relating direction of movements and microtubule organization to functions in the dendrites are at present poorly understood.

Assays for Axonal Transport

Many types of assays have been used to define the characteristics of axonal transport. One type of assay relies on radioactively labeling proteins during synthesis in the cell body and then measuring the rate at which different types of radioactive proteins appear at different distances along the axon (Figure 2). This type of assay led to the discovery that axons have both fast transport, which consists of proteins associated with vesicles, and slow axonal transport, which consists largely of soluble proteins and cytoskeletal proteins such as tubulin, actin, and neurofilaments. A second type of assay relies on physically interrupting the movement of materials along the axon by crushing a nerve containing many axons or by tying a thread around the nerve (ligation) to block physical movement (Figure 3). This assay has been used most commonly with sciatic nerve axons in which cell bodies are clustered together in the vicinity of the spinal cord and axonal termini are distributed in the periphery of the animal. Thus, ligating a sciatic nerve blocks both anterograde transport and retrograde transport and

Figure 1 Schematic diagrams of microtubule organization in a variety of cell types. leads to accumulation over time of anterograde materials on the proximal side (nearest the spinal cord) and retrograde materials on the distal side (nearest the periphery) of the ligature. Accumulated materials can be assessed either by biochemical means, such as electrophoresis and Western blotting, or by microscopic methods, such as immunofluorescence for specific proteins and organelles. These types of assay have not only led to the realization that different materials are moved at different rates in axons; they have also revealed that some materials that move from cell body to axonal terminus, such as the anterograde kinesin molecular motors, do not return to the cell body and are thus likely to be degraded at the terminus. These assays can be used to characterize both normal behavior and behavior in a variety of mutations that disrupt axonal transport or cause disease by interfering with proper axonal functions. Finally, another important type of assay of axonal transport relies on direct visualization of moving vesicles and organelles in the light microscope in live cells; these methods often use specific labeling of proteins or organelles with fluorescent molecules.

Kinesins

Kinesin molecular motor proteins were originally discovered in the giant axon of the squid. Although not recognized at the time, this new type of molecular motor protein, although biochemically distinct from myosins and dyneins, is the founding member of a diverse but related collection of molecular motor proteins that were deployed for many different functions in eukaryotic cells. The founding member of this family, originally called conventional kinesin, and now called kinesin-1, is a heterotetrameric protein composed of two kinesin heavy chains (KHCs) and two kinesin light chains (KLCs) (Figure 4). The motor activity of kinesin-1 resides in KHC in an N-terminal region of approximately 350 amino acids. This protein domain has been shown to be capable of generating adenosine 5′-triphosphate (ATP)-dependent movements along microtubules *in vitro*, has been crystallized and solved structurally, and has proven to be conserved and shared among all kinesin-related motor proteins. The nonmotor portion of KHC has two structural domains. One structural domain is an alpha-helical coiled coil that mediates KHC dimerization. The other region is of unknown structure and complexes with the KLCs to form the so-called tail or cargo binding domain of kinesin-1. KLC has a short coiled coil domain at its N-terminus that may mediate the dimerization and/or association with KHC, and then has a region of six relatively well-conserved tetratricopeptide repeat (TPR) units, whose structure has been solved in other proteins and which are predicted

Figure 2 Typical axonal transport assays and pathways. (a) Pulse-labeling experiments are typically used for measuring axonal transport rates and character. Radiolabeled protein precursors are injected into a region containing the cell bodies of particular neurons (e.g., dorsal root ganglion). After different times, the nerves are harvested and cut into segments. The segments can be used to evaluate rates of transport using scintillation counting, sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), and autoradiography, or other analytical methods. (b) Diagram of anterograde and retrograde transport pathways indicating potential cargoes and transport rates. Reproduced with permission from Goldstein LS and Yang Z (2000) Microtubule-based transport systems in neurons: The roles of kinesins and dyneins. *Annual Review of Neuroscience* 23: 39–71.

Figure 3 Schematic diagram of sciatic nerve ligation assay. Cell bodies clustered near the spinal cord define the proximal end of the nerve and are the source of materials moving in the anterograde direction. Axonal contacts with peripheral targets at the distal end of the nerve are the major source of material moving in the retrograde direction. Ligation (tying off) of the nerve results in accumulation of materials at the site of ligation.

Figure 4 Schematic diagram of kinesin-1 structure. Kinesin-1 is a heterotetramer consisting of two kinesin heavy chain (KHC) subunits and two kinesin light chain (KLC) subunits. KHC contains the motor domain, the dimerization domain, and a short terminal domain that interacts with the KLC subunits. Cargo binding may be mediated by KHC and KLC together or individually. KLC also plays roles in regulating KHC motor domain activity. ATP, adenosine 5′-triphosphate; TPR, tetratricopeptide repeat.

to form a triple alpha-helical groove composed of three TPR units. Thus, KLC is predicted to have two of these triple alpha-helical grooves that may be important in cargo binding and kinesin regulation.

The sequence of the KHC motor domain led to the discovery that eukaryotic genomes encode many different kinesin motor proteins. These proteins are all predicted to share a common motor domain but to have a variety of structurally diverse 'tail' domains attached that may harness force-generating activities by kinesins to a variety of cargoes in various cellular types and functions (Figure 5). Although the initial expectation was that all these predicted motor proteins would be plus end-directed motor proteins, a surprising degree of diversity in behavior was discovered. Some of these kinesin motor proteins mediate minus end-directed movements, and some may not be motor proteins at all and may mediate the rapid depolymerization of microtubules. Both of these types of proteins nonetheless couple ATP hydrolysis to their activities. Some kinesins may have other functional activities in the motor domain, but these have not yet been clearly elucidated. While many kinesins appear to play roles in nonneuronal cells, in particular in the process of cell division, a number are shared between neurons and nonneuronal cells. Many kinesins are specific only to neurons, where they may be involved in axonal or dendritic transport processes. For example, in mammals, on the order of 10–15 of the known kinesins among the 50 or so predicted to be encoded in the genome are specialized for cell division. In *Drosophila*, because of the smaller genome, proportionally fewer are used in mitosis and in neurons. A key question is which motor proteins move which types of vesicles and organelles in each type of neuron.

In neurons, although there is a large diversity of different kinesin motor proteins and cargoes, some simple principles have begun to emerge. For example, kinesin-1 appears to play roles in the anterograde transport of a number of different types of vesicles whose contents are needed along the axonal membrane and at the synapse, such as vesicles containing the amyloid precursor protein (APP), whose processing may cause Alzheimer's disease. Kinesin-1 also appears to play a role in the transport of neurofilaments, which are required for radial growth of axons, and in the movement of mitochondria. It is interesting to note that recent work suggests that mitochondrial movement by kinesin-1 may be mediated by a special form of kinesin-1 in which KLC is replaced by another protein, whose name is Milton. A second prominent class of kinesins, referred to as kinesin-3, appears to play roles in the movement of protein components of synaptic vesicles and may also play a role in the movement of mitochondria. Other kinesins may move mRNA particles, components of postsynaptic complexes and postsynaptic receptors, as well as other organelles, including peroxisomes, elements of endoplasmic reticulum, and the Golgi apparatus.

Figure 5 Principles of kinesin and dynein diversification. Kinesins appear to have evolved by gene duplication and divergence such that a conserved motor (shaded ovals) has become harnessed to a wide array of diverse tail domains. The location of the motor domain in the heavy chain polypeptide allows kinesin motors to be divided into several groups: an N-terminal group, a central group, and a C-terminal group. In addition, N-terminal kinesins have been found as homodimers, heterodimers, homotetramers, and monomers. Cytoplasmic dyneins appear to have conserved the bulk of their principal motor polypeptide and have generated far fewer divergent genes. Accessory chain diversification may be the principal mechanism for functional specialization. Reproduced with permission from Goldstein LS and Yang Z (2000) Microtubule-based transport systems in neurons: The roles of kinesins and dyneins. *Annual Review of Neuroscience* 23: 39–71.

An important and unresolved question is whether the movements of nonmembrane particles and proteins are mediated by direct interactions with the motor proteins or by binding to vesicle or organelle membranes and hitchhiking.

Another type of kinesin used for movements in some types of neurons is called kinesin-2. This kinesin is generally a heterotrimer of two nonidentical motor subunits associated with a third nonmotor domain protein, which may form part of the tail. This class of motor protein has been found to be used primarily for movement of materials in cilia and is thus necessary for the construction of cilia and perhaps for signaling mediated by cilia. In neurons in particular, this class of kinesin appears to be used most prominently in sensory neurons of various types, which often use modified cilia as their sensory endings within which receptors for odors or chemical molecules are bound and signals are transmitted. Vertebrate photoreceptors have a modified cilium as their light-sensing domain, the so-called outer segment, and this modified cilium also appears to require the use of this kinesin-2 type of motor protein for the movement of photoreceptive components such as opsin.

Dyneins

Dyneins provide a radically different example of the way in which motor proteins may be utilized to generate force and movement within neurons. In fact, most of the common principles learned from studying kinesins or myosins, which appear to have a shared evolutionary ancestor, appear not to be true for dyneins. A typical cytoplasmic dynein protein complex such as that used in neurons is many times the size of a native kinesin protein complex. The dynein complex generally consists of two copies of a dynein heavy chain and then several intermediate, light intermediate, and light chains, which together with the dynein heavy chains form the dynein complex and define its functions (Figure 5). The motor region of dynein is present in the heavy chains and is structurally and mechanistically different from kinesins and myosins, as it appears to use a mechanism most similar to that found in AAA ATPases. Cargo binding and regulatory activities appear to be conferred by the other subunits of dynein. Unlike kinesins and myosins, cytoplasmic dynein heavy chains are not highly duplicated and diversified in eukaryotic genomes.

Mammals have at most two or three cytoplasmic dynein heavy chain genes and a few each of genes encoding the other subunits. It has been argued that this small and relatively nondiverse collection of dynein heavy chain proteins carry out a large number of different functions in neurons, such as retrograde transport of compartments derived from endosomes and retrograde transport of components involved in signaling from the synapse to the nucleus. The needed diversity of dynein function and regulation is suggested to be provided by diversity in the accessory subunits. An unanswered question is why dyneins and kinesins have evolved so differently in eukaryotic organisms. It is conceivable that this divergent set of structural principles reflects an unknown principle about the regulatory needs in complex cells such as neurons.

Motor Regulation

Logic and experimental evidence suggests that molecular motor proteins must be regulated so that they do not move unless they are associated with an appropriate cargo. This issue is best understood for kinesin-1, which has been the subject of many studies of regulation and attachment. Early biochemical studies of kinesin-1 revealed that even though the protein could generate movement along microtubules *in vitro*, its ATPase activity measured in solution was much lower than could account for the physical parameters of movement. The answer was revealed in a series of studies that removed the tail domain from conventional kinesin in a series of recombinant constructs. These studies found that the kinesin motor domain with its tail domains attached has a very low ATPase activity while the kinesin motor domain with the tail domain removed has an ATPase activity that is high enough to account for the rates of movement seen *in vitro* and *in vivo*. In addition, structural studies revealed that kinesin-1 could exist in either a folded conformation, in which the tail and the head appeared to be associated, or in an extended conformation, in which the tail and the motor were separated; the latter conformation looks most appropriate for generating active movement. Although all the details have not yet been elucidated, considerable evidence now suggests that some combination of coupling kinesin-1 to an appropriate cargo combined with the action of soluble proteins leads to activation of the motor activity, perhaps by unfolding the motor. There is some evidence that phosphorylation mediated by signaling kinases may also be an important part of this regulation, although the details of how this is done are not yet clear. An intriguing possibility is that the signaling kinases might regulate motor protein association with appropriate cargoes in the cell.

Numerous biophysical studies have revealed that like other track-walking enzymes such as polymerases, motor proteins exhibit variation in a potentially regulatable property referred to as processivity. A simple definition of this property is that it refers to the number of sequential reaction cycles or steps along a microtubule or actin filament that a motor protein will undergo following a single encounter of the motor with the appropriate track. For example, a highly processive motor protein will take many steps, sometimes hundreds, along a microtubule after encountering it. A poorly processive motor protein will take at most a few or even only one step after an initial encounter. The biophysical basis of this behavior has been argued to be a result of the fraction of the motor's enzymatic/mechanochemical cycle that is occupied by the strongly bound state of the motor to the microtubule. Thus, a poorly processive motor is one for which the bulk of the reaction cycle is occupied by either a weak or a detached state of association of the motor to the microtubule whereas a highly processive motor is characterized by a large fraction of the cycle's being occupied by the strongly bound state. One consequence is that in solution, a single molecule of a poorly processive motor cannot walk very far, if at all, along the microtubule, whereas a highly processive motor can walk for great distances. Another consequence is that as the number of highly processive motors increases on moving particles, velocity is not expected to increase although the distance traveled is expected to increase. For poorly processive motors, both velocity and distance traveled are expected to increase as motor number increases. High processivity is a property that one might expect of a motor whose natural function is to move small vesicles over long distances. Indeed kinesin-1 appears to have as one of its functions the movement of small vesicles over long distances, and most work suggests that only a very few kinesin motors are found on most vesicles. Another consequence of this biophysical behavior is that processivity itself might represent a regulatory event for motor proteins. For example, as discussed below, kinesin-3 may be an example of clustering of single molecules of a poorly processive motor leading to highly processive behavior because one motor will remain bound while the others are detached. Cytoplasmic dynein in neurons also appears to exhibit this property, but the mediator of enhanced dynein processivity appears to be a protein complex called dynactin. Dynactin has been suggested to link dynein to some cargoes such as vesicles and organelles and also to enhance the processivity of the dynein motor by

providing a static microtubule binding function that tethers the dynein vesicle complex to a microtubule when the motor protein is in the detached state. Dynactin may thus be required for processive movement of vesicles that have small numbers of dynein molecules on their surfaces.

Another possible regulatory mechanism has emerged from studies of kinesin-3, which as a soluble native protein appears to be monomeric and has been generally found to be a poorly processive motor protein. This motor protein has a lipid-binding domain in its tail, and there is intriguing evidence that induced clustering of lipids can bring multiple kinesin-3 subunits together on the surface of a vesicle. This clustering may allow the kinesin-3 proteins to oligomerize and initiate processive movement through the action of multiple motor domains that become clustered and coordinated.

A final biophysical behavior that has been observed and that might be related to processivity and the ability of one or more molecules to generate movement is that some motor proteins, such as kinesin-1, track along a single protofilament of a microtubule in a highly linear movement process. Motor proteins such as dynein, however, appear to wander over the microtubule surface as they generate net force and movement. Whether this is a biophysical curiosity or is in some way related to the differing functions of these two motor protein types remains to be answered.

Mechanisms of Motor Protein Attachment to Vesicles and Organelles

The mechanisms by which dynein and kinesin motor proteins attach to vesicles, organelles, and other cargoes in neurons remain poorly understood. A number of candidate proteins have been found by use of yeast two-hybrid assays and other biochemical measures of protein interactions. In many of these cases, however, it is unclear whether the interactions that have been identified are required for attachment of motor proteins to cellular cargoes or whether these interactions reflect transient regulatory interactions that may occur on the surface of the cargo. In only a very few cases has strong evidence been reported for a role of an identified protein or lipid to link a motor protein to a cargo. For example, for kinesin-3 there is strong evidence that lipid associations can in some circumstances be sufficient to link this motor protein to a vesicle. How important the lipid interaction is for normal kinesin-3 attachment, and whether other protein factors might be involved, is unclear. For kinesin-1, a number of proteins have been suggested to be important for attachment, including APP, which is implicated in causing Alzheimer's disease. Evidence for this function is strong but not yet definitive, and there is some evidence that these interactions may also, or alternatively, play a role in kinesin-1 regulation. Another set of candidates for kinesin-1 attachment proteins is the c-Jun N-terminal kinase (JNK) scaffolding proteins, which may play roles in damage signaling in axons and dendrites and for kinesin-1 attachment to vesicles. There is some evidence that JNK scaffolding proteins are part of the mechanism by which kinesin-1 may be attached to APP vesicles. For dyneins, there is widespread acceptance that dynactin is important for attachment of dynein to vesicles and organelles, but definitive evidence for this point is lacking, and there is some evidence that is inconsistent with this view. At this time, considerably more experimental evidence is needed to unravel the relationship between attachment of motors to cargoes and their regulatory control. Novel methods may be needed to detect and demonstrate the functions of these interactions.

Conclusion and Perspectives

Although much has been learned about the general features of the systems that underlie movement in axons and dendrites of neurons, it is clear that many important details are not yet known. In particular, how motor proteins are attached to cargoes and regulated is particularly poorly understood. Understanding these issues is not only important for understanding the special functions of neurons in networks and systems; an emerging theme is that insults to these systems may be important in the development of a wide range of neurodegenerative disorders such as Alzheimer's disease and Huntington's disease.

Axonal Injury in Demyelinating Disease and CNS Injury

G A Criste, G J Kidd, and B D Trapp, Cleveland Clinic Foundation, Cleveland, OH, USA

Introduction

Multiple sclerosis (MS) is an inflammatory neurodegenerative disease of the central nervous system (CNS). MS is the leading cause of nontraumatic neurological disability in young adults in the United States and Europe, and approximately 2.5 million people worldwide suffer from this disease. The majority of MS patients initially exhibit a relapsing-remitting (RR) disease course (RR-MS) characterized by alternating episodes of neurological disability and recovery. Patients eventually convert to a secondary-progressive disease course (SP-MS) characterized by persistent and increasing neurological disability. Classically, MS has been characterized as a disease stemming from focal immune-mediated demyelination, which causes disability through block of conduction along demyelinated axons. More recently, however, the fundamental role of axonal injury in promoting irreversible disability in MS has been recognized and efforts to reduce or prevent axon loss have become a major focus of MS research.

Evidence that axonal injury is an early and persistent event in the progression of MS pathology comes from several sources. Histopathological studies have documented axonal loss in MS lesions (Figure 1), and neuroimaging approaches, including magnetic resonance imaging (MRI) and MR spectroscopy (MRS), have indicated that axon loss is pivotal and dynamic during the evolution of MS pathology. Proposed mechanisms of axonal injury in MS, however, remain diverse and speculative. Although generally considered to be sequelae of inflammatory demyelination, the limited success of immunotherapy in treating progressive disability in MS patients has diverted attention to neuroprotective therapies. The finding that diffused, irreversible axonal transection occurs early in the course of this complex disease has underscored the need to develop axonal neuroprotective treatments.

Axonal Pathology in MS Lesions

Histological evidence of axonal pathology was reported in the early literature on MS. These reports include descriptions of axonal swellings, axonal transection, and Wallerian degeneration, as well as discussions regarding the functional consequences of such pathology. However, the extent of axonal loss was controversial. In their classical works on MS, both Charcot and Marburg described MS pathology largely in terms of demyelination and reactive gliosis, and emphasized the relative sparing of axons in the lesions. In 1936, Putnam reported a 50% loss of axons in MS lesions from 11 patients. That same year, however, Greenfield and King reported normal axon densities in more than 90% of MS lesions from 13 patients that they studied. The differences between these studies were suggested to result from more sensitive axon staining in the latter.

More recent studies using contemporary technology such as MRI, MRS, and confocal microscopy have demonstrated that axonal transection begins at disease onset and that cumulative axonal loss provides the pathological substrate for the progressive disability that most long-term MS patients experience. Moreover, postmortem studies have shown that several histopathological abnormalities, including axonal loss, can be detected in the normal-appearing white matter (NAWM) and cortical gray matter of patients with MS, suggesting a more diffuse pathology than previously thought.

Axonal Damage Occurs during the Early Stage of MS

One important clue that axonal function was disrupted in MS lesions came from studies of amyloid precursor protein (APP). APP is transported by fast axonal transport and is normally present in axons at low levels that are not detectable by immunohistochemistry. APP accumulation in axons located in active MS lesions and at the border of chronic active MS lesions suggested axonal impairment in MS lesions. In particular, some APP immunoreactive structures exhibited the morphology of terminal axonal swellings, suggesting that axonal transection had occurred. The number of APP-labeled axonal swellings correlated with the degree of inflammation in the lesions. Similar swellings were detected with neurofilament immunostaining. Using confocal microscopy and computer-based three-dimensional reconstruction, axonal ovoids were identified as terminal ends of transected axons (Figure 2(a)). In one study quantifying axonal transections in 11 patients with disease duration ranging from 2 weeks to 27 years, extensive axonal destruction was demonstrated in cerebral white matter MS lesions. Active lesions contained over 11 000 terminal ends per cubic millimeter (Figure 2(b)), the edge of chronic active lesions contained over 3000 terminal ends per cubic millimeter, and the core of chronic

Figure 1 Axonal loss in MS patients. Axonal density is significantly decreased in a demyelinated area of MS spinal cord (a) compared to control cord (b). b

Figure 2 Axonal transection during inflammatory demyelination. Axonal transection occurs during inflammatory demyelination and induces formation of terminal axonal ovoids (a, arrows). When quantified (b), transected axons are abundant in MS lesions and appear to correlate with inflammatory activity of the lesion (* = statistically significant at $p < 0.01$). Reproduced with permission from Trapp BD, Peterson J, Ransohoff RM, Rudick R, Mork S, and Bo L (1998) Axonal transection in the lesions of multiple sclerosis. *New England Journal of Medicine* 338: 278–285, Copyright © 1998 Massachusetts Medical Society. All rights reserved.

active lesions contained on average 875 terminal ends per cubic millimeter. In contrast, less than one transected axon was found per cubic millimeter in control white matter.

Together, these data demonstrate a positive correlation between axonal transection and degree of inflammation in cerebral white matter MS lesions undergoing demyelination. The presence of axonal

ovoids in patients with short disease duration clearly demonstrated that axonal transection begins at an early stage of MS.

Axonal Loss Also Occurs in NAWM

It is well established that axons, once severed, will undergo relatively rapid Wallerian degeneration distal to the site of transection. Unlike axons, CNS myelin can persist for a long time after transection of the proximal axon. Remaining myelin sheaths may appear as empty tubes or as degenerating ovoids by microscopy. Despite this histological pathology, the white matter may appear grossly normal and appear unremarkable by conventional neuroimaging techniques.

Immunohistochemical evidence suggestive of Wallerian degeneration, such as discontinuous staining of axonal neurofilaments and presence of terminal axonal ovoids, has been demonstrated in NAWM from MS brains. Reductions in axonal density by 19–42% in areas without plaque have been reported in the lateral corticospinal tract of MS patients with lower limb weakness. By comparing axonal density in lesions and in NAWM from the cervical spinal cords of SP-S patients, one study showed how extensive axon loss can be. The average reduction in axonal density in lesions of lateral and posterior columns was 61%. In NAWM, however, the average decrease in axonal density was as much as 57%. By taking into account both decreased axonal density and reductions in tissue volume, another study showed that total axonal loss in the corpus callosum of MS patients averaged 53%; disease duration was between 5 and 34 years. The measured reduction in axonal density was only 34% in the same material. These findings emphasize the need to consider both tissue volume and axonal density to properly assess the degree of total axonal loss. These studies also indicate that white matter may appear normal judged by immunohistochemistry for myelin, or on MRI scans, but may still exhibit a considerable axonal dropout, especially in chronic patients with long disease duration.

Wallerian degeneration in NAWM has also been described by immunohistochemistry in an MS patient with short disease duration. The patient succumbed to a fatal brain stem lesion just after a 9-month history of RR-MS with few permanent neurological signs. Demyelinated lesions were not found in the spinal cord postmortem. However, the ventral column of the spinal cord, which contains axons projecting from the brain stem lesion, exhibited a 20% axonal loss. Microscopy revealed myelin ovoids and signs of myelin degradation by activated microglia, characteristic of Wallerian degeneration. Since much of the myelin remains, these can represent 'invisible lesions' as far as MRI and immunostaining for myelin are concerned.

Neuronal Pathology Also Occurs in MS Cortex

In addition to the more commonly described white matter locations, MS lesions can also involve the gray matter. The histopathological features and the clinical significance of such lesions are not completely understood. Gray matter lesions are difficult to detect macroscopically and histologically. On conventional T2-weighted MRI images, MS lesions in the cerebral cortex are much less obvious than white matter lesions. For these reasons, the frequency of cortical lesions has often been underestimated. Recent studies have shown that the use of gadolinium enhancement resulted in an increased detection of cortical lesions on MRI scans by 140%. A total of 26% of these enhancing lesions arose within or adjacent to the cerebral cortex. These results suggested that conventional MRI under-reports the presence of cortical lesions, when compared to neuropathological analysis.

In postmortem MS cortex, neurite transection is common, and TUNEL-positive neurons were detected in ~50% of chronic lesions, indicating that apoptotic loss of neurons can be significant. Interestingly, compared to white matter lesions, inflammation is substantially reduced in these lesions. Gray matter lesions contained fewer inflammatory cells, no perivascular cuffs, and consisted mainly of reactive microglia. T cells have been proposed to take a central role in the pathogenesis of MS. While T lymphocytes are found in MS white matter lesions, fewer are detected in cortical lesions that extended through both white and gray matter. In intracortical demyelinated lesions, T cell numbers were not different to T lymphocyte density in nondemyelinated cerebral cortex within the same tissue block.

It has been hypothesized that injury to neurons in cortical or subcortical lesion may provide the biological correlate to the cognitive dysfunction many MS patients experience. In fact, executive and cognitive functional deficits arise in 40–70% of these patients. Increased knowledge regarding mechanisms of neuronal damage in cortical MS lesions will contribute to the understanding of the functional significance of such lesions.

Mechanisms of Axonal Injury in MS

The pathophysiology of axonal injury in MS is poorly understood. It seems likely that different mechanisms may contribute to axonal degeneration at different stages of the disease. Elucidating the cellular and

molecular mechanisms that promote axonal loss in MS is important to the development of future neuroprotective therapies.

Genetic Susceptibility to Axonal Injury

Current evidence indicates that interactions between multiple genes influence the outcome of MS in individual patients. One line of evidence suggesting a genetic influence on axonal damage in inflammatory demyelination comes from studies of Theiler's murine encephalomyelitis virus (TMEV) disease, a viral-induced model of inflammatory CNS demyelination. Infected animals with susceptible genetic backgrounds develop neurological impairment and pathological changes comparable to those in MS. For example, infected SJL/J mice develop chronic demyelination, neurological deficits, and extensive loss of axons in the spinal cord, while C57BL/6x129 mice are resistant to TMEV-induced disease. When the major histocompatibility complex (MHC) class I protein is absent from C57BL/6x129 mice, they develop similar demyelination to SJL/J mice after infection, but do not go on to develop functional disability. In contrast, C57BL/6x129 mice lacking MHC class II developed a chronic inflammation with neurological deficits and axonal degeneration in spinal cord white. These results indicate that MHC molecules are involved in susceptibility to demyelination and axonal damage and highlight the possible role that genetic differences can play on the development of pathology during inflammatory demyelination.

Genes encoding trophic factors that are involved in neuroprotection and repair are at least as important as the immune-related genes that are thought to promote pathology. In this context, ciliary neurotrophic factor (CNTF) is an interesting candidate to promote resistance to axonal injury in MS. One study described a correlation between CNTF null mutations and early onset of MS symptoms. This suggests that axonal loss, which is the basis of disability, may be accelerated in these individuals through lack of CNTF-mediated trophic support of neurons and oligodendrocytes. Although a second study reported no correlation between CNTF genotype and disease, the initial results accord well with observations of experimental allergic encephalomyelitis (EAE) in CNTF knockout mice. After induction of EAE with myelin oligodendrocyte glycoprotein (MOG), $CNTF^{-/-}$ mice showed a significantly earlier disease onset and a delayed recovery from relapses.

Axonal Injury and Inflammation

Current knowledge suggests that MS is a primary inflammatory demyelinating disease of the CNS, and that disease activity reflects CNS inflammation, although much of the disease may not be detected clinically. For example, most RR-MS patients exhibit progressive brain atrophy and persistent inflammation, identified as gadolinium-enhancing lesions by MRI, regardless of their clinical symptoms. Since axon pathology, including transection of axons, correlates with the degree of inflammation in MS lesions, early axonal transection may reflect vulnerability of the demyelinated axons to inflammation. Indeed, the inflammatory microenvironment contains a variety of substances that could potentially injure axons, including proteolytic enzymes, cytokines, oxidative products, and free radicals produced by activated immune and glial cells. The ability of cytotoxic $CD8^{+}$ T-cells to mediate axonal transection has been described in MS tissue, EAE mice, and *in vitro*. Treatment of EAE mice with the AMPA/kainate glutamate receptor antagonist NBQX resulted in increased oligodendrocyte survival and reduced axonal damage.This suggests that excitotoxicity mediated by glutamate is involved in tissue damage in acute lesions. Directly or indirectly, inflammation may also affect energy metabolism of axons (discussed below). Inflammatory intermediates such as nitric oxide (NO) can act directly on mitochondria, while local inflammatory edema may interfere with the blood supply and potentially induce an ischemic mechanism of axonal degeneration.

Regardless of the molecular mechanisms involved, inflammation is a major factor behind accumulating axonal pathology at early stages of MS. For that reason, aggressive anti-inflammatory treatment during RR-MS may have indirect but long-term effects in preventing axonal injury in addition to important direct effects on inflammation.

Loss of Neuroprotective Effects of Myelin

The past decade has seen a deeper understanding of the intricate interdependence between the myelin-forming cells and its associated neuron. For example, axonal neuregulin has been found to control the proliferation and particularly the survival of oligodendrocytes and Schwann cells, ensuring a good match between the axon surface area requiring myelination and the number of surviving myelinating cells. Myelin-forming cells in turn have a profound influence on axonal morphology and physiology, affecting axonal diameter, neurofilament phosphorylation, cytoskeletal organization, and axonal transport rates. It follows therefore that disease processes that directly affect myelin-forming cells might also influence the underlying axon as well.

Peripheral nervous system (PNS) dysmyelinating diseases (in which myelin forms abnormally) are clearly

associated with axonal changes. Charcot–Marie–Tooth neuropathy type 1 (CMT1) is a genetically heterogeneous group of chronic dysmyelinating peripheral neuropathies. Mutations affecting the myelin genes peripheral myelin protein 22 (PMP22), protein zero (P_0), and connexin-32 account for most CMT1 cases. While the electrophysiological consequences of dysmyelination account for some of the neurological symptoms in CMT1, the main contributor to clinical progression is axon loss, as determined by measurements of nerve conduction amplitudes and motor unit numbers. As in MS, this may be related to abnormal glial–axonal interactions. Thus, axonal degeneration may be a final common outcome in a wide variety of myelin-related diseases.

In the CNS, myelin protein defects also result in axonal pathology, even though they may cause little or no myelin abnormality. Myelin-associated glycoprotein (MAG), a member of the immunoglobulin gene superfamily, is a low-abundance myelin protein enriched in the innermost myelin membrane that lies adjacent to the axon. In MAG-deficient mice, postnatal myelination progresses as in wild-type animals. From the age of 5 weeks, however, progressive axonal atrophy including reductions in axonal caliber, neurofilament spacing, neurofilament phosphorylation, and increased Wallerian degeneration is observed. MAG inhibits neurite outgrowth and causes growth cone collapse *in vitro*, suggesting that it can modulate the axonal cytoskeleton. The findings indicate that MAG has direct or indirect long-term modulating effects on the cytoskeleton via axonal kinases or phosphatases.

The X-linked myelin proteolipid protein (PLP/DM20) is the major structural protein of compact CNS myelin. Mutations, deletions, or duplications involving the PLP gene cause Pelizaeus Merzbacher disease (PMD) and spastic paraplegia of varying severity in humans. In mice, PLP mutations result in premature oligodendrocyte death and dysmyelination. Many of these phenotypes, however, are 'gain-of-function' effects due to toxicity of misfolded proteins encoded by the mutated genes. In contrast, PLP-null mice remain competent to myelinate CNS axons of all calibers and to assemble compacted myelin sheaths. Ultrastructurally, however, the electron-dense 'intraperiod' lines in myelin remain condensed, correlating with its reduced physical stability. From the age of 6 weeks, PLP-deficient mice exhibit focal axonal swellings containing dense bodies and mitochondria in CNS regions containing mainly small-diameter axons. The accumulation and distribution of organelles and neurofilaments in axonal swellings indicate impairment of retrograde axonal transport. A length-dependent axonal degeneration in the absence of demyelination and inflammation in patients with PLP-null mutations has also been reported. Replacement of PLP with P_0 in PLP-null mice resulted in normal-appearing CNS compact myelin with PNS-like membrane ultrastructure. Although initially indistinguishable neurologically from wild-type or PLP-null mice, the P_0-CNS mice exhibited accelerated rates of axonal damage and rapid progression of neurological deficits and morbidity. These results suggest that PLP gene expression is required for axonal maintenance independent of its roles in myelin formation.

Unlike other myelin proteins, CNP is not crucial to myelin assembly but is essential for axonal maintenance. CNP is distributed throughout the cell soma and in noncompacted regions of myelin. In mice lacking CNP, myelin assembly was not visibly affected. However, at about 4 months of age, the mice developed motor deficits that progress with age. Histological analysis revealed late-onset axonal pathology characterized by abnormal axonal swellings and degeneration of many axons.

These data from myelin protein defects support dual roles of the oligodendrocytes, first, in the formation of the myelin sheath, and second, in the maintenance of the underlying axon. Understanding the signaling pathways and effector molecules, such as kinases and phosphatases, may lead to new therapeutics that promote axonal preservation in demyelinating and dysmyelinating diseases.

Mitochondrial Involvement in Axonal Injury

Recent evidence suggests a hypoxia-like metabolic injury as a pathogenetic component of axonal injury in MS. Although this model was largely derived from studies of white matter injury in models of ischemia and neurotrauma, recent observations suggest that such a mechanism operates in inflammatory brain lesions in MS as well. In this model, ischemia leads to ATP depletion. The resulting energy crisis impairs the function of ATP-dependent ion channels (e.g., Na^+–K^+ ATPase, Na^+–Ca^{2+} ATPase) leading to an elevation in intracellular Na^+ concentration. Accumulation of axoplasmic Na^+ through non-inactivating Na^+ channels, together with membrane depolarization, promotes reversal of Na^+–Ca^{2+} exchange and axonal Ca^{2+} overload. Ultimately, the pathological increase in intracellular Ca^{2+} drives Ca^{2+}-dependent enzymes to damage the axon.

Mitochondrial damage could occur through several mechanisms. Astrocytes, activated microglia, and macrophages in the CNS release substantial amount of NO in MS lesions. One mechanism of the toxic action of NO is the impairment of mitochondrial function, and NO-treated white matter has

been shown to undergo ATP depletion and irreversible damage. Mitochondrial dysfunction has also been implicated by microarray analysis of postmortem MS motor cortex. Decreases in nuclear-encoded mitochondrial genes from four of the five respiratory chain complexes have been reported, which raises the interesting possibility that inherent defects in these organelles may arise in MS and further compromise energy production capacity.

Microvascular pathology also contributes a major role in the hypoxic MS pathology, starving mitochondria of oxygen and reducing their capacity to produce ATP. Edema within inflammatory lesions leads to focal disturbance of microcirculation with subsequent ischemia. Such a mechanism is likely to have greatest impact in CNS locations where room for tissue expansion is limited, such as the spinal cord and the optic nerves. Inflammatory damage to the vessel walls can also lead to activation of the clotting cascade resulting in local microvascular thrombosis and ischemic injury to the axons similar to a stroke.

Axonal compensation after demyelination may place increased demands on axonal mitochondria. Demyelinated axons revert to continuous rather than saltatory conduction by express Na^+ channels along the length of the axolemma. However, propagation of action potential under this circumstance involves much greater ion movements and hence ATP consumption. Recent reports on the beneficial aspects of Na channel blockers such as flecainide, phenytoin, and tetrodotoxin in attenuating axonal pathology in animal models of MS may reflect reduced energy demands on the demyelinated axons. Na^+ channel blockers can also reduce neuroinflammation through actions on the microglia and macrophages in EAE and MS. Thus, in addition to direct neuroprotective effect, Na channel blockers may reduce axonal degeneration through anti-inflammatory effects.

Strategies for Axonal Protection

Therapeutic strategies aimed at preventing axonal and neuronal damage are crucial in heading off permanent disability in MS patients. Most neuroprotective strategies are based on the emerging models presented above, which have provided novel perspectives on providing axonal protection.

Anti-Inflammatory Strategies

The correlation between axonal damage and magnitude of inflammation suggests that the axons may be innocent bystanders in the surrounding inflammatory milieu during active demyelination. The clinical observation that the topographic pattern of irreversible, progressive neurological deficits in MS depends on the localization of the previous inflammatory attacks seems to favor this interpretation. Anti-inflammatory agents are most effective during the RR phase when inflammation dominates the clinical picture. Since many axons are lost during this phase, early treatment with these agents is likely to be highly beneficial.

Remyelination Strategies

Myelin contributes both as a physical barrier between the axon and surrounding milieu and by providing trophic support, and so strategies that aid in remyelination can confer axonal protection. Remyelination is common in MS but not sufficiently robust to promote full and sustained recovery. Strategies based on enhancing production of endogenous myelinating cells or supplementing them by transplantation of progenitors are being explored at present.

Interruption of the Secondary Injury Cascade in Axons

In the hypoxia-like models of axonal injury, different cellular insults result in impairment in energy production that leads to a reversal of the Na^+–Ca^{2+} exchanger. The resulting surge in Ca^{2+} levels in the axoplasm drives enzymatic processes that lead to cellular destruction. Based on these pathogenetic mechanisms, treatment with Na channel blockers and Na^+–Ca^{2+} channel blockers may prevent this Ca^+-driven autolysis of neuron. In EAE models and *in vitro* studies, Na channel blockers like phenytoin and flecainide may have succeeded in providing axonal protection through this mechanism. Bepridil, an inhibitor of Na^+–Ca^{2+} exchange has been shown to protect axons from injury caused by NO *in vitro*. These drugs are worth looking into as some of them have already been in the market for decades. Once proven effective in MS, we have an immediate addition to our arsenal against MS that has a relatively well-established safety profile.

Conclusion

Axonal loss is the major cause of irreversible disability in MS. Axonal damage, including complete transection of the axon, begins early in MS and correlates with inflammatory activity. Extensive reductions in axon number may also impact nonlesioned white and gray matter. Understanding the mechanisms underlying axonal degeneration and how these mechanisms operate at different stages of disease may ultimately produce novel therapeutic interventions that enhance

axonal survival in MS brains and delay progression of neurological disability in MS patients.

Axonal Injury: Neuronal Responses

G Raivich, University College London, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Injury to neurons results in a host of many different structural, electrophysiological, and molecular responses. Some of these are associated with and may play an important role in the mounting of a successful response and the ensuing recovery of function. Others reflect the enhanced likelihood of cell death, either within hours or days of the injury, particularly in neonatal animals, or during a delayed form after a brief or lengthy regenerative phase, and/or the gradual withering away and atrophy, processes that can be addressed with neurotrophic therapy.

Axonal injury and the ensuing neuronal response can also induce a strong glial and immune reaction. These reactions can have a positive or a negative impact on neuronal regeneration. For example, cell death and the ensuing inflammation can impart a strong stimulus for the generation of new neurons. The nonneuronal responses will also provide the cellular basis for the immune surveillance of the injured brain, a key component of their overall function. The aim of this article is to present a concise overview of specific molecular, structural, and electrophysiological changes occurring in the injured neuron itself.

Early Axonal Reaction

The Initiation

The physiological and molecular signals that act as sensors of axonal injury and induce the regenerative program are still a subject of debate. Generally, three major changes appear to provide separate signals, even though they may act in a complementary and/or synergistic way:

1. Ionic flux, injury-induced discharges. There is a rapid entry of extracellular ions such as calcium and sodium through the transiently opened axonal plasma membrane, before it is resealed, resulting in depolarization and a sequence of injury-induced action potentials. The calcium influx and bystander activation of intra-axonal proteases and cytoskeleton remodeling underlie growth cone formation and may also be involved in changing intra-axonal protein synthesis.

Early changes in the cell body of axotomized neurons precede the arrival of molecules traveling by rapid axonal transport. They include the rapid elevation of calcium and cAMP, ribosomal RNA processing, and the increase of gap junction proteins such as connexin-43 in neighboring astrocytes. However, inhibition of antidromic electrical discharges does not interfere significantly with the somewhat later induction in transcription factors, glucose utilization, or the onset of regeneration.

2. The tip of the injured axon is briefly exposed to the intracellular content of neighboring axons and Schwann cells. These substances include the ciliary neurotrophic factor (CNTF), neurotrophin-3 (NT3), and fibroblast growth factors (FGFs), which are released following injury, deposited locally, and can then act on the proximal tips of the injured axons to induce a specific response. At a later time, the axons are also exposed to the extracellular environment of the inflamed neural tissue, containing a host of different proinflammatory cytokines, such as interleukin-1 and interleukin-6.

Particularly instructive is the role of CNTF and the nuclear transcription factor, signal transducer and activator of transcription-3 (STAT3), the downstream target of activated CNTF receptor. Phosphorylation and activation of STAT3 in the proximal part of injured axons clearly precede that in axotomized neurons, pointing to the retrograde transport of phosphorylated STAT3 as one of the injury-mediating signals. Neuron-specific deletion of STAT3 leads to enhanced posttraumatic cell death, suggesting that this signal is involved in promoting survival of lesioned neurons. Moreover, deletion of CNTF, a neurotrophin that is abundantly present in myelinated Schwann cells but not in or around the cell bodies of axotomized motor neurons, causes a significant delay in the appearance of the phosphorylated STAT3 and its nuclear translocation in neuronal cell bodies.

3. Block of retrograde transport. Last but not least, axonal injury also interferes with the retrograde flow of trophic signals from the normal innervation target. The data on nerve growth factor (NGF), the model neurotrophin that is retrogradely transported from periphery to neuronal cell body, are particularly instructive. In fact, analysis of its retrograde transport in the injured sciatic nerve shows a very drastic decrease immediately following axotomy. However, this initial, very strong decrease is only transient, for approximately 48 h. Nevertheless, there is a much longer, still threefold reduction that continues until the onset of regeneration. Moreover, NGF deprivation by neutralizing the endogenous activity with specific antibodies also induces axotomy-like changes

even in the intact, NGF-sensitive sensory and sympathetic neurons, particularly in the expression of transcription factors such as c-jun and a series of neuropeptides including galanin, vasoactive intestinal peptide (VIP), SP, CGRP, and NPY.

Retrograde Transfer of Injury Signal

The second, intermediate phase involves the posttraumatic generation and activation of axoplasmic proteins with the nuclear localization signal (NLS) sequences. These NLS proteins function as positive and retrogradely transported injury signals The same regulation also applies to importins, also known as karyopherins, an intermediary class of proteins that permit NLS proteins to become attached to the retrogradely transporting dynein motors and allow them to transfer injury signal(s) to the nucleus of the injured neurons. There are several ways to verify that these are indeed injury signals. For example, interference with this importin/dynein-mediated transport of NLS proteins strongly reduces the neurite outgrowth from cultured adult neurons from previously unperturbed sensory ganglia. It also blocks the much more vigorous outgrowth from cultured neurons that were conditioned by peripheral injury.

The Cell Body Response – Morphology

In the injured neurons, the axonal disconnection is followed by a complex of structural, molecular, as well as electrophysiological changes such as the long-term hyperexcitability or LTH. The structural changes are exemplified by the appearance of growth cones at the proximal tip of the lesioned axons, the swelling of the neuronal cell body associated with a strong increase in cellular metabolism, and protein synthesis.

Chromatolysis

The injured and swollen neuronal cell bodies show augmentation and regional dispersion of areas of packed rough endoplasmic reticulum (rER), the so-called Nissl bodies (NBs) (aka Tigroid substance, Nissl shoals), in neuronal cytoplasm, shown in Figure 1. Neuronal nuclei leave their typical cell body midpoint and move to a more eccentric position. On the electron

Figure 1 (a–c) Cellular and ultrastructural changes following axonal injury. (a) Schematic summary, (b, c) electron microscopy of a normal (b) and an axotomized rat facial motor neuron, 10 days after lesion (c) at higher magnification. (a) Axotomy causes a detachment of neurite terminals and filling in of empty cell surfaces with CNS glia. Inside the neuron, there is a rearrangement of rough endoplasmitic reticulum cisternae or Nissl bodies (NBs). (b, c) These NB cisternae are normally arranged in parallel (b), but take a more random and curvilinear appearance after axotomy (c). Note the enormous increase in ribosomes and enlargement of NB area. The neuronal cell surface is covered by microglial cells (MG), the neurite terminals (T) are detached. (b, c) Reproduced from Kreutzberg GW and Raivich G Neurobiology of degeneration and regeneration. In: May M and Schaitkin BM (eds.) *The Facial Nerve*, 2nd edn. New York: Thieme; 2000, pp. 67–80. Reprinted by permission of Thieme.

microscopic level, such neurons are seen to have greatly increased numbers of cellular organelles (Figures 1(b) and 1(c)). Ribosomes, either in free form or bound to the endoplasmic reticulum, are especially abundant. The organization of the rER undergoes characteristic changes. The cisternae are no longer arranged in parallel. Due to the augmentation and spreading of the rER, single NBs can no longer be seen; the cells also stain more intensively with Nissl dyes under light microscopy. The contour of the cell body's surface, which is normally smooth, becomes convex and wavy, reflecting the cellular hypertrophy and instability of the plasmalemma.

These overall changes, some of which are easily visible at the light microscopical level using basophilic dyes (eccentric nuclei, increased staining, dissolution of NBs, eccentric nuclei), were termed chromatolysis or chromatolytic reaction by Franz Nissl at the end of the nineteenth century; the term that is still used as a synonym of cellular and molecular changes in the lesioned neurons or retrograde reaction following axonal injury.

Synaptic Stripping

Structurally, these early changes are followed by retraction of neurite endings on the cell bodies of axotomized neurons. This phenomenon, called synaptic stripping, leads to a partial de-afferentation of the injured neurons and may persist for a very long time after initial injury and interfere with long-term recovery (Figure 1(c)). The emptied spaces are gradually taken over by the neighboring reactive astrocytes, which can wrap around injured neurons with multilammellar stacks of thin astrocyte processes.

Central Sprouting

In addition to the generation of new axons at the injury site, supernumerary axonal sprouts can also develop more proximally, at the nodes of Ranvier, a response first noted by Santiago Ramón y Cajal, and occasionally even at the level of the injured neuronal cell body. These latter structures have been termed dendraxons because they exhibit axonal properties and markers but frequently, though not always, grow out of the reorganized dendritic structures.

Peripheral axotomy can also induce the sprouting of central sensory processes of the affected dorsal root ganglia (DRG) neurons in the spinal cord as well as the appearance of perineuronal neurite baskets in the DRGs themselves. Together with the long-term hyperexcitability of the injured sensory neurons, both of these latter processes have been implicated to contribute to the posttraumatic neuropathic pain.

The Cell Body Response – Molecular Changes

The prompt arrival of signals for cellular injury and stress is followed by the induction of factors involved in the regulation of transcription and translation; later on, also by adhesion molecules, growth-associated proteins, and structural components required for axonal elongation. Moreover, the introduction of the different differential cDNA display and gene chip array technologies has led to a dramatic increase in the number of identified genes regulated in injured and regenerating neurons.

Translation and Signal Transduction

One of the earliest biochemical changes following axonal injury is the transient upregulation of polyamine-producing enzymes ornithine decarboxylase and transglutaminase. This has been linked to an increase in mRNA metabolism, and protein synthesis resulting in polyamines such as putrescine, spermine, and spermidine shows a strong enhancing effect on neurite outgrowth both *in vitro* and *in vivo*. The induction of polyamine-producing enzymes is followed by the upregulation of the classical, intracellular stress and growth signaling pathways – the phosphatidylinositol-3 kinase (PI3K) and the mitogen-associated protein kinase (MAPK) cascades. Both pathways are involved in stimulating neurite outgrowth. Expression of active protein kinase B, also known as Akt, a downstream target of PI3K, promotes axonal regeneration as well as neuronal survival after neonatal axonal injury. Expression of active ras, the upstream inducer of ERK1 (MAPK1) and ERK2 (MAPK2), promotes adult survival. Interference with ERK1 and ERK2 also retards axonal outgrowth.

Transcription Factors

Activation, phosphorylation, and nuclear localization of transcription factors appear as the primary signals mediating changes in gene expression in the injured neuron. The majority of transcription factors reported in the context of injury – c-Jun, JunD, ATF3, P311, Sox11, c-EBPβ, and STAT3 – go up. However, some are actually going down, for example, Islet-1, Fra-2, and ATF2. Although all of these transcriptional changes are probably involved in fine-tuning the posttraumatic and regenerative response, the data on their importance using deletion studies are now available for c-Jun, c-EBPβ, and STAT3. In the case of c-EBPβ, deletion of this transcription factor interferes with the injury-induced expression of the molecules important for the coordination of the membrane cytoskletal interface, tubulinα 1, and neuromodulin/GAP43. Deletion of neuronal STAT3 reduces the posttraumatic

survival of axotomized neurons, to the extent observed following the deletion of CNTF and LIF, pointing to STAT3 as the transcription factor that mediates these effects.

However, particularly pronounced effects are observed for neuronal deletion of c-Jun, briefly summarized in Figure 2. The absence of neuronal c-Jun (Figure 2(a)) shows the gene deletion strategy, Figure 2(b) the

Figure 2 Deletion of the *c-jun* gene in neurons interferes with the neuronal response to injury following transection of the facial nerve. (a) A summary of the three-step gene deletion strategy: (1) by introducing the loxP sites (◄) around the *c-jun* gene and the thymidine kinase (TK) and neomycine resistance *neoR* cassette, (2) removing the floxed *TK* and *neoR* cassette, and (3) deletion of the floxed *c-jun* gene through *cre* recominase under the control of *nestin* promoter active in central neuroepithelial cells. The strategy restricts *c-jun* deletion to neural cells, to avoid embryonic lethality due to global *c-jun* gene deficiency. (b) Absence of c-Jun immunoreactivity (Jun-IR) in neurons with gene deletion (Δ*n*), but not in control animals with two copies of floxed *c-jun* gene (*f/f*), which behave as wild-type controls (not shown). (c–e) Absence of neuronal c-jun blocks the axotomy-induced appearance of neuronal hyaluronic acid receptor CD44 (c), the upregulation of the laminin receptor $\alpha 7\beta 1$ integrin (d) and interferes with normal motor recovery (e). Axotomized side: axot in (c), filled bar in (d); contralateral side: contra in (c), empty bar in (d). Reproduced from Raivich G, Bohatschek M, DaCosta C, et al. (2004) The AP-1 transcription factor c-Jun is required for efficient axonal regeneration. *Neuron* 43: 57–67.

disappearance of nuclear c-Jun immunoreactivity – interferes with the induction of most proteins expressed after injury. There is a complete block in the expression of the adhesion molecule CD44 (Figure 2(c)), which functions as a receptor for hyaluronic acid. There is also a strong decrease in the laminin receptor $\alpha 7\beta 1$ integrin (Figure 2(d)) and neuropeptide galanin that are associated with axonal regeneration, a significant reduction in the speed of reinnervation and functional recovery (Figure 2(e)), and a complete inhibition of central axonal sprouting. In addition, absence of neuronal c-Jun inhibits the recruitment of lymphocytes and activation of brain microglia, showing the importance of neuronal factors for the chemoattraction of neighboring nonneuronal cells. As *in vitro*, deletion of c-Jun interferes with posttraumatic neuronal cell death. However, it also causes severe neuronal atrophy, showing that saving neurons from cell death does not automatically translate into the maintenance of a well-nourished and functional state.

Metabolic Changes

The normal neuronal response to injury is associated with a strong increase in energy metabolism, in the uptake of glucose, and in the enzyme activity of the hexose monophophate shunt (glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase). This may be related to increased production of pentoses needed for the increased synthesis of ribonucleotides. Axotomized neurons show a massive induction in the receptors for transferrin, a carrier protein for the trivalent iron ion (Fe^{3+}) and an associated uptake of iron ions into the affected facial motor nucleus. There is also an increase in the neuronal uptake of fatty acids, which is probably involved in the provision of additional constituents to the newly formed axonal membranes.

Neurotransmission and Neurochemical Differentiation

As a general rule, proteins associated with neurotransmission are decreased after injury. This includes the acetylcholine-synthesizing enzyme cholinacetyltransferase and the degrading enzyme acetylcholinesterase in the cholinergic sympathetic and cranial and spinal motor neurons, enzymes involved in catecholamine synthesis (noradrenaline, dopamine), in adrenergic sympathetic and dopaminergic nigrostriatal neurons, or substance P and CGRP in the peripheral sensory neurons responsible for the pain modality. This downregulation is frequently accompanied by reduction in the level and activation of neurotrophin receptors that may be responsible for the neurochemical shift toward a more immature and embryonic phenotype. In sensory, sympathetic, and motor neurons, this shift is also accompanied by an upregulation of other neuropeptides, such as galanin and VIP, which are more typical of their embryonic phenotype.

Typically, the synthesis of neurofilament proteins is also reduced. However, there is strong upregulation of peripherin and the tubulin subunits T-$\alpha 1$ and T-$\beta 3$. Tubulins are major components of the microtubules which are assembled from α- and β-subunits. These microtubules are prominent axonal organelles that function as a carrier for kinesin, a molecular motor that drives axonal transport. Changes in cytoskeletal proteins thus appear important in promoting axonal regeneration. However, they may also lead to the overt morphological alterations at the level of the injured neuronal cell body.

Cell Adhesion Molecules and Cell Surface–Cytoskeletal Interactions

Increased expression or *de novo* appearance of adhesion molecules on the cell surface of the injured neuron appears to be one of the primary motors in changing the growth status of the lesioned neuron and permitting it to extend along, as well as sprout additional fibers in the injured peripheral nerve. Axotomized neurons upregulate a variety of integrin subunits that serve as receptors for extracellular matrix and cell surface molecules. They increase in receptors for the hyaluronic acid and galactoside residues such as CD44 and galectin-1 and express cell multimodal surface molecules involved in homophilic binding such as ninjurin and gicerin/CD146. The latter molecule is also a heterophilic receptor for the neurite outgrowth factor, a member of the laminin family. Another cell surface molecule strongly upregulated after axotomy is FLTR3, which contains numerous leucin-rich repeats and a fibronectin III-type extracellular domain and can form complexes with receptors for the FGF and promote FGF signaling.

Although the common assumption is that most of these molecules are involved in regeneration proper, some may also contribute to aberrant sprouting. For example, deletion of $\alpha 7$ integrin subunit is associated with a strong upregulation of its corresponding $\beta 1$counterpart, but also with a significant increase in central axonal sprouting. This may imply compensatory mechanisms involving other closely related α subunits. Central axonal sprouting on injury-induced neuronal cell surface molecules such as L1 and the close homolog of L1 (CHL1) relies on $\beta 1$-integrin function and may be involved in the effects observed in $\alpha 7$-deficient mice.

Successful axonal regeneration is accompanied by the appearance of numerous, functionally diverse families

of molecules that regulate the surface–cytoskeletal interaction. The best known so far is the GMC family that includes cytoplasmic proteins GAP43, MARCKS, and CAP23. These molecules codistribute with the phosphoinositol-4,5-diphosphate, PI(4,5)P2, at the semicrystalline, raft regions of the cell membrane. These GMC molecules are functionally exchangeable, bind exclusively to acidic phospholipids such as PI-(4,5)-P2, calcium/calmodulin, protein kinase C, and actin filaments, modify the raft recruitment of signaling molecules such as src, regulate actin cytoskeleton polymerization, organization, and disassembly, and have a formative role in the appearance of filopodia and microspikes, in addition to the process of neurite outgrowth.

Posttraumatic Neuronal Death and Cell Death Signals

Several cell surface molecules have been shown to mediate neuronal cell death following neonatal and adult axonal injury, including fas, tumor necrosis factor receptors (TNFRs) 1 and 2, and FAS. Some of these receptors carry a cytoplasmic death domain that exerts a pro-apoptotic signal through FADD; expression of dominant negative form of FADD has been shown to block the axotomy-induced cell death signal due to fas and TNFR. Recent evidence also points to glutamate excitotoxicity.

Associated downstream cytoplasmic cell death signals play a key role in promoting neuronal cell death in neonatal and immature animals that are sensitive to axonal injury, for example, noxA. Some heat shock proteins, for example, hsp27, are neuroprotective. Deletion of bax or inhibition of caspase 3 or the whole family of caspases has also been shown to prevent cell death, but with an enhanced and more persistent effect for broad caspase inhibitors than caspase 3 alone. In both cases, bax and caspases appear to act downstream of the phosphorylation of the transcription factor c-Jun and the decrease in neuronal metabolism, suggesting a sequence of events beginning with phospho-Jun, leading to atrophy, activation of bax, and ending with the initiation of the caspase cascade, resulting in neuronal cell death.

Axonal mRNA Transport and Functions

F P G van Horck and C E Holt, University of Cambridge, Cambridge, UK

Introduction

Neurons are highly polarized cells consisting of a cell body, multiple dendrites, and a single axon. During development, axons and their highly dynamic structures at the tip, the growth cones, navigate through the complex environment of the embryo to reach their synaptic targets, which are often long distances from their cell bodies. Along the pathway, growth cones encounter and respond to molecular guidance cues that are present in gradients or localized to discrete choice points. Once they arrive at their destination, axons must select the appropriate neurons with which to form synapses. The specialized functions of the axon and growth cone require a subset of proteins different from those needed in the cell body or in the dendritic compartment. Neuronal function therefore relies on an asymmetric distribution of protein and protein complexes, both during development and throughout the life of mature neurons.

Asymmetric protein distribution can be achieved by two mechanisms: axonal transport of proteins and local protein synthesis. It was long thought that the cell body was the exclusive site of protein synthesis, with newly synthesized proteins being transported into the neuronal processes by selective axonal and dendritic transport mechanisms. This view was altered by the discovery of local protein synthesis in dendrites, beginning with the detection of polyribosomes in postsynaptic structures and followed by the identification of dendritically targeted messenger RNAs (mRNAs). Local translation in dendrites is now known to play an important role in synaptic plasticity and long-term memory storage. The concept of local protein synthesis in axons has been more controversial and has been accepted only since the early 2000s. Although electron microscopy studies in the 1970s of growing axons *in vivo* revealed the presence of polyribosomes in axons, the failure to unambiguously detect components of the protein translation machinery in biochemical axonal preparations hampered further progress. Moreover, *in situ* hybridization studies revealed the presence of mRNAs in young hippocampal neurons but not in mature axons. This transient appearance of mRNAs in developing axons was thought to reflect the fact that transport mechanisms that mediate RNA sorting in mature neurons had not yet developed. However, the process of axonal translation gained more support when individual mRNAs, such as β-actin, were detected in both invertebrate and vertebrate developing axons. Evidence that these mRNAs are translated in axons was initially provided from studies in invertebrates, in which mRNAs injected into isolated axons were shown to be translated into functional proteins. Studies in invertebrates have been viewed with caution, however, since invertebrate axons have both receptive and transmissive capacities and therefore combine the functions of both dendrites and axons. Subsequent work has shown that vertebrate axons can also actively synthesize proteins. Indeed, vertebrate axons have been suggested to represent about 5% of total neuronal protein synthesis. There is, however, a relative paucity in our understanding of the molecular mechanism underlying axonal mRNA transport and translation as the field of local translation in neurons has been dominated by studies in dendrites. This article focuses on the mRNAs that have been identified in axons, the mechanism of axonal mRNA transport, and the way translation of axonal mRNAs controls critical functions in neuronal behavior.

Which mRNAs Are Transported into the Axon?

To date, the main group of mRNAs identified in axons and growth cones are those encoding cytoskeletal proteins, such as β-actin, or regulators of cytoskeletal dynamics, such as actin depolymerizing factor (ADF)/cofilin, profilin, β-thymosin, microtubule-associated protein (MAP)1b, and tau. However, mRNAs for proteins involved in cell signaling, such as RhoA and transmembrane receptors such as EphB2 have also been found, albeit to a lesser extent. Most axonal mRNAs have been identified by candidate approaches, such as by using fluorescent *in situ* hybridization on axonal cultures *in vitro*. Other approaches involve the generation of pure axonal preparations and subsequent biochemical analysis of mRNAs associated with ribosomal proteins or molecular analysis of the mRNA content. The latter approach has also led to the identification of mRNAs in regenerating adult axons. In this approach dorsal root ganglia (DRG) neurons are damaged in the animal and then allowed a period of recovery in order to allow induction of the regeneration program (see the section titled 'Axonal mRNA transport in adult axons') prior to neuronal isolation. Purified axons of these so-called injury-conditioned neurons contain, besides cytoskeletal mRNAs, those encoding heat shock proteins, resident endoplasmic reticulum (ER) proteins, proteins associated with

neurodegenerative diseases, antioxidant proteins, and metabolic proteins. This implies that axons can contain a wide range of mRNAs. The repertoire of axonal mRNAs is likely to vary depending on neuronal cell type, function, and developmental stage.

Mechanism of Axonal mRNA Transport

Targeting Elements

As has been found in nonneuronal cells, mRNA localization in axons depends on *cis*-acting sequences, called zipcodes. Zipcodes are essential for the transport of the mRNAs, and removal or mutations to them impair the targeting of the transcript. Zipcodes are usually present in the 3′ untranslated region (UTR) of the mRNA and are occasionally found in the 5′UTR or even in the coding region. Zipcodes can be short segments with defined nucleotide sequences but can also be secondary or tertiary structures such as stem loops. A well-studied example in axons is β-actin mRNA. Localization of the β-actin mRNA into growth cones is dependent on the 3′UTR. Mutation analysis has defined a 54-nucleotide sequence within the 3′UTR that is necessary and sufficient for targeting β-actin mRNA into the growth cone of chick forebrain axons. β-actin mRNA localization can be inhibited by antisense oligonucleotides directed against the 54-nucleotide sequence as well as by mutations that disrupt the secondary structure. Similarly, the mRNA for the MAP tau is targeted to the axon by an AU-rich sequence in the 3′UTR. Fusion of the tau 3′UTR axonal localization signal to a gene normally not present in axons results in axonal localization of its mRNA. In most cases, the mRNA localization signals are more complex and lack a simple consensus. Together with the fact that axonal localization signals are not highly conserved among species, it is not yet possible to predict from the primary sequence whether an mRNA is targeted into the axon.

RNA-Binding Proteins

The targeting elements in mRNAs are recognized by RNA-binding proteins (RNBPs), which are essential for mRNA transport. To date only a limited number of zipcode-binding RNBPs have been identified in axons. These include zipcode-binding proteins (ZBPs)-1 and 2, HuD, cytoplasmic polyadenylation element binding protein (CPEB), survival of motor neuron protein (SMN), and fragile X mental retardation protein (FMRP); all of which are proteins with well-established roles in mRNA localization in oocytes, embryos, and fibroblasts. RNA binding is modulated by RNA-binding domains such as RNA recognition motif, heterogeneous nuclear ribonucleoprotein K homology domains, and Arg-Gly-Gly boxes. RNBPs often harbor multiple RNA-binding modules and have the potential to interact with multiple mRNAs, as well as with other proteins involved in transport or translation. Together they form large protein complexes that are actively transported into the axon (Figure 1).

Figure 1 Examples of RNA-binding proteins (RNBPs) and messenger RNA (mRNA) complexes identified in axons and growth cones. mRNAs are depicted that have been shown to interact either directly or indirectly with the indicated RNBP in axons. RNBPs interact with the mRNAs via conserved RNA-binding modules, such as RNA recognition motif (RRM), heterogeneous nuclear ribonucleoprotein K homology (KH), and Arg-Gly-Gly (RGG) boxes. Survival of motor neuron protein (SMN) lacks any of these recognizable RNA-binding domains. Numbers refer to amino acids. FMRP, fragile X mental retardation protein; CPEB, cytoplasmic polyadenylation element binding protein; ZBP1, zipcode-binding protein 1; HuD, a zipcode-binding RNBP; MAP, microtubule-associated protein; GAP, growth-associated protein.

Active Transport

There are several mechanisms known to localize mRNA to specific subcellular regions, including mRNA diffusion and anchoring, local degradation, and active transport along cytoskeletal filaments. Of these, active transport of mRNAs has been implicated as the major localization mechanism in neurons. A consensus view of this process has come primarily from studies on dendrites, as well as from *Xenopus* and *Drosophila* early development systems. Findings on mRNA localization in axons are limited but in agreement with the current model of active transport, which encapsulates the following multistep pathway: RNA granule formation, cytoskeleton transport and release, anchoring, and translation.

RNA granule formation As soon as mRNAs are generated, they are subject to multiple dynamic interactions with RNBPs involved in mRNA processing

and nuclear export. Once in the cytoplasm, some proteins dissociate from the mRNAs whereas others remain attached. For example, both ZBP1 and 2 associate with the β-actin mRNA zipcode in the nucleus. However, while ZBP1 remains bound to β-actin mRNA in the cytoplasm, ZBP2 is a shuttling RNBP that is thought to be released for return to the nucleus. Next, proteins that are required for cytoplasmic transport, translation, degradation, and anchoring associate with the mRNA, resulting in the formation of large particles, called ribonucleoprotein (RNP) complexes or RNA granules. RNA granules can be identified by phase light microscopy, in which they appear as large, clustered aggregates. Biochemical characterization of these granules from neuronal extracts has revealed the presence of many localized mRNAs, RNBPs, ribosomal proteins, and proteins involved in the regulation of translation, as well as motor proteins that connect RNA granules to the cytoskeletal transport network. The assembly of transport particles, containing multiple mRNAs and both nuclear and cytoplasmic RNBPs, is therefore an important step in mRNA localization.

Movement along the cytoskeleton Active transport is characterized by directed movement of RNA granules at a speed that is too fast to be explained by cytoplasmic flow. Live cell imaging of mRNA or RNBP movement shows that active transport can reach velocities of 0.1–2 $\mu m\ s^{-1}$. How is such rapid transport achieved? RNA granules contain motor proteins that connect the RNP complexes with the cytoskeleton. In an analogous fashion to vesicle transport, motor proteins mediate RNP transport along cytoskeletal filaments in an adenosine triphosphate-dependent manner. In axons, the shaft consists of actin filaments and bundles of stabilized microtubules, which extend, together with some dynamic microtubules, into the growth cone central domain and are therefore an ideal track for transport into the axon.

Active transport via the cytoskeleton is mediated by specific motor proteins. Kinesin and dynein are microtubule-based motor proteins, whereas myosin is required for transport along actin filaments. In general, anterograde movement along plus end microtubules (i.e., away from the cell body, into the axon) is mediated by kinesin, whereas retrograde transport along minus end microtubules (i.e., toward the cell body, out of the axon) might involve dynein. However, the kinesin motor family comprises many family members with different expression patterns and cargo specificities, and some family members have also been shown to mediate retrograde transport. Kinesin-2 is involved in anterograde transport and is expressed in axons. One of the microtubule-based motor subunits of kinesin-2, KIF3A, interacts with HuD in HuD-tau mRNA-containing granules in axons. Moreover, inhibition of KIF3A expression abolishes tau mRNA transport into the axon, resulting in decreased levels of axonal tau protein. Since tau is important for microtubule stabilization, the decrease in expression levels causes neurite retraction. Other RNBPs have been shown to interact with several different kinesin family members, albeit not specifically in axons or growth cones. In *Drosophila* neuronal cells, FMRP granule transport depends on both kinesin-1 and cytoplasmic dynein. Knockdown of either kinesin-1 or cytoplasmic dynein is sufficient to impede both anterograde- and retrograde-directed FMRP transport, indicating that the two transport mechanisms are coupled.

The identity of the motor proteins suggests that axonal mRNAs are transported along microtubules. Indeed, treatment of neurons with inhibitors of microtubule polymerization, such as nocodazole or colchicine, reduces transport of ZBP1, SMN, and FMRP granules into the axon, showing that these granules are predominantly transported along microtubules. It should be noted that granule movement is not solely unidirectional. Detailed analysis of enhanced green fluorescent protein (eGFP)-tagged RNBP dynamics shows a variety of movements, uni- and bidirectional, as well as oscillatory movements with no net displacement. The cytoskeleton of the peripheral domain of growth cones is comprised mainly of actin filaments, which are either arranged in a network forming the lamellipodia or in f-actin bundles forming the filopodia. RNBPs such as ZBP1, SMN, and FMRP are detected in developing growth cones, suggesting that within the growth cone, transport can also take place along actin filaments. Indeed, the actin depolymerizing drug cytochalasin D blocks transport of eGFP–SMN, but it mainly inhibits short-distance-directed movements and oscillatory movements. Thus axonal mRNA transport seems to involve long-distance-directed movement of RNA granules along microtubules in the axon shaft as well as short-distance-directed movements along actin filaments in growth cones.

mRNA release and anchoring To restrict protein synthesis to a specific subcellular domain, mRNAs must not be translated until they reach their destination. This implies that a tight coupling between mRNA transport and repression of protein translation exists, and RNBPs are thought to play a key role in this regulation. ZBP1, for example, is not only essential for β-actin mRNA localization; it also represses the translation of β-actin mRNA during transport in neuroblastoma cells. Once an mRNA

Figure 2 Model for axonal messenger RNA (mRNA) transport. Axonal mRNA localization is a multistep process, involving ribonucleoprotein (RNP) assembly in nucleus and cytoplasm, followed by active transport along microtubules and actin filaments. Once arrived at the growth cone, transported mRNAs are released and anchored until needed for translation. RNBP, RNA-binding protein.

granule arrives at its site of action, the mRNA has to be released and anchored in the correct place until needed for translation. In the case of ZBP1, this has been shown to involve a phosphorylation-dependent mechanism. The nonreceptor kinase Src phosphorylates ZBP1, which reduces the ability of ZBP1 to bind to β-actin mRNA and thereby releases the translational repression. It is interesting that this regulatory step seems to take place in the growth cones, suggesting that external cues might induce this process leading to local β-actin translation. The molecular mechanism of mRNA anchoring in neurons is not well understood. One of the components of the translation machinery, elongation factor 1a, has been implicated in anchoring β-actin mRNA to the actin filaments, where polysomes are also known to reside. Furthermore, FMRP is associated with translating polyribosomes in neuronal cells, where it is thought to regulate translation (Figure 2).

mRNA translation mRNA translation in axons is thought to involve the cap-dependent translation machinery. Cap-dependent mRNAs are abundant in growth cones, and molecular cues shown to stimulate translation in growth cones (see below) induce the rapid phosphorylation of the translation initiation factor eIF4E binding protein 1 (4EBP) and the translation initiation factor eIF4E. Hypophosphorylated 4EBP blocks translation initiation by sequestering the rate-limiting eIF4E. Hyperphosphorylation causes 4EBP to release eIF4E and allows translation initiation to proceed. In turn, eIF4E is phosphorylated by the kinase target of rapamycin (TOR, which is inhibited by rapamycin). Although rapamycin blocks translation in retinal growth cones, translation is not completely inhibited, indicating that cap-independent translation may also be involved. Which other components of the translation initiation machinery are required for axonal mRNA translation and how the process is spatiotemporally regulated are currently unknown.

Functions of Axonal mRNA Transport

Axonal mRNA transport serves to spatially restrict protein synthesis to the axon and growth cone. How is this ability to locally transport mRNAs important functionally for the axon? Axons are continuously exposed to molecular cues, which regulate their outgrowth and pathfinding. *In vitro* assays on cultured neurons have revealed that molecular cues are able to regulate mRNA transport. For example, in chick forebrain neurons, the neurotrophic factor Neurotrophin-3 (NT-3) increases β-actin mRNA localization in the growth cone within a short timescale (10 min). This increase is blocked when, prior to NT-3 stimulation, the axons are incubated with antisense oligonucleotides that interfere with the binding of ZBP1 to β-actin mRNA, indicating that NT-3 stimulates axonal mRNA transport rather than local mRNA stability. Indeed, detailed analysis of ZBP1 granule movement shows that NT-3 increases the rapid ZBP1 transport into the growth cone. Furthermore, cue-induced stimulation of mRNA transport seems to be selective since, for example, in axons from regenerating adult DRG neurons, brain-derived neurotrophic factor and nerve growth factor selectively induce the transport of a subset of mRNAs, including β-actin, vimentin, and peripherin. The precise functional significance of this finding is unknown but is presumed to reflect proteins that are required for axonal responses in both developing and adult axons.

Axonal mRNA Transport in Developing Axons

Developing axons are characterized by their ability to grow, navigate, and innervate their target region. Each of these processes requires cytoskeletal

rearrangements. Significantly, mRNAs encoding cytoskeletal proteins and cytoskeletal-associated proteins have been isolated from axons of developing neurons from a wide range of organisms. Given the importance of cytoskeletal dynamics in developing neurons, this suggests multiple roles for local translation in regulating axon and growth cone behavior, such as axon growth and pathfinding.

Axon growth Addition of protein synthesis inhibitors to cultured *Xenopus* retinal or spinal axons does not affect their rate of extension over the short term (1 h), suggesting that local translation of axonal mRNAs is not critical for short-term axon outgrowth. In contrast, disruption of the interaction between ZBP1 and β-actin mRNA by antisense oligonucleotides has been shown to impair the persistent forward movement of growth cones. This apparent discrepancy could reflect a difference in the requirement for translation and mRNA transport. Several *in vitro* studies indicate that mRNA transport is important for long-term axonal growth. Expression of a mutant ZBP1, which cannot release the β-actin mRNA, reduces neurite outgrowth in hippocampal neurons. Similarly, manipulation of HuD levels in rat cortical neurons results in significant changes in neurite outgrowth. More-direct evidence that axonal transport is important for growth comes from studies on SMN. Transport of SMN from the nucleus into the cytoplasm requires exon 7. Neurons transfected with an exon 7 deletion mutant (SMNΔ7) have shorter processes, both of the minor neurites and the incipient axon. It is important to note that this axon outgrowth defect can be rescued by redirecting SMNΔ7 into neurites by an axonal targeting sequence from growth-associated protein 43, indicating that SMN-mediated mRNA transport is critical for axon outgrowth. Further complexity is apparent from the ability of some translated mRNAs to inhibit axon outgrowth. For example, mRNA of β-thymosin, a negative regulator of actin polymerization, is accumulated in the distal neurites of *Lymnaea* neurons, and reducing the β-thymosin mRNA levels in isolated neurites increases the rate of neurite outgrowth. Thus, locally synthesized proteins can both positively and negatively regulate axonal growth.

Axon guidance As axons grow, their growth cones encounter a wide variety of signals that influence their navigation. Growth cones react to local attractive and repulsive cues in their environment by extending and retracting filopodia (fingerlike protrusions) and lamellipodia (flattened, veillike extensions), which determines the net direction of migration. Turning is caused by extension of filopodia on one side and withdrawal or collapse of filopodia on the other. Using two different chemotropic assays, the behavior of *Xenopus* retinal ganglion cell (RGC) axons *in vitro* has provided an insight into the role of local mRNA translation in growth cone guidance. In turning assays, growth cones grow toward a gradient of an attractant and turn away from a gradient of repellent over the course of 30–60 min. In collapse assays, bath application of a repellent causes complete withdrawal of growth cone filopodia and lamellipodia within 10 min. Embryonic *Xenopus* RGC growth cones are attracted to a source of netrin-1, but this attractive response is blocked by protein synthesis inhibitors. Moreover, protein synthesis inhibitors block the repulsive turning as well as the collapse response of RGCs toward the repellents Slit-2 and Semaphorin 3A (Sema3A). It is important to note that this inhibition of chemotropic responses by protein synthesis inhibitors also takes place in growth cones that have been severed from their cell bodies, showing that the translation occurs locally, in the growing axon. Indeed, netrin-1, Slit-2, and Sema3A are able to induce rapid (within 5–10 min) protein translation in the growth cone as measured by phosphorylation of eIF4E and eIF4EBP and the incorporation of labeled amino acids. It is striking that netrin-1, Slit-2, and Sema3A elicit local translation by activating different intracellular pathways involving mitogen-activated protein kinases (MAPKs). For example, netrin-1 and Slit-2, but not Sema3A, induce translation that depends on p38 MAPK. The netrin-1, Slit, and Sema3A pathways are dependent on mammalian TOR, indicating that cue-induced translation is cap-dependent.

These findings have provided evidence that growth cone turning and collapse depend on local protein synthesis, but which mRNAs are translated in these processes? Since growth cone turning involves remodeling of the microtubule and actin cytoskeleton, translation of mRNAs encoding cytoskeletal regulators are good candidates. Consistent with this hypothesis, Slit-2 has been shown to induce a protein synthesis-dependent increase in ADF/cofilin in *Xenopus* RGC growth cones. Moreover, Sema3A-mediated growth cone collapse in DRG neurons is dependent on the local translation of the small GTPase RhoA. RhoA is a key regulator of the actin cytoskeleton, and its mRNA is targeted to the growth cone by a specific sequence located in its 3′UTR. The local translation of RhoA is both sufficient and necessary for Sema3A-mediated growth cone collapse, suggesting that basal levels of RhoA are not sufficient to mediate the Sema3A responses. Thus, the local translation of cytoskeletal proteins provides the developing axon and growth cone with a mechanism to rapidly

modulate the cytoskeleton in response to extracellular cues (Figure 3).

Local mRNA translation in growth cones also plays a role in growth cone adaptation, a process whereby the growth cone desensitizes and resensitizes to a guidance cue. Adaptation is thought to be an integral part of the steering mechanism, enabling growth cones to adjust their sensitivity in a way that allows them to navigate in gradients of axon guidance cues. In *Xenopus* spinal neurons, attractive turning responses toward netrin-1 or brain-derived neurotrophic factor are attenuated if either of the chemoattractants is present in the bath. After 30 min, the desensitization disappears, and the growth cones regain their normal turning behavior. Protein synthesis inhibitors block this resensitization process, indicating that locally synthesized proteins play a role in regaining responsiveness. Collapse assays in *Xenopus* retinal growth cones show that desensitization and resensitization can even occur at a much shorter timescale (2–5 min) in response to repellents. Resensitization in response to Sema3A and netrin-1 under repulsive conditions is ligand-specific and requires new protein synthesis. Growth cone resensitization to Sema3A and netrin-1 correlates with a protein synthesis-dependent increase of their respective receptors, neuropilin and deleted in colorectal cancer, at the plasma membrane, indicating that resensitization might involve, at least partly, the translation of guidance cue receptors. In this way, growth cones can adjust their sensitivity as a function of exposure to a specific ligand.

Although functional studies on axonal mRNA transport are mostly conducted *in vitro*, local protein synthesis has also been implicated in axon navigation *in vivo*. When growing over long distances,

Figure 3 Diagram showing the role of axonal messenger RNA (mRNA) transport and local translation in growth cone behavior in developing axons. (a) Growth cones exposed to Sema3A induce the translation of RhoA, a small guanosine triphosphatase. The newly synthesized RhoA is required and sufficient to mediate Sema3A-induced growth cone collapse. (b) Local translation at the midline intermediate target. Translation of a reporter construct encompassing green fluorescent protein (GFP) and the 3′ untranslated region (3′UTR) of the EphA2 receptor is upregulated as growth cones enter the midline and reaches high levels as they emerge from the midline. Translation of the reporter construct is dependent on the cytoplasmic polyadenylation element sequence in the 3′UTR, suggesting that cytoplasmic polyadenylation element binding protein (CPEB) may be involved in mRNA localization or translational control.

axons use intermediate targets to which they are directed by local attractive and repulsive cues. After reaching the intermediate target, the axons must continue their journey and change responsiveness to the cues that guide them to the next target. One way to change responsiveness at an intermediate target is by changing the repertoire of guidance receptors at the plasma membrane. Studies in chick embryonic commissural neurons have suggested that this can be achieved by local translation of a receptor. Spinal commissural axons are initially attracted toward the midline floor plate, but after crossing the midline, axons lose responsiveness to the midline attractants and gain responsiveness to a new set of guidance cues. When these commissural axons are transfected with a construct encompassing the 3′UTR of the EphA2 receptor and GFP, protein expression is detected in the cell bodies but not in the growth cones. However, the protein is expressed in the growth cones of axons that have crossed the midline, suggesting that translation of the reporter construct is selectively activated after midline crossing. Translation is dependent on a cytoplasmic polyadenylation element binding element in the 3′UTR, indicating that CPEB might target the EphA2 mRNA to the growth cone.

Thus, local protein synthesis may play a crucial role in axon guidance. It has been known for decades that axons that are separated from their cell body retain their ability to grow and even make accurate guidance decisions. The ability of axons to locally translate proteins may explain this observation. By locally synthesizing proteins, the growth cone can autonomously respond to its environment. Different guidance cues along the pathway might stimulate the transport and the translation of a specific subset of mRNA needed for immediate growth cone turning, adaptation, and responses at intermediate targets. Moreover, protein synthesis may play a role presynaptically in the establishment of arbors and synapses, and studies in invertebrates indeed suggest a role for local translation in regulating synaptic connections in response to activation. It should be noted that not all cues elicit protein synthesis in the growth cones, indicating that local translation is not a ubiquitous mechanism in cue-directed growth.

Axonal mRNA Transport in Adult Axons

In contrast to developing axons, neuronal function of mature axons is not dependent on major cytoskeletal rearrangements like those involved in growth cone steering but rather on maintaining the integrity of the cytoskeleton, except when an axon is disconnected from its targets on injury. Neuronal regeneration is dependent on many factors, including severity of the injury and cell type. Peripheral nervous system neurons have regenerative capacity, whereas neurons of the central nervous system do not. Successful regeneration requires the tip of the cut axon to be remodeled and reformed into a growth cone. Experiments in cultured adult sensory and retinal axons have demonstrated that the formation of a growth cone, after axotomy, depends on local axonal protein synthesis (and degradation). It is important to note that the intrinsic regenerative capacity of the different types of neurons correlates with the levels of intra-axonal protein synthetic machinery: sensory neurons with high regenerative ability contain high levels of ribosomal proteins and activated translational initiation factors, whereas these proteins are absent in retinal axons, which have a low regenerative ability. Similar to developing axons, growth cone reformation after injury depends on activation of MAP kinases. A mechanism for the role of translation and MAP kinases has been proposed in the peripheral nervous system. Nerve injury leads to the activation of MAP kinases in the axon as well as the translation of the intermediate filament protein vimentin and the nuclear import protein β-importin. Vimentin then undergoes proteolytic cleavage, and these vimentin fragments bind to the activated MAP kinases to couple them to the importin–dynein complex for transport to the cell body. This is thought to provide a mechanism to retrogradely transport an injury signal to the nucleus to facilitate the regenerative response. Maintenance of regenerative growth, after the initiation of growth cone formation, might be regulated by extracellular stimuli. A proteomic approach has identified multiple axonally synthesized proteins in injury-conditioned DRG axons, but the growth-promoting neurotrophins selectively increase the levels of some cytoskeletal mRNAs into the axon, presumably to retain growth cone motility. Thus, axonal mRNA translation is important for multiple steps during regeneration, including growth cone formation, generation of an injury signal, and maintenance of axonal growth (Figure 4).

Axonal mRNA Transport and Neurological Diseases

Although *in vivo* data on the function of axonal mRNA transport and translation are still lacking, the importance of these processes becomes evident when the function of key regulators such as RNBPs is impaired. For example, mutations in the FMR1 gene on the X chromosome lead to the fragile X syndrome, which is the most common cause of inherited mental retardation. Mutations in the FMR1 gene lead to transcriptional silencing of the gene and a consequent lack of FMRP and FMRP-transported mRNAs. Furthermore, HuD is associated with

Figure 4 Local translation in injured mature axons. (a) Uninjured axons transport mRNA along the axon, presumably for cytoskeletal maintenance. (b) Once an axon is lesioned, the growth cone undergoes degeneration and loss of connections with its targets. At the site of the lesion, protein translation is induced. (c) Newly synthesized proteins include cytoskeletal proteins such as β-actin for growth cone reformation and of vimentin and β-importin for the generation of an injury signal. Vimentin protein is proteolytically cleaved, which generates fragments that link phospho-extracellular signal-regulated kinase (P-ERK) to β-importin to the dynein motor protein. This complex is retrogradely transported along microtubules into the nucleus to regulate gene expression to facilitate the regeneration process. Adapted from Willis DE and Twiss JL (2006) The evolving roles of axonally synthesized proteins in regeneration. *Current Opinion in Neurobiology* 16: 111–118.

paraneoplastic encephalomyelitis, a neurological disorder caused by an autoimmune reaction against HuD. Moreover, low levels of SMN protein result in spinal muscular atrophy, which is an autosomal recessive disorder and the leading hereditary cause of infant mortality and is characterized by a loss of α motor neurons in the spinal cord. In most cases, the causes of these neurological diseases have not been directly attributed to specific defects in axonal mRNA transport. However, knockdown of SMN in zebra fish has been shown to result in motor axon-specific outgrowth and pathfinding defects, emphasizing the importance of regulated mRNA transport for neural development. Future studies on the identification of RNP complexes and their functions might explain the cellular consequences of RNA misregulation that underlie distinct types of neurological diseases.

Conclusion

The concept of local translation at growth cones has gained increasing acceptance during the past 5 years, and it is now clear that mRNAs are transported into the axon and growth cone and can be translated in response to environmental cues. Axonal mRNA transport serves to spatially restrict protein synthesis to the axon and growth cone, providing axons with the capacity to autonomously regulate their structure and function during axonal growth, navigation, and regeneration. A general model about the molecular mechanism of neuronal mRNA transport and translation has come from studies in dendrites, and although this mechanism seems to be highly conserved, many aspects of axonal mRNA function remain completely undefined. For instance, characterization of the identity of RNA granules and determination of the ways environmental cues regulate mRNA localization within the milieu of the elongating axon are incompletely understood. One recently proposed hypothesis is that RNBPs transport mRNAs as a set that encodes proteins with a common biological function. Some dendritic RNBPs, for example, transport a coherent subset of mRNAs to specifically mediate synaptic plasticity. It will be fascinating to determine whether axonal RNA granules function in an analogous fashion to regulate

specific axon and growth cone function. Elucidating how axonal mRNA transport and translation regulate growth and pathfinding *in vivo* should provide key insights into the ways dysfunction in these processes can lead to neurological diseases.

Introduction

Building a brain requires the precise formation of connections between vast numbers of neurons, often separated by significant distances. Axon pathfinding is thus a crucial process in the development of a functioning nervous system. A better understanding of the principles and mechanisms underlying axon pathfinding has both clinical and broader practical importance. From a clinical perspective, our ability to treat or prevent some neurological defects will be improved by a better understanding of how axon guidance can fail. Furthermore, the regeneration of damaged nerves requires axons to reconnect to their appropriate targets; hence, understanding axon guidance will be necessary for the development of therapeutic techniques. In a broader context, our understanding of axon pathfinding ties into our understanding of the nervous system as a whole: what principles underlie its formation and function? can we harness those principles in order to improve our own engineering processes, such as in the construction of self-wiring computers?

Mathematical and computational models are very useful tools for understanding the constraints on nervous system development. Ultimately, such constraints are quantitative and set by the physics of the system; hence, they must be modeled mathematically to yield the best predictive power and generate strong hypotheses. Models may also prove valuable in the development of therapies. For instance, how can axons be made to grow toward a specific target area? What additional information is needed by axons which are failing to develop correctly? Sufficiently detailed theoretical models have the potential to guide experimental research in axon pathfinding through simulations done *in silico*.

Experimental Data

Guidance Cues

Axons grow along their correct trajectories by following a molecular map consisting of spatiotemporal patterns of guidance cue molecules. Four main families of molecules have been identified based on their guidance abilities – the netrins, the Slits, the semaphorins, and the ephrins – consisting of approximately 100 distinct molecules altogether (although several other classes of molecules also provide guidance information for axons, including the neurotrophins and some classical morphogens). The netrins were first identified as attractive guidance cues which direct contralaterally projecting neurons toward the midline. The transmembrane proteins DCC and Unc-5 have been shown to act as receptors for netrin-1. Both netrins and their receptors are highly conserved between species. Netrin-1 is known to have a bifunctional role, typically attracting growth cones expressing only the DCC receptor but repelling growth cones expressing both DCC and Unc-5. The Slits and their receptors, the roundabout family (the Robos), were first identified as repellents preventing contralaterally projecting neurons from recrossing the midline. Subsequently, they were also shown to stimulate axon outgrowth and branching. The semaphorins appear to act primarily as short-range cues which repel axons from particular regions or, by forming the walls of corridors, hem axons into a preferred path. However, they have also been reported to act as long-range chemoattractants. Semaphorins are classified by their structure into eight groups. They signal through multimeric receptor complexes, with the precise structure of a complex determining its specificity for a semaphorin subgroup. Semaphorin receptor molecules include the neuropilins, the plexins, and the cell adhesion molecule L1. The ephrins are substrate-bound molecules best known for their role in the formation of topographic maps in the central nervous system. For example, the graded expression of the Eph tyrosine kinases – the ephrin receptors – in the retina combined with graded expression of the ephrins in the tectum aid in the formation of an ordered topographic mapping between the two structures. Similar strategies appear to orchestrate the formation of other topographic maps. Although ephrin/Eph signaling induces axon repulsion in these examples, under other contexts the ephrins can also act to attract axons.

The Growth Cone

Growing axons are tipped by special sensorimotor structures known as growth cones. These probe their local environment and, depending on the signals they detect, direct axon outgrowth, turning, branching, and pruning. Growth cones exhibit complex morphology, as illustrated in Figure 1. They are conceptually divided into three sections: an actin-rich peripheral region, a transitional region, and a central region containing organelles and microtubules. Fingerlike protuberances extending from the edge of the growth cone known as filopodia are supported by bundles of filamentous actin (F-actin). These appear to act as sensory devices, extending the effective

Figure 1 (a) Rat superior cervical ganglion neuron *in vitro*. The neuron was grown on a substrate of laminin for 48 h and then fixed and stained for β-tubulin. The cell body is at the bottom left, and the growth cone is at the top right. (b) Anatomy of the growth cone. This figure illustrates the division of the growth cone into three domains: transitional (T), peripheral (P), and central (C). The peripheral domain is rich in actin, which exhibits two forms of organization: loosely linked networks giving rise to lamellipodial structures and tight bundles supporting filopodia. The central domain contains organelles and microtubules which extend from the axon shaft into the growth cone. Rat SCG neuron image courtesy of Z Pujic.

sensing range of the growth cone. Structures based on more chaotic meshworks of F-actin are known as lamellipodia and have also been implicated in growth cone movement.

Growth cones undergo constant morphological change thought to be driven by remodeling of the actin network controlled by actin-binding proteins such as myosin, ARP2/3, and WASP. Growth cone motility appears to be driven by an 'actin treadmill.' Unpolymerized G-actin diffuses outward into the peripheral region and preferentially polymerizes near the cell membrane. The entire network of polymerized actin is drawn toward the central region by myosin and undergoes depolymerization in the transitional region. This constant cycle of polymerization, retrograde flow, and depolymerization is thought to generate traction when coupled to a permissive substrate through adhesion molecules.

Microtubules also play a significant, although unclear, role in growth cone motility and axon guidance. Interactions between microtubules and actin in the transitional region appear to have a strong influence on axon outgrowth and guidance.

Guidance cues influence growth cone behavior, and subsequent axon outgrowth, through cytoskeletal effectors activated or inhibited by cascades of intracellular second messengers triggered by receptor binding. Several molecules have been implicated as playing roles in this process, particularly calcium and the cyclic nucleotides cAMP and cGMP. These have been the focus of much attention, with the finding that, in some circumstances, changing the relative concentrations of these molecules within the growth cone can switch the effect of several guidance cues from attraction to repulsion or vice versa. Further intriguing findings have demonstrated that protein synthesis occurring locally within the growth cone is necessary for correct growth cone behavior.

Theoretical and Computational Models of Axon Pathfinding

Axon Extension and Branching

Experimental evidence suggests that tubulin molecules are synthesized only in the soma and then assembled into microtubules predominantly in the growth cone. This implies that axon outgrowth is limited by the rate at which microtubules can be transported to regions of active extension. A number of theoretical models have explored this idea, including various effects such as diffusive and active transport of tubulin monomers, competition between neurites for tubulin, viscoelastic stretching of axon segments, calcium-induced microtubule depolymerization, and varying intrinsic rates of tubulin polymerization and depolymerization within different growth cones. These models have been successively refined, ultimately incorporating compartment-based modeling with dynamic compartment allocation. Most strikingly, this modeling program has demonstrated that small variations in polymerization and depolymerization rates in the growth cones of different neurites can lead to sharp changes in elongation rate, including growth cone pausing and neurite retraction.

Growth cone behavior and axon extension are thought to be mediated by partially independent but related processes. This has led to modeling work

focused on characterizing the interaction between the two. The majority of this work has been phenomenological, using sophisticated mathematical machinery to better describe experimental data. Work in the mid-1980s showed that in some circumstances, axon elongation can be regarded as a one-dimensional random walk, with parameters varying with neuronal type, substrate, and chemical environment. In the mid-1990s, this was extended by performing correlation analysis which showed that axon outgrowth dynamics exhibit significant anticorrelation. Subsequent analysis showed significant correlation between the dynamics of microtubule polymerization in the central region and growth cone advance.

Growth Cone Morphology

The complex and dynamic nature of growth cone morphology further complicates our understanding of the contribution of growth cones to axon pathfinding. By statistically analyzing time-lapse images of growth cones undergoing dynamic changes in morphology, researchers have developed probabilistic rules specifying the likelihood of filopodial initiation and retraction, and also the spatial distribution of filopodia in terms of a limited number of parameters. In this model, growth cone morphology is described by the instantaneous length and angle of each filopodium, and the dynamics of the filopodia are characterized by the following parameters: the rate at which filopodia extend, the rate of retraction, the average rate at which new filopodia are initiated (modeled as a Poisson process), and the shape parameters for a gamma distribution that gives the time over which a filopodium extends before retracting. The model also specifies a simple conditionally random rule for where a filopodium initiates, and it assumes that filopodia extend radially from the center of the growth cone. Computer simulation then gives qualitatively realistic morphologies, which also satisfy quantitative constraints such as the correct average number of filopodia. By mapping the effects of external cues onto the parameters of the model, one can hope to gain some intuition as to how those cues might operate.

Other researchers have directly modeled the processes underlying actin dynamics in order to understand filopodial formation, stability, and behavior. This analysis indicates that the maximum length of a filopodium is determined by the number of bundled actin filaments in its core. For less than approximately 10 bundled actin filaments, the strain exerted on the bundle by the membrane is sufficient to cause buckling for even very short filopodia. As the number of included filaments increases, it becomes less likely that a filopodium will buckle; however, more G-actin is required for the structure to continue extending. Thus, when the number of filaments is too large, a filopodium is also unable to extend. The best tradeoff between stability and G-actin depletion is achieved with approximately 30 actin filaments. The model predicts average filopodia lengths between 1 and 10 μm, which are in agreement with experimental data. Similar work has examined the mechanisms behind lamellipodial structures.

Axon Turning and Guidance

Axons are thought to be guided by external cues through two processes: gradient-based guidance, in which the growth cone attempts to climb or descend a concentration gradient (chemoattraction or chemorepulsion), and contact-mediated guidance, in which the growth cone interacts with small regions of highly concentrated guidance cues and modulates its behavior accordingly. For gradient-based guidance, the growth cone must detect a potentially shallow gradient in the presence of noise, whereas for contact-mediated guidance the growth cone is essentially involved in a search process.

Gradient guidance Single cell chemotaxis – the attraction or repulsion of organisms such as bacteria, leukocytes, or slime molds by chemical gradients – has received a large amount of theoretical attention. Much of this can be directly applied to the case of the growth cone. Of particular relevance is a seminal contribution by Berg and Purcell, who argued that gradient detection by any small sensing device is fundamentally limited by statistical fluctuations, both due to variations in local ligand concentration and due to the inherent stochasticity of receptor binding. Growth cones are believed to sense and respond to gradients by comparing receptor binding across their spatial extent: the side of a growth cone exposed to the highest concentration of ligand will, on average, also display the largest amount of receptor binding. If growth cones do use such a spatial-sensing strategy, then in order for a growth cone to detect and reliably respond to a chemical gradient, the noise due to fluctuations in receptor binding cannot be much larger than the difference in receptor binding across its spatial extent. By modeling the physics of receptor–ligand interaction, one can estimate the limitations growth cones face when responding to chemical gradients. If the root mean squared error in a concentration measurement is given by σ_C, then the error associated with taking the difference between two such measurements is $\sigma_{\Delta C} = \sqrt{2\sigma_C}$. This gives an order of magnitude lower bound on the difference in concentration, ΔC, that the growth cone can

detect: $\Delta C_{min} \approx \sigma_{\Delta C}$. Using a simple model of receptor binding mechanics, it has been shown that for the timescale on which growth cone behavior usually occurs ($\sim$100 s), growth cones can detect gradients with a steepness of between 1% and 10%, depending on whether the guidance cue is diffusing freely or is substrate bound. However, over much longer periods (several days), experimental work has demonstrated that growth cones can respond to gradients of 0.2% or less across their spatial extent. Furthermore, at sufficiently high and low concentrations, almost all or almost no receptors are bound: this leads to further reductions in sensitivity. Experimental and theoretical work has confirmed that the highest sensitivity is achieved when approximately half of the receptors are bound, which occurs when the concentration is equal to the dissociation constant for binding.

Aside from these general constraints on gradient detection, models have also been developed which directly simulate the behavior of growth cones and axons in the presence of guidance cue gradients. Several models have focused on biochemical networks which are putatively responsible for growth cone motility and guidance. Such models are difficult to construct, partly due to the complexity of growth cone biochemistry and partly due to the lack of experimental data on important quantities such as reaction rate constants, concentrations, and interactions between molecular species. One model has focused on the Rho-GTPase signaling network, which is known to play an important role in actin-driven cell motility. Due to incomplete experimental data, the investigators took a qualitative approach, simulating the behavior of several plausible interaction networks and kinetic constants and using the results of these simulations to form hypotheses about the underlying mechanisms of growth cone motility. They found that the Rho-GTPase network undergoes a sharp transition in its dynamics when a threshold concentration of a particular signaling molecule is reached. The authors linked these two dynamic behaviors to different modes of growth cone motility, developing a model which could reproduce some experimentally observed phenomena.

Other models have placed less emphasis on specific biochemical mechanisms and have focused instead on the potential role of filopodia in axon guidance or on more general signal-processing strategies that a growth cone may implement, such as temporally or spatially averaging receptor inputs in order to reduce noise. Spatial averaging involves pooling the inputs from multiple receptors, whereas temporal averaging combines information from different time points. An interesting conclusion from this study is that spatial averaging provides the most benefit when the average is taken over approximately one-third of the growth cone's spatial extent. This optimum averaging range occurs because although spatial averaging reduces noise in a local concentration measurement, it also reduces the spatial resolution of the measurement. Because gradient detection requires concentration measurements to be made at multiple locations, the advantages gained in noise reduction are offset by the loss in resolution. Assuming growth cones use such a strategy, this has implications for the intracellular signaling network, suggesting that second messenger molecules implementing the spatial averaging process must diffuse at a rate much slower than expected for cytosolic compounds. One possibility is that spatial averaging is achieved through membrane-bound molecules.

In addition to detecting a chemical gradient, the growth cone must also amplify the possibly extremely shallow gradient in receptor binding in order to achieve a definite motile response. Understanding the mechanisms underlying this amplification has been a general focus for experimental and modeling work on microbial chemotaxis. In one influential model, amplification is achieved by coupling the external signal to a pattern formation system involving local activation and long-range inhibition. The system begins in a spatially symmetric, but unstable, steady state. Symmetry is broken by the external signal, which pushes the system into a stable, asymmetric state that reflects the direction in which the symmetry was broken. A difficulty with this approach is that the system then becomes stuck, unable to respond to new inputs such as a change in the external signal. Several additional mechanisms have been proposed to work around this, each postulating a second process which serves to reset the system to its original, unstable state. Further generalizations of this class of models suggest mechanisms for the formation of filopodia and generate testable predictions for the spatiotemporal distribution of such structures.

Contact-mediated guidance Axons are also guided by cues which are more tightly localized in space, referred to as short-range or contact-mediated cues. For example, filopodial contact with single cells expressing appropriate cues can entirely redirect an axon's trajectory. For this kind of guidance, noise is less of an issue because the signal is essentially binary: either the growth cone contacts the cue or it does not. In this situation, an appropriate theoretical framework is that of stochastic search. The question of how filopodial dynamics of the growth cone affects its ability to locate and respond to highly localized guidance cues has been addressed with the aid of the models describing growth cone morphology in terms of filopodial dynamics. The efficacy with which a growth cone is able to locate a guidance cue has been mapped against

the parameters defining the dynamics, suggesting some behaviors one might expect to observe depending on the geometry of the guidance cue distribution. This work suggests that filopodial dynamics are set, and possibly modulated, in order to increase a growth cone's ability to detect and respond to relevant cues. In a more abstract approach, growth cone movements were described by a combination of stochastic (e.g., deflection by random adhesion to the substrate) and deterministic (e.g., a tendency to move in the direction of past axon extension) motions. The growth cone was found to more effectively respond to short-range guidance signals when the two processes contributed equally. This prompted the authors to propose that growth cones modulate the relative influence of stochastic and deterministic movements depending on the importance of short-range cues at different stages in development – a suggestion consistent with experimental observations of growth cone behavior.

Axon–Axon Interactions

The models described so far consider the guidance of single neurons in isolation. However, the development of the nervous system involves the correct guidance of many axons simultaneously, and it is well established that axons use one another as additional sources of information during development. One of the earliest computer models of axon guidance attempted to explain the characteristic 'sheetlike' pattern of axon outgrowth observed in the formation of the ventral commissure of the spinal cord. Using a descriptive model of individual axon behavior, including several experimentally observed features of ventral commissural axon growth – a tendency for straight growth, for initial outgrowth to be directed ventrally, and for growing axons to extend preferentially over the surrounding matrix and not other axons – this work attempted to distinguish the most important features of individual axon behavior for the formation of axon sheets. From computer simulations, the authors concluded that initially polarized outgrowth, a suitably high density of neurons, preferential adhesivity for extension over the substrate rather than other axons, and a tendency for straight growth were sufficient to generate the observed patterns. Another model examined the possibility that growth cones secrete diffusible guidance cues in order to attract or repel one another to create or break up axon bundles.

Topographic Map Formation

A specific example of axon guidance that has been well studied theoretically is the formation of the topographic map between the retina and optic tectum/superior colliculus. In 1963, Roger Sperry first proposed that such maps could arise because gradients of molecular labels in the retina are matched to gradients of labels in the tectum. The subsequent discovery of gradients of Eph receptors and their ligands, the ephrins, in the retina and tectum confirmed this prediction. However, a large number of experiments investigating how such matching might work in detail have suggested that several other constraints are also important. Since the 1970s, numerous theoretical models of such map formation have been proposed in order to gain insight into this complexity. Some of the simplest propose sorting mechanisms, whereby an initial random map is refined by comparing the retinal origin of axons terminating at neighboring sites in the tectum. Others have hypothesized that tectal labels are at least partly induced or modified by transport of retinal labels into the tectum. Several models have highlighted the importance of competition in map formation, both between axons for tectal target space and between tectal targets for axons. Another important theme has been cooperative effects between axons, somewhat similar to the axon–axon interactions discussed previously. Increasing data on the precise role of Eph/ephrins in map formation have provided new challenges for such models, many of which are yet to be addressed.

Guidance Cue Patterning

A further area of active research aims to understand how guidance cue patterns are generated in the first place, and how effectively particular patterns can guide axons. The modeling of gradient systems in developing organisms has a long history, and gradients are thought to be a primary means for generating spatial ordering. In general, molecules expressed as gradients in order to provide spatial information are known as morphogens, and several classical morphogens have been shown to also guide axons.

A number of models have been proposed to explain how gradients of appropriate shape and stability could be set up. The simplest model assumes that the molecule of interest is diffusing away from a continuous source through a homogeneous medium. More complex models recognize the inhomogeneous nature of the medium, degradation of molecules, binding of molecules to cells, endocytosis, and active transport processes. A further complication which arises when attempting to generalize results from one experimental model to another is that of scaling: gradients form on a typical length scale, and different species have embryos of different sizes at developmental stages when axon wiring is forming. Hence, a system which works in one embryo may not work in another.

Additional constraints are placed on the formation of gradients useful for axon guidance. The ability of a

growth cone to detect and respond to a gradient varies with background concentration and gradient slope. The minimum gradient that a growth cone can detect over a particular background concentration specifies limitations on gradient-based guidance. It allows the construction of optimal gradients, in which the gradient slope is always equal to the minimal detectable gradient for the growth cone. Following this line of argument, coupled with estimates of parameters central to the model, it can be shown that the maximum distance over which growth cones can be guided by an optimal gradient is on the order of 1 cm.

Future Directions

This article provided an overview of the kinds of models which have been applied to axon guidance and how these have helped us to understand axon pathfinding. However, research of this kind is still at an early stage. Important questions remain to be answered and are the focus of active research. For instance, how sensitive can growth cones be to gradients of guidance cues? How close do they come to achieving fundamental sensitivity limits? What are the actual mechanisms they use to detect gradients? How do developing neurites integrate information from multiple guidance cues? What searching strategies do growth cones use to locate local guidance cues? What roles do axon branching and pruning play in axon guidance? How do microtubules and the F-actin cytoskeleton interact to support axon outgrowth and steering? How much of a role do axon–axon interactions play in the formation of the nervous system, and when are they important?

In addition to fresh modeling approaches, answering these questions will require significant experimental advances. A wealth of experimental data is available on axon guidance, but most studies have been aimed at identifying guidance cue molecules or intracellular molecules mediating or eliciting particular behaviors. Although such data are obviously crucial, in order to generate sufficiently constrained models, data of a more quantitative nature are needed. Recognizing this need, experimental techniques for producing well-controlled and flexible patterns of guidance cues have been developed. Ultimately, these techniques should allow us to develop better constrained models and, using them, obtain additional power to tease apart the mechanisms and principles underlying axon guidance.

Finally, the discovery that new neurons are constantly being born in adult brains opens up another area for exploration. These nascent neurons must somehow find their way to their appropriate niches and extend axons to make functional connections. Modeling axon guidance thus has a central role to play in understanding both the initial development and the normal functioning of the nervous system.

Axonal Pathfinding: Extracellular Matrix Role

P Letourneau, University of Minnesota, Minneapolis, MN, USA

Introduction

Normal behavior and other neural activities depend on the correct wiring of neural circuits during development. A critical step in forming neural circuits is the growth of axons from nerve cell bodies to the sites where synaptic connections are made. In spanning between neural somata and their synaptic targets, growing axons forge pathways that become the axonal tracts and peripheral nerves of the mature nervous system. The routes that axons take to reach their targets are determined by motile activities at their tips, called growth cones. Growth cones extend fine protrusions that adhere to nearby cells and surfaces. These adhesive contacts provide a toehold from which further protrusions are made. As growth cones crawl forward, they choose a path by detecting and responding to the spatial and temporal distributions of extracellular guidance molecules encountered in their local environments. Five major families of extracellular molecules – netrins, neurotrophins, semaphorins, slits, and ephrins – provide positive and negative cues that orient the migration of growth cones to their targets. These guidance molecules bind receptor proteins on growth cones and initiate cytoplasmic signals that regulate the motility and adhesive contacts that determine the advance, retreat, turning, branching, and stopping of growth cones. This article describes molecules that play a key role in axonal pathfinding by mediating the adhesive interactions necessary for growth cone migration.

Mechanism of Growth Cone Migration

Cytoskeletal Dynamics

Growth cone migration and axonal elongation involve the cytoskeletal components, microtubules and actin filaments. Axon elongation requires the advance and polymerization of microtubules, which are bundled in the axon but which spread apart in the growth cone, where individual microtubules dynamically probe forward to the front of a growth cone via polymerization and movement involving microtubule motor molecules (Figure 1). Axonal growth occurs where the main microtubule bundle and associated organelles advance in the growth cone, as determined by the positions and stabilization of these forward 'pioneering' microtubules. These dynamic microtubules project forward into an actin filament network that fills flattened dynamic projections, called lamellipodia, and fingerlike filopodia. This extensive filament system is continually remodeled, as actin filaments initiate and polymerize at the front margin and are then moved back to be fragmented and depolymerized, recycling subunits to the front. Multiple actin-binding proteins regulate this dynamic organization of actin filaments.

Growth cone migration is driven by forces produced within this actin filament domain. Actin polymerization creates protrusive forces that expand lamellipodia and elongate the tips of filopodia. Myosin motor molecules bind actin filaments and generate mechanical forces that move cargo bound to the myosin tail domains or pull on actin filaments to create tensions. Myosin II motor activity pulls actin filaments rearward, where they are depolymerized. Tensions generated by myosin II activity in the actin-rich leading margin can either direct or halt microtubule advance, depending on the situation. Myosin II-generated tensions produce the exploratory movements of lamellipodia and filopodia, whereas excessive levels of tension may sweep microtubules back in a contracting actin network that can collapse a growth cone. It is in the context of these dynamic cytoskeletal activities that adhesive interactions are critical to growth cone migration (Figure 2).

Adhesive Contacts of Growth Cones

Growth cone plasma membranes contain adhesion receptors that bind noncovalently to adhesion molecules on other cells or surfaces. Lamellipodia and filopodia initiate adhesive interactions as they explore their environment, and if these bonds persist, receptors cluster to form discrete adhesive contacts, which include intracellular adhesion complexes. Adhesion complexes remain in place or shift rearward as a growth cone advances. These adhesive complexes play two roles in growth cone migration. First, they include proteins that anchor actin filaments at adhesive sites. These links constitute a 'clutch' that stops the retrograde movement of actin filaments and permits the advance of microtubules and axonal organelles (Figure 2). Without stabilization provided by adhesive contacts growth cone migration fails, and tensions within the axonal cytoskeleton cause axonal retraction. Second, these complexes include proteins of signaling cascades, protein kinases, protein phosphatases, and Rho GTPases, which act on proteins that regulate the organization of actin filaments and microtubules. Thus, adhesive contacts provide points

Figure 1 The distribution of microtubules and actin filaments in developing neurons and in axonal growth cones. Microtubules (green) are densely packed in the neuronal cell bodies (S) and are bundled in the axons and branches. Actin filaments are arrayed in filament networks and bundles in the peripheral domains (P) of the growth cones and along the shafts of the axons, where small areas of actin filament dynamics may give rise to collateral branches (B). In a growth cone, the microtubules from the central bundle of the central domain (C) splay apart and individual microtubules extend into the P domain and into filopodia (arrows).

Figure 2 A model of the mechanism of growth cone migration. Actin polymerization pushes the leading margin of the growth cone forward. Forces generated by myosin II pull actin filaments backwards, where filaments are disassembled. When growth cone receptors make adhesive contacts with a surface, a 'clutch' links the adhesive contact to actin filaments of the leading edge, and the retrograde flow of actin filaments stops. This permits the advance of microtubules and organelles and promotes axonal elongation. Intracellular signaling generated by attractive and repulsive axonal guidance cues interacts with the molecular mechanisms of actin polymerization, myosin II force generation, adhesive contacts, and microtubule advance to regulate the paths of growth cone migration.

of stability that are essential to growth cone migration, and they are signaling centers from which regulatory activities promote growth cone motility.

The genetic regulation that determines neuronal phenotype also directs expression of receptors for adhesive ligands and guidance cues by the growth cones of neurons of a particular type. Extracellular positive and negative axonal guidance cues, whether surface bound or soluble, signal through their receptors to modulate an interacting set of pathways that regulate cytoskeletal and membrane dynamics. Thus, growth cone behaviors reflect a complex integration

of signaling events triggered at multiple receptors for guidance cues and adhesion molecules. By locally regulating the interplay of adhesive contacts and cytoskeletal dynamics within a growth cone, guidance cues determine the pathways of axonal growth (Figure 2).

Three major types of adhesive interactions promote growth cone navigation. Growth cones migrate within extracellular spaces that contain a complex mixture of glycoproteins, organized into an extracellular matrix (ECM) of fibers, protein aggregates, and basal laminae, which are discrete ECM layers at tissue interfaces. One major adhesive interaction of growth cones involves binding of integrin receptors to adhesive ECM proteins, especially the laminins. Two other major adhesive interactions involve growth cone contacts with cells or other axons along their pathways. These interactions involve two groups of adhesive molecules, the cadherins and the immunoglobulin superfamily of cell adhesion molecules (IgCAMs). Cadherins are expressed on all tissue types, including neurons and axons. Cadherin adhesions involve homophilic binding between like cadherin molecules on two interacting cells. Weaker heterophilic interactions between different cadherins can also occur. IgCAMs are also expressed on all tissues, including neurons. Adhesive interactions of IgCAMs can involve homophilic interactions, similar to cadherins, but also heterophilic interactions in which an IgCAM on a growth cone binds a different IgCAM on adjacent cells. Even heterophilic interactions of IgCAMs with non-IgCAMs occur.

Integrin adhesion receptors Integrin receptors are heterodimers of alpha and beta subunits. More than 20 integrin heterodimers have been identified in humans. The binding specificity for ECM components depends on the particular combination of alpha and beta subunits in a heterodimer. The 12 integrin dimers that are expressed in the mammalian nervous system include receptors for collagens, laminin-1 and laminin-5, fibronectin, tenascin, thrombospondin, vitronectin, and VCAM-1. A growth cone can express multiple integrins, allowing interactions with multiple ECM molecules. The cytoplasmic domains of integrins lack enzymatic activities, but when integrins bind adhesive ligands, conformational shifts in the cytoplasmic domains trigger formation of focal contacts that involve integrin clustering and creation of docking sites for proteins that initiate signaling and links to the cytoskeleton. When lamellipodia and filopodia of growth cones bind laminin-1, proteins that localize to the contact sites include paxillin, talin, vinculin, zyxin, and focal adhesion kinase (FAK). Vinculin and talin link actin filaments to the adhesive contacts, providing a clutch for growth cone migration (Figure 3). The presence of the adapter protein paxillin and activation of FAK initiates further protein interactions and signaling by Src family kinases, MAP kinases, and Rho GTPases. Activation of Rac1 and Cdc42 GTPases promotes actin polymerization by regulating actin-binding proteins and actin filament dynamics. Thus, when integrins on growth cones bind laminin-1, growth cone migration is stimulated by increased actin filament polymerization to protrude the leading margin and by the establishment of adhesions to stabilize these protrusions and promote the advance of microtubules.

Cadherins and IgCAMs Stimulation of N-cadherin and IgCAMs, such as NCAM and L1, by ligand binding between cells leads to activation of the FGF receptor tyrosine kinase, which triggers signals involving PLC-gamma, DAG lipase, cytoplasmic [Ca^{2+}] elevation, and activation of MAPK. IgCAMs also signal via Src kinases to activate Rac1, PI3K, and MAPK. Cadherin signaling is also reported to activate Rac1. Thus, several pathways activated by cadherins and IgCAMs promote actin filament polymerization. Adhesive binding of cadherins and IgCAMs provides anchorage for actin filaments, creating the clutch necessary for growth cone migration. The cytoplasmic tails of many cadherins, such as N-cadherin, bind catenins, which bind actin filaments and link N-cadherin adhesive sites to the actin cytoskeleton in growth cones (Figure 4). The cytoplasmic domain of L1 binds the cytoskeletal linker ankyrin, but L1–ankyrin interactions are involved in stable adhesive junctions, such as at nodes of Ranvier, and not in growth cone migration. Members of the ezrin–moesin–radixin (ERM) proteins mediate actin filament binding to membranes, and interactions of L1 (and other IgCAMs) with ERM proteins may serve as a clutch in growth cone protrusions that bind via L1 or other IgCAMs.

These adhesion receptors can be regulated in ways that are important to growth cone pathfinding. The expression levels of integrin receptors on growth cones are increased when laminin levels are low or when ECM proteins, such as proteoglycans, which interfere with laminin–integrin binding, are present. These responses would maintain growth cone adhesion and migration in environments when access to laminin is reduced. L1 is endocytosed from central regions and recycled to the leading margin of growth cones, increasing availability of L1 for adhesive contacts of lamellipodia and filopodia. The functions of adhesion receptors can also be modulated from the cytoplasm in an 'inside-out' manner or via *cis* interactions with other components of the plasma membrane. An important manner in which guidance

Figure 3 A model of integrin binding to ECM molecules and the formation of intracellular adhesive complexes. An alpha–beta integrin heterodimer is shown bound to a collagen fibril, and the intracellular adhesion complex is pictured, showing the proteins vinculin and talin, which are involved in linkage to actin filaments, and FAK kinase, which initiates signaling cascades. The Arp2/3 complex nucleates actin filament assembly. Reproduced from Brakebusch C and Fässler R (2003) The integrin–actin connection, an eternal love affair. *EMBO Journal* 22: 2324–2333, with permission from Nature Publishing Group.

molecules exert their positive and negative effects on growth cone pathfinding is by modulating the functions of adhesive receptors (Figure 2). For example, the negative cue semaphorin 3A may inhibit growth cone migration by blocking integrin-mediated cell adhesion. In addition, adhesion mediated by N-cadherin is inhibited by the negative guidance cue Slit protein via its receptor, Robo. Thus, the negative or repulsive effects of semaphorin 3A and Slit on growth cone pathfinding can involve these inhibitory effects on growth cone adhesion. On the other hand, the attractant netrin signals to activate the kinase FAK, which promotes integrin-mediated adhesion, suggesting that positive guidance cues activate adhesive interactions of growth cones.

Adhesion Molecules and Growth Cone Pathfinding

What are the roles of these adhesion molecules in the pathfinding behaviors of growth cones? Major pathways that are followed by many growing axons offer multiple adhesive ligands for growth cone migration, such as laminins, fibronectin and collagens in the ECM, and cadherins and IgCAMs on adjacent cells and axons. These multiple options for adhesion may provide redundancy, ensuring growth cones form sufficient adhesive contacts for effective migration. The first growth cones that 'pioneer' a pathway have limited options for binding to ECM or cell surface adhesion molecules on adjacent cells, whereas growth cones that enter an established pathway can track along previously extended axons by binding to cadherins and IgCAMs expressed on the surfaces of axonal shafts. Several *in vivo* examples of pathfinding roles of adhesion molecules are described in the following sections.

Laminins

Laminins are large adhesive glycoproteins (MW 1 000 000 Da) that consist of heterotrimers of alpha, beta, and gamma chains. Ten laminin chains are known, forming 11 known heterotrimers with widely varied expression throughout different tissues. The laminins present several domains that mediate laminin binding to several cell surface receptors and to other ECM components. The most common laminins are typically present in basal laminae, an ultrastructural ECM layer associated with epithelia, muscle cells, Schwann cells, and glia. Laminin-1, which has been studied the most, promotes axonal growth *in vitro* from virtually every type of neuron, indicating that laminins have broad roles in promoting growth cone migration. Examples of growth cone migration along basal laminae include growth cones of Rohon–Beard

Figure 4 A model of homophilic adhesion between cadherin adhesion molecules and the intracellular binding to actin filaments. Cadherin molecules bind between cells and become linked to actin filaments by way of interactions with alpha and beta catenins. From Weis WI and Nelson WJ (2006) Re-solving the cadherin–catenin–actin conundrum. *Journal of Biological Chemistry* 281: 35593–35597.

neurons in *Xenopus*, growth cones of retinal ganglion cells in the retina and optic nerve, and pioneer axons in the grasshopper limb bud. However, in addition to basal laminae, laminin is transiently expressed in the loose cellular environments of developing tissues, including the nervous system, on cell surfaces and associated with sparse ECM fibers. The growth cones that pioneer pathways, such as the corticofugal pathway of the neocortex or the medial longitudinal fasciculus from the brain into the spinal cord, migrate within loose extracellular spaces in the wall of the immature central nervous system (CNS), where the cells are labeled in a punctate manner by laminin antibodies. The expression of laminin on these cells is transient, and eventually laminin immunoreactivity is restricted to the basal lamina at the outer boundary of the CNS wall. In the developing peripheral nervous system (PNS), laminin is expressed in basal laminae and at early stages in the mesenchyme through which motor and sensory axons extend. Schwann cells express abundant laminin, forming the basal laminae that enclose axon–Schwann cell units. This punctate cellular expression of laminin diminishes during development, although laminin remains present in basal laminae.

In view of the wide distribution of laminins and the ability of laminin-1 to promote robust axonal growth from many neuronal types, it is thought that laminins function permissively, providing adhesion that is required for growth cone migration, but not in an instructive manner to influence pathfinding decisions. Laminins and other ECM molecules may broadly promote growth cone migration along a pathway, whose boundaries are defined not by the absence of adhesive ECM molecules but, rather, by the expression in adjacent tissues of negative guidance cues, such as slits or semaphorins. This 'surround repulsion' occurs in both developing CNS and PNS. Several mutational studies have reported specific errors in pathfinding when a laminin is absent or blocked. Laminin function is essential for growth cone turning in the grasshopper limb bud, and zebra fish with mutations in the laminin-alpha-1 chain exhibit multiple axon guidance defects throughout the CNS, but not in every location. These results suggest that laminin-mediated adhesion is essential for growth cone navigation in at least some instances.

Fibronectin

Fibronectin is a large adhesive glycoprotein (MW 250 000 Da) that is widely distributed in the ECM, including within ganglia and the endoneurium of the PNS. Like the laminins, the fibronectin molecule contains multiple domains that mediate binding to other ECM components and to multiple cellular receptors, including several integrin heterodimers. During development of the PNS and CNS, fibronectin is present in a punctate distribution in loose cellular spaces of immature nervous tissue, and eventually fibronectin expression diminishes as development ends, especially in the CNS. In tissue culture studies, fibronectin promotes axonal growth, but not as vigorously as does laminin. In addition, axonal growth by PNS neurons on fibronectin surfaces exceeds the responses of CNS neurons, probably because PNS neurons express higher levels of fibronectin receptors than CNS neurons. Evidence is lacking for a requirement for fibronectin in growth cone pathfinding.

Integrins

Because neurons express multiple integrin subunits and because many ECM components, such as collagen, laminin, or fibronectin, can bind more than one integrin heterodimer, the essential roles of particular integrins in growth cone pathfinding are not clearly defined. Mouse knockouts of α_1 and α_6 integrins,

which are laminin-1 receptors, do not reveal clear defects, however, injections of anti-β_1 integrin, part of several neuronal receptors for ECM proteins, into *Xenopus* embryos disrupts retinal axonal pathfinding. Similarly, conditional knockout of β_1 integrin in sensory neurons results in deficits in innervation of skin, where sensory axons extend through the dermal ECM and along the epidermal basal lamina. The α_4ß$_1$ integrin heterodimer is specifically implicated in the growth and arborization of sympathetic axons within cardiac muscle. In *Drosophila*, mutations in the integrins α-PS1 and-PS2 lead to pathfinding errors.

Cadherins

Cadherins are characterized as single-pass transmembrane proteins that contain an ectodomain of five cadherin repeats and a conserved cytoplasmic tail. Binding of calcium ion stabilizes an extended rodlike structure of the ectodomain, which is necessary for optimal adhesion by alignment of cadherin molecules on apposing cells. There are at least 100 cadherins, and most are expressed in the developing vertebrate brain on immature cells, neurons, and glia. Their functions are numerous, including cell sorting, boundary formation, target recognition, synaptogenesis, and synapse function. Regarding axonal pathfinding, the widely expressed N-cadherin stimulates *in vitro* axonal growth from a variety of CNS and PNS neurons. *In vivo* studies involving antibody injection or genetic mutation also implicate N-cadherin in axon growth and fasciculation. These results indicate that cadherins promote growth cone migration along axons in highly populated common pathways, but it is unclear whether cadherins play a role in the pathfinding of early pioneer growth cones. In some cases, a common pathway may be shared by several classes of elongating axons, which are distinguished by the expression of different cadherins. For example, the tectofugal projections of chickens express four different cadherins among different axon fascicles. These cadherins may mediate specific pathfinding, as the formation of homophilic adhesions of growth cones to axons expressing the same cadherin directs growth cones along specific axon fascicles toward their targets. Forced expression of specific cadherins causes growth cones to abnormally follow fascicles that express the same cadherin. Finally, growth cones often share expression of specific cadherins with neurons in their particular target. Thus, cadherins also have roles in target recognition and subsequent synaptogenesis.

L1 and NCAM IgCAMs

Proteins that contain an immunoglobulin (Ig)-like domain constitute the Ig superfamily, which makes up more than 2% of human genes, constituting the largest gene family. The neuronal Ig superfamily includes a large number of molecules, which have functions in axonal pathfinding not only as cell adhesion molecules but also as axonal guidance cues and as receptors of guidance cues. This discussion is restricted to two members of this large family, L1 and NCAM. The IgCAM L1 is widely expressed on axons in the developing CNS and PNS, and tissue culture studies show that substrates coated with L1 promote homophilic adhesion and axonal growth from many neuronal types. Spontaneous human mutations in the L1 gene and mouse L1 knockout studies both indicate important roles for L1 in brain development and function. Multiple anatomical and functional deficits result from human and mouse L1 mutations, including a failure of corticospinal axons to decussate in the hindbrain pyramids. Crossing defects were not found in other tracts or were not so extensive. L1 also interacts in *cis* with receptors for other guidance cues, including the semaphorin 3A receptor, suggesting that the defect in pyramidal decussation observed in L1 mutants could be due to disrupted pathfinding responses to semaphorin 3A and other guidance cues, as well as to reduced growth cone tracking along axons.

Another prominent neuronal IgCAM is NCAM, the first neuronal IgCAM identified. NCAM is widely expressed on immature neurons and glia and also on other embryonic cells, such as myoblasts. In tissue culture studies, NCAM mediates neuronal adhesion and axon growth. In addition to homophilic adhesive interactions, NCAM also forms heterophilic adhesive interactions. Antibodies against NCAM can induce axon defasciculation *in vitro* and *in vivo*. Several isoforms of NCAM are expressed, and in some situations NCAM carries a carbohydrate polysialic acid (PSA) moiety that reduces NCAM adhesion. In NCAM-deficient mice defects in fasciculation of hippocampal axons were observed, but in general only minor defects in development or behavior were observed. Perhaps, in the absence of NCAM, other cell adhesion molecules serve the same functions.

Adhesion Molecules and Axonal Regeneration

When the pathfinding phase of circuit construction ends, as growth cones reach their targets, the expression of neural cell adhesion molecules and their receptors is downregulated. However, injury or damage to nervous tissues can disconnect neural circuits, and axons must regenerate in order to reconnect neurons. When axons are injured in the PNS, axon regeneration is often robust, leading to varying degrees of functional recovery. Schwann cells, which ensheath all PNS axons, stimulate axonal regeneration by upregulating their expression of growth factors, and

laminins, fibronectin, and cadherin, as substrates for growth cones. Axon regeneration in the PNS is also promoted by increased expression of integrin receptors by regenerating neurons. In the CNS of adult mammals, regeneration of injured axons is poor, and recent research has focused on inhibitory components of myelin and glial scars that block growth cone adhesion and trigger signals that inhibit growth cone motility. In lower vertebrates, CNS regeneration is often successful, and this involves the upregulation of expression of adhesive ligands, such as L1 and cadherins, as demonstrated in regenerating zebra fish optic nerves and spinal cords.

Several strategies for improving axonal regeneration in mammalian model systems, and eventually humans, emphasize measures to improve the adhesive environment for growth cone migration. When stem cells that express L1 are transplanted into a mammalian CNS lesion, increased regeneration of corticospinal axons occurs. Purkinje cells transfected to express L1 and GAP43 show enhanced axonal regeneration. *In vitro* regeneration of axons by adult neurons on laminin and fibronectin is improved by transfection of neurons to express increased levels of the appropriate α integrin chains. Finally, many natural and synthetic bridges have been designed that include adhesion molecules to promote axonal regeneration across lesion sites. These studies demonstrate that strategies to increase the adhesive interactions of regenerating growth cones can stimulate axonal regeneration after injuries in adults. Probably, improved axonal regeneration in adults will also require an increase in the intrinsic ability of adult neurons to sprout and grow axons. This may involve upregulation of genes for adhesion receptors, for other guidance cue receptors, and for proteins that drive the dynamic cytoskeletal functions of immature neurons.

Summary

Growth cone adhesion is integral to the mechanism of growth cone migration and pathfinding. Adhesive interactions of growth cones provide stability for lamellipodial and filopodial protrusions of growth cones and also act as signaling centers that regulate actin and microtubule dynamics and organization in a migrating growth cone. The adhesive interactions of growth cones are also a target of guidance cues that determine where growth cones turn, branch, and stop migrating. Migrating growth cones make three kinds of adhesive contacts with ECM and with other cells. These contacts involve integrin receptors, which recognize laminin and other ECM components; cadherins, which form homophilic adhesions; and IgCAMs, which can form homophilic and heterophilic adhesive interactions. Major pathways of growth cone migration during development contain one or, perhaps more typically, multiple adhesive ligands available to growth cones. The navigational decisions of growth cone pathfinding are based on local differences in adhesive stability for growth cone protrusions and in dynamic protrusive activity, as based on adhesive signaling and the integration of signaling triggered from other guidance cues.

Introduction

Over the past decade, genetic, biochemical, and molecular approaches have led to the identification of four major conserved families of guidance cues with prominent developmental effects: the netrins, slits, semaphorins, and ephrins. More recently, members from three other families of secreted signaling molecules have been shown to act as guidance cues: the wingless/Wnt, the hedgehog (Hh), and the decapentaplegic/bone morphogenetic protein/transforming growth factor-β (Dpp/BMP/TGF-β) families. In addition to their axon guidance properties, these molecules share a common characteristic of having been previously identified as morphogens controlling cell fate and tissue patterning. This discovery has opened the door to the study of an entirely new set of axon guidance cues.

This article focuses on the role of the morphogen Shh in axon guidance. After briefly introducing the role and the signaling pathway of Shh in patterning the neural tube, we discuss the emerging evidence that Shh is reused later in development to guide axons, both in the developing spinal cord and the retina. We conclude by discussing the implications for Shh signaling in axon guidance.

The Hedgehog Family in Cell Fate Specification and Tissue Patterning

Morphogens are signaling molecules produced in a restricted region of a tissue; they provide positional information by diffusing from their source to form long-range concentration gradients. A cell's program of differentiation in response to a morphogen is dictated by its position within the gradient and thus on its distance from the morphogen source. Two criteria have gained acceptance as the evidence needed to qualify a secreted signaling protein as a morphogen: it must have a concentration-dependent effect on its target cells and it must exert a direct action at a distance. In vertebrates, Sonic hedgehog (Shh) has been shown to fulfill these criteria and function as a morphogen to specify cell fate in the developing neural tube.

Hedgehog proteins are found in insects and vertebrates, but not nematodes. They are encoded by a single hedgehog gene in flies, and three in mammals: *Shh*, Indian hedgehog (*Ihh*), and Desert hedgehog (*Dhh*). In vertebrate embryos, one of the first steps in the development of the nervous system is the specification of the diverse neural cell fates of the neural tube. Shh is secreted by the notochord and by floor plate cells at the ventral midline of the neural tube, and functions as a graded signal for the generation of distinct classes of ventral neurons along the dorsoventral axis of the neural tube (Figure 1(a)). In agreement with its role as a morphogen, Shh is able to induce a range of ventral spinal cord cell fates in a concentration-dependent manner and has been shown to exert a direct action at a distance to specify neural tube cell fate.

Much evidence indicates that the cell fate specification and tissue patterning activities of Hhs are mediated by members of the Ci/Gli transcription factor family, but the signaling mechanisms that lead to activation of these transcription factors are not fully elucidated. Genetic and biochemical experiments have shown that Hhs activate signaling by binding to their receptor Patched (Ptc), which leads to the relief of Ptc-mediated inhibition of Smoothened (Smo), also a transmembrane protein, which can then activate downstream signaling (Figure 2). Smo associates directly with a Ci-containing complex, which contains the atypical kinesin Costal-2 (Cos2), the protein kinase Fused (Fu), and the Suppressor of Fused (Su(fu)). This complex constitutively suppresses pathway activity. Activation of Hh signaling reverses this regulatory effect and allows Ci to activate transcription of Hh target genes, thus specifying cell fate.

Roles of Shh in Axon Guidance

Shh Is a Chemoattractant for Commissural Axons

During spinal cord development, commissural neurons, which differentiate in the dorsal neural tube, send axons that project toward and subsequently across the floor plate, forming axon commissures (Figure 1(b)). These axons project toward the midline in part because they are attracted by netrin 1, a long-range chemoattractant secreted by the floor plate. In mice mutant for *netrin 1* or the netrin 1 receptor gene, *Dcc* (*deleted in colorectal cancer*), many commissural axon trajectories are foreshortened, fail to invade the ventral spinal cord, and are misguided. However, some of them do reach the midline, indicating that other guidance cues cooperate with netrin 1 to guide these axons. Further analysis of *netrin 1* knockout

Figure 1 Neuronal cell fate specification and guidance of precrossing commissural axons by Sonic hedgehog (Shh) and netrin 1; cross-section representations of the developing neural tube. Shh is first used to pattern neural progenitors in the spinal cord and then appears to be reused as a guidance cue for commissural axons. (a) In the early neural tube, Shh – together with bone morphogenetic protein (BMP) and Wnt – protein concentration gradients act to specify neural cell fate in the ventral (and dorsal, for BMP and Wnt) spinal cord. (b) Later, the axons of differentiated commissural neurons are attracted to the ventral midline by the combined chemoattractant effects of netrin 1 and Shh. BMPs also contribute to commissural axon guidance by repelling axons from the dorsal midline. V0–V3, ventral interneuron subpopulations; dI1–dI6, dorsal interneuron subpopulations; MN, motor neurons; RP, roof plate; FP, floor plate; D, dorsal; V, ventral; P, posterior; A, anterior. mice suggests that the floor plate might actually express an additional diffusible attractant(s) for commissural axons.

Given its expression by the floor plate and its long-range effects in the spinal cord, Shh was a candidate for a midline-derived axonal guidance cue. Shh was indeed shown to function as an axonal chemoattractant that can mimic the netrin-1-independent chemoattractant activity of the floor plate in *in vitro* assays. The chemoattractant activity of Shh, like the chemoattractant activity of floor plate derived from *netrin 1* mutants, can be blocked by cyclopamine, which blocks the actions of Shh in cell fate determination by inhibiting the Shh signaling mediator Smo. This shows that Smo is required for Shh-mediated axon attraction and, importantly, that the netrin-1-independent chemoattractant activity of the floor plate also requires Hh signaling. Since Shh is the only Hh family member expressed in the spinal cord at this stage, these results suggest that Shh functions as a floor plate-derived chemoattractant for commissural axons.

While the reorienting effect of Shh could be due to a direct chemoattractant effect, an alternative explanation was suggested by the fact that Shh is a potent morphogen. Since in these assays commissural axon turning occurs within the spinal cord tissue explant, it seemed possible that Shh was not acting directly on the axons but rather was repatterning and altering the expression of guidance cues by cells within the explant, which then secondarily guided the axons to the Shh source. Arguing against this possibility was the finding that the spinal cord explants used to assess chemoattractant activity are at a developmental stage at which they have apparently lost the competence to be repatterned by Shh, as assessed using a battery of markers of dorsoventral patterning.

A direct action of Shh in attracting the axons was supported further by two sets of experiments. First, Shh was shown to attract the growth cones of isolated *Xenopus* spinal axons in dispersed cell culture in a cyclopamine-dependent manner, proving that Shh, acting via Smo, can function as a chemoattractant, at least for these *Xenopus* axons. A second way of providing evidence that Shh can act directly on commissural axons to guide them relied on blocking Shh signaling selectively in commissural neurons without blocking it in the terrain through which their axons course. This was achieved by conditional inactivation of a floxed allele of *Smo* using the Cre recombinase

expressed under the control of the Wnt1 promoter, which drives expression in the dorsal spinal cord (as well as in neural crest progenitors). When Cre, driven by this promoter, was used to delete a floxed *Smo* allele in the dorsal spinal cord, commissural axon trajectories were defective in the ventral spinal cord, where Cre is not expressed (Table 1). This result strongly implies that the axonal misrouting is not due to repatterning of the ventral spinal cord, and must instead reflect a guidance defect arising from loss of Smo function in commissural neurons. Taken together, these results suggest that Shh functions to guide commissural axons both *in vitro* and *in vivo* by acting directly as a chemoattractant on these axons through an Smo-dependent signaling mechanism.

Figure 2 The Sonic hedgehog (Shh) signaling pathway. Genetic and biochemical experiments have shown that hedgehogs activate signaling by binding to their receptor Patched (Ptc; a 12-pass transmembrane protein), which leads to the relief of Ptc-mediated inhibition of Smoothened (Smo), a 7-pass transmembrane protein, which can then activate downstream signaling. Smo associates directly with a Gli/Ci-containing complex which contains the atypical kinesin Costal-2 (Cos2), the protein kinase Fused (Fu), and the Suppressor of Fused (Su(fu)). This complex constitutively suppresses pathway activity by leading to the proteolytic cleavage of Ci, which acts as a transcriptional repressor. Activation of hedgehog signaling reverses this regulatory effect and leads to the production of full-length Ci, which activates transcription of hedgehog target genes.

Boc Is a Receptor for Shh in the Guidance of Commissural Axons to the Floor Plate

Although Shh acts through Smo to attract commissural axons to the floor plate, Smo does not bind Shh, and the binding receptors acting with Smo to mediate the effect of Shh in axon guidance remain elusive. Cdon (cell adhesion molecule-related/downregulated by oncogenes) and Boc (biregional Cdon binding protein) have been implicated in enhancing muscle differentiation. They are type I transmembrane proteins consisting of four to five immunoglobulin (Ig) and two to three fibronectin type III (FNIII) repeats in the extracellular domain. This domain architecture is highly related to that of axon guidance receptors of the Robo and Dcc families. Both Cdon and Boc share a high degree of homology in their extracellular domains and are expressed during early stages of central nervous system (CNS) development. Interestingly, mice with homozygous mutations in Cdon display a microform of holoprosencephaly (HPE), a developmental defect of the forebrain and midface caused by a failure to delineate the midline. In both humans and mice, many forms of HPE are caused by disruptions in the Shh signaling pathway, suggesting that Cdon and Boc might regulate Shh signaling, a possibility supported by the finding that a Cdon/Boc homolog in *Drosophila*, iHog, is required for Hh signaling. Taken together, these observations suggested that Cdon and/or Boc might function in Shh-mediated axon guidance in vertebrates.

The ability of Boc and Cdon to bind Shh was tested and they were found to bind specifically and directly to Shh, suggesting that they could function as Shh receptors. These results are consistent with recent reports demonstrating that Cdon, Boc, and iHog bind and

signal through the Hh pathway. To explore their involvement in commissural axon guidance, the expression of Cdon and Boc was examined in the developing mouse spinal cord. Boc is expressed by differentiating commissural neurons and the Boc protein, but not Cdon, is expressed by growing commissural axons. To assess the functions of these receptors in commissural axon guidance, Boc and Cdon mutant mice were generated and sections of spinal cord from Boc and Cdon mutant embryos were analyzed. Although commissural axon projections appeared normal in Cdon mutant animals, abnormal projections of commissural axons were observed in Boc mutants: the axons were highly dispersed and invaded the ventral spinal cord, with ectopic projections extending over the motor columns. Analysis of various neural tube markers indicated that neuronal patterning is occurring normally in these animals. This phenotype is similar to that observed in mice following conditional removal of the Shh signaling mediator Smo in commissural neurons (using a Wnt1 promoter to drive Cre expression; see earlier) and suggests that Boc acts in the same pathway as Smo to guide commissural axons in response to Shh. Finally, using an *in vitro* commissural axon turning assay to test the role of Boc in Shh-mediated axon turning, it was shown that RNA interference (RNAi)-mediated knockdown of Boc impaired the ability of commissural axons to turn toward an ectopic source of Shh *in vitro*. These results indicates that Boc is required for commissural axons to respond to the chemoattractive effect of Shh. Collectively, these data suggest that Boc plays an essential role as a receptor for Shh in commissural axon guidance.

Consistent with a role for Boc in axon pathfinding, an earlier study showed defects in forebrain axon guidance in zebra fish treated with morpholinos directed against Boc. However, based on indirect evidence, these results were interpreted to reflect a role for Boc as a repulsive ligand. In the mammalian spinal cord, the aforementioned results argue that Boc functions as a receptor for Shh-mediated attraction; whether it can also function as a repulsive ligand in other contexts in mammals remains to be explored. Additionally, it will be of interest to determine whether Boc and Cdon also play a role in the guidance of other axonal tracts in the developing mammal and fish embryos.

Figure 3 Guidance of postcrossing commissural axons by Sonic hedgehog (Shh) and Wnt4. (a) After crossing the floor plate, chick commissural axons are repelled from the posterior pole by an increasing anterior to posterior Shh gradient. (b) In rodents, commissural axons are attracted to the anterior pole by an increasing posterior-to-anterior Wnt4 gradient. Left panels in a and b are cross-section representations of the developing spinal cord, and right panels are open-book representations. Shh Guides Commissural Axons along the Longitudinal Axis of the Spinal Cord

After commissural axons have reached and crossed the floor plate, they make a sharp anterior turn toward the brain (Figure 3). The molecules involved in the dorsoventral projection of commissural axons to and at the floor plate have been well described, but it is only recently that cues controlling anteroposterior guidance have been identified. Remarkably, the guidance of commissural axons to the floor plate is not, apparently, the only effect of Shh on commissural axons: recent evidence suggests that Shh also guides postcrossing commissural axons in the rostral direction along the longitudinal axis of the spinal cord. Using a subtractive hybridization approach to identify guidance cues responsible for the rostral turn of postcrossing commissural axons in chick embryos, Bourikas and colleagues identified differentially expressed candidates whose function they investigated by RNAi-mediated *in ovo* gene silencing. Unexpectedly, one of their candidates turned out to be Shh. In agreement with these results, silencing of the *Shh* gene by a different RNAi construct or injection of a hybridoma producing a function-blocking Shh antibody led to axon stalling at the contralateral floor plate border, with some axons

turning caudally or rostrally, apparently in a random manner. Importantly, marker analysis revealed that the patterning of the spinal cord was not apparently affected by these manipulations, suggesting that these experiments were performed after neural cell fate specification by Shh has occurred. Finally, postcrossing commissural axons were shown to avoid ectopic Shh *in vivo*. Together, these results provide strong evidence that Shh is essential for the normal guidance of commissural axons along the longitudinal axis of the spinal cord, at least in chick embryos.

An Shh gradient could guide commissural axons along the longitudinal axis directly, or could alternatively be acting only indirectly by controlling a graded distribution of a distinct guidance cue. Two lines of evidence, however, were provided for a direct role of Shh. The first came from an investigation of the receptor mechanism for this guidance. Interestingly, neither cyclopamine nor Smo RNAi interfered with the rostral turn of commissural axons along the longitudinal axis, suggesting that Smo might not be involved in this process. Instead, RNAi-mediated silencing of *Hip1*, a gene encoding an Shh-binding membrane protein transiently expressed in commissural neurons at the time when they cross the floor plate, as well as in the periventricular region, resulted in the same postcrossing phenotype as seen with Shh RNAi. These results, which contrast with the essential role of Smo in Shh-mediated attraction of commissural axons to the floor plate, suggest that Hip1 might be involved in transducing an Shh guidance signal in postcrossing commissural neurons. The relatively restricted expression of Hip1 mRNA to commissural neurons would be consistent with a direct action of Shh on these axons. A second line of evidence that supports a direct role for Shh was obtained by *in vitro* experiments, which showed that postcrossing commissural axons from spinal cord explants can be repelled by Shh beads *in vitro*. Taken together, these results suggest a model in which Shh could be functioning directly through Hip1 as a chemorepellent for postcrossing commissural axons.

Prior to the finding that Shh controls the anteroposterior guidance of commissural axons in chicks, Wnt4 was reported to play a role in this process in rodents. Using a novel *in vitro* assay, evidence was obtained that the activity responsible for the anterior guidance of postcrossing commissural axons in rodents is an increasing posterior to anterior gradient of a diffusible attractant. Although it is not yet known whether Wnt4 guides postcrossing commissural axons in chicks and whether Shh guides postcrossing commissural axons in rodents, it is nonetheless interesting to note that, if this is the case, the complementary Wnt4 and Shh gradients might act cooperatively in the rostral guidance of commissural axons. Additionally, since Boc plays a role in the guidance of precrossing commissural axons, it will be interesting to determine whether it also plays a role in the guidance of postcrossing commissural axons.

Shh Is a Negative Regulator of Retinal Ganglion Cell Axon Growth

Retinal ganglion cell (RGC) axons growing toward the diencephalic ventral midline are faced with the decision to project either contralaterally or ipsilaterally in response to guidance cues at the optic chiasm (Figure 4). Homozygous inactivation of the mouse *Pax2* gene alters the development of the optic chiasm, and RGC axons never cross the midline in these mice. Interestingly, whereas in wild-type mice Shh expression is downregulated in the chiasm as RGC axons are migrating toward this region, Shh expression is ectopically maintained along the ventral midline in *Pax2*$^{-/-}$ mice. These observations raise the possibility that the continuous expression of Shh at the ventral midline might contribute to preventing RGC axon crossing. In agreement with this idea, Trousse and colleagues found that ectopic expression of Shh in the midline region interferes with RGC axon growth and prevents them

Figure 4 Sonic hedgehog (Shh) expression at the chiasm border defines a barrier within the ventral midline implicated in guiding retinal ganglion cell (RGC) axons. RGC axons growing toward the diencephalic ventral midline are faced with the decision to project either contralaterally or ipsilaterally in response to guidance cues at the optic chiasm. The Shh expression domain is shown in blue. Shh can inhibit retinal axons *in vitro*, suggesting that *in vivo* it may be acting on the axons directly rather than by altering the expression of distinct guidance cues in the chiasm, although conclusive evidence for this guidance function *in vivo* remains to be obtained. A, anterior; P, posterior; POA, preoptic area; VH, ventral hypothalamus. Adapted from Charron F and Tessier-Lavigne M (2005) Novel brain wiring functions for classical morphogens: A role as graded positional cues in axon guidance. *Development* 132: 2251–2262.

from crossing the midline (Figure 4). Consistent with the idea that Shh might be acting directly on RGC axons, it was shown that these manipulations do not affect patterning and neural differentiation in the eye. Further experiments will be required to determine whether the chiasm region is repatterned in these experiments, but *in vitro* experiments support the idea that Shh acts directly to control RGC axon migration: addition of exogenous recombinant Shh to retinal explants decreases the number and length of growing axons, without interfering with the rate of proliferation and differentiation of cells in the explant, and time-lapse analysis shows that addition of Shh to retinal explants rapidly causes growth cone arrest and subsequent retraction of RGC axons. Since the response of the growth cone to many extracellular guidance cues appears to be modulated and in some cases perhaps even mediated by intracellular cyclic nucleotide levels (cyclic adenosine monophosphate and cyclic guanosine monophosphate, cAMP and cGMP), the possibility was explored that the effect of Shh on retinal axons *in vitro* might be due to a change in cAMP levels. In agreement with this, addition of Shh to retinal growth cones was shown to decrease intracellular levels of cAMP, a finding consistent with the observation that lowering cAMP levels favors growth inhibition.

Taken together, these results provide evidence that Shh expression at the chiasm border helps define a barrier within the ventral midline that serves to guide RGC axons, and suggest that Shh may be acting on the axons directly, rather than indirectly by repatterning the chiasm. The finding that Shh acts directly to guide RGC axons is also supported by a recent study suggesting that Shh acts directly and rapidly on the growth cone of RGCs cultured *in vitro*. Proving that the effect *in vivo* is direct will, however, require additional studies, such as identifying the mechanism that mediates retinal growth cone responses to Shh and showing that cell-autonomous inhibition of this signaling pathway in the neurons results in guidance defects *in vivo*.

Molecular Mechanism underlying Shh-Mediated Axon Guidance

The aforementioned studies, summarized from several laboratories, have provided evidence that Shh plays a role in the guidance of at least two types of axons: commissural and RGC axons. In the case of precrossing commissural axons, Shh acts as a chemoattractant and its effect is mediated by Boc, a recently identified Shh receptor related to Dcc and Robo family members. In addition, the chemoattractant effect of Shh requires the canonical Shh signaling molecule Smo. After commissural axons have crossed the floor plate, evidence indicates that Shh then functions as a chemorepellent to direct their anterior migration. This later effect of Shh appears to require the Shh binding protein Hip1 and might occur independently of Smo activity. Finally, in the case of RGCs, Shh acts as a negative regulator of axonal growth, at least *in vitro*, but the receptor and the signaling molecules involved in this effect remain elusive.

Although the chemoattractant and chemorepellent effects of Shh might appear to be inconsistent with one another, many other guidance cues have been shown to be bifunctional and exert opposite effects, depending on the context. For example, extrinsic factors can convert netrin attraction to repulsion by modulating cyclic nucleotide levels. Thus, the opposite effects of Shh on pre- and postcrossing commissural and retinal axons might be due to an intrinsic or extrinsic factor that modulates cyclic nucleotide levels. Alternatively, as the molecular mechanisms underlying the effects of Shh on commissural and retinal axons are poorly understood, it is also possible that these pre- and postcrossing effects are mediated by distinct signaling pathways that result in opposite guidance effects – a possibility that also has a precedent in the case of netrins, which can attract axons by activating Dcc family receptors and repel them by activating UNC5 family receptors.

In all of the studies summarized here, Shh was shown to act rapidly (in an hour or less) to affect growth cone morphology. Although these results appear inconsistent with the model that the Shh axon guidance effect function through the transcriptional signaling pathway to the nucleus, this needs to be formally proved, as none of the studies described here has addressed this issue directly. Nonetheless, even if a transcriptional response is found to be required for their guidance effects, additional local signaling would still be required to be elicited in the growth cone in order to generate a polarized response leading to growth cone turning in a specific direction. Indeed, a purely transcriptional response consisting of a retrograde signal to the nucleus, followed by an anterograde signal back to the growth cone, cannot account for the polarized turning effect of a guidance cue. Further studies aimed at understanding the molecular mechanisms underlying growth cone turning by Shh will be necessary to identify the molecules linking Shh signaling to localized growth cone effects.

In this regard, despite many efforts, the canonical Hh signaling pathway is only beginning to be understood, and many intermediate signaling molecules remain to be identified and characterized. Thus, it

is possible that the signaling proteins eliciting the growth cone effects are simply components of the signaling pathway required for cell fate specification that are awaiting identification and further characterization to uncover their function in axon guidance.

Alternatively, Shh might be acting through entirely different signaling pathways in axon guidance and cell fate specification, including the use of a different receptor. For example, although Smo and Boc are required for Shh-mediated commissural axon guidance to the floor plate, it is not known whether Ptc, the canonical Shh-binding component of the Shh receptor, is involved. This finding contrasts with chick postcrossing commissural axon guidance, in which Smo does not appear to be required for the rostral turn away from the Shh gradient. Additional experiments on commissural and retinal axons will be required to determine the receptor components and intracellular signaling molecules mediating the effects of Shh on axon guidance.

Conclusion

The discovery that the morphogen Shh can be reused to guide axons has generated considerable excitement in the field, and it will be interesting to see to what extent its signaling components are conserved between the morphogenic and guidance responses. The characterization of the Shh chemotropic signaling pathway will open new avenues to study how guidance signals regulate the motility and steering of the growth cones, and will help elucidate the mechanisms directing the complex wiring of the nervous system.

Introduction

Directing growing axons to their targets is an essential step toward establishing appropriate connections in the nervous system. The growth cone, located at the motile tip of an axon, senses cues within its environment to guide extending axons. Extracellular guidance cues can attract or repel axons. They may be transmembrane, glycosylphosphatidylinositol (GPI)-linked, or secreted cues. Secreted cues have the unique capacity to function at a distance by diffusing away from their source. The netrin family contains both secreted members (netrin-1–netrin-4) and GPI-linked members (netrin-G1 and netrin-G2).

The discovery of the netrin family can be traced back to observations made in the late nineteenth century by the Spanish neuroscientist Santiago Ramón y Cajal. He was the first to propose that gradients of diffusible cues might guide axons. One location where he thought this may occur is in the developing spinal cord where commissural axons extend ventrally toward the floor plate (Figure 1(a)). Specifically, he proposed that a gradient of a diffusible cue, emanating from the floor plate at the ventral midline, would function to attract growing commissural axons. In the 1980s, co-culture studies using explants of embryonic neural tube provided experimental evidence for the presence of guidance cues secreted by the floor plate. Initial experiments demonstrated that axon bundles would extend from an explant containing the cell bodies of commissural neurons, through a collagen matrix toward a floor plate explant cultured at a distance (Figure 1(b)). Subsequent experiments placed an ectopic floor plate perpendicular to the normal trajectory of commissural axons, resulting in the axons being redirected within the neural epithelium toward the ectopic floor plate (Figure 1(c)). An activity that promoted commissural axon outgrowth was then identified in lysates of embryonic chick brains. Two related proteins were purified, their corresponding cDNAs cloned, and recombinant protein shown to mimic the ability of the floor plate to attract commissural axons. Sequence analysis identified homology to UNC-6, a protein required for the circumferential guidance of cells and axons in the roundworm *Caenorhabditis elegans*. These proteins were named netrins, based on the Sanskrit word *netr*, meaning 'one who guides.'

Netrin Family Members

Four secreted netrins (netrin-1–netrin-4) have been identified in vertebrates, along with two membrane-anchored forms, netrin-G1 and netrin-G2. Thus far, orthologs of netrin-2 have only been identified in birds and fish. Mammals express secreted netrin-1, netrin-3, and netrin-4. The netrin family can be divided into three subfamilies: netrins 1–3 (sometimes called 'classical netrins'), netrin-4, and netrin-G1 and netrin-G2. Based on sequence, netrin-4 and the netrin-Gs are more similar to laminins than to netrins 1–3, which exhibit a high degree of similarity to each other (Figure 2(b)). Another compelling argument for this subdivision is based on evolutionary conservation. Orthologs of netrins 1–3 have been detected in all bilaterally symmetrical animals studied so far, while orthologs of netrin-4 and netrin-Gs have only been found in vertebrate species (Figure 2(c)). Functional differences also support this distinction. Different receptors mediate the function of netrins 1–3 and netrin-Gs. Furthermore, netrins 1–3 similarly elicit axon outgrowth from embryonic spinal commissural neurons, while netrin-Gs do not.

Netrin Structure

Despite these differences, all netrins are classified into a single family on the basis of their size, approximately 600 amino acids, the presence of two characteristic conserved N-terminal domains, domains V and VI, and a more variable C-terminal domain, domain C. Domains V and VI in netrins are homologous to domains V and VI found at the N-terminal ends of the extracellular matrix protein laminin (Figure 2(a)). Laminins are large secreted heterotrimers made up of α, β, and γ subunits. Domains V and VI of netrin-4 and netrin-Gs are most similar to β subunits of laminin, while those of netrins 1–3 are more similar to the γ subunits (Figure 2(b)).

Domain VI, at the N-terminal end of netrins and laminins, is composed of approximately 300 amino acids. In laminins, this domain interacts with heparin, cell surface receptors, and extracellular matrix (ECM) proteins, and is required for calcium-dependent multimerization that generates a larger matrix of laminin molecules. Genetic studies in *C. elegans* have demonstrated that the highly conserved sequence SXDXGXS/TW within domain VI of the netrin UNC-6 is required for both axon attraction and repulsion. The middle

Figure 1 (a) The floor plate (FP) attracts commissural neuron (CN) axons, in part, by releasing netrin-1 (MN, motor neuron). (b) Commissural neurons will extend axon bundles from an explant of dorsal embryonic spinal cord through a collagen matrix when either floor plate or cells expressing netrin are placed within 200–300 μm. (c) An ectopic floor plate or a cell line expressing netrin-1 will attract commissural neuron axons when placed perpendicular to their trajectory.

netrin domain, domain V, is approximately 150 amino acids long and contains three cysteine-rich epidermal growth factor (EGF) repeat subdomains named V-1, V-2, and V-3. Mutation of the third EGF repeat (V-3) disrupts chemoattraction in *C. elegans*, whereas repulsion is lost following mutation of either V-2 or V-3 domain.

The C-terminal domain C of secreted netrins (netrins 1–4) exhibits relatively limited sequence similarity to domains found in the complement C3, C4, and C5 protein family (i.e., CC3, CC4, and CC5), secreted frizzled-related proteins (sFRPs), type I C-proteinase enhancer proteins (PCOLCEs), and tissue inhibitors of metalloproteinases (TIMPs). The majority of netrin protein in the embryonic or mature central nervous system (CNS) is not freely soluble. Structure–function analyses of domain C suggest that it contributes to binding netrins to cell surfaces or extracellular matrix. Domain C includes many basic amino acids that may bind negatively charged sugars associated with proteoglycans, such as heparan sulfate proteoglycans and chondroitin sulfate proteoglycans. Presentation of

Figure 2 (a) Netrins contain N-terminal domains V and VI related to corresponding N-terminal domains of laminins. Domain V is composed of cysteine-rich epidermal growth factor repeats. Domain C in secreted netrins contains many positively charged, basic residues (GPI, glycophosphatidylinositol). (b) Phylogenetic tree based on the sequences of domains VI and V in human netrins and laminins. (c) Evolutionary tree diagram highlighting the presence of netrin homologs in a wide variety of bilaterally symmetrical organisms.

netrins bound to surfaces may be a common mode of action in the netrin family; although the domain C is not conserved in the netrin-Gs, a C-terminal GPI link anchors them to cell surfaces.

Netrin Expression and Function during Development

Orthologs of netrin-1 have a firmly established, evolutionarily conserved role as secreted cues that direct axon guidance relative to the midline of developing bilaterally symmetric nervous systems. In fact, a netrin-1 ortholog has been identified in the stellate sea anemone *Nematostella vectensis* – an organism thought to exhibit some of the earliest hallmarks of bilateral symmetry (**Figures 2(c)** and **3(g)**). Multiple lines of evidence support the conclusion that netrin-1 attracts commissural axons toward and repels subsets of motor neuron axons away from the midline. Expression of a netrin-1 ortholog at the midline early in neural development is highly conserved (**Figure 3**). Ectopic expression of netrin-1 is sufficient to alter axon extension. Furthermore, netrin-1 ejected from a micropipette functions as a chemoattractant or chemorepellent, depending on the axons stimulated. Genetic disruption of the netrin UNC-6 in *C. elegans* disrupts circumferential axon extension toward and away from the ventral midline. Loss of netrin-1 function in mice generates major disruptions in multiple axon commissures, including the spinal ventral commissure, the corpus callosum, and the hippocampal commissure.

Netrin-1 also influences axon guidance away from the midline. It is required for retinal ganglion cell axons to exit the retina, for dopaminergic axon guidance in the ventral midbrain, and for thalamocortical projections. Netrin-1 also directs neural precursor cell migration, attracting cells that will become inferior olivary, pontine, luteinizing hormone-releasing hormone (LHRH), antidiuretic hormone (ADH), and oxytocin neurons, and repelling striatal neuronal precursors, cerebellar granule cells, spinal accessory neurons, and oligodendrocyte precursor cells. Although netrin-3 can mimic the ability of netrin-1 to attract spinal commissural axons and repel trochlear motor neuron axons *in vitro,* its expression in the spinal cord begins after the initial commissural axons have pioneered the path to the floor plate. Netrin-3 may, however, influence guidance of dorsal root ganglia axons to peripheral targets in the developing peripheral nervous system (PNS).

Very little is known regarding the role of netrin-4 in the development of the nervous system. It is widely expressed in the developing olfactory bulb, retina, and dorsal root ganglia, as well as by cerebellar granule, hippocampal, and cortical neurons. A relatively low level of netrin-4 expression has been detected adjacent to floor plate cells in the developing spinal cord, but only after the first commissural axons have crossed the midline. As discussed later, netrin-Gs do not appear to have a major role in the outgrowth and guidance of axons. They are expressed primarily by neurons, with very limited expression outside the nervous system. Netrin-G1 is expressed in the dorsal thalamus, olfactory bulb, and inferior colliculus, whereas netrin-G2 is expressed in the cerebral cortex.

Netrin-Induced Signal Transduction

Research investigating the signaling mechanisms elicited by netrins has focused on netrin-1, and there is little known about signaling by other netrins. Here we review current insight into netrin-1 signal transduction during axon guidance. The DCC ('deleted in colorectal cancer') family and the UNC5 homolog family are well-established receptors for netrin-1. In vertebrate species, these include DCC and neogenin, as well as UNC5A–UNCD. Both classes of receptors are single-pass transmembrane proteins that are also members of the large immunoglobulin superfamily.

Chemoattractant Signaling in Response to Netrin-1

DCC is required for axon chemoattraction to netrin-1. Although initially identified in vertebrates as a potential tumor suppressor, the importance of DCC in axon guidance was realized shortly after the discovery of netrin-1 as a result of mutational studies done in the roundworm *C. elegans*. While mutation of the *netrin* homolog *unc-6* affects both ventrally and dorsally directed neurons, mutations of the *C. elegans* homolog of *dcc*, *unc-40*, primarily disrupt ventrally directed axons. It was quickly realized that this phenotype was consistent with a potential role for UNC-40/DCC during axon attraction to netrins/UNC-6. Loss of DCC function in mice was then shown to cause neurodevelopmental defects very similar to loss of netrin-1 function, including disruption of the spinal ventral commissure, corpus callosum, and hippocampal commissure.

Structurally, the extracellular domain of DCC contains six fibronectin type 3 (FN3) repeats and four immunoglobulin (Ig) repeats. Netrin-1 appears to bind to the FN3 repeats of DCC, though reports conflict as to the exact domain involved. The DCC intracellular domain has no known catalytic activity; rather, it contains several putative phosphorylation

Figure 3 Midline expression of netrin homologs in a variety of organisms. The diagrams in panels (a), (d), and (i) illustrate simplified models of the distributions of netrin protein at the midline in the developing mouse spinal cord, fruit fly and *C. elegans* nematode worm, respectively. In each case, sensory neurons extend toward, while motor neurons extend away from, the source of netrin protein at the midline. *In situ* hybridization illustrates floor plate cells expressing netrin-1 in the embryonic day 9.5 mouse spinal cord (b). Whole-mount staining for expression of a β-galactosidase reporter gene shows netrin-1 expression in an entire E12.5-day-old mouse embryo, illustrating netrin-1 expression along the full rostrocaudal extent of the spinal cord, the developing brain, and the peripheral nervous system (h). *In situ* hybridization reveals netrin expression in the fruit fly (e) and the stellate sea anemme *N. vectensis* (g) during neural development. The distribution of netrin protein in the embryonic day 9.5 mouse spinal cord (c), as well as fruit fly (f) and *C. elegans* (j) embryos are also shown. and binding sites for intracellular proteins. Based on particularly strong evolutionary conservation, three domains (P1, P2, and P3) within the intracellular domain of DCC have been described. The P2 domain is rich in proline residues, containing four PXXP putative SH3 domain-binding motifs, while the P3 domain contains several highly conserved possible phosphorylation sites.

Numerous studies have now described signal transduction events implicated in the response to netrin-1, but our understanding of the mechanisms underlying how a growth cone responds to netrin-1 as a chemoattractant remains fragmentary. Netrin-1-induced multimerization of DCC via its P3 intracellular domain is thought to be essential for chemoattraction. Netrin-1 binding DCC activates the Rho GTPases Rac1 and Cdc42, key intracellular coordinators of cytoskeletal and adhesive interactions. Furthermore, intracellular proteins reported to associate with the intracellular domain of DCC include the adapter protein Nck1, the tyrosine kinases Fak and Fyn, the actin-binding proteins Ena/Vasp and N-Wasp, and the serine/threonine kinase Pak, a downstream effector of Rac1 and Cdc42 activation. Netrin-1 binding DCC also triggers generation of phosphoinositides and their breakdown by phospholipase C into inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol, leading to calcium release from intracellular stores and activation of protein kinase C. Figure 4(a) outlines a speculative model of the signal transduction events that occur during chemoattraction to netrin-1.

Chemorepellent Signaling in Response to Netrin-1

Axonal repulsion in response to netrin-1 requires a member of the UNC5 protein family. Four family members are present in mammals: UNC5A, UNC5B, UNC5C, and UNC5D. In *C. elegans*, in contrast to mutation of the *dcc* homolog *unc-40* that affects ventrally extending axons, mutation of *unc-5* predominantly causes defects in dorsally directed axons (i.e., those extending away from the source of UNC-6 netrin). Misexpression of *unc-5* is sufficient to redirect them dorsally, away from the ventral source of UNC-6. The extracellular domain of UNC5 homologs contains two membrane-proximal thrombospondin repeats and distally two immunoglobulin repeats. Netrin-1 binds to both immunoglobulin repeats. The intracellular domain of UNC5 contains three identified conserved domains: a ZU5 domain, a DCC-binding (DB) domain, and a death domain (DD). Although the specific function of the ZU5 domain is not known, a homologous domain is present in the scaffolding protein zona occludens-1 found at tight junctions, and deletion of the UNC5 ZU5 domain in *Drosophila* disrupts UNC5-mediated chemorepulsion.

Interestingly, depending on the distance of the growth cone from the source of netrin, different signaling mechanisms appear to be engaged. Long-range repulsion to netrin requires expression of both UNC5 and DCC, whereas short-range repulsion requires UNC5, but DCC is not essential. One hypothesis for this difference is that DCC and UNC5 together may form a more sensitive netrin receptor complex that is able to respond to the lower concentrations of netrin present at greater distances. At long range, the cytoplasmic domains of UNC5 and DCC associate directly. At short range, genetic studies in *C. elegans* have stressed the importance of an association between UNC5 cytoplasmic ZU5 and DD domains. Several proteins that interact with the UNC5 intracellular domain have been identified. These include the tyrosine kinase Src1, the tyrosine phosphatase Shp2, the F-actin anti-capping protein Mena, the structural protein ankyrin, and the adapter protein Max1. Netrin-1-mediated growth cone repulsion triggers tyrosine phosphorylation of UNC5's intracellular domains at multiple sites. A speculative model outlining intracellular events that occur during short- and long-range netrin-mediated growth cone repulsion is illustrated in Figure 4(b).

Regulating Growth Cone Response to Netrin-1

Single growth cones have been shown to have the capacity to rapidly switch between responding to netrin as an attractant or a repellent. The mechanisms that control this shift in responsiveness have been the topic of intense investigation.

Altering UNC5 or DCC expression is one mechanism that influences how a growth cone responds to netrin. For example, the homeobox transcription factor 'even-skipped' promotes *unc5* expression in the fruit fly *Drosophila melanogaster*. Local protein synthesis within the growth cone also appears to contribute to the attraction of axons to netrin-1, though the exact mechanism of action is not clear. DCC expression can be downregulated through proteolytic degradation by either extracellular metalloproteinases or intracellularly, being ubiquitinated by an interaction with Siah-1, a RING domain-containing protein. The intracellular domains of UNC5 proteins are substrates for proteolysis by caspases.

The concentration of cyclic nucleotides within an axonal growth cone has a profound influence on how it responds to guidance cues. In particular, the intracellular concentration of cyclic adenosine monophosphate (cAMP), which activates protein kinase A (PKA), can regulate the response to netrin-1. High levels of cAMP are associated with attractant responses to netrin-1, while growth cones with low concentrations are repelled. Although cAMP and PKA activation may regulate intracellular signal transduction, a specific mechanism regulating the direction of the response made by a growth cone has not been identified. It has been shown that activating PKA leads to the recruitment of DCC from an intracellular pool of vesicles to the growth cone plasma membrane, thereby enhancing chemoattraction to netrin-1. In addition, activating protein kinase C (PKC) leads to endocytosis of UNC5 proteins inducing neurons to

Figure 4 Speculative models outlining chemoattractive, chemorepellent, and modulatory signaling in response to netrin-1. (a) Chemoattraction to netrin-1 can be divided into three conceptually different stages: in the absence of netrin-1, during the initial response to netrin-1, and during cytoskeletal remodeling triggered by netrin-1. The adapter protein Nck1 and the tyrosine kinase Fak associate with the intracellular domain of the DCC ('deleted in colorectal cancer') protein in the absence of netrin-1. Upon netrin-1 binding, DCC multimerizes through association of its P3 domains. Phosphatidylinositol transfer protein-α (PITPα) can also bind the P3 domain of DCC and promote the generation of phosphoinositides (PIPs) by phosphatidylinositol 3-kinases (PI3Ks). PIPS can then be hydrolyzed by phospholipase C (PLC) into inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG), leading to Ca^{2+} release from intracellular stores and activation of protein kinase C (PKC). Netrin-1 binding to DCC leads to phosphorylation of the intracellular domain of DCC and association of proteins such as Fak, Fyn, and Pak. Intracellular Ca^{2+} increases can lead to activation of the Rho GTPases Cdc42 and Rac, and cause remodeling of the cytoskeleton through proteins such as the Wiskott–Aldrich syndrome protein (N-Wasp), Ena/Vasp, and Map1b. (b) Short- and long-range repellent signaling to netrin-1. In the absence of netrin-1, Mena and ankyrin link UNC5 to the cytoskeleton. Upon binding netrin-1, UNC5 is tyrosine-phosphorylated, independently of DCC, by tyrosine kinases such as Src1. Netrin-1 induces recruitment of the tyrosine phosphatase Shp2 to a phosphorylated tyrosine residue in the ZU5 domain. PIPs have been proposed to regulate interaction of Max-1 with UNC5. (c) Long-range repulsion to netrin-1 requires association between the intracellular domains of UNC5 and DCC. (d) Both DCC and UNC5 can traffic between intracellular vesicular pools and the cell surface. Protein kinase A (PKA) can recruit DCC to the plasma membrane. PKC induces endocytosis of UNC5 from the cell surface. AC, adenylate cyclase; cAMP, cyclic adenosine monophosphate; PICK1, protein interacting with C kinase-1.

switch their response to netrin-1 from repulsion to attraction. These findings suggest that neuromodulatory factors that regulate PKA or PKC may influence axon outgrowth by altering which netrin receptors are presented by the growth cone.

Other Potential Netrin Receptors

Receptors for secreted netrins, other than DCC, neogenin, and UNC5 proteins, have been suggested. The G-protein-coupled adenosine A2B receptor has been

proposed as a receptor for netrin-1. Through an influence on intracellular cAMP concentration, it is possible that A2B may influence the response to netrin-1; however, contrary to an early report, A2B is neither expressed by nor required for spinal commissural axon guidance. Integrins, best known for their role as receptors for extracellular matrix components, have also been implicated as netrin receptors. Specifically, an adhesive interaction between netrin-1 and integrins $\alpha 6\beta 4$ and $\alpha 3\beta 1$ has been suggested to contribute during development of the pancreas; however, evidence of this *in vivo* remains to be demonstrated. Interestingly, the region of netrin reported to interact with these integrins is not in domains V and VI that are homologous to laminins, which are ligands for integrins. Rather, $\alpha 6\beta 3$ and $\alpha 3\beta 1$ integrins bind to a highly charged sequence of basic amino acids at the C-terminus of netrin-1.

Netrin Expression in the Mature Nervous System

Roles for netrins beyond directing axon and cell migration during development are beginning to be identified. Netrins and their known receptors are expressed in the adult nervous system: netrin-1 is expressed by neurons, Schwann cells in the PNS, and oligodendrocytes in the CNS. Subcellular fractionation of mature CNS white matter has determined that netrin-1 protein is enriched at the interface – known as periaxonal myelin – between axons and oligodendrocytes, suggesting that a function for netrin-1 in the mature CNS may be to regulate axon oligodendroglial interactions. Interestingly, as the mammalian spinal cord matures, DCC expression falls while UNC5 homolog expression increases. This suggests that UNC5 repellent signaling may be the dominant mode of responsiveness to netrin in the adult spinal cord. Although the functional significance of netrin-1 expression in the adult CNS remains unknown, an intriguing hypothesis is that netrins contribute to maintaining appropriate connections in the intact CNS by restraining inappropriate axonal sprouting.

The expression of netrin-1 by myelinating oligodendrocytes raises the possibility that it might function as a myelin-associated inhibitor of axon growth following injury. Netrin-1 does not appear to be a major component of an injury-induced glial scar in the mature spinal cord, but essentially normal netrin-1 expression persists on either side of the injury site. Although an influence of netrin-1 on axon regeneration in the adult CNS has not been demonstrated directly, these findings suggest that netrin-1 may be a component of CNS myelin that inhibits axon regeneration by neurons expressing UNC5 following injury. Such a role may explain, in part, why increasing cAMP in neurons promotes the ability of axons to grow in the adult mammalian CNS, as increasing cAMP recruits DCC to plasma membranes of growth cones and converts netrin-mediated repulsion to attraction. Interestingly, studies carried out in lamprey, a primitive vertebrate with the capacity for substantial axon regeneration following spinal lesion, correlated poor axonal regeneration following lesion with neuronal expression of UNC5 protein.

Netrin-3, netrin-4, netrin-G1, and netrin-G2 are also expressed in the adult brain. In humans, mutation of the netrin-G1 gene is a rare cause of the childhood neurodevelopmental disorder known as Rett syndrome. This disease is characterized by normal early development followed by loss of purposeful use of the hands, distinctive hand movements, slowed brain and head growth, gait abnormalities, seizures, and mental retardation. In mice, netrin-G1 deficiency does not lead to any obvious changes in neural circuitry, but does lead to altered synaptic responses and defects in sensorimotor gating behavior. Similarly, the netrin-G2 receptor NGL-2 influences the formation of glutamanergic synapses through an interaction with the postsynaptic scaffold protein PSD-95. Together, these findings indicate that netrin-G proteins have a role in the maturation, refinement, and maintenance of synapses, rather than in the guidance of axons.

Netrin Outside of the Nervous System

Netrins are expressed in many tissues. Netrin-1 is expressed in the heart, tongue, lung, inner ear, intestine, mammary gland, and pancreas, netrin-3 is expressed in the bowel, pancreas, and muscle, and netrin-4 is expressed in the intestine, pancreas, spleen, vascular networks, kidney, ovaries, and lung. Functional roles for netrins have been demonstrated in several developing tissues. Netrin-1 has been implicated in vascular patterning, although some disagreement remains regarding whether it functions principally as a repellent, acting via UNC5B, or an attractant, acting via undefined receptors, or both (in different vascular beds). Both netrin-1 and netrin-4 shape the developing lung through an influence on branching of the epithelial endoderm. In the developing mammary gland, netrin-1 is expressed by a layer of luminal cells, and an interaction with neogenin is required for proper organization of the terminal end buds.

Conclusion

Homologs of netrin-1 are evolutionarily conserved guidance cues that function as chemoattractants and

chemorepellents that direct cell and axon migration in the developing nervous system. The receptor DCC is essential for chemoattraction to netrin-1, and UNC5 proteins are required for chemorepulsion. The netrin-G subfamily contributes to the maturation, refinement, and maintenance of synapses. In addition to these roles in the CNS, netrins also influence the development of a variety of other tissues.

Axonal Regeneration: Role of Growth and Guidance Cues

Introduction

Compared to other organ systems, the central nervous system (CNS) in the adult human has one of the lowest regenerative capacities following pathological insults, and within the phylogenetic tree the mammalian nervous system is the least capable to renew itself. Besides traumatic nerve injury, a great number of neurodegenerative diseases exhibit marked axonal pathologies, which often precede the histologically more impressive neuron cell death and possibly represent an early stage in disease progression. A functional restoration in a structure as complex as the nervous system therefore requires not only the preservation of cell bodies, but also the maintenance and/or reconstruction of axonal connections to their physiological target regions.

Increased life expectancy has resulted in a continuous rise in the incidence and prevalence of neurodegenerative diseases. The understanding of basic cellular and molecular mechanisms underlying the lack of CNS regeneration is thus not only of interest for the life science community but also of major socioeconomic relevance. Clearly, a deeper insight into mechanisms of axonal de- and regeneration is indispensable for the identification of future treatment strategies in the field of clinical neurosciences.

In this article, developmental mechanisms of axon guidance which regulate axonal pathfinding during embryogenesis are discussed. Interestingly, numerous molecules with developmental roles persist throughout adulthood and may take new functions in the lesioned nervous system, inhibiting or fostering axonal regeneration.

Developmental Guidance Cues: Orchestrating a Symphony of a Thousand

During development, a multitude of signals are required in order to shape naive cells to form adult tissue. Molecular gradients of the so-called morphogens have been identified to regulate cell fate by the induction of transcriptional changes, which, for example, results in cell-type specification according to a cell's position in the gradient. Cellular processes, such as axons, similarly react to molecular gradients of guidance molecules, which act to direct motile structures toward a target area. Four major groups of largely conserved developmental guidance molecules are known to date: ephrins, semaphorins, netrins, and slits. Recent evidence, however, suggests that morphogens are able to route growth cones in a similar way, in addition to their classical function in the commitment of cell fate. The versatile calcium ion influences growth cone development in a precise spatiotemporal manner, including the mediation of pathway cross-talk.

Classical Morphogens with Novel Old Functions

Morphogens are signaling molecules that during development have a locally confined expression in a specific source region from where a concentration gradient is established. The exact mechanism of gradient formation is still a matter of debate, and evidence supports diffusive mechanisms as well as repeated cycles of endo- and exocytosis. Cells positioned in morphogen gradients react to concentration differences by modification of their differentiation program inducing cell fate specification. In addition to this classical morphogen role, evidence is growing for morphogens as axon guidance molecules (Figure 1).

Sonic hedgehog (Shh) is a member of the hedgehog protein family of which two other members are known in mammals. It is produced in the notochord and in the ventral midline of the CNS – the floor plate cells, where it is involved in shaping the dorsoventral axis of the neural tube. Signaling through its receptor patched (Ptc), Shh induces the release of the G-protein-associated mediator smoothened (Smo), which eventually activates zinc finger transcription factors of the Ci/GLI family.

As a midline-derived molecule, Shh has been shown to function as a chemoattractant for commissural neurons, guiding their axons toward the midline. This could be inhibited by the inactivation of the Shh signaling mediator Smo, suggesting a direct action of Shh on the axons rather than the induction of secondary guidance cues. In contrast to commissural axons of the spinal cord, retinal ganglion cells (RGCs) are prevented from crossing the midline by continuous expression of Shh. Here, Shh signaling has been shown to induce an inhibition of cyclic AMP (cAMP) production in the cell, which is known to result in growth inhibition. The opposing effects of the same guidance cue on axonal growth of different cell types remain puzzling. It is likely to assume different signaling pathways resulting in diametrical effects or an interplay with other guidance cues present at the same time. A context-specific effect of Shh, for example, dependent on intracellular cAMP levels, is also proposed.

Figure 1 Morphogens involved in commissural axon guidance during embryonic development. Gradients of bone morphogenetic proteins (BMPs) and sonic hedgehog (Shh) shape the dorsoventral axis, while gradients of Shh and Wnt4 regulate the posteroanterior guidance. Cross-section of developing spinal cord (a) and 'open-book' conformation (b). CN, commissural neuron.

Similar to the regulation of the fate of ventral neurons by Shh, members of the bone morphogenetic protein (BMP) family regulate the fate of dorsal interneurons and commissural neurons. BMPs as well as the related growth and differentiation factors (GDFs) belong to the large superfamily of transforming growth factors-β (TGF-β) and signal through type I and type II TGF-β receptors. Through receptor-regulated SMADs and co-SMADs, the signal is transduced to the nucleus, where transcription is activated. BMPs have been shown to equally act as guidance cues for commissural axons after their initial role as morphogens. Heterodimers of GDF7 and BMP7 guide axon growth of commissural neurons, which could be shown by defective outgrowth of commissural axons in knockout mice lacking GDF7, BMP7, or both. A role for BMPs in the development of RGC axons has been suggested by studies in which a deletion of the BMP receptor Ib resulted in misrouting of ventral RGC axons, enabling them to enter the optic nerve head.

The Wingless/Wnt family of morphogens is expressed by roof-plate cells and participates in the developmental specification of dorsal interneurons. Binding to the Frizzled (Fz) receptors is a common denominator for members of the Wnt family, but signaling pathways that are employed downstream of Fz can be diverse: Wnt binding to the Fz receptor and its coreceptor LRP5/6 eventually results in the inhibition of glycogen synthase kinase 3β (GSK3β). In the absence of Wnt signaling, GSK3β phosphorylates β-catenin, which is then ubiquitinated and targeted for degradation by the proteasome. In this so-called canonical pathway, Wnt signaling thus induces stabilization of β-catenin. Stabilized β-catenin induces transcriptional activation of Wnt target genes via association with the lymphoid enhancer factor (Lef/Tcf). Additionally, GSK3β phosphorylates microtubule-associated proteins (MAPs), and Wnt signaling therefore may directly alter the cytoskeletal structure. Other Wnt signaling pathways involve c-Jun-N-terminal kinase (JNK) activation (the so-called planar cell polarity pathway), directing cytoskeletal organization and coordinated cell polarization as well as the release of intracellular calcium and consequent calcineurin activation (Wnt/Ca^{2+} pathway).

Similar to other morphogens, Wnt family members can act as guidance cues for developing neurons. For example, Wnt5 has been shown to repel anterior commissural axons in *Drosophila*. In mouse embryos, Wnt4 acts as a chemoattractant for postcrossing commissural axons. Again, molecules from the same family show opposing effects on axon outgrowth, which may be explained by utilization of different signaling pathways or, as in the case of Wnt5 signaling in *Drosophila*, even the employment of the unconventional receptor Derailed (Drl).

Neurotrophins

As early as in 1939 limb bud transplantation experiments performed by V Hamburger in chick embryos suggested the existence of a target-derived soluble factor that guides the developing axons of sensory neurons. The protein, now known as nerve growth factor (NGF), was later identified by S. Cohen and R. Levi-Montalcini and turned out to serve as growth and survival factor for sympathetic neurons. Besides NGF, the family of neurotrophins – named after their survival and growth-promoting effects on neurons – today comprises three other structurally related proteins in mammals: brain-derived neurotrophic factor (BDNF), neurotrophin 3, and neurotrophin 4/5. All neurotrophins share a common signaling mechanism involving binding to receptor tyrosine

kinases (trk) and the so-called low-affinity neurotrophin receptor p75NTR.

Upon neurotrophin binding, the appropriate trk receptor dimerizes and induces the activation of multiple signaling pathways, of which protein kinase A (PKA), phospholipase C-γ (PLC-γ), and phosphatidylinositol-3-kinase (PI3K) are the most important ones. Neurite elongation and axon guidance mediated by neurotrophins are likely to be transduced via the actin depolymerizing factor (ADF)/cofilin pathway and consequent f-actin rearrangement (Figure 2).

NGF is able to precisely control neurite outgrowth via local action on distinct cellular segments. Targets of sympathetic and sensory neurons secrete NGF and thus a chemoattractant function of the molecule was suggested. Later, NGF was shown to foster sensory axon elongation and arborization. In culture, NGF induces outgrowth of dorsal root ganglion (DRG) neurons.

Very similar to NGF, other members of the neurotrophin family have effects on neuronal growth, survival, and axon guidance. BDNF, for example, is able to promote the elongation of RGC axons *in vivo*. Motor neurons show an expression of all neurotrophin receptors during development, and this coincides with the expression of all neurotrophins in their muscular target tissue, promoting the hypothesis of neurotrophins as target-derived guidance cues for developing motor neurons. Interestingly, neurotrophins may act in a chameleon-like manner, changing their chemoattractant properties into a repulsive character, depending on the preconditioning of the neuron: NT-3 acted as a chemoattractant for DRG neurons, except when the culture was pretreated with NT-4/5. Preconditioning of DRG cultures with NT-3 rendered them unsusceptible toward NGF-mediated attraction. Furthermore, growth cones of DRG neurons pretreated with NGF were collapsed by local application of BDNF. The activation and cross-talk of different intracellular signaling pathways as well as a regulation of receptor expression in preconditioned cultures may be discussed as a reason for the differential effects mentioned.

Figure 2 Signaling pathways of neurotrophins involved in axon guidance. Neurotrophin binding to the trk receptor results in activation of the phosphatidylinositol-3-kinase (PI3K), protein kinase A (PKA) or phospholipase C (PLC). Signaling through intermediate molecules results in decreased phosphorylation and thus activation of actin depolymerizing factor (ADF)/cofilin inducing neurite growth.

Besides the neurotrophin family, many other growth factors may act as guidance cues, of which only two examples are given: glial cell line-derived neurotrophic factor (GDNF), one of the most potent survival factors for dopaminergic neurons, has chemoattractive functions on peripheral neurons via activation of cyclin-dependent kinase 5 (Cdk5). Studies in rat explant cultures identified hepatocyte growth factor/scatter factor (HGF/SF) as a mesenchyme-derived chemoattractant for developing motor neurons. In addition to its function as survival factor, HGF/SF thus was able to promote axon growth into the limb bud after binding to the c-Met trk.

Ephrins

A model system for the study of axonal guidance cues in the developmental period is the retino-tectal projection. Axons of RGCs follow a precise topographical projection pattern innervating their target areas in the tectum: RGCs in the dorso-ventral axis terminate along the medio-lateral axis of the tectum, while the temporo-nasal distribution in the retina finds its tectal representation in the antero-posterior axis. The involvement of a chemical gradient derived from the target tissue which regulates the targeted outgrowth of RGC axons was suggested by stripe explant experiments. RGC axons originating from the temporal half of the retina would preferentially grow into stripes derived from the rostral part of the tectum, while stripes derived from the caudal colliculus induced growth cone collapse. A similar preference was observed for RGC axons from the dorsal retinal part, which preferred the lateral tectum stripes and vice versa. When the stripes were treated with phosphatidylinositol-specific phospholipase C (PI-PLC) this effect was no longer observed, suggesting that the guidance molecule is membrane bound via a GPI anchor. The guidance molecules responsible for this part of retinal pathfinding are now known as ephrins: two of them, ephrinA5 and ephrinA2, play a pivotal role in the establishment of the topographical map in the retinotectal projection. Studies with knockout mice for either ephrinA5 or ephrinA2 showed a

Figure 3 Establishment of retinotectal projections by gradients of Eph receptors and ephrins. Temporonasal gradients of EphA and dorsoventral gradients of EphB define RGCs projecting to the tectum. Anteroposterior gradients of ephrinB and mediolateral gradients of ephrinA result in a retinotopical termination of RGC axons in the tectum.

disorganization of the retinotectal projection, while the double knockout shows an even more prounounced disturbance of axonal wiring. Two families of ephrins are known to date: the GPI-anchored ephrinAs and the transmembrane domain-linked ephrinBs. Trks, termed EphA and EphB, respectively, are responsible for the mediation of the Ephrin signal. It is now confirmed that ephrinA/EphA gradients establish the antero-posterior tectal architecture, while ephrinB/EphB gradients determine the mediolateral projections (Figure 3).

Semaphorins

The large family of semaphorins comprises proteins that are either secreted or membrane-bound and that were initially identified for their ability to collapse growth cones of cultured neurons. Up to now, more than 20 semaphorins have been identified and classified into eight subclasses. In invertebrates, subclasses 1 and 2 are expressed, while vertebrates express subclasses 3–7. Nonneurotropic DNA viruses encode for V class semaphorins. All semaphorins are characterized by the so-called sema domain, which is located in the N-terminal region. Semaphorins of classes 3 and 4 homodimerize, which appears to be required for their function.

Neuropilins were the first receptors identified to bind class 3 semaphorins, and they establish target selectivity by formation of multimeric complexes. As is now known, neuropilins bind only to the secreted class 3 semaphorins. However, because of the shortness of their cytoplasmic domain, neuropilins alone are not capable of transducing the signal and therefore form complexes with another type of semaphorin receptors – the plexins. Four subfamilies of plexins have been identified in mammals, termed plexin-A through plexin-D. In contrast to neuropilins, plexins do not need to heteromerize for signal transduction. In their monomeric form plexins represent the receptors for membrane-bound semaphorins of classes 1, 4, 5, 6, and 7.

Additionally, the transmembrane cell adhesion molecule L1 has also been shown to form a complex with neuropilin-1 and act as a semaphorin receptor, modulating the effects of Sema3A: in its soluble form, L1 is able to block the Sema3A-induced growth cone collapse, while L1-deficient mice do not respond to Sema3A-mediated repulsion (Figure 4).

Netrins

In the search for factors responsible for the pathfinding of commissural axons in the spinal cord, the biochemical purification revealed two largely homologous proteins – Netrin-1 and -2. To date, Netrins 1–4, which are secreted, and Netrin-G, which is GPI-anchored, are known to exist in vertebrates. Mammalian netrins show homologies to the *Caenorhabditis elegans* UNC-6 protein, which in turn is related to laminin. Two protein families, DCC (deleted in colon cancer) and UNC-5, give rise to netrin receptors.

Netrins seem to have specialized in modeling bilateral symmetry via either chemoattraction (via DCC) or repulsion (via UNC-5). Netrin-1 stimulates outgrowth of commissural axons at different levels in the CNS, and *netrin-1*-deficient mice show severe defects in the establishment of the forebrain commissures. In addition, Netrin-1 is required for developmental pathfinding of RGC axons as they enter the optic nerve, and genetic ablation of Netrin-1 leads to optic nerve hypoplasia. Thalamocortical and corticospinal as well as hippocampal and cerebellar projections equally depend on Netrin-1 signaling for their proper development. One of the intriguing netrin features is its ability to change from attractant to repellent depending on developmental state and intracellular cAMP levels.

Slits

Similar to the midline-forming activity of netrins, the secreted and chemorepellent slits are involved in the

Figure 4 Guidance cue signaling activating growth inhibitory pathways. Membrane-bound ephrins bind to Eph receptors while soluble semaphorins bind to neuropilin/plexin receptors. Both receptor types can elicit growth inhibitory signaling via activation of the RhoA/ROCK cascade, finally inducing actin destabilization and growth inhibition. PAK, p21-activated kinase.

formation of symmetrical structures, such as the optic chiasm. Once bound to axonal Roundabout (Robo) family receptors, slits drive axons away from the midline. Commissural axons initially express low levels of Robo but upregulate the receptor after they successfully crossed to the contralateral side, which prevents them from recrossing the midline. Slits 1–3 have been identified in vertebrates so far, which are able to bind to all three known receptors: Robo 1, Robo 2, and Rig-1.

Left to say, that most of the molecules described above have functions outside the nervous system. Vasculogenesis represents one of the other major processes, where semaphorins, ephrins, netrins, and slits exert their function as guidance cue in development and pathology.

Calcium

The divalent calcium ion is a multifunctional player with roles as a second messenger in the transduction of intracellular signals and as mediator of the action potential. Intracellular cytoplasmic calcium levels ($[Ca^{2+}]_i$) seem to regulate growth cone motility. It has been shown that increased $[Ca^{2+}]_i$ decreases growth cone motility and a reduction of $[Ca^{2+}]_i$ promotes it. However, continuous elevation of $[Ca^{2+}]_i$ can result in adaptation of growth cone behavior, suggesting that targets of Ca^{2+} signaling are downregulated or adjust their sensitivity to the stimulus.

Growth cone motility is not only regulated by baseline cytoplasmic calcium levels, but largely responds to local fluctuations of $[Ca^{2+}]_i$, the so-called calcium transients. Such temporally and locally confined $[Ca^{2+}]_i$ shifts can be generated by calcium flux through ion channels and/or calcium release from intracellular stores. Numerous neurotransmitters are known to regulate calcium channels and thus calcium influx, which in turn can lead to repulsion or attraction of growth cones. For example, the inhibitory neurotransmitter γ-aminobutyric acid (GABA) can act as an attracting stimulus for growth cones, when binding to $GABA_A$ receptors, while exerting repulsive properties, when acting through the $GABA_B$ receptor. The precise spatial and temporal regulation of calcium levels within the growth cone appears to be crucial for the regulation of filopodial dynamics. A proposed binary response to calcium transients, however, greatly oversimplifies the complexity of the growth cone responses. For example, filopodial protrusion can be stimulated by short local Ca^{2+} elevations, but the repeated induction of calcium transients results in the opposite effect.

Downstream targets of calcium include proteins regulating actin dynamics, such as myosin family members, fodrin, α-actinin, gelsolin, and ADF/cofilin. Intracellular calcium sensor proteins, such as calmodulin (CaM), bind calcium and regulate diverse signaling cascades via Ca^{2+}/CaM-dependent phosphatases and kinases. One of the most prominent family members is the Ca^{2+}/CaM-dependent protein kinase II (CaMKII), which shows isoform-specific calcium sensitivity and controls developmental neurite extension.

Guidance Cues in the Adult and Lesioned Nervous System – Play It Again, Sema!

For a long time, the function of axonal guidance cues seemed limited to the developmental period, where neuron–target connection have yet to be established. After successful target innervation, the role of guidance cues seemed obsolete. There is, however, a growing body of evidence that molecules acting as guidance cues and that initially have been attributed classical developmental roles persist throughout adulthood. Even more importantly, experimental data suggest their involvement in the pathophysiology of the lesioned CNS. Next to commonly known inhibitory molecules derived from CNS myelin, the persistence or reexpression of repulsive guidance cues seems to be at least partially responsible for the insufficient regenerative response of the CNS. On the other hand, molecules with neurotrophic properties during embryogenesis may help to overcome regenerative inhibition and support the survival and outgrowth of lesioned neurons.

Myelin-Based Inhibitors of Axon Growth

In contrast to developing axons, neuronal processes in the adult CNS are ensheathed by oligodendrocytes allowing for fast, saltatory conduction of the action potential. Oligodendrocyte-derived myelin has been established as one of the most important inhibitors of axonal growth, while Schwann cells derived from peripheral nerves showed to be permissive toward regenerating axons.

Myelin-based inhibitors of axon growth, that is, Nogo, oligodendrocyte-myelin glycoprotein (OMgp), and myelin-associated glycoprotein (MAG), were initially proposed to account for most of the myelin-derived inhibitory activity. If this were the case, knockouts for one or several of the known myelin-based inhibitors should have markedly improved regenerative capacities in CNS lesion models. However, mutant mice lacking one or all three Nogo isoforms (Nogo-A, B, and C) showed only moderate to no increase in regeneration after spinal cord injury. A similar failure to increase regeneration was observed in MAG knockout mice.

The Nogo receptor (NgR1) transduces the Nogo signal by binding of the 66-amino-acid extracellular domain of Nogo. For signaling, NgR trimerizes with the p75NTR, a versatile receptor initially identified as the low-affinity neurotrophin receptor, and the recently identified LINGO-1, a leucine-rich repeat transmembrane protein. Besides Nogo, MAG and OMgp signal through the trimeric NgR1/p75NTR/LINGO-1 receptor complex. Similar to Nogo knockouts, NgR-deficient mice show a persistent axonal growth inhibition by myelin *in vitro*, while axons from p75NTR-deficient mice were less inhibited, suggesting a more influential role for p75NTR in the regenerative response. Nevertheless, regeneration of corticospinal tract axons after spinal hemisection was not improved either in NgR- or p75NTR-deficient mice, questioning the major role of Nogo/NgR in the mediation of regenerative inhibition. Several hypotheses have been brought forward to explain the persistent lack of regeneration in mice deficient for MAG, Nogo, p75NTR, or NgR. Myelin-based inhibition may employ pathways different from NgR/p75NTR-receptor signaling to induce inhibition. For example, the tumor necrosis factor receptor family member TROY, which is highly expressed in the adult cortex, is able to form a trimeric complex with NgR and LINGO-1 and thus substitute for p75NTR (**Figure 5**).

Next to the 'classical' myelin-based inhibitors, a number of other outgrowth-inhibiting molecules are known to be expressed in the adult CNS. Chondroitin sulfate proteoglycans (CSPGs), such as versican and brevican, are present on differentiated oligodendrocytes and participate in the inhibition of the regenerative response.

Neurocan and phosphacan are two nervous system-specific CSPGs that show high-affinity binding to the extracellular matrix protein Tenascin-C and other cell adhesion molecules, such as Ng-CAM/L1, N-CAM, and TAG-1/axonin-1. Tenascin-R is yet another extracellular matrix protein, which is expressed on oligodendrocytes of adult mice and is upregulated after lesion injury *in vivo*, strongly suggesting an inhibitory role in axonal regeneration.

Developmental Guidance Cues in the Adult

In spite of the overwhelming presence of myelin-derived regeneration inhibitors in the adult, it was equally tempting to suggest that molecules known for their repulsive function as guidance cues during developmental axonal pathfinding additionally act as inhibitory substrates in adulthood.

As outlined previously, ephrins are involved in developmental patterning and axonal guidance and exert their action after binding to transmembrane trks, the Eph receptors. *In situ* hybridization studies in mice revealed that ephrins and Eph receptors are also widely expressed in the adult CNS, although the expression is attenuated compared to the embryonic tissue. Especially, the EphA4 receptor shows a high expression pattern throughout the CNS, while ephrinBs and EphB receptors are highly expressed in regions of known plasticity, such as the olfactory bulb, the hippocampus, and the cerebellum.

A graded expression pattern of ephrinAs in the superior colliculus similar to that during development,

Figure 5 Inhibitory pathways triggered by myelin-based growth inhibitors. Nogo, myelin-associated glycoprotein (MAG), and oligodendrocyte-myelin glycoprotein (OMgp) signal through the trimeric NgR/LINGO-1/p75 receptor. RhoA activation via guanine nucleotide exchange factors (GEFs) induces activation of Rho-associated protein kinase (ROCK) and LIM kinase (LIMK). LIMK phosphorylates cofilin, inducing actin destabilization and growth inhibition.

was observed in the adult mouse before and after differentiation by axotomy. This suggests a requirement for topographic guidance information for functional regeneration of the retinocollicular projection.

Spinal cord hemisection induced an upregulation of EphA4 in astrocytes at the lesion site of wild-type mice. Knockout mice lacking EphA4 were shown to better regenerate corticospinal and rubrospinal axons after spinal cord hemisection than their wild-type littermates. In this paradigm, the regeneration response was improved even though the 'classical' inhibitory signaling cascade via NgR1/p75 was not affected. Myelinating oligodendrocytes in the adult spinal cord further show an expression of ephrinB3 and postnatal cortical neurons express the EphA4 receptor showing sensitivity toward ephrinB3. These data strongly suggest a persistent inhibitory function for developmental repellent molecules.

In analogy to ephrins, a permanent role for semaphorins in the adult CNS has been recently described. Oligodendocytes and astrocytes of postnatal rat optic nerves show expression of multiple semaphorin family members, and RGCs express the neuropilin-1 semaphorin receptor. Of all semaphorins tested, Sema5A had the most pronounced inhibitory effect on growth cone collapse of RGCs. When RGCs were seeded on P8 optic nerve explants, outgrowth was significantly increased after treatment with a Sema5A neutralizing antibody, suggesting an inhibitory role for Sema5A in the regeneration of adult RGC axons. Sema4D/CD100 is expressed on oligodendrocytes of adult mice and acts as a strong inhibitor for postnatal sensory and cerebellar granule cell axons. After spinal cord lesion, Sema4D expression was transiently highly upregulated in oligodendrocytes at the periphery of the lesion. Class 3 semaphorins show an upregulation in the scar tissue of spinal cord-lesioned rats, and receptors for semaphorins are expressed on lesioned cortico- and rubrospinal tract axons.

The involvement of netrins and slits in regenerative paradigms of the adult CNS is less clear. Recently, however, netrin-1 has been shown to promote outgrowth of dopaminergic neuron axons via its DCC receptor, while slit-2 repelled dopaminergic axon growth via its Robo receptor *in vitro*. Whether axonal regeneration of dopaminergic neurons *in vivo* is equally regulated by netrins and slits remains to be determined.

One common denominator of inhibitory molecules seems to be the signaling via the Rho/ROCK pathway. Similar to NgR1/p75/LINGO-1, EphA4 activates the small GTPase RhoA, which in turn leads to an activation of the Rho kinase (ROCK). Rho kinase activates LIM kinase-1 (LIMK1), which phosphorylates cofilin at its serine 3 residue and thus inactivates cofilin. As a potent regulator of actin filament dynamics, the inactivation of cofilin results in actin polymerization and reduced axonal growth.

The role of classical morphogens for axonal regeneration in the lesioned system has not been studied to a great extent yet. However, there is experimental evidence to suggest neuroprotective effects. Supranigral administration of Shh provided an increased survival of dopaminergic neurons after lesion with the selective dopaminergic neurotoxin

1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) in common marmosets and improved their locomotor activity. Adenovirally administered Shh has also been shown to protect motor neurons after axotomy of the facial nerve in adult rats.

Neurotrophic Factors Promoting Axonal Regeneration in the Adult

In contrast to the presence of inhibitory molecules, trophic support derived from neurotrophic factors seems rather limited after CNS lesions. In the mechanically lesioned spinal cord of adult rats, for example, only a marginal upregulation of BDNF and GDNF and its appropriate receptors was observed. Schwann cells of corresponding nerve roots, however, showed a much more pronounced increase in NGF and GDNF mRNA levels, indicating the better regenerative capacity of the peripheral nervous system.

The administration of neurotrophic factors in a therapeutical approach thus seems promising. In the visual system, regeneration of RGC axons can be studied in a crush model of the optic nerve, where the integrity of the nerve is conserved and the transected axons face a nonpermissive environment for regeneration. Several growth factors have been shown to promote not only the survival of RGCs after crush, but equally improve the regrowth of RGC axons into the optic nerve.

Ciliary neurotrophic factor (CNTF) has been shown to promote regeneration of RGC into peripheral nerve grafts, and axotomized RGCs express the appropriate receptors CNTF receptor α and leukemia inhibitory factor receptor (LIFR). The application of CNTF and a Nogo-neutralizing antibody was even synergistic toward promotion of the regenerative response. GDNF, a member of the TGF-β superfamily and potent survival factor for dopaminergic neurons, has been tested for proregenerative properties in spinal cord injury. Mini-guidance channels filled with GDNF and placed into a hemisection gap lesion promoted the regrowth of spinal cord axons into the implant and increased the number of propriospinal neurons.

The combination of growth factors has been the subject of several studies to promote axonal regeneration. For example, fibroblast growth factor-2 (FGF-2), Neurotrophin-3 (NT-3), and BDNF had a synergistic effect on regeneration of RGC axons following crush axotomy, being more effective than treatment with either growth factor alone. BDNF and aFGF promote regeneration of spiral ganglion cell axons into the lesioned organ of Corti. BDNF and NT-3 enhanced propriospinal axonal regeneration in the adult rat spinal cord. The effects of NT-3 and BDNF on regeneration have been shown to be at least partly mediated by enhanced polymerization of f-actin in growth cones.

Intrinsic Regenerative Capacity

The proregenerative effect of neurotrophic factors decreases with the age of neurons. Several factors have been brought forward to be responsible for age-dependent susceptibility to neurotrophic factors and decreased intrinsic regenerative capacity. Differential downregulation of neurotrophin receptors on adult neurons and the increased signaling of inhibitory pathways are likely to contribute to this. An age-dependent reaction of the nervous system toward lesion and a better restoration ability of the peripheral nervous system has been well known from clinical experience. The marked difference between regeneration responses of central and peripheral neurons in the adult CNS may also be explained by differential regulation of transcriptional programs upon lesioning. Pseudo-unipolar DRG neurons, for instance, show a pronounced regenerative response in their peripheral branch, while the ascending central branch is unable to regenerate after injury. Expression of the transcription factor c-Jun, in DRG neurons, is markedly upregulated after lesion of the peripheral branch, while central lesions induce only weak c-Jun upregulation. This correlates with the restricted regeneration potential of the central branch. However, placing a dorsal root into the hemisection site, promoting regeneration into the transplant, again induced marked c-Jun expression in DRG neurons. A very similar effect was shown on the upregulation of growth-associated protein 43 (GAP-43) expression, which is increased equally after lesion of the peripheral branch and almost nonexistent after central lesion. The upregulation of c-Jun and GAP-43 in paradigms of regeneration suggested that these proteins are involved in shaping the cell-intrinsic answer to successful regeneration. Therefore, an overexpression, for example, by viral vectors, has been proposed. Several studies, however, showed that simple overexpression of GAP-43 may not be sufficient to induce regeneration. In the current picture, GAP-43 and c-Jun are standing at the end of a transcriptional program involving the expression of a whole plethora of other so-called regeneration-associated genes (RAGs). However, c-Jun may also act as a two-sided sword in regeneration and death signaling. It has been shown that c-Jun is upregulated after optic nerve axotomy. Moreover, proximal axotomy resulted in stronger c-Jun upregulation and in fewer surviving RGCs than distal optic nerve transection. The arguments for c-Jun as an important apoptosis mediator and potential therapeutical target are supported by the fact that siRNA-mediated downregulation of c-Jun may indeed protect RGCs from axotomy-induced cell death. Thus, the reactivation of growth-associated, developmentally

regulated programs is a necessary prerequisite for axonal regeneration. However, it also renders the adult neuron more susceptible to apoptotic cell death.

In striking contrast to the mammalian nervous system, the CNS of amphibians and fish shows a vigorous regeneration reaction following traumatic lesion. Goldfish, for example, readily regrow their axons after optic nerve transection to functionally reinnervate the tectum and even restore vision. Fish RGC do not degenerate after axotomy, but show a pronounced hypertrophy with dense nucleoli, suggesting an activation of protein and RNA synthesis. Similar to mammals, trophic factors, like NGF, stimulate the outgrowth of explanted fish RGC *in vitro*. Proteins secreted by the sheathing cells of the optic nerve (axogenesis factor-1 and -2) have also been found to promote regeneration. Myelin-based inhibitors of axon growth are also present in the fish optic nerve. However, their composition seems to be different from mammalian myelin: RGC explants from fish regenerate readily on fish myelin, but fail to regenerate on rat myelin. Finally, lesion-induced intrinsic transcription programs in fish and amphibians may lead to expression of different target genes than in mammals. For example, the cell adhesion molecule Contactin 1 (Cntn1) is duplicated in fish and activated after optic nerve lesion, suggesting a regeneration-promoting role similar to L1, N-CAM, or TAG-1. The retinol-binding protein purpurin was shown to be upregulated following axotomy and promoted neurite outgrowth of retinal explants. In summary, differences in the intrinsic regenerative capacity by activation of specific transcriptional programs in fish and amphibians may be at least as important for successful regeneration as a more permissive environment.

Preconditioning lesions to the peripheral branch of DRG axons induced an increased regenerative response in the central branch of the DRG in the dorsal column. This was accompanied by an elevation of intracellular cAMP and inhibition of PKA. Increased regeneration in response to application of neurotrophic factors has also been shown to be mediated by elevated levels of cAMP. As could be demonstrated in cerebellar neurons, priming with BDNF or GDNF incurred resistance against MAG-induced outgrowth inhibition via cAMP elevation and activation of PKA. This involves inhibition of phosphodiesterase by activation of the extracellular-signal regulated kinase (ERK). Direct injection of a cell-permeable cAMP analog (dibutyryl-cAMP; db-cAMP) into the dorsal column of a lesioned spinal cord fostered regeneration. Elevated cAMP levels may modulate the response to lesion via activation of the cAMP response element binding protein (CREB) transcription factor. However, CREB activation alone may be insufficient, as was implicated in a study combining neurotrophin treatment and cAMP in a model of spinal cord injury (Figure 6).

Taken together, axonal regeneration in the adult mammalian CNS is restrained by a multitude of intrinsic and extrinsic factors: an inhibitory environment consisting of repulsive guidance cues and myelin-derived growth inhibitors paired with lack of

Figure 6 Preconditioning may change intrinsic growth capacity via induction of growth-associated genes. Traumatic lesion to the central branch of the dorsal root ganglion (DRG) results in its degeneration. Preconditioning lesions to the peripheral branch of the DRG and subsequent lesion of the central branch induces a regenerative response in the central branch. This is accompanied by an elevation of intracellular cyclic AMP (cAMP) levels.

trophic support and pro-regenerative transcriptional programs result in insufficient functional renewal capacity. Strategies to overcome regenerative failure will therefore most likely be based on a combination of approaches, targeting several pathways simultaneously.

Introduction to the Problem of Regeneration Failure

Unlike their counterparts in the peripheral nervous system (PNS), axons of the central nervous system (CNS) fail to regenerate following injury. With the exception of olfactory sensory neurons within the olfactory bulb and hypothalamo-neurohypophysial axons within the hypothalamus, regeneration of axonal tracts is not observed following disruption of the CNS in adult mammals. The regenerative success of these two pathways has been attributed to the specialized support cells present in these regions: olfactory ensheathing cells in the olfactory bulb and tanycytes in the mediobasal hypothalamus. Interestingly, numerous studies have been conducted using these two cell types, along with Schwann cells, the growth-promoting glia of the PNS, as bridging cells in other regions of the CNS with some success. Typically, adult CNS axons are, at best, capable of abortive sprouting, which results in the failure of these neurons to re-innervate their targets. In fact, the vast majority of functional recovery reported following CNS lesions in experimental models is thought to be due to plasticity of spared or uninjured processes and not to new growth of damaged fibers. Functional recovery of adult CNS neurons is limited because tissue damage following injury initiates a cascade of events that lead to structural and molecular changes within the lesion that are inhibitory to regeneration. There are numerous obstacles for regenerating axons to overcome, but our focus in this article is on the role of the extracellular matrix (ECM) in the glial scar.

The Glial Scar

What Is the Glial Scar?

The glial scar is a complex milieu consisting mainly of reactive astrocytes and secreted ECM molecules. In more severe injuries in which the blood–brain barrier (BBB) is broken down and the meninges are compromised, connective tissue elements, such as fibroblasts, as well as invading immunological cells, such as macrophages, may mix with astrocytes in the lesion (Figure 1). Immediately following damage to the CNS, astrocytes begin to undergo a process known as reactive gliosis, in which they become extremely hypertrophic, dramatically upregulate expression of intermediate filament proteins such as glial fibrillary acidic protein (GFAP) and vimentin, and increase secretion of ECM components. Although the response is termed gliosis, implying an increase in cell division, proliferation of astrocytes is actually rather limited and confined to the penumbra surrounding the lesion core. Recent evidence has shown that depletion of the proliferating population of astrocytes following injury prevents reestablishment of the BBB and results in increased lesion size and an exacerbated inflammatory response. Therefore, despite its devastating effect on axonal regeneration, the glial scar plays an important role in secluding the damaged site and protecting the surrounding uninjured tissue from secondary injury.

Development of the glial scar begins within hours of injury, subsequent to the introduction of non-CNS molecules and cell types into the parenchyma of the brain or spinal cord via disruption of the BBB. The BBB remains permeable to blood and serum components for up to 2 weeks, continuously bathing the CNS with numerous exogenous proteins and factors. There is a correlation between the areas of the most significant BBB breakdown, highest infiltration of activated macrophages, and maximal glial scaring. As the lesion matures, the enlarged and entangled astrocytic processes and secreted ECM components form a tenacious and rubbery scar.

Inhibitory Nature of the Glial Scar

Historically, the association of dystrophic axonal endings with dense reactive astrocytic processes within a CNS lesion led to the hypothesis that the glial scar presents a physical barrier to regenerating fibers. The distinct morphology of struggling growth cones was first described by Ramón y Cajal, and for many years these growth cones were thought to be dead endbulbs or retraction clubs and were considered sterile and incapable of growth. Recent evidence suggests that dystrophic endings retain their ability to regenerate and are capable of returning to an active state. Injured spinal cord neurons can grow into a peripheral nerve graft 4 weeks after injury, despite having stalled in the lesion for an extensive period of time. Shrunken cell bodies of injured rubrospinal tract neurons (Figure 1, E) increase in size following brain-derived neurotrophic factor (BDNF) stimulation 1 year post lesion and can extend growth-associated protein-43 (GAP-43)-positive axons into a peripheral nerve graft.

Figure 1 Cellular and molecular elements of a typical penetrating spinal cord lesion. The lesion core is devoid of neurons and astrocytes and is populated by phagocytic macrophages that can cause cavitation. Fibroblasts deposit basal lamina and form a barrier between the lesion core and lesion penumbra. Macrophages and reactive astrocytes occupy the lesion penumbra, where reactive astrocytes secrete inhibitory CSPGs in an increasing gradient toward the lesion core. Other important factors in the lesion penumbra include semaphorins, slits, and Eph/ephrins. A and B, Neurons have been axotomized from the lesion and fail to regenerate, resulting in a dystrophic club ending. B, Dystrophic neuron turns away from the intensely inhibitory lesion core and stops growing in a region of high levels of inhibitory proteoglycan. C, D, Neurons undergo Wallerian degeneration (dotted line) as a result of damage. C, Neuron has been deformed by the lesion and subsequently degenerates because of structural damage and inflammation. D, Axon dies only as a result of secondary damage due to inflammation. E, 'Ghost' neuron atrophies as a result of axotomy. The axon forms a dystrophic endbulb, and the cell body shrinks. The neuron is dormant but may be awakened by growth factors. F, Undamaged axon becomes demyelinated (purple line) both near the lesion and in regions farther away from the lesion. G, Undamaged axon sprouts to re-innervate the spinal cord. Note a contusive injury would be similar to a penetrating injury; however, it would lack the fibroblast infiltrates with their associated ECM components (basal lamina).

Even at extended time periods post lesion, the supposedly sterile endings in the corticospinal tract have been shown to be capable of sprouting.

Axonal Response to the Glial Scar

While initial studies indicated that axons retract significantly from the lesioned area after axotomy, improved tracing techniques have revealed that dystrophic axons actually persist in the vicinity of the lesion (Figure 1, A and B). This implies that even though they are stalled and do not elaborate synapses, an intrinsic mechanism is in place that allows them to maintain their viability and stability. It is possible to generate dystrophic endings on adult sensory neurons *in vitro* by culturing them on inverse gradients of the growth-promoting ECM substrate laminin and the potently inhibitory chondroitin sulfate proteoglycan (CSPG) aggrecan (see below; Figure 2). Time-lapse imaging of these dystrophic endings using this model first demonstrated that these endbulbs are, in reality, quite dynamic. The endbulbs actively rearrange their cytoskeletons, rapidly recycle their plasma membranes, and alter the location of their repertoire of integrin receptors, which bind to ECM substrates and are critical for adhesion and migration. Further work has shown that alteration of integrin expression and membrane turnover also occur *in vivo* following spinal cord injury.

It is essential to distinguish between the states of dystrophy and collapse when describing axonal responses to injury. Following direct contact with myelin components and mature oligodendrocytes, growth cones of mature neurons become shrunken,

Figure 2 Normal and dystrophic growth cones. (a) Normal growth cone of adult DRG on laminin. The growth cone uses filopodia and lamellopodia to sample the environment for cues. (b) Dystrophic growth cone on a decreasing gradient of laminin plus an increasing gradient of inhibitory proteoglycan (arrow). The growth cone forms a bulbous, dystrophic ending when it encounters inhibitory CSPG, as is characteristic in the CNS lesion environment. Scale bar = 10 μm.

retracting their filopodia and lamellipodia, and enter a temporary state of quiescence. This process is known as collapse and has been well characterized *in vitro*. After some time, growth cones will begin to extend once more only to collapse again upon renewed contact with the collapsing agent. While collapse also results in stalled growth, it is very different from dystrophy, which is a highly dynamic state. Collapse is also prevalent in development and occurs frequently when pathfinding axons encounter transitions between ECM substrates. Observations of the inhibitory nature of myelin *in vitro* led to its implication as another barrier to CNS regeneration, and numerous studies of its major inhibitory element, the Nogo receptor, have used antibodies to block its binding of myelin components to enhance growth of regenerating fibers *in vivo*. While many of these studies have had some success in generating limited functional improvement, recent evidence has suggested that this is due, at least in part, to an increase in plasticity of uninjured fibers.

Immature Astrocytes Promote Regeneration while Mature Astrocytes Make Scars and Block Growth

Embryonic and early postnatal animals have a much higher capacity for regeneration following damage to the CNS than adults. While the neurons undoubtedly differ in their intrinsic growth potential (see below), there are also differences between embryonic and adult astrocyte responses to injury. When hippocampal or retinal ganglion cell (RGC) neurons are cultured on astrocyte explants from lesioned animals, neurite outgrowth is inhibited by reactive mature astrocytes and actually promoted by reactive immature astrocytes. In fact, mature reactive astrocytes can even inhibit the enhanced growth potential of embryonic neurons. Remarkably, when immature astrocytes are transplanted into the adult brain, they can alter the response of endogenous astrocytes and repress formation of the glial scar.

What Are the Molecular Triggers of Glial Scarring?

While the factor or combination of factors responsible for stimulating glial scar formation has not yet been elucidated, there are several putative candidates. Expression of both transforming growth factor beta (TGF-β) 1 and 2 is upregulated in the CNS following injury, and TGF-β2 is known to radically increase production of proteoglycans by astrocytes. The serine protease thrombin has also been implicated as a potential trigger of reactive gliosis. Thrombin, an integral element of the blood coagulation cascade, has additionally been shown to be involved in the chemotaxis and adhesion of monocytes, macrophages, and neutrophils, as well as the regulation of neurite outgrowth, induction of astrocyte proliferation, and activation of microglia in the CNS. Inflammatory cytokines appear to possibly contribute to glial scar formation as well. Members of the interleukin family may also be involved as interleukin 1, which is released by mononuclear phagocytes, has been shown to generate an inflammatory response in astrocytes. Application of interferon gamma has been shown to increase proliferation of astrocytes *in vitro* and treatment of the injured brain with it causes scar expansion. Basic fibroblast growth factor also increases proliferation of astrocytes *in vitro* and its expression increases in the CNS after injury. However, it is important to note that astrocyte proliferation is only a small part in the formation of the glial scar. It is thought that the presence of macrophages is in large part responsible for stimulating astrocytes to take on a reactive state and to construct the glial scar. When Zymosan A, a potent activator of

macrophages, is injected into the CNS, extensive migration of astrocytes away from the inflammatory site leads to cavitation, severe upregulation of proteoglycans, and substantial glial scarring. *In vitro* work has further shown that astrocyte migration away from areas of inflammation can cause axonal stretching and secondary axotomy through neuronal–glial interactions. Therefore, factors derived from blood and/or serum coupled with macrophage invasion combine to contribute to the formation of the glial scar and secondary lesion phenomena, including the demyelination of nearby otherwise healthy axons.

Proteoglycans

Proteoglycans Are ECM Molecules

There are four classes of proteoglycan: CSPG, dermatan sulfate proteoglycan, heparan sulfate proteoglycan, and keratan sulfate proteoglycan. Proteoglycans are components of the ECM that are involved in adhesion, growth, receptor binding, migration, barrier formation, and interactions with other ECM molecules. Proteoglycans consist of a protein core to which glycosaminoglycan (GAG) side chains are bound by a tetrasaccharide link (Figure 3). These GAG chains are composed of repeating disaccharide units formed from two alternating monosaccharides, usually either *N*-acetylglucosamine or *N*-acetylgalactosamine followed by uronic acid. GAG chains can vary dramatically in length, and as many as 100 can be attached to the core protein. The number of GAG chains along with their sulfation pattern and the core protein to which they are bound yield a tremendous amount of variability within and between classes.

CSPGs are inhibitory ECM molecules CSPGs include aggrecan, brevican, neurocan, NG2, phosphacan (also classified as a keratan sulfate proteoglycan), and veriscan. CSPGs are present throughout development and are crucial for axon guidance in the

Figure 3 CSPGs and the action of chondroitinase ABC. CSPGs are often anchored to cell membranes, hyaluronan, and other ECM components (gray bar). (a) CSPGs are composed of a core protein linked to GAG side chains by a tetrasaccharide linker of xylose, glucose, and uronic acid. GAGs are disaccharides of *N*-acetylglucosamine or *N*-acetylgalactosamine and uronic acid. These disaccharides repeat to form a long chain. (b) Chondroitinase ABC (ChABC) is a bacterial enzyme that cleaves GAG chains, resulting in a stub of carbohydrates. This abolishes the majority of inhibition from CSPGs.

roof plate, the midline of the rhombencephalon and mesencephalon, the dorsal root entry zone (DRE2), the optic tract and chiasm, and the retina. An elegant study utilized the enzyme chondroitinase ABC (ChABC) from the bacterium *Proteus vulgaris* to digest the GAG chains of CSPGs in the developing retina. The absence of the CSPG GAG chains resulted in pathfinding errors of RGC neurons whose axons grew aberrantly into regions of the retina from which they are normally excluded. The expression of CSPGs changes after the critical period as the animal matures and the axons have reached their targets.

More on the inhibitory nature of CSPGs The physical nature of the glial scar barrier takes several weeks to months to fully develop, which cannot explain the inhibition to axonal growth observed acutely following injury. Interestingly, CSPG expression is robustly upregulated by mature astrocytes in the glial scar within 24 h of CNS injury in adult mammals and maintained for several months. This evidence, along with their inhibitory role in embryonic pathfinding in specific regions, implicated CSPGs as a barrier to regeneration in the CNS. In the early 1990s, it was shown that CSPGs are potently inhibitory to adult neurite outgrowth both *in vitro* and *in vivo* and play a significant role in CNS regeneration failure. CSPGs are not only potent inhibitors of axonal growth when encountered alone, but they can also block the growth-promoting effects of substrates such as laminin, fibronectin, and L1. *In vitro* adult neurites avoid stripes of laminin mixed with aggrecan when given the choice between this combination of substrates and stripes containing laminin alone. When RGCs are cultured on scar explants that are removed from the adult (but not the neonatal) brain, they can only extend long neurites if the wound tissue is pretreated with ChABC, indicating that CSPGs are potent inhibitors of neurite outgrowth *in vivo* as well.

Different neuronal populations experience varying degrees of growth retardation when exposed to CSPGs *in vitro*. RGCs are able to extend further up a stepwise gradient of aggrecan on laminin than either forebrain neurons or embryonic dorsal root ganglion cells (DRGs), although growth was significantly stalled at the transitions between steps. Immature neurons seem to be able to grow on CSPGs by upregulating integrin receptor expression until a threshold concentration of the inhibitory substrate is reached, and they can grow no further. This threshold is different for different populations of neurons. As mentioned earlier, adult DRGs grow up a smooth gradient of CSPG until the potently inhibitory rim is reached, where they stall and form dystrophic endings (Figure 2). In development, some neurons are capable of growing through proteoglycan-rich areas. For example, embryonic hippocampal neurons and thalamocortical fibers growing through the subplate are capable of extending neurites on oversulfated CSPGs. *In vitro*, when neurons are plated on low concentrations of CSPGs mixed with laminin, neurites fasciculate tightly as they would in the subplate *in vivo*. In both embryonic and adult systems *in vitro* and *in vivo*, the balance of proteoglycans and other ECM molecules is critical to the determination of growth cone behavior as well as bundling and branching patterns of axons.

Neuronal populations have different thresholds for proteoglycan inhibition when presented in a gradient *in vivo*, but all populations will eventually become dystrophic within a spinal cord lesion (Figure 1). Proteoglycan concentration is highest at the lesion epicenter and decreases in a gradient throughout the penumbra. As axons enter the lesion, they receive more inhibitory cues, and form increasing numbers of dystrophic endings as they approach the core of the developing glial scar. Axons of motor neurons are not able to grow into the lesion at all, but instead sprout in the undamaged region adjacent to the lesion. Serotonergic neurons are capable of growing to the lesion edge, and sensory axons can grow further into, but not through the lesion. Amazingly, adult sensory neurons have the ability to regenerate robustly through intact and degenerating white matter when gently microtransplanted (without creating a scar) well distal to a large lesion in the spinal cord (i.e., beyond the zone of BBB disruption). However, regeneration stops when the rapidly growing axons reach the lesion environment, indicating the potently inhibitory nature of the glial scar.

Chondroitinase ABC

ChABC digests inhibitory GAG chains on proteoglycans The use of ChABC is currently the most effective method of removing the inhibition of CSPGs (Figure 3). A single injection of ChABC into the normal uninjured brain causes a widespread reduction in the concentration of CSPGs within the ECM for at least 4 weeks. It is important to note that ChABC digestion only cleaves the GAG side chains of CSPGs and that some carbohydrate residues remain attached to the core protein. These residues can be labeled with specialized antibodies to demonstrate digestion of CSPGs in a ChABC-specific manner. While the core proteins of CSPGs are somewhat inhibitory to neurite outgrowth, the vast majority of the inhibitory nature of CSPGs lies within their GAG side chains, which is evident from the work by various laboratories showing that removal of CSPGs from the glial scar enhances regeneration and can provide some functional recovery. Administration of ChABC following a nigrostriatal pathway lesion promoted regeneration

of dopaminergic neurons to the point of re-innervating their target area in the striatum. In animals receiving a bilateral dorsal column injury, intrathecal delivery of ChABC induced growth of ascending sensory and descending motor axons into and possibly slightly past the lesion, which resulted in improved function of both proprioception and locomotion. ChABC treatment has also resulted in increased regeneration of Clarke's nucleus neurons following a hemisection lesion. Similar CSPG digestion and improved regeneration have also been observed in cats receiving hemisection and rats receiving contusion injuries. This gives hope that-continuing efforts to increase the efficacy of this technique could potentially lead to treatments for spinal cord injury in primates and hopefully in humans. Typically, ChABC is administered to the CNS through a pump or by direct injection. ChABC then remains active for 3 days *in vivo*. An alternative strategy might be to genetically engineer CNS cells to express ChABC, allowing for controlled, continuous delivery of the enzyme.

The perineuronal net and the regulation of synaptic plasticity Proteoglycans in the gray matter of the brain and spinal cord may encapsulate synapses with a lattice-like accumulation of ECM known as the perineuronal net (PNN) and prevent neuritic sprouting and synaptic plasticity. PNNs consist mostly of CSPGs produced as the animal passes through critical periods of CNS maturation. As the animal matures, PNN production increases and the potential for plasticity decreases as the synaptic connections are firmly established. Application of ChABC to the uninjured cerebellum in rats induces sprouting of unmyelinated Purkinje cell axon terminals. This CSPG-mediated inhibition of sprouting prevents changes in functional connectivity, which could lead to formation of aberrant synaptic connections. However, it may be advantageous to restore plasticity following injury. For instance, when the adult visual cortex is treated with ChABC, plasticity can be recovered. This has important applications in restoration of vision in adult strabismic animals that have been monocularly deprived since weaning and are therefore cortically blind in one eye. ChABC-induced plasticity could also be important during rehabilitation after stroke and in treating epilepsy.

Other Inhibitory ECM Molecules

In addition to CSPGs, there are many other molecules known to be upregulated following CNS injury. It is well known that axon repellants such as semaphorins, slits, and Eph/ephrins play critical roles in embryonic development, but their roles as inhibitors of regeneration in the mature CNS are just beginning to be understood.

Semaphorins The expression of semaphorin 3, a chemorepellant to growing axons during development, is upregulated by invading fibroblasts following stabbing types of injuries to the spinal cord, cortex, and lateral olfactory tract. Semaphorin 3's high-affinity receptor, neuropilin 1, is upregulated in neurons attempting to regenerate into the lesion. Regenerating axons are excluded from areas near the lesion core that contain semaphorin 3, indicating that semaphorins may be another inhibitory cue present in fibroblast-rich lesions of the CNS.

Eph/ephrins The Eph receptor and its ligand, ephrin, function in cell migration, axon guidance, and tissue patterning during development and are upregulated following CNS injury. Often, the interaction of the Eph receptor and ephrin ligand results in cell repulsion. This finding suggests that Eph/ephrin signaling might be inhibitory to axon regrowth at the lesion site, or may be important in cell migration and tissue repair. Recent work has shown a correlation between segregation of reactive astrocytes and meningeal fibroblasts and ephrinB2 and EphB2 expression, respectively, following spinal cord injury in the adult rat. EphrinB2-positive astrocytes and infiltrating meningeal fibroblasts expressing EphB2 undergo a period of intermingling, which is followed by strict segregation during formation of the glial/mesenchymal scar. EphrinB3 has been characterized as a myelin-based inhibitor of axon outgrowth and is present on myelinating oligodendrocytes. Additionally, adult corticospinal neurons express EphA4, the receptor for ephrinB3, suggesting that these axons may be inhibited by Eph/ephrin signaling in the lesion environment.

Slits Slit proteins also play important roles in cell migration and axon guidance during development and have been implicated in regeneration failure because they are upregulated after injury. The slit proteins are ligands of glycipan-1 and the Robo receptor. Cortical astrocytes express both slit and glycipan-1 mRNA following cortical injury. Robo-1 mRNA is also present on macrophages and fibroblasts following injury, which further implies that slit-mediated repulsion could be playing a role in the inhibitory environment of the lesion. While ChABC treatment removes much of the inhibition in the glial scar due to CSPGs, additional strategies must be developed to overcome inhibition resulting from other molecules present in the lesion environment.

Adult Neurons Lack a Robust, Intrinsic Regrowth Potential

Using ChABC and other treatments to remove the extrinsic inhibitory cues of the glial scar may not be

sufficient to allow long-distance regeneration because adult neurons also lack a strong intrinsic ability to regenerate following a CNS lesion. Multiple strategies have been used *in vitro* and *in vivo* to successfully amplify the growth potential of adult neurons: application of neurotrophic factors, elevation of intracellular cyclic adenosine monophosphate (cAMP) levels, and utilization of a conditioning lesion.

Neurotrophins/Growth Factors Can Increase Axonal Outgrowth and Overcome the Glial Scar

Treatment of transected dorsal column axons with nerve growth factor (NGF) or neurotrophin-3 (NT-3) increased their growth into and out of a peripheral nerve bridge as well as through the glial scar and back into host tissue. Administration of NGF into a dorsal column crush lesion resulted in increased sprouting into the lesion. Using either intrathecal or adenoviral application of NT-3 or NGF to the injured promoted regeneration of DRG axons through the DREZ and into the spinal cord, restoring nociceptive function. It is critical to understand, however, that treatment with neurotrophins can cause regenerating axons to overcome inhibition by CSPGs and other components of the glial scar, whereas ChABC treatment simply removes the source of inhibition. The increase in the capacity for outgrowth of adult axons observed following neurotrophin application is most likely due to increased expression of growth-enhancing genes in the damaged neuron.

Conditioning Lesions/cAMP Can Also Increase Axonal Outgrowth

Conditioning lesions also enhance the capability of adult neurons to regenerate and this is due at least in part to an elevated cAMP concentration within the cell body. This effect can be mimicked in adult sensory neurons by injecting cAMP into the DRG. cAMP is known to act through protein kinase A (PKA) to influence cellular sprouting and outgrowth, and it may be possible to take advantage of PKA-mediated pathways in order to overcome inhibition by the glial scar and myelin. Inhibition of the Rho GTPase increases neurite outgrowth on proteoglycan- and myelin-containing substrates, and the inhibitory activity of CSPGs within the glial scar is mediated though the Rho/ROCK signaling pathway.

Inflammation: Good or Bad?

Inflammation, although intimately linked with scar formation, may also have a positive effect on regeneration by stimulating an intrinsic growth response in neurons. Using Zymosan A (a purified yeast cell wall extract) to activate macrophages outside of the CNS compartment via intravitreal injection promotes regrowth of RGCs into and slightly past an optic nerve crush. Injection of Zymosan A into the DRG *in vivo* enhances the ability of those neurons to extend neurites on a smooth gradient of aggrecan and laminin, as well as through the DREZ and into the spinal cord following a crush injury to the dorsal root. One mediator of the Zymosan A effect is mannose, a monosaccharide. Surprisingly, treatment of neurons with mannose alone can increase their capacity to regenerate, which may be due to an increase in the overall energy reserves of the neurons. Another effector of increased axon growth, a protein secreted by macrophages, has recently been found. Thus, the combination of mannose, macrophage-derived factor, and cAMP should act synergistically to stimulate axon growth.

Combination Treatments Stimulate Regeneration Best

Recent work has combined stimulation of the intrinsic ability of adult neurons to regenerate using neurotrophins or growth factors with glial scar remodeling to decrease the inhibitory nature of the CSPGs within the glial scar. Retinal lesions, which result in denervation of the superior collicus, cause some minimal sprouting of uninjured RGC axons; however, this sprouting is not robust enough to provide functional recovery. Combining ChABC treatment of the superior colliculus with BDNF stimulation of the RGC cell bodies promoted an increase in sprouting greater than either treatment alone. Some of these sprouting fibers displayed synaptic markers indicating a real potential for some functional recovery. Perhaps the therapeutic value of ChABC treatment will be an increase in functional recovery through an enhanced sprouting response.

Conclusion

The physical and chemical barrier of the glial scar is a formidable opponent for axons attempting to regenerate. Reactive astrocytes, macrophages, fibroblasts, and a host of ECM components including inhibitory CSPGs all play a part in restricting CNS axon regeneration. Strategies to promote regeneration have had partial success, mostly resulting in sprouting of undamaged axons and limited regrowth of damaged axons. In order to overcome the inhibitory environment of the glial scar, a multipartite strategy will most likely be required that (1) removes extrinsic inhibitory factors present within the scar, (2) provides a growth-promoting bridge across or around the scar, and (3) stimulates the neurons to increase their intrinsic capacity for growth, which might allow for long-distance regeneration and functional recovery.

Axonal Transport and ALS

Introduction

Motor neuron diseases involve the selective degeneration and death of motor neurons, leading to muscle atrophy. While some forms of motor neuron disease show an early onset consistent with developmental defects, the most prevalent forms are later in onset and are characterized by inexorable and fatal neurodegeneration.

The cellular and molecular mechanisms leading to the specific degeneration and death of motor neurons have been extensively examined. While many hypotheses have been proposed, there is a particular focus on the unique size and shape of motor neurons, which are huge cells with extended processes. Due to their morphology, motor neurons are uniquely dependent on active intracellular transport. Therefore, specific defects in transport, particularly along axons that may extend up to a meter in length, may lead to degeneration and cell death. Here, we focus on the hypothesis that defects in axonal transport may be a critical component of the neuronal degeneration observed in motor neuron diseases such as amyotrophic lateral sclerosis.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease, has a typical age of onset of 50–60 years, usually leading to death within 5 years due to widespread loss of motor neurons and subsequent muscle atrophy. Currently, there are no available therapies that significantly affect the course of the disease.

The worldwide prevalence of ALS is ~5 in 100 000. Most of these cases (~90%) are sporadic, with no known etiology. Proposed triggers for the disease include environmental influences, such as viral infection or exposure to toxins, or immune dysfunction. However, there are not yet sufficient epidemiological data to support any specific cause. Significantly, the course of disease in sporadic cases is indistinguishable from that observed in the majority of familial cases, consistent with a common pathway of degeneration.

Familial ALS

About 10% of ALS cases are familial, and the identification of the genetic defects involved has provided significant insights into the pathophysiology of the disease, while also raising many further questions. The most common gene linked to ALS encodes Cu/Zn superoxide dismutase 1 (SOD1); *SOD1* is a ubiquitously expressed gene involved in the conversion of superoxide. More than 100 different mutations within the *SOD1* sequence have been identified in patients with familial ALS. These mutations are not limited to the active site of the enzyme; instead they are found throughout much of the coding sequence in *SOD1*. Some but not all of the mutations inactivate the enzyme. As loss of *SOD1* expression does not cause disease in knockout mice, most of the known mutations in *SOD1* are thought to act via a toxic gain-of-function mechanism involving alterations in enzyme folding, stability, or aggregation rather than changes in enzyme activity.

Alternative genetic defects have also been identified in patients with either typical or variant forms of familial ALS (Table 1). The affected proteins include alsin, the product of the *ALS2* gene, senataxin, the product of the *SETX* ('amyotrophic lateral sclerosis 4′) gene, and vesicle-associated membrane protein (VAMP)-associated protein B (VAPB), the product of the *VAPB* ('amyotrophic lateral sclerosis 8′) gene. Two of these proteins, alsin and VAPB, are implicated in vesicle trafficking pathways in the cell. A less severe form of inherited motor neuron disease is due to a mutation in the *DCTN1* gene encoding the $p150^{Glued}$ subunit of dynactin, which is required for transport within the neuron. While neurofilaments may play a role in the pathogenesis of ALS, mutations in neurofilament genes are not a significant cause of inherited ALS.

Animal Models of ALS

The identification of mutations in the *SOD1* gene in familial ALS patients led quickly to the development of transgenic animal models for the disease. Analysis of knockout mice demonstrated that loss of *SOD1* gene expression is not sufficient to induce disease. Instead, overexpression of mutant human *SOD1* results in a mouse model with degenerative disease that mirrors the human disease in several aspects.

The first, and most widely studied model involves the overexpression of the human *SOD1* gene with a G93A mutation. This model has a fully penetrant phenotype with disease onset 3–4 months after birth; affected animals die within 4–5 months. Pathological analysis indicates that motor neurons are primarily affected, and the degeneration and death of motor neurons leads to muscle atrophy. A number of other *SOD1* mutations identified in patients with familial

Table 1 ALS-linked genes involved in transport and trafficking

Protein	*Gene*	*Position*	*Onset*	*Clinical presentation*
SOD1	*SOD1* (*ALS1*)	21q22	Adult	Amyotrophic lateral sclerosis
Alsin	*ALS2*	2q33	Juvenile	Spastic paraparesis; slowly progressive
VAPB	*VAPB* (*ALS8*)	20q13	Adult	Amyotrophic lateral sclerosis
$p150^{Glued}$	*DCTN1*	2p13	Adult	Vocal cord paralysis; slowly progressive weakness of hands, limbs

ALS have also been expressed in mouse models; these models vary in age of onset and severity of disease but show a common phenotype of motor neuron disease. Rat models have also been developed, and display pathology very similar to that seen in the mouse.

Mouse models of other genetic defects linked to ALS have also been developed. For example, knockout of the alsin (*ALS2*) gene associated with juvenile ALS have been generated, which demonstrate only subtle neuropathological defects. At the cellular level, defects in endosomal trafficking are apparent, but these defects are not sufficient to induce significant motor neuron loss or muscle atrophy. Mouse models with mutations or targeted defects in dynein or dynactin function are described in the following sections.

Mechanisms of Cell Death

Initial studies of both mouse models and patient autopsy material revealed two important observations: axonal degeneration of motor neurons and formation of protein aggregates. Based on these observations, and the relative specificity of the disease for motor neurons, a hypothesis was developed that axonal transport was blocked, potentially by the formation of aggregates of mislocalized or mutant protein, and that this in turn leads to the degeneration of the axon, followed by cell death.

Axonal transport The large size and extended processes of motor neurons make them particularly dependent on axonal transport (Figure 1). Diffusion alone is not sufficient to maintain cells of this size. Long-distance transport within the cell is dependent on microtubules, which form a polarized network extending out from the microtubule-organizing center (MTOC), positioned near the nucleus within the cell body. Transport outward from the cell body to the cell periphery is driven by members of the kinesin superfamily of molecular motors (Figure 1). This anterograde transport is required to supply the distal axon and neuromuscular junction with newly synthesized proteins and lipids, including the replenishment of synaptic vesicle components. Multiple kinesins drive anterograde transport, with some functional specification of motor for cargo, but also some redundancy in the system.

Retrograde transport, from cell periphery to cell center, is driven by the molecular motor, cytoplasmic dynein, and its activator, dynactin (Figure 1). In contrast to the extensive nature of the kinesin superfamily, retrograde transport is driven by a single major motor, cytoplasmic dynein. Retrograde transport is required to return damaged and misfolded proteins to the cell center for efficient degradation. Retrograde transport is also critical in signaling pathways, such as neurotrophic factor signaling and injury response pathways. Both the motor domain of dynein and several of the subunits of dynactin are encoded by single genes. The resulting lack of redundancy suggests that mutations in genes encoding subunits of either dynein or dynactin would have a deleterious effect on the neuron, and this prediction is consistent with observations to date.

Active transport is essential for a cell that can extend up to a meter, and thus axonal transport may be an 'Achilles heel' for the motor neuron. Therefore, it is a reasonable hypothesis that defects in axonal transport, either caused directly by mutations in motor proteins or indirectly due, for example, to the accumulation of toxic protein aggregates which might impede efficient transport, could be sufficient to induce distal axonal degeneration. Further, the key role of retrograde transport in pathways such as neurotrophic factor signaling suggests that inhibition of transport may lead more directly to cell death through the perturbation of signal transduction pathways and consequently the activation of apoptosis.

Alternative models for motor neuron death While defects in transport processes provide a plausible model for motor neuron degeneration, and are well supported by data from both genetic and cellular studies, this aspect of motor neuron biology may represent just one piece of the puzzle. Alternative models to explain motor neuron-specific cell death in ALS have also been proposed, including the formation of toxic protein aggregates, excitotoxicity, the destabilization of neuromuscular junctions, oxidative damage due to either mutant *SOD1* or dysfunctional

Figure 1 Axonal transport in the motor neuron is driven by microtubule motor proteins. Kinesins drive fast anterograde transport of vesicles carrying newly synthesized proteins and lipids from the Golgi outward along the axon toward the neuromuscular junction. Cytoplasmic dynein and its activator dynactin drive retrograde transport of vesicles, neurotrophins (NGF, nerve growth factor; BDNF, brain-derived neurotrophic factor), and misfolded and aggregated proteins from the cell periphery back to the cell body. Slow anterograde transport of cytoskeletal polymers such as neurofilaments involves the combined activities of both kinesin and cytoplasmic dynein.

mitochondria, and inflammatory processes sparked by activated microglia.

It is critical to note that these pathological processes are not mutually exclusive. It is actually most likely that some initial trigger, such as an accumulation of toxic protein aggregates or the loss of adequate trophic factor support, can lead to activation of cellular stress pathways, which in turn can lead to the triggering of caspase activity, leading to cell death. There is also likely to be a parallel activation of an inflammatory response, which in turn may lead to more widespread death of motor neurons. This model is consistent with recent work demonstrating that while motor neurons are the primary site of disease onset, non-cell-autonomous mechanisms contribute to disease progression.

Evidence for Defective Transport in Mouse Models of ALS

Neurofilament aggregation One of the first indications that defects in axonal transport might be linked to ALS came from the observation of neurofilament aggregates along the axons of motor neurons from affected patients; similar aggregates are observed in animal models. To test for a link between neurofilament aggregation and defects in axonal transport, transgenic mice were generated to overexpress the neurofilament subunit NF-H. Analysis of these mice demonstrated an inhibition in the transport of newly synthesized neurofilaments from cell body outward to the distal axon (Table 2). The transport of other cytoskeletal proteins, such as tubulin and actin, was also found to be inhibited.

Slow axonal transport Neurofilaments and other cytoskeletal polymers are transported down the axon at a rate of 0.2–8 mm day^{-1}, in a process known as 'slow' axonal transport. This transport is orders of magnitude slower than the transport of vesicular cargos in 'fast' axonal transport, at rates of ~200–400 mm day^{-1}. For a long time, the mechanisms driving the slow anterograde transport of neurofilaments were unclear. However, recent progress has shown that slow transport along the axon involves the same microtubule motor proteins that drive fast transport. The key difference is that for cargo such as neurofilaments that undergo slow transport, rapid excursions in either the anterograde or retrograde direction are punctuated by prolonged pauses. Both the frequent changes in direction and the extended pauses contribute to an overall net slow outward movement.

The reasons why cytoskeletal polymers are transported in such an apparently inefficient mechanism remain to be determined, but one possibility is that

Table 2 Defective axonal transport in mouse models of motor neuron disease

Model	*Experimental approach*	*Observed defect*
$Tg^{NF\text{-}H}$	Injection of [^{35}S]methionine followed by profiling of ^{35}S-labeled proteins along the sciatic nerve	Inhibition of slow anterograde transport
$SOD1^{G93A}$	Injection of [^{35}S]methionine followed by profiling of ^{35}S-labeled proteins along the ventral root	Inhibition of slow anterograde transport, selective inhibition of fast anterograde transport
	Tracking of retrograde tracer from muscle injection to motor neuron cell body	Inhibition of retrograde transport
	Electron microscopy of axon hillock and initial segment of anterior horn cells	Aberrant accumulation of neurofilaments and mitochondria
$SOD1^{G37R}$	Injection of [^{35}S]methionine followed by profiling of ^{35}S-labeled proteins along the L5 root and sciatic nerve	Inhibition of slow anterograde transport
$SOD1^{G85R}$	Injection of [^{35}S]methionine followed by profiling of ^{35}S-labeled proteins along the L5 root and sciatic nerve	Inhibition of slow anterograde transport
$Tg^{dynamitin}$	Tracking of retrograde tracer from muscle injection to motor neuron cell body	Inhibition of retrograde transport
Loa	Live imaging of a fluorescently labeled tetanus toxin fragment in cultured embryonic motor neurons	Inhibition of retrograde transport

the oppositely oriented forces, applied simultaneously by plus and minus end-directed motors, result in a continuous tension on the cargo. In the case of neurofilaments, this tension may keep the long, flexible filaments stretched out along microtubules, and therefore may counteract aggregation. Support for this hypothesis comes from the observation that knockdown of dynein expression or inhibition of dynein/dynactin function leads to the distal accumulation of neurofilaments along neuronal processes.

Axonal transport defects in mSOD1 mice – the slowing of slow transport Direct assays for anterograde transport have been performed in mouse models expressing mutant SOD1 (Table 2). Injection of [^{35}S] methionine into the spinal cord of either $SOD1^{G93A}$ or $SOD1^{G37R}$ mice, followed by the profiling of ^{35}S-labeled proteins along the axon, allows the analysis of transport rates of newly synthesized proteins in comparison to those observed in wild-type control mice. In these studies, fast anterograde transport was not generally inhibited, although there may have been some preferential inhibition of specific cargos. However, inhibition of slow axonal transport was observed, including delays in the transport of both neurofilaments and tubulin. This inhibition of transport occurred in both models prior to disease onset.

Defects in retrograde transport in mSOD1 mice Retrograde transport has also been investigated in mice expressing mutant SOD1. In studies in which a retrograde neurotracer was injected into muscle and transport to the cell bodies of motor neurons was assayed, significant inhibition of transport was observed in transgenic mice expressing $SOD1^{G93A}$ as compared to wild-type littermate controls (Table 2). The observed inhibition was at a very early point in the course of disease; inhibition was significant by 50 days after birth, well prior to the onset of clinical disease in this model. This observation suggests that disruption of retrograde transport is a very early event in the course of motor neuron degeneration and death.

Studies on axonal transport in embryonic motor neurons cultured from the $SOD1^{G93A}$ mouse also show a significant slowing of retrograde transport (Table 2). Live cell analysis of the retrograde motility of a fluorescently labeled fragment of tetanus toxin shows a shift in the speed profile, indicative of an increased frequency of pauses and oscillatory movements, as compared to the more efficient transport observed in motor neurons from wild-type mice.

The only other marker that shows such an early defect in the $SOD1^{G93A}$ model is the disruption of the Golgi apparatus, which has been observed by 30 days after birth. Disruption of the Golgi is also observed in patient tissue. This is potentially of interest, since in addition to its role in retrograde axonal transport, cytoplasmic dynein drives endoplasmic reticulum (ER)-to-Golgi trafficking in the cell body and is required to maintain an intact Golgi apparatus near the MTOC of the cell. Inhibition of dynein leads to the disruption of the Golgi apparatus.

Thus, both the observed slowing of retrograde transport in the $SOD1^{G93A}$ model and the disruption of the Golgi observed in ALS patients and in a mouse model are consistent with a functional disruption in the activity of cytoplasmic dynein within the neuron. The inhibition of slow anterograde axonal transport observed in mice expressing mutant *SOD1* may also be consistent with a defect in dynein function, as dynein interacts directly with neurofilaments as they move along the axon.

Yet to be determined is the mechanism by which the expression of mutant *SOD1* can disrupt dynein function. One possibility is that the disruption is indirect, due to the activation of stress response pathways by the accumulation of misfolded SOD1 protein. Alternatively, the mechanism may be more direct. Dynein co-localizes with SOD1 aggregates in neurons expressing mutant *SOD1*; these aggregates may deplete the pool of active motors along the axon. Further work will be required to address this question.

Defective Retrograde Transport Is Sufficient to Cause Motor Neuron Degeneration

The dynamitin transgenic mouse In order to test the hypothesis that disruption of retrograde axonal transport is sufficient to induce motor neuron degeneration, a transgenic mouse was developed with a targeted inhibition of dynein/dynactin function in motor neurons. The dynactin subunit dynamitin was expressed at high levels in motor neurons; overexpression of this subunit is sufficient to disrupt the integrity of the dynactin complex and thus effectively disrupts dynein-mediated transport. The resulting $Tg^{dynamitin}$ line exhibits late-onset, slowly progressive degeneration of motor neurons, leading to preferential loss of large-caliber motor neurons and subsequent muscle atrophy.

Loa and Cra1 mutant mice Further evidence linking defects in axonal transport to the development of motor neuron disease comes from the analysis of two lines of *N*-ethyl-*N*-nitrosourea (ENU)-mutated mice, Loa and Cra1. Both lines were found to have point mutations in the gene encoding the heavy chain of cytoplasmic dynein, which includes the motor domain of the enzyme. While neither of the point mutations maps to the motor domain of dynein, both are in domains involved in subunit interactions within the dynein holoenzyme. Therefore, the two mutations are not predicted to abrogate dynein function, but are more likely to make the motor either less stable or less effective in driving motility along the axon.

Both Loa and Cra1 heterozygous mice display phenotypes remarkably similar to the phenotype of the $Tg^{dynamitin}$ mouse. Both lines exhibit late-onset, slowly progressive degeneration of motor neurons. Importantly, while the mutations are ubiquitously expressed, the degeneration is limited to motor neurons in heterozygous mice. Consistent with an impairment but not a block in dynein function, neither mutation is lethal when heterozygous. When homozygous, both mutations are lethal within a day of birth, which may be due to an impaired ability of the pups to suckle resulting from abnormal development of facial motor neurons. However, there are no gross perturbations of the nervous system, suggesting that the mutant dynein, while functionally impaired, is sufficient to drive normal development. In contrast, a complete knockout of dynein heavy chain is lethal early in embryogenesis in the mouse.

The effects of the Loa mutation on intracellular transport have been investigated. Transport of a retrograde tracer, a fragment of tetanus toxin, was not significantly affected in embryonic motor neurons cultured from heterozygous mice, suggesting that either the impairment is subtle, or that the wild type gene is haplosufficient over this time scale. In neurons cultured from Loa/Loa mice, there was a decrease in the extent of high-speed transport of the retrograde tracer, and a marked increase in the frequency of pauses. These data indicate a significant defect in the efficiency of retrograde transport (Table 2).

A somewhat unexpected but potentially important result has come from studies examining the effects of crossing either the Loa or Cra1 mutant mice to transgenic mice overexpressing mutant *SOD1* (the $SOD1^{G93A}$ line). Rather than showing an additive or even synergistic effect on motor neuron cell death, mice expressing both the $SOD1^{G93A}$ mutant and either the Loa or Cra1 mutation showed an extension of life span (by 28% and 12%, respectively). Disease onset was also delayed. The mechanism behind this result is not yet understood. One interesting possibility is that the impairment of dynein function induced by either the Loa or Cra1 mutation delays the transmittal of a signal indicative of cellular stress, thus slowing the onset of cell death pathways.

Alternatively, it has been proposed that the expression of mutant dynein may rescue the axonal transport defect caused by the expression of mutant *SOD1*, perhaps by righting the balance between anterograde and retrograde transport and therefore restoring axonal homeostasis. Numerous studies have suggested that anterograde and retrograde transport along the axon are intimately linked, as mutations or inhibitory reagents that should selectively affect transport in a single direction instead have a bidirectional inhibitory effect. Mechanisms of motor coordination may involve either direct links between motors or between motors and adapter proteins such as dynactin, or more indirect links through coordinated regulation of motor protein activity.

Mutant Dynactin in Motor Neuron Disease

Clear demonstration of a link between the axonal transport machinery and motor neuron disease in humans came from the identification of a mutation in the gene encoding the $p150^{Glued}$ subunit of dynactin as the cause of an inherited form of motor neuron disease.

Patients with a G59S mutation in the *DCTN1* gene display an autosomal dominant, slowly progressive form of inherited motor neuron disease. Onset in early adulthood is marked by vocal fold paralysis, leading to breathing difficulties, as well as progressive weakness of the muscles in the face and hands, with distal limb atrophy developing later. Unlike typical ALS, this mutation is not uniformly fatal.

Dynactin is a required activator for most dynein functions in the cell. Dynactin enhances the processivity of dynein, meaning that the motor complex takes longer runs along the microtubule per binding encounter. Dynactin also links dynein to some intracellular cargos. The $p150^{Glued}$ mutation identified in affected patients is a G59S substitution in a critical domain of the polypeptide, known as the CAP-Gly domain, which binds directly to microtubules. The mutation affects the ability of the polypeptide to bind to microtubules, but also increases the propensity of the polypeptide to misfold and to aggregate. Thus, at the cellular level, the G59S mutation both inhibits dynein function and results in the formation of intracellular protein aggregates. Together, these detrimental effects lead to the specific death of motor neurons. Pathological protein aggregates labeled with antibodies to both dynein and dynactin have been observed in motor neurons from affected patients, consistent with this hypothesis.

More recently, four additional mutations have been identified in the coding region of the *DCTN1* gene in patients with ALS. In all cases reported to date, there are insufficient genetic data to determine if these mutations are causative, contributory, or merely allelic variants. Further analysis will be required to determine how significant dynactin mutations are to the development of full-blown ALS.

Why Are Motor Neurons So Susceptible to Defects in Axonal Transport?

Consistently, studies on mouse models of motor neuron disease demonstrate defects in retrograde transport as well as enhanced protein aggregation. Defects in anterograde motors can also lead to neurodegenerative disease. For example, one form of Charcot–Marie–Tooth disease is caused by a point mutation in a kinesin motor protein. However, motor neurons appear to be uniquely susceptible to defects in retrograde axonal transport.

Three different mechanisms may explain these observations. The first is that the health of a motor neuron depends on a continual interaction with its environment. For example, a continuous supply of neurotrophic factors may be required. Neurotrophins, secreted by target tissues, bind to receptors on the motor neuron and are then transported from the synapse back to the cell body to activate signal transduction pathways and modulate gene expression patterns. Inhibition of retrograde transport would block this continuous signaling and thus could deleteriously affect the cell. None of the models studied to date show a complete block in retrograde transport, but instead show a partial inhibition. Slowed or inefficient neurotrophin signaling over time may lead to the late-onset and progressive cell death seen in ALS patients, as well as to patients expressing mutant dynactin.

Alternatively, cell death may result from the defective clearance of misfolded or aggregated proteins. Protein aggregation is a common feature observed in both patients and model systems. Further, dynein has been implicated as a key player in the clearance of misfolded proteins through autophagy. Mutations in dynein/dynactin or alterations in the function of the complex may lead to accumulation of toxic protein aggregates along the axon, which would further impede transport. This could represent a generalized defect in clearance of misfolded proteins or a more specialized defect – for example, in the clearance of mutant SOD1 protein or of aggregated neurofilaments. This mechanism has the potential to amplify the initial defect; dynein co-localizes with aggregates of mutant SOD1 protein and this association may deplete the pool of active motor protein. Dynein also interacts with neurofilaments; loss or inhibition of dynein leads to neurofilament aggregation, a common pathological marker of motor neuron disease.

Finally, alterations in axonal transport may be secondary to the real defect. Inhibition of dynein function may lead to more critical insults to the neuron, such as the disruption of dynein-mediated trafficking (e.g., from the ER to the Golgi). Motor neurons may be uniquely sensitive to trafficking defects, given their large size and metabolic load. Or, the key defect could be in the dynein-driven motility of intracellular organelles, such as the mitochondria. Mislocalization of mitochondria may lead to mitochondrial dysfunction, which in turn may be sufficient to initiate cell death pathways. In support of this possibility, mislocalization of mitochondria has been observed in motor neurons of patients with ALS.

Defects in Transport, Trafficking, and Cytoskeletal Proteins Linked to Neurodegenerative Disease

Recent progress in identifying the genetic causes of inherited neurodegenerative diseases has turned up some intriguing results. As already noted, the identification of mutations in motor proteins has

provided strong support for the hypothesis that active axonal transport is critical to maintain the health of neurons. Further, mutations in other proteins (such as Huntingtin or amyloid precursor protein) may also affect axonal transport either directly or indirectly. Together, these data suggest that neurons are absolutely dependent on axonal transport, and are uniquely vulnerable to defects in the motors and other cytoskeletal proteins involved in this transport. A better understanding of the underlying cell biology of motor neurons will therefore be required to fully understand the development of pathology in patients with ALS, and to design rational approaches to therapeutic interventions.

Axonal Transport and Alzheimer's Disease

Basic Features of Alzheimer's Disease

The initiating symptoms or presenting symptoms of Alzheimer's disease (AD) are well known. Problems with memory, language, and cognition are all characteristic features of the behavioral symptoms that signal the initiation of this terrible neurodegenerative disorder. Most AD occurs relatively late in life, generally after 65 years of age. It afflicts 10% of people over the age of 65 and 50% of people over the age of 85. The time from diagnosis to fatality is highly variable, ranging anywhere from a few years to over a decade or more. The tragedy of AD is that not only are there substantial deficits in cognition accompanied by neurodegenerative changes in the brain, there are presently no effective drugs and no effective treatments, and the disease progresses inexorably in its course to end stage, in which a persistent vegetative state is common.

The pathological hallmarks in the brains of people who have had AD are well recognized in postmortem autopsy material. These features include amyloid beta (Aβ) plaques and neurofibrillary tangles. Amyloid plaques consist of aggregated Aβ peptides derived by proteolytic processing of the amyloid precursor protein (Figure 1). Amyloid plaques are generally associated with dystrophic neurites, which can be abnormal axons or dendrites that are characterized by substantial swelling and distension, and accumulations of vesicles and organelles. Dystrophic neurites surround and invade the plaques, but are also in regions of diseased brains that lack amyloid plaques. Neurofibrillary tangles are aggregates of a protein called tau that normally binds to and stabilizes microtubules, and which, following hyperphosphorylation and conformational change, forms characteristic paired helical filaments. Although amyloid plaques and neurofibrillary tangles are the hallmark diagnostic pathological features, their correlation with cognitive characteristics of AD is not consistent and is controversial. Many researchers have argued that loss of synapses in key areas of the diseased brain is the earliest pathological feature of AD that is most highly correlated with cognitive defects. Neuronal death is an invariant though relatively late feature of AD, as is loss of axons and white matter. The loss of axons, white matter, and synapses could be a consequence of early changes in axonal transport in AD.

Although most AD is late onset, there are well-recognized hereditary forms (familial AD, or FAD) that can begin as early as the fourth decade of life and are highly virulent in their course. Mutations in the gene encoding amyloid precursor protein (APP) and mutations in the genes encoding presenilin (PS) proteins are the major recognized causes of FAD. Duplications of the APP gene can also give rise to mid- to late-onset AD. Two other major risk factors are known. One major genetic risk factor is the allelic state in the gene (*APOE*) encoding apolipoprotein E (ApoE), which has a role in cholesterol trafficking. While the $\varepsilon 2$ variant of the *APOE* gene is protective, the $\varepsilon 4$ variant predisposes to late-onset AD. Another major risk factor is traumatic brain injury. How these risk factors lead to AD is far from clear, and indeed, what molecular defects and pathways lead to any form of AD remain controversial.

The dominant hypothesis proposed to account for the molecular and cellular changes found in AD is the amyloid cascade hypothesis, which proposes that AD is caused by toxic Aβ_{40} or Aβ_{42} peptide fragments liberated by proteolysis of APP (Figure 2). In this hypothesis, the hereditary FAD mutations are proposed to generate excess toxic forms of Aβ, and apolipoprotein E variants are proposed to affect the rates of turnover of these peptides. Most important, the amyloid cascade hypothesis and its major variants indicate that the toxic Aβ peptides initiate a biochemical and cellular cascade of pathology leading to synaptic loss, neurofibrillary tangles, and ultimately neuronal death. While there is considerable evidence for the amyloid cascade hypothesis, principally in the human APP FAD mutations, questions remain, and there are a number of alternative hypotheses that have been proposed over the years. Another class of hypothesis suggests that early deficits in axonal transport either cause, or contribute substantively to, the development of AD.

Axonal Transport Is Disrupted in AD

There has been considerable evidence for some time that axonal transport is disrupted at late stages of AD. For example, although basal fore-brain cholinergic neurons exhibit phenotypes that suggest that they lack retrograde neurotrophic input from nerve growth factor, diseased brains appear to retain high levels of

Figure 1 Schematic diagram of amyloid precursor protein. The cytoplasmic region is thought to interact with the axonal transport machinery either directly via binding to the kinesin light chain subunit of kinesin-1, or indirectly via binding to the Jun N-terminal kinase-interacting protein 1, JIP1. Sites for proteolytic activity by β- and γ-secretases are shown, which together liberate amyloid beta (Aβ) peptides that are either 40 or 42 amino acids in length.

Figure 2 A standard view of the amyloid cascade hypothesis in which the various mutations, genetic variants, and environmental insults induce a series of molecular events caused by increasing levels of toxic human amyloid beta ($A\beta_{40}$ or $A\beta_{42}$), culminating in Alzheimer's disease (AD). FAD, familial Alzheimer's disease; APP, amyloid precursor protein; PS1/2, presenilins 1 and 2; TBI, traumatic brain injury; APOE, apolipoprotein E.

nerve growth factor in the cortex where basal forebrain cholinergic neurons ordinarily connect to cells that secrete nerve growth factor (Figure 3). The levels of cholinergic enzymes in the cortex appear also to be reduced in AD, even though basal forebrain cholinergic neurons appear to express normal levels of cholinergic markers even after the onset of AD.Finally, there are reports that axonal transport is defective in neurons taken from brains of AD patients postmortem, and there are long-standing observations of destruction of the microtubule cytoskeleton in axons in diseased neurons. These disruptions have for some time been thought to be related to the hyperphosphorylation and aggregation of tau protein into neurofibrillary tangles, although what events are causative and what events are consequences of each other remain unclear.

The observation that axonal transport is defective at late stages of AD has led a number for workers over the years to propose that axonal transport defects might be early, possibly causative, events in AD. However, evidence for early defects in axonal transport in AD was lacking until recently. Recent work has provided evidence for early changes in axonal transport in postmortem AD brains and in animal models of AD in which APP is overexpressed. One striking example is the finding of dystrophic axons early in AD and in AD models prior to the formation of amyloid plaques, and thus not associated with, or in the vicinity of, amyloid plaques. These dystrophic axons exhibit signs of axonal transport failure, including massive accumulations of vesicles and organelles in axons that appear to be distended by these accumulations. This type of phenotype is characteristic of mutations that disrupt the axonal transport machinery directly in *Drosophila* and in the mouse. In this context, there is some evidence that deficits in axonal transport can induce formation of, or enhance accumulation of, Aβ. A final line of evidence that raises the possibility that axonal transport deficits are relevant to the initiation of AD is the body of evidence that suggests that there are age-dependent changes and reductions in microtubules in axons. Observed changes include accumulation of APP and other transported material in axons, increases in axonal dystrophies, and some direct evidence that transport itself is reduced in aging neurons relative to younger neurons.

Figure 3 Pathway of nerve growth factor (NGF) signaling from cortical neurons to target cholinergic neurons in the basal forebrain. This transport and signaling pathway appears to be defective in Alzheimer's disease. Secretion of NGF by cortical neurons (1) is followed by internalization at presynaptic endings of basal forebrain cholinergic neurons (2). Retrograde transport of vesicles containing NGF and activated TrkA in postendosomal carriers (3) culminates in arrival at the basal forebrain cholinergic neuron cell body and signaling (4).

Roles and Effects of AD Risk Factors and Genes in Axonal Transport

Several reports suggest that APP and its proteolytic products may play normal roles in, and/or be able to interfere with, axonal transport. For example, deletion of the APP gene in *Drosophila* and in the mouse appears to generate mild defects in axonal transport. Overexpression of APP and its relatives dramatically interferes with axonal transport in *Drosophila* and in the mouse, and even simple duplication of the APP gene in the mouse appears to significantly inhibit some forms of axonal transport – in particular, retrograde transport of the nerve growth factor (NGF)–neurotrophin receptor signaling complex to the basal forebrain. Although this could be the result of, and often has been interpreted as such, an excess of toxic human Aβ, strong evidence in *Drosophila* and in the mouse suggests that even if human Aβ is toxic to axonal transport, other factors, perhaps the C-terminus of the APP protein, may be bigger contributors to these defects.

The mechanism of APP-induced defects in axonal transport remains unknown. One suggestion, based on biochemical evidence from a number of groups, is that the cytoplasmic tail of APP can form either a direct or indirect interaction with the kinesin light chain subunits of conventional kinesin, kinesin-1. If indirect, this interaction may occur via formation of a ternary complex with the Jun kinase scaffolding protein called JIP1 (c-Jun N-terminal kinase-interacting protein 1). There is also evidence from the squid and *Drosophila* that the C-terminus of APP interacts with the axonal transport machinery and is required for interference with axonal transport in overexpression situations. This C-terminus is also required to generate movements of APP in *Drosophila* neurons and in squid axoplasm. These findings are consistent with the proposal that overexpression of APP poisons axonal transport by competing for either JIP1 or kinesin light chain, which are needed for axonal transport of other materials (Figure 4). Although several groups have provided evidence in favor of this hypothesis, other groups do not agree. Strong additional evidence in support of this idea comes from the observation that reductions in kinesin-1 subunits in *Drosophila* or in the mouse enhance transport defects caused by overexpression of APP.

There is considerable evidence that FAD mutations and deletion mutations in the gene encoding presenilin 1 may also interfere with axonal transport. One obvious mechanism that is consistent with the amyloid cascade hypothesis is that presenilins might cause axonal transport defects by enhancing or altering Aβ production in neurons, which is then toxic to axonal transport. However, the presenilin mutations that cause familial forms of AD in humans can poison axonal transport of APP, and perhaps other proteins, in the mouse in the absence of human APP. These findings, combined with considerable evidence that kinesin-1 is required for APP transport in axons and with evidence that presenilin and β-secretase and related proteins may be in a common axonal vesicle with APP suggest that these processes may be tied together in a way that does not rely on APP processing to generate Aβ. For example, one possible mechanism of presenilin influence on the axonal transport machinery may be via control of kinesin light chain phosphorylation by glycogen synthase-3β (GSK-3β) or other kinases. A related and surprising finding is that overexpression of β-secretase, which is another protease that may generate Aβ from APP, can generate defects in axonal transport of APP, and may shift the cellular sites of Aβ production and secretion. These ideas have been hotly debated in the literature; further evidence is required to establish or refute these proposals.

Figure 4 A possible mechanism by which excess amyloid precursor protein (APP) poisons axonal transport. In the normal situation, there is enough membrane-bound kinesin-1 to move APP and non-APP vesicular and organellar cargoes. In the presence of excess APP, competition for limiting kinesin-1 may occur so that some vesicles (intermittently) lack kinesin-1 and can stall in the axon, leading to axonal blockages and transport deficits. Although this schematic shows kinesin-1 as the limiting protein, other proteins or adapters, such as Jun N-terminal kinase-interacting protein 1 (JIP1), could be the vulnerable limiting component.

Another possible link of axonal transport to the pathogenesis of AD is via tau protein. This protein, which aggregates into neurofibrillary tangles, appears to play a normal role in the control of vesicle transport along microtubules, perhaps most prominently for vesicles transported by kinesin-1. There is considerable evidence that tau protein, which binds to microtubules, may directly regulate the movement of vesicles by kinesin-1 along microtubules. This function, in addition to the potential role of tau in initiating the polymerization of microtubules or in enhancing the stability of microtubules, may play important roles in the effects of tau protein and its mutants or of inappropriate phosphorylation variants on the axonal transport machinery. There is also evidence that overexpression of tau protein and its disease-causing mutations poison axonal transport directly.

Another important risk factor for AD is traumatic brain injury. There is evidence that injury to the brain induces so-called diffuse axonal injury, among other consequences. Diffuse axonal injury is of particular interest because it is effectively injury to the axons, which has been reported to result in large accumulations of APP and Aβ peptides at injury sites in axons. The possibility that axonal injuries cause biochemical changes in the axonal transport machinery is likely, given recent evidence that injury to axons induces activation of the damage-signaling kinase, Jun kinase (JNK). JNK is known to phosphorylate tau protein, and has been implicated in some aspects of axonal transport regulation. Thus traumatic brain injury may exert its influence on axonal transport defects via JNK activation and phosphorylation of targets such as tau and perhaps the kinesin heavy chain subunit of kinesin-1.

Another possible risk factor for AD is cholesterol. It is known that genotypic variants at the apolipoprotein E gene in humans have a large influence on the probability of developing late-onset AD. The $\varepsilon 4$ variant confers the highest risk and the $\varepsilon 2$ variant is protective. There is accumulating evidence that cholesterol and phospholipids might have important regulatory effects, not only on vesicular traffic, but also on kinesin-mediated axonal transport. One important kinesin family that is known to be essential for the transport of synaptic vesicle proteins is kinesin-3. This type of kinesin motor can bind to phospholipids in membrane bilayers, and has been reported to be activated by lipid clustering in vesicular membranes via oligomerization of the motor protein. Since cholesterol may have an impact on the ability of phospholipids to cluster, such a mechanism might affect transport directly. Another possible linkage of cholesterol to AD comes from the pediatric disease called Neimann–Pick

C type 1 (NPC1), which is a disorder of cholesterol transport and metabolism caused by defects in the *NPC1* gene. Such mutations appear to interfere with cholesterol trafficking in nonneuronal cells, possibly via the endocytic pathway. It is less clear what NPC1 mutations do in neurons, but it is clear that the mutations induce significant neurodegeneration in patients who have them, and ultimately lead to death. The striking clue is that these mutations appear to generate excess Aβ peptides and to induce the aberrantly phosphorylated forms of tau protein that lead to the formation of neurofibrillary tangles. Further work will be necessary to establish the precise molecular link between cholesterol trafficking and AD. It is intriguing, however, that defects in movement of cholesterol and related components in axons may be an important part of the problem.

Finally, Aβ peptide has been reported by a number of groups to induce phenotypes in cultured neurons that mimic those seen in neurons bearing axonal transport mutations. One group has reported that this may be a result of the effects of Aβ peptides on the state of microtubules; this influence appears to be mediated by extracellular Aβ peptides. Further work is necessary to clarify this association.

Role of Axonal Transport Failure in AD

The key issue is whether axonal transport defects are an early or late event in AD, and whether they are a consequence of Aβ toxicity, or a stimulus for Aβ generation or turnover, or both. Although further work is clearly required to resolve these issues, a testable type of hypothesis, presented in Figure 5, encapsulates some key features. Key elements are that axonal transport defects can induce synaptic defects directly, activate kinases that may induce tau hyperphosphorylation, and instigate or enhance Aβ

Figure 5 One possible alternative to the amyloid cascade hypothesis that incorporates axonal transport deficits into early stages of Alzheimer's disease (AD) causation or progression. (1) In familial Alzheimer's disease (FAD), mutant presenilins (PS1/2), excess amyloid precursor protein (APP), traumatic brain injury (TBI), and apolipoprotein E ε4 (APOE4) are suggested to initiate neuronal damage by interfering with axonal transport and/or causing axonal damage. (2) Axonal damage and axonal transport deficits may cause synaptic damage directly, or indirectly by the indicated alternative pathways. Axonal damage might lead to increased amyloid beta or increased ratio of the two types (Aβ_{40}, Aβ_{42}) (2A), which may cause synaptic damage directly (2B), or may lead to further axonal damage and transport defects in an autocatalytic loop (2C). Axonal damage may also lead to activation of Jun N-terminal kinase, which could initiate hyperphosphorylation of tau protein and formation of neurofibrillary tangles (2D), which may cause synaptic damage (2E) and cause further defects in axonal transport and axonal damage (2F) in an autocatalytic loop. Synaptic damage caused by all of these insults may be the primary neuronal defect causing cognitive symptoms in AD (3). How FAD mutant APP might initiate these proposed events is unknown, but could happen either by directly interfering with axonal transport or causing axonal damage (4A) or by increasing Aβ formation (4B).

formation, which may have its own toxic consequences. Unique aspects of this class of hypothesis include an autocatalytic spiral of events and multiple entry points, including mutation and environmental insults. In at least one form of hereditary AD, it can be argued strongly that this hypothesis may have validity in view of evidence that moderate increases in APP expression can induce significant axonal transport deficits in the absence of human Aβ. Although these ideas focus on axons, it is likely that comparable phenomena and behaviors exist in dendrites, for which less information is currently available.

Conclusion and Perspectives

The fundamental problem in evaluating whether defects in axonal transport can induce or significantly accelerate early stages of AD derives from the nature of the experimental systems. Only humans develop true AD, but axonal transport and biochemical defects induced by agents and mutations that can cause AD can only be rigorously studied at present in animal models of the disease. Further resolution of these issues will require noninvasive imaging suitable for studying axonal transport in living human patients, and the development of true human neuronal models of disease, perhaps using human embryonic or other types of stem cells. Finally, it is likely that truly effective therapies for AD will require a detailed and mechanistic understanding of the events leading from causative insults to the biochemistry of neuronal function and viability; axonal transport appears to be an important process in disease progression, and its role needs to be rigorously evaluated.

Axonal Transport and Huntington's Disease

F Saudou and S Humbert, Institut Curie and CNRS UMR 146, Orsay, France

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Huntington's disease (HD) is a dominantly inherited neurodegenerative disease caused by abnormal polyglutamine (polyQ) expansion in a specific protein. HD is characterized by uncontrolled movements (chorea), personality changes, and dementia. Patients typically die 10–20 years after the appearance of the first clinical symptoms. In HD, the specific dysfunction and death of neurons in the striatum and cerebral cortex has been reported. The mutated protein is huntingtin, a large ubiquitous protein, the function of which is not fully understood. However, there is evidence that huntingtin is an antiapoptotic protein. Indeed, it is necessary for development since knockout mice die soon after gastrulation and conditional knockout mice, in which huntingtin is selectively turned off in brain and testis during adulthood, show a progressive degenerative neuronal phenotype and sterility. Moreover, overexpression of normal huntingtin protects striatal cells from a variety of apoptotic stimuli. Huntingtin becomes toxic when it contains an abnormal polyQ expansion. PolyQ-huntingtin induces the formation of neuritic and intranuclear inclusions, neuronal dysfunction, and, finally, neuronal death. The precise mechanisms underlying these phenomena are not well understood, and it is not known how increased neuronal death in the brain relates to huntingtin function and dysfunction.

Evidence suggests that huntingtin is involved in intracellular transport and that axonal transport is impaired in HD. Herein, we review studies demonstrating that huntingtin belongs to a protein complex that controls intracellular transport and that the alteration of this complex may participate in the pathogenesis of HD.

Intracellular Transport and Neurons

Neurons are highly polarized cells composed of a cell body and an extensive network of cell processes: dendrites, and a single axon. The axonal extension can reach up to 1 m in length. Most protein synthesis is restricted to the cell body. Therefore, active transport is required to supply the axon with newly synthesized materials. Conversely, external signals have to be transmitted to the cell body from the cell's extremities, where the signaling cascade is activated. Here also, active transport of receptor–ligand complexes is required for a quick and appropriate response. Due to the length of their processes, transport efficiency is of particular importance in neurons.

To allow efficient communication between cell bodies and axon termini, molecular motor proteins continuously shuttle vesicles and organelles along the microtubules and actin filaments that make up the cellular cytoskeleton. This transport process mostly involves microtubules, which are polarized structures with 'plus' (cell extremity) and 'minus' (cell body) ends. Molecular motors are considered to be unidirectional: Dynein complexes are connected to retrograde transport (from plus to minus end), whereas kinesins are connected to anterograde transport (from cell body to plasma membrane).

These two classes of motor complexes are required for efficient transport in neurons. Disruption of these complexes has dramatic consequences on neurons and leads to severe diseases.

Huntingtin and Intracellular Dynamics

There is growing evidence to suggest that huntingtin plays a role in intracellular dynamics. Cytoplasmic huntingtin co-localizes with microtubules and interacts with β-tubulin. Huntingtin is also found in neurites co-localizing with vesicles. In addition to this specific distribution, huntingtin interacts with many proteins that are implicated in intracellular trafficking. The best-described example is the case of huntingtin-associated protein 1 (HAP1), which is discussed later. Huntingtin also interacts with huntingtin-interacting protein 1 (HIP1), which binds to the clathrin light chain and regulates clathrin assembly, linking huntingtin to the control of endocytosis. A role of huntingtin in the control of endocytosis is further supported by the observation that huntingtin bound to the HAP40 protein acts as an effector of the small guanosine triphosphatase Rab5. In the pathological situation, a reduction of endosomal motility and endocytic activity in HD fibroblasts and mutant cells is observed. Finally, huntingtin associates with PACSIN1, a protein that is part of the endocytic machinery, which could act as a negative regulator.

In addition to regulating endocytosis at the plasma membrane, huntingtin may also regulate secretion and trafficking of proteins or organelles from the Golgi region. Indeed, HIP14, another huntingtin interacting protein that contains an ankyrin domain, is found at the Golgi and at vesicles. This protein is a palmitoyl

transferase involved in the sorting of proteins from the Golgi region. Also, huntingtin binds optineurin, a protein associated with Rab8 and myosin VI. This complex is found at the Golgi and in vesicles. The depletion of optineurin leads to the disruption of the Golgi ribbon structure and to the reduction in the transport of VSV-G from the Golgi complex to the plasma membrane. Finally, two other proteins that are dysregulated in HD participate in the sorting of organelles from the Golgi complex. The DNAJ-containing HSJ1b protein, possibly by regulating clathrin uncoating, promotes the processing of vesicles that contain the brain-derived neurotrophic factor (BDNF) from the Golgi to the cytoplasm. HSJ1b protein colocalizes with the transglutaminase 2 (TGase 2) enzyme that has a negative role in BDNF sorting from the Golgi. Interestingly, TGase 2 is inhibited by cystamine and by its reduced form, cysteamine, resulting in an increase in the sorting of BDNF-containing vesicles from the Golgi and in the release of this trophic factor from the cell. Treating HD mice with cysteamine results in an increase in BDNF release in the brain and in the reduction of the loss of striatal neurons in HD mutant mice. That a compound such as cysteamine, which is a Food and Drug Administration-approved drug, is neuroprotective by enhancing the intracellular processing of vesicles suggests that strategies aiming at restoring the defects in intracellular trafficking of organelles are of therapeutic interest.

Huntingtin Associates with the Molecular Motor Complex

The identification of HAP1 and its characterization with respect to huntingtin led to the hypothesis that both proteins may have an important function in the axonal transport machinery. Indeed, huntingtin and HAP1 are transported both anterogradely and retrogradely in rat sciatic nerves. Both proteins are associated with synaptic vesicles and localize with microtubules in neurites. The discovery in 1997 that HAP1 associates with the $p150^{Glued}$ subunit of dynactin further supported this possibility. Since then, a growing body of evidence has suggested that huntingtin has a major function in the control of axonal transport and that this function requires the HAP1 protein. Indeed, HAP1 binds not only to the $p150^{Glued}$ subunit of dynactin but also to the kinesin light chain 2, a subunit of the kinesin-1 complex. In agreement, depletion of HAP1 reduces kinesin-dependent transport of amyloid precursor protein vesicles. In addition to the indirect association of huntingtin to dynactin through HAP1, huntingtin also interacts with the dynein light chain of the dynein complex. Finally, huntingtin and HAP1 comigrate in the same fractions after sucrose gradient fractionation, further supporting the idea that huntingtin belongs to the molecular motor complex dynein/dynactin/kinesin-1.

Huntingtin Stimulates Axonal Transport

In addition to the previously discussed biochemical evidence, videomicroscopy approaches in cells and in *Drosophila* have further established a functional role of both HAP1 and huntingtin in axonal transport. In *Drosophila*, reduction in huntingtin protein level by the RNAi approach results in axonal transport defects. Furthermore, huntingtin directly promotes intracellular transport of vesicles along microtubules in neuroblastoma and striatal cells. Indeed, using BDNF as a marker of intracellular trafficking in cells, Gauthier and collaborators showed that expression of huntingtin enhances the velocity of BDNF-containing vesicles while reducing the percentage of time spent pausing. In support of a positive role of huntingtin in stimulating axonal transport of vesicles that contain BDNF, downregulation of huntingtin by RNAi approaches resulted in a decrease in the velocity of moving vesicles and an increase in the percentage of time spent pausing. BDNF was chosen because it is an important factor in HD. It is produced in the cortex and is transported to the striatum, the major site of degeneration in HD, where it supports neuronal differentiation and survival. It inhibits polyQ–huntingtin-induced neuronal death and its level is abnormally low in HD patients. BDNF is synthesized from the large precursor protein pre-pro-BDNF that is proteolytically processed and moves through the Golgi apparatus to the trans-Golgi network, where it is packaged into vesicles. BDNF-containing vesicles are then transported along microtubules (MTs) to the plasma membrane and subsequently released through the regulated secretory pathway. BDNF-containing vesicles are immunopositive for the classical markers of secretion and their activity-dependent release requires an intact MT network because it is blocked by nocodazole, an MT depolymerizing agent.

The huntingtin-dependent transport of BDNF vesicles is bidirectional because huntingtin stimulates both anterograde and retrograde transport in axons. It requires the HAP1 protein. Indeed, short N-terminal fragments of huntingtin that do not contain the HAP1 interacting region are unable to stimulate intracellular transport. Also, BDNF transport is reduced after downregulation of HAP1 protein and, in these conditions, huntingtin is unable to enhance BDNF trafficking. The HAP1-dependent transport is not restricted to BDNF vesicles since the movement of amyloid precursor protein vesicles is also reduced by decreasing HAP1 levels. Since it is known that the movement of amyloid precursor protein vesicles is kinesin dependent, one can infer an important role

of huntingtin and HAP1 in both anterograde and retrograde transport.

Although these studies revealed a role for huntingtin in axonal transport, the extend to which axonal transport depends on huntingtin remains unknown. Huntingtin stimulates the dynamic of BDNF-containing vesicles; however, whether other types of vesicles are regulated by huntingtin remains to be established. The observations that transport of amyloid precursor protein vesicles depends on HAP1 and that downregulation of huntingtin alters the general axonal transport in *Drosophila* strongly suggest that huntingtin regulates the transport of other small vesicles.

Milton, a *Drosophila* ortholog of HAP1, participates in the axonal transport of mitochondria, thus raising the possibility that huntingtin and HAP1 could also regulate the transport of mitochondria. However, the velocity of mitochondria is not regulated by huntingtin, and whereas HAP1 overexpression leads to the redistribution of BDNF vesicles in cells, it has no effect on mitochondria. Conversely, Milton, although known to redistribute mitochondria in cells, has no effect on BDNF vesicles. Therefore, HAP1 and Milton show specificity in the type of cargoes they are transporting.

HD Pathological Situation and Axonal Transport Defects

Several studies indicate an alteration of axonal transport in the polyQ situation. However, depending on the stage of the disease, different mechanisms may be involved.

In striatal cells and in neurons, whereas normal full-length huntingtin stimulates BDNF transport, full-length huntingtin with an abnormally expanded polyQ expansion has lost this stimulatory ability. Also, a reduction in transport of BDNF is observed in striatal cells derived from knockin mice in which a CAG expansion has been inserted in the endogenous mouse huntingtin gene. These mutant striatal cells express full-length huntingtin at endogenous levels. Similarly, polyQ-containing polypeptides encompassing amino acids 1–548 of huntingtin inhibit fast axonal transport in isolated axoplams without the formation of detectable morphological aggregates. Thus, polyQ expansion of huntingtin results in a loss of huntingtin function in transport. This phenotype is mediated by HAP1, which forms a protein complex by binding to the $p150^{Glued}$ subunit of dynactin and simultaneously binding to a domain located in the N-terminal region of huntingtin. The formation of this complex subsequently stimulates microtubule-based transport. In contrast, when huntingtin contains an abnormal polyQ expansion, it interacts more strongly with HAP1 and $p150^{Glued}$, leading to the detachment of the molecular motors from the microtubules and thus to less efficient transport of BDNF vesicles.

The presence of an abnormal polyQ expansion in huntingtin leads to a reduced anterograde and retrograde transport of BDNF-containing vesicles. In cortical neurons that deliver BDNF to striatal neurons, the reduced transport of BDNF in the pathological situation has a direct consequence on the ability of these cells to release BDNF, rendering striatal neurons particularly vulnerable. In agreement, cortical ablation of BDNF in mice induces striatal dendrite deficits followed by neuronal loss. Once released, BDNF binds to its receptor TrkB; the BDNF–TrkB complex is endocytosed in striatal neurons and transported retrogradely to the nucleus, where it activates downstream signaling pathways. The consequences of axonal transport defects in these neurons remain to be established.

A critical step in HD pathogenesis is the cleavage of polyQ–huntingtin into N-terminal fragments containing the polyQ expansion. These fragments translocate into the nucleus and induce the formation of aggregates. In the nucleus, polyQ–huntingtin fragments cause neuronal death by a gain-of-function mechanism, leading to the dysregulation of transcriptional activity. In addition, N-terminal huntingtin fragments and their aggregates accumulate in axonal processes and terminals. What are the consequences of these aggregates on axonal transport? In *Drosophila*, N-terminal huntingtin polypeptide fragments containing the polyQ expansion accumulate in axonal inclusions and cause axonal trafficking defects. This subsequently induces neuronal death and organismal death. Furthermore, mutant huntingtin aggregates alter vesicular and mitochondrial transport in mammalian neurons. These aggregation-induced defects in transport may be due to a physical blockage of vesicles but may also involve the sequestration by mutant huntingtin aggregates of motor proteins (particularly $p150^{Glued}$ and kinesin heavy chain) from other cargoes and pathways. Interestingly, this aggregation-induced alteration of general transport appears to be independent of the protein context since it has also been reported to occur in other polyQ disorders.

In summary, in early stages of the disease, the role of huntingtin in transport is lost following the alteration of the huntingtin (soluble form)/HAP1 interaction. In later stages, polyQ–huntingtin forms neuritic aggregates that contribute to a trafficking defect by a gain-of-function mechanism.

Disruption of Axonal Transport and Neurodegenerative Disorders

Transport defects have also been described in other polyQ neurodegenerative disorders. The polyQ-containing androgen receptor, the mutation of which is

responsible for spinobulbar muscular atrophy, inhibits fast axonal transport. Non-polyQ neurodegenerative diseases have also been linked to transport failure. In Alzheimer's disease (AD), mutation of the amyloid precursor protein, responsible for familial forms of AD, disrupts axonal transport. Similarly, overexpression of tau, a neuronal microtubule-associated protein that accumulates in AD, inhibits organelle trafficking. Several different neurodegenerative disorders are caused by mutation within motor proteins. For instance, Charcot–Marie–Tooth disease type 2 is caused by a loss-of-function mutation in the kinesin KIF1B, and hereditary spastic paraplegia type 10 is caused by a missense mutation in KIF5A. Finally, a mutation in the $p150^{Glued}$ subunit of dynactin has been identified in a family with an autosomal dominant form of lower motor neuron disease. Furthermore, inhibition of dynein-mediated axonal transport causes neurodegeneration in mouse models.

Conclusion

Slowing of transport might be a general phenomenon in neurodegenerative diseases. It can be either causative or contributory, depending on the disease. Neurons are highly susceptible to dysregulation of transport. Indeed, because transport in neurons occurs over very long distances, a decrease in intracellular trafficking has dramatic consequences on their viability. The development of accurate models of intracellular transport in neurons should therefore help researchers understand the molecular mechanisms underlying these diseases.

Axonal transport is a promising target for designing and testing treatments to slow or block neurodegeneration. In the case of HD, compounds that enhance transport or rescue huntingtin dysfunction might be of therapeutic interest since huntingtin directly controls transport of the pro-survival factor BDNF. This is of utmost importance because no treatment currently exists for this devastating disorder.

Axonal Transport and Neurodegenerative Diseases

Introduction

The primary functions of the neuron are to receive, process, and transmit information. A typical neuron has multiple dendrites and a single elongated process, the axon. The dendrites and the cell bodies play a role in the collection and processing of information, and the axon is responsible for the transmission of information to other neurons via synapses. Whereas dendrites are usually in close proximity to the neuronal cell bodies and have some capacity for protein synthesis, axons can extend up to tremendous lengths, sometimes several feet, and are generally devoid of the protein synthetic machinery. As a result, axonal proteins are synthesized in the cell bodies and subsequently transported into the axons and synapses. This process is called axonal transport. Axonal transport is essential for the survival of axons and synapses, and it occurs throughout the life of the neuron.

The unique architecture of the axon combined with its dependence on the remotely located cell body for growth and maintenance makes it especially vulnerable to a variety of insults. Not surprisingly, axonal and synaptic defects are characteristic features of most neurodegenerative diseases, and it was long suspected that defects in axonal transport could play a major role in these diseases. Although correlative evidence linking axonal transport defects and neurodegenerative diseases was well known, recent experimental evidence from several laboratories suggests that many neurodegenerative diseases may be a direct consequence of altered or defective axonal transport. In this article, we first highlight the basic principles of the mechanisms of axonal transport. Then, we review some of the evidence that links axonal transport to neurodegenerative diseases, including pathogenic mutations in human genes that encode proteins involved in axonal transport and studies of animal models of disease showing impairments of axonal transport.

Basic Mechanisms of Axonal Transport

Although many specific details of axonal transport mechanisms are not fully understood, the basic principles are well established. In general, to move any cargo, two components are required – motors to move the cargo and rails to transport it. In addition, motor proteins often require adaptor/linker proteins to attach the motors to the cargo. For the rails, the neurons use the structural network of the cell, the cytoskeleton. Most long-range transport is dependent on the microtubules, but actin filaments also play a role in short-range movements. Microtubules in axons are polarized (unlike dendrites), allowing a directional bias in the movement of the motors and their cargo. For the motors, the neurons have an abundance of small molecular machines, known as kinesins and dyneins, moving the cargo mainly anterogradely (away from the cell body to the axon tip) or retrogradely (toward the cell body), respectively (Figure 1). The anterograde transport consists of components required for maintaining synapses, cytoskeletal proteins required for maintaining axonal structure and function, as well as a variety of other proteins required for neuronal function, including mitochondria, various chaperones, and glycolytic enzymes. The retrograde transport consists mainly of endosomal/lysosomal organelles that carry degraded proteins back to the cell bodies for degradation and also neurotrophic factors required for neuronal survival. In reality, however, most transport is bidirectional, with a bias either in the anterograde or in the retrograde direction.

Our understanding of the mechanisms of transport has increased dramatically during the past few decades due to advances in the development of model systems to dissect basic transport mechanisms and advances in biochemistry and genetics that have led to the identification and characterization of the molecular motors and their cellular functions. Model systems developed to visualize the transport process revealed that the bulk of proteins are transported anterogradely in two broad, discrete groups. Whereas some of the proteins are transported rapidly, at rates of 100–400 mm day^{-1} (1–5 μm s^{-1}), quickly reaching up to the tip of the axon, others move at rates that are several orders of magnitude slower, at approximately 0.2–5 mm day^{-1} (0.0002–0.05 μm s^{-1}). These two components are called fast axonal transport and slow axonal transport, respectively. Whereas fast transport mainly comprises vesicular cargo, including synaptic proteins, ion channels, and other components, slow axonal transport is primarily composed of transported cytoskeletal proteins, mainly microtubules, neurofilaments, and actin, along with many additional cytosolic proteins involved in neuronal homeostasis. Visualization of slow transport of the cytoskeleton revealed that despite moving with overall distinct dynamics, both slow and fast transport use similar

Figure 1 Basic principles of axonal transport. Cargo is transported anterogradely and retrogradely by the molecular motors kinesin and dynein, respectively. A variety of additional adaptor/linker proteins may also help in binding kinesin to the cargo (not shown). Dynactin, a multiprotein complex, links dynein to its cargo and is thought to increase the efficiency of the motor. Long-range movement occurs along cytoskeletal 'tracks,' mainly microtubules.

underlying mechanisms. These studies showed that slow cargo moves rapidly like fast cargo, but unlike fast cargo, it pauses for prolonged times during transit. Thus, the overall movement is infrequent and intermittent, leading to a slow overall rate of the transported cytoskeletal population. It has also been shown that slow and fast transport share similar molecular motors.

Progress in biochemistry and genetics has led to the identification of approximately 45 members of the kinesin superfamily (Kifs), grouped into 14 subfamilies, and two members of the cytoplasmic dynein family. Besides this large array of motor proteins, there are also a number of linker/adaptor proteins responsible for binding cargo to the motor proteins that have been identified. This heterogeneity is thought to play a major role in the recognition of specific motors to their cargo. Many excellent reviews on the subject are available.

Axonal Transport and Neurodegenerative Diseases

The following developments have dramatically highlighted the role of axonal transport disruptions in human neurodegenerative diseases: (1) the discovery of motor protein mutations in human neurodegenerative diseases, (2) axonal transport defects in animal and *in vitro* cellular models of neurodegenerative diseases, and (3) newly discovered roles in axonal transport regulation for known pathogenic proteins involved in neurodegenerative diseases. With a focus on specific diseases, we discuss some of the recent finings linking axonal transport to neurodegenerative diseases.

Kinesin Mutation in Hereditary Spastic Paraplegia

Hereditary spastic paraplegias (HSPs), also known as familial spastic paraplegias, represent an autosomal dominant inherited group of neurodegenerative diseases. Patients present in their thirties or forties with symptoms in the lower limbs, with gradual proximal spread of symptoms. Neuropathologically, a distal axonopathy is seen, with severe degeneration and gliosis of the distal corticospinal tracts and relative sparing of the tracts in the brain stem and proximal cord. Due to the peculiar distal-to-proximal 'dying back' axonopathy observed in this disease, it had been hypothesized that dysfunctions in axonal transport leading to selective damage of the distant portions of the axons may be responsible for the pathogenesis of HSPs.

Indeed, a missense mutation in one of the genes encoding a major kinesin protein (the gene for kinesin heavy chain Kif 5a) was found in a family with HSP. The same mutation was found in all affected

members of the family, as well as in some presymptomatic members. This mutation occurs within a functional motor domain of the kinesin protein and a homologous mutation in yeast has been found to decouple kinesin binding to microtubules, highlighting the functional role of the kinesin mutation in the pathology of HSPs.

Dynactin Mutations in Distal Spinal and Bulbar Muscular Atrophy

Dynactin is a large protein complex linked to the retrograde motor dynein, and it is thought to link the motor to its cargo and/or increase the processivity of the motor. Animal models disrupting the dynein/dynactin complex develop late-onset motor neuron degeneration, and missense mutations in a dynein subunit cause progressive motor neuron degeneration in mice. Due to the central role of the dynein/dynactin complex in axonal transport, and based on data from the animal studies, it was hypothesized that mutations in the dynein/dynactin complex could play a role in neurodegeneration. Indeed, mutations in the gene encoding a subunit ($p150^{Glued}$) of the dynactin complex have been reported in a family with the neurodegenerative disease distal spinal and bulbar muscle atrophy (SBMA). In familial SBMA cases, the disease is transmitted in an autosomal dominant fashion and is manifested as is a primary lower motor-type neuropathy with patients presenting in their thirties, often with breathing difficulty due to vocal fold paralysis, which later leads to weakness in the face and distal extremities. Neuron loss as well as inclusions containing dynein and dynactin were also seen in autopsy studies from one patient. The mutation reduces the binding affinity of dynactin to microtubules and also causes subtle defects in dynein function.

Kinesin Mutations in Charcot–Marie–Tooth Disease

Charcot–Marie–Tooth (CMT) disease comprises a heterogeneous group of inherited peripheral neuropathies characterized by motor and sensory deficits, often presenting in young adults as tingling, numbness, and loss of deep reflexes. The progression of the disease varies among individuals, with symptoms ranging from mild neuropathy to complete disability. Two basic forms can be recognized, with primary demyelinating (CMT1) or axonal (CMT2) types of degeneration predominating. Various genes have been implicated in CMT syndromes, including several genes known to play a role in myelination (PMP22 and MPZ) and genes for gap junction proteins (Connexin 32). However, in a remarkable series of studies, it was shown that mutations in a kinesin subunit protein (Kif 1B beta) can lead to an axonal type of CMT (CMT type 2A).

While studying animal models of kinesin knockout mice, it was found that heterozygous knockout mice for one of the kinesins, Kif 1B, developed progressive muscle weakness with normal motor nerve conduction velocities, symptoms resembling axonal type CMT, CMT type 2. Incidentally, the gene for CMT type 2A had been mapped to the same interval as the gene for Kif 1B, and genomic analysis of pedigrees with CMT type 2A revealed that these patients had a mutation in the Kif 1B gene. It was further shown that the mutant motor protein may not tightly bind to microtubules, thus suggesting a loss of function of the Kif 1B protein in patients with CMT type 2A.

Axonal Transport Defects in Alzheimer's Disease and Other Tauopathies

The story of the role of axonal transport in Alzheimer's disease (AD) is a rapidly developing one. Neuropathologically, the two hallmarks of AD are deposits of fibrillar Aβ into diffuse and neuritic plaques in the extracellular space, and filamentous accumulations of tau proteins as neurofibrillary tangles and neuropil threads within neurons and their processes. Amyloidogenic Aβ peptides are generated by proteolytic processing of the Aβ precursor proteins (APPs), conveyed by fast axonal transport. Several enzymes are involved in the proteolytic processing of APPs to Aβ, including the gamma- and beta-secretases (presenilins and BACE, respectively). Human mutations of both APPs and presenilins are seen in familial AD cases, highlighting the critical roles of these two proteins in AD. On the other hand, tau is a microtubule binding protein thought to stabilize microtubules *in vivo*.

The accumulation of tau in neuronal cell bodies and axons, as well as axonal swellings seen in AD, prompted the notion that axonal transport failure was important in the pathogenesis of this disease. Recent observations indicate that defects in axonal transport can occur long before the onset of severe symptoms in animal models of AD as well as in patients with AD. Interestingly, global reduction of axonal transport by reduction of kinesin levels can also exacerbate AD-type pathology in mouse models, further highlighting the role of diminished axonal transport in the pathogenesis of this disease.

The previous observations suggest that axonal transport defects play a role in the pathogenesis of AD. In addition, many key proteins directly involved in AD are also thought to play roles in the regulation of axonal transport. Studies of several different model systems have suggested that APP may act as a receptor for kinesin, thus proposing a direct link between a pathogenic protein and the axonal transport machinery. However, other studies have been unable to confirm

these results. It has also been proposed that APPs may be transported in a vesicular complex containing presenilins and BACE, the gamma- and beta-secretase enzymes, and altered processing of APPs within this complex can lead to exacerbation of AD. These findings suggest that misregulation of APPs, either directly from known APP mutations (as in familial AD) or indirectly via proteins associating/interacting with APPs, can lead to disruption of fast axonal transport in general, thus leading to axonal depletion of critical components and neurodegeneration.

Another interesting line of evidence highlighting the role of presenilins in the regulation of fast axonal transport in AD derives from studies of presenilin mutant mice. As mentioned previously, presenilins are proteins responsible for regulated proteolysis of APPs, and mutations in presenilins are seen in most cases of early familial AD. Several studies indicate that presenilins interact with glycogen synthase kinase-3β (GSK-3β). GSK-3β is a kinase with many different roles, including the phosphorylation of kinesin light chains, and it has been shown that GSK-3β-mediated phosphorylation of kinesin light chains led to detachment of the kinesin motor from the cargo, thus preventing further transport of cargo. By using transgenic presenilin mutant mice, it was also shown that mutant or absent presenilin increased GSK-3β levels, thereby phosphorylating kinesin light chains, detaching the kinesins from their cargo, and impairing axonal transport.

Roles in axonal transport regulation have also been assigned to tau. Because tau binds to microtubules and is thought to stabilize them, it was proposed that dysfunctions in tau can destabilize microtubules and lead to a failure of axonal transport. Indeed, human tau mutations impair the ability of tau to bind to and stabilize microtubules, and tau overexpression in cellular models can lead to defects in axonal transport. In addition, the mechanisms causing the accumulation of tau in AD are also beginning to be understood. Defective axonal transport of disease-associated mutant tau has also been demonstrated in mouse models, providing experimental evidence for a mechanism of tau accumulation.

A final line of evidence suggesting a role for axonal transport defects in AD comes from studies of ApoE4, a gene whose allelic state is associated with an increased risk for AD. Mice expressing human ApoE4 exhibit defects in axonal transport, and the receptor for ApoE4, ApoER2, binds to JIP1/2, a protein that appears to mediate the binding of APPs to kinesin I. Thus, it can be postulated that overexpression of ApoE4 protein can lead to misregulation of JIP1/2-mediated binding of kinesin to APPs, leading to defects in fast axonal transport.

Stabilization of microtubules is also being explored as a therapeutic option in AD. The proof of principle for this concept was demonstrated in a study that showed that a microtubule-stabilizing drug (paclitaxel) could ameliorate the neurodegenerative phenotype in transgenic tau mice by offsetting the loss of tau function by stabilizing the microtubules and correcting the fast axonal transport defects in these mice.

Axonal Transport and Huntington's Disease

Neuropathologically, Huntington's disease is characterized by atrophy and degeneration of striatal neurons, with aggregates of pathological polyglutamine containing the protein huntingtin. Huntingtin is a predominantly cytoplasmic protein that associates with vesicles and moves in the fast axonal transport component. Although it has been known for several years that polyglutamine repeats within the huntingtin protein cause a gain of deleterious function leading to neurodegeneration, the exact pathogenic role of the repeats is unclear. By infusing huntingtin-harboring pathological polyglutamine repeats into a model for studies of fast axonal transport, it was shown that fast axonal transport was specifically inhibited by pathologically expanded polyglutamine repeats (but not normal proteins), along with inhibition of neurite extension in cultured cells. Furthermore, disruption of the *Drosophila* huntingtin gene also caused axonal transport defects. These findings lend support to a model in which aggregates of polyglutamine repeats disrupt fast axonal transport. Whether the disruption of axonal transport is a direct effect of the polyglutamine repeats or a secondary phenomenon remains to be established.

Axonal Transport and Amyotrophic Lateral Sclerosis

The histopathologic observation of prominent neurofilament-rich inclusions in the axons of spinal motor neurons of patients with amyotrophic lateral sclerosis (ALS) led to the hypothesis that disrupted axonal transport of proteins may play a role in the pathogenesis of the disease. However, the first direct evidence that axonal transport is disrupted in ALS awaited the development of transgenic mouse models of familial ALS based on expression of mutant superoxide dismutase (SOD-1) protein mutant mice that replicate several key aspects of ALS. Studies of these SOD-1 transgenic mouse models of ALS showed that the transport of neurofilament proteins was retarded in these animals, even before the mice were symptomatic, thereby implicating impaired axonal transport as an early deficit in ALS. Mutations in the p150 subunit of dynactin have also been reported in ALS patients.

Axonal Transport and Synucleinopathies

Synucleinopathies, also known as α-synucleinopathies, are a group of neurodegenerative disorders in which the primary pathology is the intracytoplasmic accumulation of α-synuclein primarily in neurons and, in some cases, glial cells. These disorders include Parkinson's disease, dementia with Lewy bodies, the Lewy body variant of AD, multiple system atrophy, and neurodegeneration with brain iron accumulation. In familial forms of Parkinson's disease, autosomal dominant missense mutations in genes encoding for α-synuclein are seen, suggesting a role of α-synuclein in the pathogenesis of these disorders. α-Synuclein is a highly conserved protein belonging to a multigene family that includes β-synuclein and γ-synuclein. α-Synuclein is strongly expressed in neurons, highly enriched in presynaptic terminals, and transported predominantly in the slow component. Axonal transport abnormalities of α-synuclein have been proposed in synucleinopathies, based on the observation that axonal α-synuclein pathology is pronounced in the disease and also on experimental evidence suggesting that α-synuclein may play a role in transport of presynaptic vesicles. Age-related retardation in the normal transport of α-synuclein was also seen in a study. Collectively, these studies propose a model in which age-related retardation of α-synuclein transport leads to accumulations of the protein over time, predisposing to the α-synuclein pathology in axons. Although these findings are interesting, many questions remain unanswered. The physiological role of synuclein is far from clear, and much work needs to be done to identify the role of synuclein in neurodegenerative disorders.

Conclusions and Future Directions for Research

A growing body of evidence implicates axonal transport defects in the etiology and pathogenesis of neurodegenerative diseases. Although motor protein defects in neurodegenerative diseases are direct evidence for this, it is likely that many other disease proteins are directly or indirectly linked to the complicated machinery of axonal transport. Thus, studies on the molecular mechanisms of transport are necessary to facilitate our understanding of the role of axonal transport in these diseases. Since pathogenic proteins in AD have roles in the regulation of axonal transport, and these proteins have been extensively studied, the time is perhaps ripe to uncover the links between AD and impaired axonal transport. With greater understanding of the other neurodegenerative diseases, it is likely that many more links to axonal transport will be uncovered. Another exciting but largely neglected avenue of research is drug discovery efforts to counteract axonal transport impairments as therapeutic interventions for neurodegenerative diseases. Indeed, if axonal transport defects are shown to be part of a common mechanism of disease in many neurodegenerative disorders, the discovery of drugs that modulate axonal transport could result in the development of important therapeutic interventions for the treatment of these disorders.

Fast (Anterograde and Retrograde) Transport and Slow Transport

Membranous organelles, such as vesicles, are transported at rapid velocities (i.e., up to 400 mm day^{-1}) in both the anterograde (i.e., away from the cell body) and retrograde (i.e., toward the cell body) directions. For example, proteins critical for synthesis of transmitters and their uptake, vesicle trafficking, transmitter release and recycling, etc. are, for the most part, rapidly delivered to terminals where they are essential for events involved in synaptic transmission. Some protein moves bidirectionally. Trophic factor receptors (e.g., the Trk receptors) are transported as inactive (non-phosphorylated) proteins in an anterograde direction to terminals, whereas active Trk receptors (phosphorylated) and their ligands (nerve growth factor and brain-derived neurotrophic factor) are carried retrograde to cell bodies where they influence transcription and, ultimately, the biology and survival of neurons. Moreover, transported proteins can be involved in disease in different ways. APP, the amyloid precursor protein, is a type 1 transmembrane protein that is rapidly transported anterograde along β- and γ-secretases in the central nervous system and is the source, when cleaved by these secretases, of the amyloid β (Aβ) peptide. Neurotoxic Aβ peptides are released at synaptic terminals where they accumulate as Aβ oligomers (and amyloid) which interfere with synaptic communication. When mutated, dynactin, a motor protein involved in retrograde transport, is the cause of amyotrophic lateral sclerosis (ALS), a motor neuron disease (Table 1). Moreover, tetanus toxin and some viruses (poliovirus and rabies virus) enter terminals and are carried by retrograde transport to cell bodies where their activities cause diseases such as tetanus, polio, and rabies.

The Cytoskeleton and Motor Proteins

Tubulin and microtubule-associated protein, including tau, as well as specific motor complex proteins (kinesin, dynein, dynactin, etc.), are transported within axons and provide the pathways and mechanisms for the bidirectional movement of membranous organelles and other constituents (e.g., mitochondria) in axons. Microtubules, which provide the rails for much of transport, have a uniform polarity, with their plus ends directed toward axonal terminals. Similarly, dynein, dynactin, and other components of retrograde motors play critical roles in the transport of components from terminals toward cell bodies. Kinesins, dynein, dynactin, and other proteins play key roles in the movement of membranous organelles toward either the plus end (anterograde direction) or minus end (retrograde direction) of axonal microtubules. Anterograde transport relies on kinesins, which are members of a family of highly conserved motor proteins that are critical for intracellular trafficking and transport. In neurons, kinesin is the principal motor for anterograde transport, with kinesin-associated proteins mediating binding of cargo.

The cytoskeletal proteins (including actin, tubulin, and tau) move slowly down axons. Tubulin, actin, clathrin, dynein, dynactin, and glycolytic enzymes are members of slow component b (SCb) and move at a rate of 2–8 mm day^{-1}. Some tubulins and the neurofilament (NF) proteins, NF-L, -M, and -H, which play distinct roles in filament assemblies, appear to be slowly transported in the anterograde direction at velocities of 1–5 mm day^{-1}. Evidence is consistent with the idea that some of these proteins, including the NF proteins, move in the slow component because their movement, although sometimes rapid, is asynchronous and infrequent. Thus, the NF proteins pause, go, and pause – a phenomenon leading to an overall slow rate of transport. Kinesin and dynein and its partners may participate in forward and return movements of these proteins, respectively.

Axonal Injury

Axonal transection (acute axotomy) of peripheral nerves is the simplest model used to investigate the effects of injury on transport processes. Both fast anterograde and retrograde transport are interrupted, and rapidly moving membranous organelles (and bidirectionally moving mitochondria) accumulate at the cut ends of the proximal and distal nerve stumps. Subsequently, the distal stump degenerates (Wallerian degeneration (Wlds)), and regenerating sprouts extend from the proximal stump at the rate of 3–5 mm day^{-1}. Axonal regeneration requires the presence of cytoskeletal proteins and membranous elements supplied by 'slow' and 'fast' anterograde transport, respectively. After axonal transection, changes occur in the expression and transport of a variety of proteins, including those of the cytoskeleton. Elevated expression of actin and tubulin is associated with the increased delivery of these proteins to regenerating axons. At the same time, levels of NF proteins are reduced, resulting in

Table 1 Select genetic forms of ALS

Subtype	*Gene locus*	*Onset*	*Inheritance*
ALS1	*SOD1*/21q21	Adult	Autosomal dominant
ALS2	*ALS2*/2q33	Juvenile	Autosomal recessive
ALS3	18q21	Adult	Autosomal dominant
ALS4	*SNTX*/9q34	Juvenile	Autosomal dominant
ALS5	15q15	Juvenile	Autosomal recessive
ALS6	16	Adult	Autosomal dominant
ALS	*DCTN1*/2q13	Adult	Autosomal dominant
ALS8	20q13 *VAPD*	Adult	Autosomal dominant

a decrease in the amounts of NF proteins transported in the proximal stump. Because NF polymers play a major role, along with neuregulin signaling in determing axonal caliber in myelinated nerve fibers, the decrease in transport of NF proteins is associated with reductions in axonal caliber that originate in proximal axons (near the cell body) and propagate distally at rates comparable to the velocity of NF transport. This phenomenon is referred to as somatofugal axonal atrophy. After axonal injury, alterations in levels of the membrane-associated proteins transported in the fast component are more subtle with the notable exception of increased expression of GAP-43, a membrane-associated phosphoprotein involved in the guidance of growth cones. Alterations in gene expression, levels of specific proteins, and axonal transport usually return to normal after regenerating axons have reinnervated targets.

Disorders Associated with Abnormalities of Axonal Transport

Impairments of axonal transport have profound consequences for the structure and functions of nerve cells. Alterations in axonal transport can be classified by the time course (acute, subacute, or chronic), the character of the pathology (accumulations of membranous or cytoskeletal organelles, swelling or shrinkage of axons), the locations of abnormalities within axons (proximal vs. distal, as exemplified by proximal NF axonal swellings vs. distal dying back axonopathies), the regions of the nervous systems affected by disease (central nervous system or peripheral nervous system (PNS)), and types of neuron (motor, sensory, or other) vulnerable to disease.

Axonal degeneration occurs in a variety of disorders of motor and sensory neurons, including genetic disease (Charcot–Marie–Tooth disease, mutant *SOD1* and *DCTN1*-linked fALS, giant axonal neuropathy linked to mutations in the *GAN* gene, etc.), toxic neuropathies (*n*-hexane, vincristine, Taxol, and cisplatin), demyelinating diseases (Guillain–Barré syndrome), and neurodegenerative diseases such as ALS and Alzheimer's disease. Neuroaxonal dystrophy, a prototype of membranous neuropathy, is characterized by the presence of membranous organelles accumulating in the distal regions of axons. Similar pathology occurs in experimental disorders (vitamin E deficiency and intoxication with *p*-bromophenylacetylurea) and in a variety of human illnesses, including those that occur in childhood (infantile neuroaxonal dystrophy) and in aging (dystrophy of axons in the dorsal columns). It has been speculated that the accumulation of rapidly transported membranous materials may occur because of failure of local utilization, excessive anterograde delivery, or failure of recycling/removal (turnaround) by retrograde transport.

Several experimental and clinical axonopathies are associated with the pathology of the cytoskeleton, particularly the accumulation of NFs. Experimental exposure to β,β'-iminodipropionitrile (IDPN) is a prototype for this type of disorder. This toxin selectively blocks transport of NF, perhaps by altering interactions of NFs with microtubules or with anterograde motors. The transport of other cytoskeletal proteins, including actin and tubulin, is relatively unaffected, and fast anterograde and retrograde transport appear to be relatively normal. After systemic intoxication with IDPN, NF synthesis is not altered, and newly synthesized NF proteins continue to enter the axon normally. Because transport of these proteins along axons is markedly impaired, NFs accumulate and distend proximal axons (with secondary local demyelination). NF axonal pathology occurs in other experimental models, including aluminum intoxication; the overexpression of wild-type NF transgenes (altering the stoichiometry of NF protein); the expression of a mutant NF transgene which encodes a protein that fails to interact properly for assembly; and progressive motor neuronopathy, a disease in mice homozygous for mutations in *Tbce* (tubulin-specific chaperone E). Hereditary canine spinal muscular atrophy, an inherited motor neuron disorder in Brittany spaniels, shows severe accumulation of NF in proximal axons, closely resembling lesions seen in IDPN models and in ALS. Disorganization of the NF network occurs in humans with giant axonal neuropathy linked to mutations in *GAN*, which encodes gigaxonin, a member of the cytoskeletal BTB/Kelch family. Dynein and dynactin (*DCTN1*) play roles in retrograde axonal transport, and alterations in the biology of these proteins are associated with disease. For example, slowly progressive autosomal dominant ALS has been linked to a G59S mutation in the $P150^{glued}$ subunit of *DCTN1*. The dynactin complex, which includes P150 and dynamitin, provides a linker between cargo, microtubules, and dynein. In the index family, the mutation

occurs in a motif in the *P150^{glued}* subunit that mediates binding to microtubules. Modeling studies suggest that this mutation impacts on protein structure to create steric hindrance and distortion of the folding of the microtubule-binding domain. Consistent with this concept is the observation that the mutant protein binds less well to microtubules. Members of our group at Johns Hopkins have created a mutant *P150^{glued}* model of fALS with a robust motor neuron disease phenotype.

Axonal abnormalities are well documented in ALS (Lou Gehrig's disease). NF accumulates in the neuronal cell bodies and in proximal axons; the latter lesions resemble those produced by IDPN exposure and appear to reflect the impaired transfer of newly synthesized NF proteins from the cell body to the axon. Eventually, in ALS, axons degenerate and neurons die. Importantly, mutant *SOD1* fALS mice exhibit weakness and muscle atrophy associated with pathological features of human SOD1-linked ALS. These mice exhibit evidence of impaired axonal transport and develop proximal axonal swellings and more distal Wallerian degeneration followed by death of motor neurons. In a number of disorders, lesions occur more distally (NF swellings and accumulation of membranous organelles) and are often associated with distal axonal degeneration. These diseases are termed 'dying back' neuropathies because the distal axons/terminals exhibit conspicuous and early abnormalities distally and extend retrograde toward the cell bodies. Recent evidence suggests that similar processes occur in disease of the CNS.

Axon Regeneration and Protection

Intriguingly, in both experimental and human disease, regeneration and recovery can occur. The classical example of this process is regeneration after axotomy in the PNS. Usually, the distal axons of the PNS show Wallerian degeneration after transection, and eventually they regenerate successfully. Significantly, degeneration of these axons can be prevented genetically by the presence of an unusual gene. Significantly, mice (C57BL/Wlds) expressing a mutant gene (*Wlds*) exhibit slow Wallerian degeneration of axons distal to transections. The protective gene encodes an N-terminal fragment of ubiquitination factor E4B (Ube4b) fused to a nicotinamide mononucleotide adenyltransferase. The mechanism of this semidominant protection is not fully understood, and it has been suggested to be related to altered ubiquitination, changed purine nucleotide metabolism, or sirtuin-like activity. This unique genetic model provides an opportunity to discover new pathways whereby axons may be protected from degeneration.

Axonal Transport Tracers

L G Bilsland and G Schiavo, Cancer Research UK London Research Institute, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The formation of highly ordered and specialized neural networks during development is critical for the assembly of a functional nervous system. To gain a better understanding of these higher brain structures, it is necessary to correlate functional information with the intricate anatomy of specific neural circuitry, a process that becomes essential to evaluate changes in neural networks in circumstances of disease and injury. The discovery that exogenous proteins can be retrogradely transported in peripheral nerves initiated the development of neuroanatomical mapping techniques based on axonal transport tracing. The anatomical tracers now available can be classified according to their direction of axonal transport. Anterograde tracers are taken up by the cell soma or dendrites and transported down the axon to the nerve terminals. In contrast, retrograde tracers are taken up at the nerve terminals and transported toward the soma. Transport of tracers is predominantly in either an anterograde or a retrograde direction, although on closer examination it appears that most tracers are transported bidirectionally to some extent. In addition, several probes, termed transsynaptic tracers, are transferred from the original neuron to synaptically connected neurons. Neuroanatomical studies based on the detection of anterograde, retrograde, and transsynaptic tracers can provide a detailed knowledge of cellular projections and consequently morphology. Furthermore they allow investigation of neuronal connectivity that can divulge information on the organization and potential regulation of neural networks.

Early tracing studies were based on the induction of axonal degeneration. Following a brain lesion, axon degeneration was traced back to the cell soma by means of Golgi silver impregnation techniques. In the 1970s, advances in anterograde tracing included the injection of radiolabeled amino acids into specific brain regions. The anterograde transport of radiolabeled peptides and proteins was then monitored by autoradiographic techniques. This technique is still in use, although it has largely been superseded by tracers that require simpler detection methods and have improved anatomical resolution.

Anterograde and Retrograde Transport Tracers

Horseradish Peroxidase

The plant enzyme horseradish peroxidase (HRP) was one of the first retrograde tracers used. Application of HRP is generally by pressure or iontophoretic injection into the region of interest, where it is taken up by either damaged or intact axons and is endocytosed at nerve terminals via a fluid-phase mechanism. Histochemical detection of HRP is based on the production of a permanent electron-dense precipitate after HRP reacts with hydrogen peroxide and diaminobenzidine tetrahydrochloride (DAB) or tetramethylbenzidine. HRP labeling is, however, restricted to the cell soma and proximal dendrites. Conjugation of HRP with wheat germ agglutinin (WGA) significantly increases its ability to label axon terminals and allows transsynaptic transfer.

Fluorescent Dyes

The most frequently used axonal tracers are a range of fluorescent, hydrophilic dyes which include fast blue, rhodamine isothiocyanate, lucifer yellow, propidium iodide, and diamidino yellow. These dyes can be injected into the region of interest where they are taken up by fluid-phase endocytosis, or alternatively they can be microinjected directly into the cell soma. Several dyes can be used simultaneously to trace multiple cellular projections. Generally these dyes are bidirectionally transported, although some, such as fast blue and diamidino yellow, are predominantly transported in the retrograde direction. The majority of these probes are, however, not transsynaptically transferred. They are sensitive tracers, providing good resolution of cellular morphology. However, as with all fluorescence-based techniques, photobleaching can be a problem as well as saturating signals, which might obscure fine morphological details.

Fluorogold

Developed in 1986, the fluorescent retrograde tracer fluorogold has largely superseded the use of fluorescent dyes. Fluorogold can be applied by either pressure or iontophoretic injection into the region of interest, where it is taken up by damaged neurons and at nerve terminals by fluid-phase endocytosis. The advantage of this tracer lies in the availability of specific antibodies to fluorogold. Immunostaining can then be converted to a permanent electron-dense precipitate through the use of a biotinylated

secondary antibody followed by processing with an avidin–HRP conjugate and then reaction with DAB. Fluorogold provides sensitive staining of the axonal and somatodendritic compartments but does not undergo transcytosis.

Carbocyanine Dyes

This highly lipophilic family of dyes, which includes DiI (1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate) and DiO (3,3′-dioctadecyloxacarbocyanine perchlorate), are fluorescent membrane tracers. Carbocyanine dyes can be applied via pressure injection, placement of dye crystals in the region of interest, or biolistic methods and can also be used postfixative. These lipophilic dyes diffuse laterally ($2\,\mathrm{mm\,month^{-1}}$) through the phospholipid bilayers of the cell membrane, giving extensive labeling of cellular processes and hence detailed morphological information. Transsynaptic transfer of these dyes is not a common occurrence unless two cell membranes are very closely associated. *In vivo*, membrane fragments labeled with carbocyanine dyes can also become endocytosed into vesicles, which are then transported bidirectionally, but not transsynaptically. Thus *in vivo*, the detailed membrane labeling typical of carbocyanine dyes is replaced with a granular cytoplasmic labeling that prevents good resolution of cellular processes.

Biocytin

Extensive labeling of neuronal arborization can also be achieved with biocytin, a peptide derivative of biotin. Applied either by iontophoretic injection or as a pellet, biocytin is actively internalized and rapidly transported, predominantly in the anterograde direction, although with large injection volumes, retrograde transport is also seen. The high affinity of biocytin for avidin enables detection either with avidin–HRP followed by DAB staining or through the use of fluorescent avidin conjugates. However, biocytin is rapidly catabolized and therefore is only suitable for short-term tracing.

Fluorescent Microbeads

Introduced in the 1980s, fluorescent microbeads consist of either polystyrene or latex beads that are labeled with dyes of different colors, permitting double labeling experiments. Pressure injection of the microbeads in the brain results in a highly restricted region of uptake, the mechanism of which has not been defined, although it is likely to be due to local phagocytosis. Uptake is followed by retrograde transport of the beads. The microspheres produce stable fluorescent labeling. However, the signal is restricted to the cell soma; thus, information on cellular projections is very limited.

Dextran Amines

Fluorescent or biotinylated dextran amines were first investigated as transport tracers in the late 1980s and early 1990s. Dextrans can be applied either by pressure or iontophoretic injection or via application of dye crystals to the region of interest, where they undergo fluid-phase endocytosis. Transport then occurs in either an anterograde or retrograde direction depending on the molecular weight of the dextran. Dextrans of greater than 10 kDa are predominantly anterogradely transported, whereas dextrans of molecular weight of 3 kDa are transported retrogradely on injection in an acidic vehicle. This differentiation based on molecular weight represents a major advantage over other bidirectional tracers, allowing clearer and unequivocal results. Following standard aldehyde fixation, these hydrophilic polysaccharides are easily detected either by fluorescence or by processing of biotinylated dextran amines with an avidin–HRP conjugate followed by DAB staining to generate an electron-dense product. Dextrans are highly sensitive, nontoxic tracers that provide detailed labeling of fine cellular arborization.

Cholera Toxin B Subunit

Cholera toxin (CT) is a bacterial protein toxin produced by *Vibrio cholerae*, which binds to cellular membranes with high affinity. CT is composed of an active subunit (A), which induces toxicity by continuously activating stimulatory G-proteins (Gs), thereby increasing cyclic adenine monophosphate levels, and a homopentameric binding subunit (B). The B subunit (CTB) binds to the monosialoganglioside GM1 that is clustered in membrane microdomains on the plasma membrane of different cell types, including neurons. Once bound at the nerve terminal, CT becomes internalized in endocytic vesicles and then undergoes retrograde transport (at a rate of $102\,\mathrm{mm\,day^{-1}}$). Recombinant CTB maintains the specific binding of full-length CT and is completely atoxic, thus constituting an ideal transport probe. CTB was first used as a retrograde tracer, but recently it has been found to also be a very sensitive anterograde transport marker that gives fine definition of neuronal processes and nerve terminals. Application of CTB subunit is either by iontophoresis or pressure injection into the region of interest. Cellular labeling can then be detected with either a fluorescent or a biotinylated secondary antibody or by the use of fluorescently conjugated CTB.

The examples of anterograde and retrograde transport tracers discussed above are well established

and widely used. However, their transport, and consequently their labeling, is restricted to the neurons where their uptake occurs, which greatly limits their ability to map neuronal circuitry. Transsynaptic tracers circumvent this limitation by spreading from the initial neurons to synaptically connected second- and third-order neurons, thus providing information on neuronal connectivity.

Transsynaptic Tracers

Plant Lectins

Plant lectins are carbohydrate-binding proteins that have high binding affinity for specific sugar components of glycoproteins and glycolipids on cell membranes. One of the first applications of lectins as neuronal tracers was WGA conjugated to HRP, which significantly enhanced the tracing sensitivity of free HRP. However, *Phaseolus vulgaris* leucoagglutinin, WGA, and barley lectin (BL) are also commonly used as tracers. Application of lectins is by iontophoresis or pressure injection into the region of interest. Following binding at the plasma membrane, lectins are actively internalized and transported predominantly in an anterograde direction, although retrograde transport is also observed. Lectins label neuronal arborization and the cell soma and are also transsynaptically transferred, thus providing information on neuronal connectivity. Although specific antilectin antibodies exist, their direct conjugation with fluorescent dyes, biotin, or HRP represents a better alternative and permits their direct detection by fluorescence microscopy, immunohistochemistry, or enzymatic methods, as discussed previously.

Unfortunately, several disadvantages are associated with lectin-mediated neuronal tracing. Following injection into the brain, lectins cannot be targeted to a specific neuronal subtype, and nonspecific labeling can occur. Furthermore, lectins can be released from neurons and taken up by neighboring glial cells. The bidirectional transport of lectins can also make interpretation of neuronal circuitry data very difficult. A further disadvantage is that WGA administration can induce a severe immune response in the host and marked inflammation at the injection site. However, the use of transgenic technology in combination with plant lectin tracers can minimize some of these issues, as discussed in the section titled 'Genetic targeting with specific neuronal promoters.'

Tetanus Toxin

Tetanus toxin (TeNT) is a bacterial protein toxin produced by *Clostridium tetani*. After entering the bloodstream, TeNT binds with high affinity to a receptor complex at the neuromuscular junction. Neurospecific binding of TeNT involves the interaction with polysialogangliosides of the G1b series, such as GT1b and GD1b (Figure 1 (a)), and glycosylphosphatidylinositol-anchored proteins, including Thy-1. TeNT internalization requires the integrity of membrane microdomains, and it is preceded by the lateral sorting of TeNT from the lipid component of its receptor complex. A specialized clathrin-mediated endocytic pathway delivers TeNT into stationary early endosomes that mature into fast retrogradely transported carriers in a mechanism dependent on the small GTPases Rab5 and Rab7. Following its transcytosis into inhibitory interneurons, full-length TeNT blocks neurotransmitter release by cleaving vesicle-associated membrane protein (VAMP)/synaptobrevin, a SNARE protein localized on synaptic vesicles. This induces a spastic paralysis, which is often fatal. *In vivo*, TeNT retrograde transport and trancytosis occur not only in motor neurons/inhibitory interneurons but also in other neuronal networks, such as the pre- and postganglionic neurons innervating the superior cervical ganglion and the avian paravertebral ganglion.

TeNT consists of two associated fragments, a 50 kDa light (L) chain and a 100 kDa heavy (H) chain. The L chain has a zinc endopeptidase activity responsible for the cleavage of VAMP/synaptobrevin. The H chain consists of two domains, the N-terminal domain (H_N), which is involved in the pH-dependent membrane penetration and translocation of the catalytic domain, and the C-terminal portion (H_C) responsible for neurospecific binding. A recombinant H_C fragment (TeNT H_C) retains the high affinity for neuronal membranes and retrograde transport capacity of the native toxin but lacks toxicity. Consequently, TeNT H_C provides a useful biological tool for the investigation of both retrograde axonal transport and neuronal connectivity. Generation of hybrid proteins consisting of TeNT H_C linked to reporters such as green fluorescent protein (GFP), lacZ, or HRP permits the tracing of axonal transport.

The ability of the H_C fragment of TeNT to be endocytosed and transported in a manner similar to that of the native toxin has allowed the development of a real-time transport assay that permits the quantitative analysis of the retrograde transport of fluorescent TeNT H_C in purified primary motor neurons in culture. The speed distribution of TeNT H_C carriers *in vitro* overlaps with that seen *in vivo* ($0.8–3.6\,\mu m\,s^{-1}$). The axonal transport of TeNT H_C occurs primarily by a cytoplasmic dynein-mediated process along microtubules, although there is evidence to suggest that fast retrograde transport of TeNT H_C also involves F-actin and myosin motors,

Figure 1 The binding fragment of tetanus toxin is an axonal retrograde marker *in vitro* and *in vivo*. (a) Structure of the TeNT H_C fragment. The black arrow indicates the position of one of the two ganglioside binding pockets, which are necessary for highly specific binding to the neuronal surface and trafficking. For further details, see Lalli G, Bohnert S, Deinhardt K, Verastegui C, and Schiavo G (2003) The journey of tetanus and botulinum neurotoxins in neurons. *Trends in Microbiology* 11(9): 431–437. (b) Axonal retrograde transport of fluorescently tagged. Binding fragment of tetanus toxin (TeNT H_C) in differentiated spinal cord motor neurons in culture. This probe (in blue) is cotransported in axonal carriers with brain-derived nerve growth factor fused with green fluorescent protein (BDNF-GFP) and with an antibody specific for the neurotrophin receptor $p75^{NTR}$. The motor neuron cell body is located out of view to the right. Arrows point out a TeNT H_C carrier positive for the neurotrophin and $p75^{NTR}$. (c) Retrograde labeling of the hypoglossal nucleus after intramuscular injection in the tongue of TeNT H_C. Mice were injected with control buffer, wild-type TeNT H_C, and a TeNT H_C mutant in which the ganglioside binding region highlighted in purple in (a) has been deleted. Only the specimen treated with the wild-type protein shows a strong staining in the region of the hypoglossal nucleus (arrow), which indicates that TeNT H_C undergoes retrograde transport *in vivo*. Scale bar = 5 μm (b), 167 μm (c). (b) Adapted from Deinhardt K, Salinas S, Verastegui C, et al. (2006) Rab 5 and Rab control endocytic sorting along the axonal retrograde transport pathway. *Neuron* 52: 293–305; Sinha K, Box M, Lalli G, et al. (2000) Analysis of mutants of tetanus toxin H_C fragment: Ganglioside binding, cell binding and netrograde axonal transport properties. *Molecular Neurobiology* 37: 1041–1051.

in particular myosin Va. Significantly, this assay has also identified that TeNT H_C is retrogradely transported in vesicles that also contain nerve growth factor, brain derived neurotrophic factor, and their receptors, $p75^{NTR}$ and TrkB (Figure 1(b)). Therefore, it appears that TeNT H_C exploits an essential physiological route of transport, which validates this assay as a tool to investigate endogenous retrograde transport in both health and disease. With this *in vitro* assay, a significant deficit in retrograde transport, which may contribute to disease pathogenesis, has been shown in embryonic motor neurons isolated from animal models of motor neuron disease, including the 'legs at odd angles' mouse, which has a mutation in dynein heavy chain, and the mutant $SOD1^{G93A}$ mouse.

Several studies have taken advantage of the specific retrograde transport and transsynaptic transfer of TeNT H_C for the investigation of neuronal circuitry. Early studies based on the detection of TeNT H_C labeled with colloidal gold by electron microscopy established the validity of the method. More recently, injection of either lacZ-TeNT H_C protein or complementary DNA into the tongue of mice produced strong β-galactosidase staining in the hypoglossal nucleus after retrograde transport in the hypoglossal motor neuron axons (Figure 1(c)). Furthermore, β-galactosidase staining is evident in the lateral reticular formation and several midbrain projections, such as the mesencephalic trigeminal nucleus, which are second- and third-order neurons of this network. Similarly, to investigate the regulation of locomotor activity, GFP–TeNT H_C was injected into the medial gastrocnemius muscle. Following internalization at the neuromuscular junction, GFP–TeNT H_C was retrogradely transported to the cell soma of motor neurons innervating the medial gastrocnemius muscle. Specific transsynaptic transfer allowed identification of the premotor neurons responsible for controlling the activity of gastrocnemius motor neurons. This tracing technique is not restricted to use in mammalian systems and has been shown to be effective in other organisms.

However, interpretation of circuits and connectivity revealed by the use of TeNT H_C as a neuronal tracer must take into account the dependence of TeNT H_C uptake on synaptic activity. Hence, the tracer will be

internalized rapidly at the most active synapses and more slowly at less active synapses via synaptic vesicle recycling. It is possible, therefore, that labeling of weak synaptically connected second-order neurons may coincide with the timing of labeling of strong synaptically connected third-order neurons. Furthermore, the extent of labeling is dependent on the quantity and quality of TeNT H_C initially administered.

Neurotropic Viruses

The application of neurotropic viruses as neuronal tracers exploits their infectious nature and ability to replicate within the target cell, which provides a self-amplifying signal. Furthermore, their ability to cross synapses to synaptically connected cells permits visualization of higher-order neurons and the mapping of neuronal circuits. A variety of viruses, including herpes simplex virus types 1 and 2 (HSV-1 and HSV-2), rabies and pseudorabies virus type 1, adenovirus, and adeno-associated virus, have been used for tracing motor, visual, and auditory neuronal networks *in vivo*. After injection into the brain, neurotropic viruses bind to specific receptors, are endocytosed via a variety of different pathways, and are then transported to the nucleus, where the viral genome is replicated. Viruses can be manipulated to express a capsid protein fused with a GFP variant, or else a GFP variant is translated on viral replication, thus allowing infected cells to be identified easily (Figure 2). The majority of neurotropic viruses are retrograde tracers. However, adeno-associated viruses and strain H129 of HSV 1 are predominantly anterograde tracers.

Viral neuronal tracing, however, has several limitations. As a consequence of their virulence, the infection and replication of certain viruses (e.g., herpes virus) can induce neuronal degeneration. Following replication, certain viruses can also spread to local glial cells or nonsynaptically connected neurons, thus generating nonspecific labeling. The extent of neuronal tracing is dependent on the viral strain, the dose, and the postinoculation time. However, use of a virulent strain to increase the tracing capacity may exacerbate neuronal death or increase nonspecific viral labeling. This drawback is partially avoided in case of viruses characterized by a long incubation period before the onset of symptoms (e.g., rabies). Alternatively, attenuated viruses display a limited spread to nonneuronal cells and a longer neuronal survival time postinoculation, thus extending the time available for transsynaptic transfer. It is important to note that certain viruses bind to receptors that are specific to neuronal membranes. For example, canine adenoviruses (CAVs) bind to the neuronal

Figure 2 Retrograde transport of adenoviruses in the rat central nervous system. Both a canine adenovirus serotype 2 (CAV-2) vector expressing green fluorescent protein (CAVGFP) and a human adenovirus serotype 5 (HAd5) expressing DsRed2 (AdRFP) were stereotactically coinjected into the rat striatum (10^9 particles for each vector). Rat brains were cut rostrocaudally into 150 μm sections and were screened simultaneously for GFP and RFP expression. Each confocal image represents an approximate depth of 130 μm. At the site of injection (a), there was a dense concentration of AdRFP-transduced striatal astrocytes (~70%) and neurons (~25%) as well as some neurons transduced by both vector (yellow; white arrows). Only CAVGFP underwent significant retrograde transport from the striatum to afferent neurons in the cortex (b) and substantia nigra (c). Schematic inserts show midsagittal and frontal cross sections of the rat brain and the location of the injection site relative to the location of the transduced cells. Red asterisk represents contralateral cortex. CPU, caudate putamen. Adapted from Soudais C, Laplaec-Builhe C, Kissa K, Kremer EJ (2001) Preferential transduction of neurons by canine adenovirus vectors and their efficient retrograde transport *in vivo*. *FASEB Journal* 15: 2283–2285.

human coxsackievirus and adenovirus receptor. Consequently, CAV infection is restricted to neuronal cells in rat spinal cord cultures *in vitro*, in rat striatum *in vivo*, and in human brain biopsies *ex vivo* (Figure 2). Similarly, the rabies virus does not infect glial cells. In contrast, human adenovirus serotype 5 predominantly infects glial cells, and strains of HSV-1 and pseudorabies virus can also infect glial cells. The use of viral tracing technology therefore requires careful consideration and understanding of the benefits and limitations of each viral strain.

Genetic Tracing Technology

The development of multiple anterograde and retrograde tracers, as listed above, has provided extensive information on neuronal projections. Furthermore, the advent of transsynaptic labeling has enabled significant advances in neuroanatomical mapping. In spite of their flexibility, these tools also have severe limitations. One of the major drawbacks is their rather cumbersome targeting: The application of such tracers is normally by stereotactic injection or by administration of dye crystals into a chosen brain region. In addition, these methods do not allow the labeling of a specific neuronal population and often give rise to nonreproducible results between animals.

Recent advances in genetic technology have led to the development of novel methods for the mapping of neural networks. Specific labeling of a neuronal subset can be achieved via expression of a transgene encoding a transsynaptic tracer fused to a marker molecule, under the control of a neuronal-specific promoter. Continuous expression of the transgene enhances cellular detection and may promote a greater synaptic transfer, increasing the sensitivity of neuronal mapping. Unambiguous conclusions can therefore be made regarding the connectivity of specific neuronal subsets after monitoring axonal transport of the tracer. Genetic mapping will also prevent the nonspecific labeling that occurs after tracer injection and circumvents the need for invasive brain surgery that may damage the neural circuit under investigation. Furthermore, this technology can be used to investigate the development of neuronal circuits *in utero* and may provide functional insights since transsynaptic transfer of tracers will occur only in active circuits.

Genetic Targeting with Specific Neuronal Promoters

Transgenic expression of WGA or BL under the control of the rat olfactory marker protein gene promoter, which is expressed almost exclusively by olfactory sensory neurons in olfactory epithelium (OE) and vomeronasal epithelium (VNO), has provided reproducible mapping of olfactory circuitry. Lectin immunostaining was evident in the axons, dendrites, and cell soma of OE and VNO neurons, the first-order neurons. Furthermore, transsynaptic transfer permitted the labeling of neurons of the main and accessory olfactory bulbs, which represent the terminal fields of OE and VNO neurons (second-order), and of granule cells of the olfactory cortex (third-order), which are innervated by neurons from the main and accessory olfactory bulbs. However, immunostaining was not restricted to these areas but was also present in several neuromodulatory regions of the olfactory cortex, which indicated that retrograde transport had also occurred. BL expression has also been used to map sensory input in the olfactory cortex. Co-expression of BL with two distinct odorant receptor genes generated a transsynaptic tracer that could be monitored in localized areas of the OE, through the mitral and tufted relay neurons in the olfactory bulbs, to specific clusters of olfactory cortical neurons.

Similarly, following use of an L7 (Pcp2) promoter, WGA messenger RNA was expressed in cerebellar Purkinje cells. WGA was also detected in the synaptically connected deep cerebellar nuclei (second-order) and the red nucleus and thalamic ventrolateral nucleus, the third-order targets of cerebellar efferent axons. Furthermore, insight into neuronal connectivity in the *Drosophila* visual system was revealed by expression of WGA under the GAL4/UAS promoter, which drives expression in the R1–R6 photoreceptors in the retina. WGA immunoreactivity was present in the retina (first-order neurons), in monopolar cells (second-order targets of the photoreceptor cells), and also in the medulla, the target of the monopolar cells (third-order).

Transgenic mice expressing the GFP–TeNT H_C fusion protein have also been used to investigate neuronal circuitry. GFP–TeNT H_C under the control of a calbindin promoter, which drove the expression of the tracer in specific brain regions, has been studied. The transgenes also contained an internal ribosome entry sequence to allow co-expression of the lacZ reporter. This enabled differentiation of the neurons at the origin of the circuit, which expressed both β-galactosidase and GFP–TeNT H_C, and those receiving the protein as a consequence of transcytosis, which were only GFP–TeNT H_C-positive. Beta-galactosidase was detected in Purkinje cells, whereas GFP–TeNT H_C was also present in cerebellar granule cells, basket cells, and Golgi cells (second-order cells) due to the retrograde transport of GFP–TeNT H_C. Expression of a TeNT H_C–GFP fusion protein under the control of the orexin promoter has also been used to investigate

the neuronal regulation of orexin-expressing neurons in the lateral hypothalamic area involved in states of sleep and wakefulness. The use of TeNT H_C as a tracer has distinct advantages over lectins since it is only transported retrogradely, whereas lectins are transported bidirectionally.

Potentially viral vectors can also be genetically targeted to specific neuronal populations via insertion of a neuron-type specific promoter into the coding region of the viral glycoprotein gene. Further manipulation via insertion of additional genes, such as β-galactosidase or WGA, into the glycoprotein-coding region will induce selective protein expression. Indeed, in the olfactory system, intranasal application of an adenovirus encoding a WGA transgene under the chromogranin A promoter induced a pattern of lectin expression in the OE neurons (first-order), the main olfactory bulbs (second-order), and the main terminal fields of the olfactory cortex (third-order) similar to that obtained with transgenic expression of lectins under the olfactory marker protein promoter.

Genetic Recombination Strategies

The Cre/loxP recombination system has also been used to direct expression of transsynaptic tracers in selected neuronal populations. Breeding mice that express WGA only after excision of a loxP-flanked lacZ gene with mice expressing Cre recombinase under the control of the L7 (Pcp2) promoter generated offspring expressing WGA selectively in Purkinje cells. Anterograde transport analysis of WGA revealed connections with neurons of the deep cerebellar and vestibular nuclei (second-order) and the red nucleus of the midbrain and the thalamic ventrolateral nucleus (third-order).

This technology has also been applied in combination with viral tracing methods. A pseudorabies virus has been generated that requires Cre mediated recombination for its replication. Subsequent viral infection of transgenic mice that expressed Cre recombinase only in neuropeptide Y-expressing neurons consequently induced viral replication only in this neuronal population. Tracing of the subsequent viral spread has revealed the anatomical location of synaptic inputs regulating these neurons. More recently, a viral transcomplementation method was also employed to restrict viral expression to selected neuronal populations. A pseudotyped, GFP-expressing rabies virus, unable to spread transsynaptically, was used to infect brain slices in which relatively isolated neuronal populations had been transfected with both viral receptors and the viral glycoprotein gene required for transsynaptic spread. Following replication in transfected cells, the virus could spread transsynaptically, in a retrograde direction only, to monosynaptically connected neurons, identified by enhanced GFP expression, but no further due to the lack of glycoprotein in those neurons. Potentially, this technology may be used in combination with single-neuron electroporation to allow the electrophysiological characterization of synaptic contacts of selected neurons.

The tetracycline transactivator system provides an alternative strategy for the genetic regulation of neuronal mapping. In one example, mice transgenic for a TeNT H_C–alkaline phosphatase (AP) fusion protein under the tetracycline operator promoter were bred with mice expressing the tetracycline-controlled transactivator under the control of a cyclic phosphodiesterase splice variant, PDE102A, promoter. Expression of the fusion protein in the offspring was restricted to striatal spiny neurons, although retrograde transfer of TeNT H_C–AP revealed second-order connections with neurons of the ventral tegmental area/substantia nigra pars compacta, the dorsal raphe nucleus, and the mesopontine tegmentum.

Recombination systems can also provide greater control over the onset of transgenic tracer expression. As described above transgenic mice expressing WGA only after Cre recombinase-mediated excision of a lacZ gene have been developed. Microinjection of an adeno-associated virus expressing Cre recombinase and GFP, as a marker of viral infection, into the cerebellar cortex or visual cortex induced expression of the WGA protein in the infected areas and allowed its transsynaptic transfer to connected neurons.

Concluding Remarks

Over recent years the use of transsynaptic tracers has led to significant developments in the anatomical mapping of neural circuitry. Ongoing developments in genetic technology have further facilitated the mapping of functional interactions within selected neuronal populations, allowing their in-depth functional analysis, such as by electrophysiological recordings. The ability to identify specific connections within a given neural network *in utero* will now permit the onset of functionality in specific circuits to be determined. Ultimately, correlation of anatomical circuitry with neuronal functions will lead to a greater understanding of higher brain functions.

Babinski's Reflex/Sign

W M Landau, Washington University School of Medicine, St. Louis, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

The sign of Babinski is a qualitative distortion of the human lower extremity flexion reflex; its occurrence is a highly sensitive correlate of functional or structural disturbance of the upper motor neuron (corticospinal/pyramidal) system. The sign has not been reported in lower primates.

The flexion reflex is a stereotyped reaction of obvious teleology: the coordinated withdrawal of the limb from a noxious stimulus is manifest when a human steps on a tack, or a frog's toe is dipped in acid, or a lobster's foot is pinched by a rock. Analysis of the mammalian flexion reflex was a major accomplishment of the Sherringtonian school. The flexion of the hind limb includes coordinated movements at foot, ankle, knee, and hip joints that bring the foot away from the stimulus toward the trunk. Note that the human muscles that dorsiflex (raise) the ankle and toes in this response are anatomically named extensors, for example, extensor digitorum longus. Conversely, plantar flexion (lowering) of the toes by flexor digitorum longus may be part of the extension support reflex that maintains upright stance.

In the normal, conscious, alert, relaxed human subject, the flexion reflex is most effectively elicited by a mildly noxious stimulus, usually a firm but dull point of pressure that moves distally in the S-1 dermatome to the ball of the foot, along the lateral plantar surface (classical Babinski site), or along the lateral side of the foot toward the fifth toe (Chaddock site). The polysynaptic spinal reflex is triggered by cutaneous nociceptive endings of small myelinated and unmyelinated afferent nerve fibers. The normal threshold response is a contraction of the short toe flexors, perhaps teleologically useful to cup the foot and move it away from the noxious stimulus. Early associated contractions, especially of tibialis anterior and extensor digitorum longus, dorsiflex the foot at the ankle; associated contractions of knee and hip flexors occur in strong responses. The coordinated movement program is generated entirely within the lumbosacral spinal cord gray matter; it is transiently depressed during the spinal shock phase evoked by acute cord transection.

The normal synergy includes plantar flexion of all the toes, due largely to activity in the short toe flexors, and in spite of the extensor digitorum longus activity that acts primarily to dorsiflex the foot at the ankle joint. In the normal subject, the extensor hallucis longus, the major dorsiflexor of the great toe, is not reactive. In clinical terminology, this normal pattern in which all toes go down is called the flexor response because the prime movers are anatomical flexors.

When the upper motor neuron pathways to the S-1 segment are impaired, structurally or functionally, the efficacy of evoked synaptic activation in the spinal segment gray matter is increased (released). This is clinically manifested by stronger and more extensive motor response, by decreased stimulus threshold, and by spread of excitable anatomical loci beyond the S-1 segment. This concept is evident in the parallel hyperactivity of monosynaptic stretch reflexes (tendon jerks) that is also elicited by upper motor neuron/tract lesions.

The useful and unique feature of the pathological plantar response is a result of this output hyperexcitability; extensor hallucis longus is recruited into contraction with its close anatomical neighbors and fellow ankle dorsiflexors, tibialis anterior and extensor digitorum longus. As a result there is hallux dorsiflexion (extension) at the metatarsophalangeal joint. Electromyographic and nerve block studies demonstrate an actual mechanical competition; the downward force of the short plantar flexors of the hallux is overcome by the counterforce extensor hallucis longus. For the plantar reflex, the only consistent manifestation of the upper motor neuron impairment is this dorsiflexion of the great toe, the extensor response of Babinski. Fanning (spreading apart) and even slight extension of the other four toes may occur with strong flexor as well as extensor responses and is not pathologically significant.

The critical movement to be observed in response to the noxious stimulus along the lateral sole of the foot is flexion or extension at the hallux metatarsophalangeal joint; with extension, the extensor hallucis longus tendon is conspicuous. In the real world most patients can relax satisfactorily, and with unrushed repetition a reliably consistent plantar reflex of one sort or another can be observed and reported, but not always. Analogous to the wide range of normal tendon jerk response, hallux flexion in the normal plantar reflex may range from near nil to near 90°. Borderline or variable responses may reflect borderline pathologic process. Whether a hallux that wiggles a little up and then down is pathologically more significant than one that wiggles down and then up is unproven. Some patients do relax poorly and display ticklish or 'voluntary withdrawal' behavior. The bottom line is that the plantar reflex is not

confined to two sharply defined up and down flavors; equivocal observations deserve verbal description with associated clinical judgment of reliability. Variations of consistency over extended periods are often important clinical data.

It is important to recognize that the plantar reflex, flexor or extensor, is an involuntary physiological measure of segmental spinal coordination pattern. Although the extensor reflex response may be associated with impaired performance of voluntary coordination and strength tasks by the cooperative patient, these phenomena are qualitatively different aspects of movement performance in the clinical neurological examination. The long-term maintenance of the extensor reflex usually marks a fixed pathological lesion like those of cerebral palsy, stroke, or destructive tumor. But its evolution and devolution may usefully mark even the hourly or daily course of transient pathological change, as with transient ischemia, trauma, hepatic, renal, and toxic encephalopathy, multiple sclerosis, subdural hematoma, meningitis, and encephalitis. There are, indeed, exceptional cases in which the plantar reflex does not reflect proven pyramidal tract lesions. Some are due to collateral lesions of spinal motor neurons, but a few are unexplained.

Whether the Babinski sign is released in the immature nervous system was long controversial. But the definitive studies of healthy infants by the Bodensteiner group found extensor responses in 100% at birth, 95.5% at 2 months, 64.8% at 6 months, 0.7% at 9 months, and 0% at 1 year. As movement behavior reflects brain growth and myelination, the pathological significance of the extensor response is a contingency of age during the first year of life.

Based upon experiments with electrical stimuli delivered to many areas over the buttock and lower extremity, Kugelberg et al. inferred concepts of wholly separate flexion and extension reflex patterns in normal subjects. Nevertheless, they concur that "pathological reflexes ... are not new reflexes ... they are the result of the breakdown of the harmonious integration of flexion and extension components in the normal reflex mechanism. Disorders of suprasegmental control impair the discriminating capacity of the reflex mechanism as regards the strength, modality and site of the sensory stimulus" (1960: 408).

In summary, the sign of Babinski is not a different reaction from the normal nociceptive polysynaptic reflex; rather, it is a hyperactive flexion reflex in which extensor hallucis longus is included by irradiation, that is, synaptic hyperexcitability within the S-1 spinal neuropil. Note that the generic name of this reflex is plantar reflex. The normal reaction with downgoing great toe is called flexor plantar reflex (response). The pathological extensor plantar reflex (response) is manifested by hallux dorsiflexion at the metatarsophalangeal joint. The eponym Babinski sign (response, or reflex) is synonymous with extensor plantar reflex (response). The term Babinski should not be used to indicate the plantar reflex or the site of stimulation; there is no such thing as a negative Babinski.

What Is a BAC?

BAC is the acronym for bacterial artificial chromosome, a recombinant plasmid that contains a large insert of genomic DNA, typically in the 100–300 kb range. These plasmids differ from those used in routine cloning manipulations in that the BAC vectors have been derived from the fertility (F) factor, a large low-copy-number plasmid well documented for its ability to stably maintain large segments of *Escherichia coli* chromosomal DNA.

The vectors used to clone BACs were engineered to include only a small portion of the F factor, the region containing the origin of replication as well as genes that ensured its precise segregation during bacterial cell division. The low copy number (one or two per bacterium) helped to improve the stability of the inserted DNAs by reducing the probability of recombination between plasmids. The first use of an F factor-based vector to clone large DNAs was reported by Welcome Bender and colleagues (Harvard University), who assembled a 125 kb fragment of *Drosophila* genomic DNA in 1989. This vector was modified by Mel Simon and co-workers (Caltech), who used it to clone multiple large human genomic DNA fragments in 1992. These investigators introduced the term bacterial artificial chromosome, and the cloning of these human DNAs, some of which exceeded 300 kb in length, is generally considered to be the first paper on BACs.

The production of BAC genomic libraries by the laboratories of Mel Simon and Pieter de Jong (Children's Hospital Oakland Research Institute) played a key role in the genome mapping and sequencing projects. BAC libraries have larger average insert sizes than the original versions of the bacteriophage P1-derived artificial chromosome (PAC) libraries, in which the maximum insert size of 100 kb was determined by the capacity of the phage head. However, more recent versions of the PAC system that no longer use viral packaging, instead introducing DNAs via electroporation, have permitted insert sizes comparable to BACs. Despite their similarities, BACs have become the predominant platform as a result of their preferred use in the human genome project. One advantage of BACs over PACs was that their smaller vector size rendered them less costly to shotgun sequence.

Despite having very large DNA inserts that can range up to 1 Mb, the use of yeast artificial chromosomes (YACs) has been largely supplanted by BACs. BACs bear a number of advantages, including their maintenance in *E. coli*, which are easier to manipulate than yeast. Circular BAC DNAs are easier to prepare and less likely to fragment than the linear YAC DNAs. The large YAC inserts are more likely to be chimeric, that is, to be formed by the ligation of two unrelated genomic segments. In addition, the inserts in BACs are more stable and appear to undergo fewer deletion events. However, for genes that are too large for BACs, researchers may consider using YACs.

Why Are BACs Useful?

A typical BAC clone contains a segment of genomic DNA large enough to include most conventional-size mammalian genes. Because most BAC clones have inserts less than 300 kb in length, very large genes will not fit on to a single BAC. BACs that contain both a gene's coding exons and its regulatory regions are particularly useful when used as transgenes because they are likely to be expressed in a manner similar to that of the endogenous gene. The large size of a BAC helps to insulate it from the effects of transcriptional activity at the site of transgene insertion. Accordingly, mice containing one or more copies of a BAC transgene may be anticipated to express that gene in a spatially and temporally faithful manner, although at elevated levels as a result of the increase in gene dosage.

Transgenic mice produced using large BAC-based transgenes have been used to genetically complement loss-of-function mutations. This has facilitated efforts to positionally clone genes and has permitted the production of murine models of human disorders. In the earliest example of BAC transgenesis, mice generated using a 140 kb clone containing the wild-type circadian *Clock* gene were used to rescue two different lines of *Clock* mutant mice, one exhibiting a long circadian period and the other a loss-of-rhythm phenotype. Furthermore, transgenic mice bearing multiple copies of the *Clock* gene BAC exhibited a shorter period length, providing additional evidence in support of a role for this gene in the circadian pacemaking process.

BAC transgenic-mediated rescue has also been used to prove that the defect in the mutant mouse wobbler, which is characterized by motor neuron disease and defects in spermiogenesis, resided in the gene encoding the vacuolar-vesicular protein sorting factor 54 (Vps54). BAC transgenics have also been used to demonstrate that defects in the Psd-95, Dlg, and ZO1 (PDZ) domain-containing gene *whirlin* cause deafness in the whirler mouse. This gene also underlies the human autosomal deafness locus DFNB31.

Transgenic mice produced using human BACs have been used to complement defective genes in mice. In addition to providing evidence for the conservation of regulatory elements between mouse and human, this has permitted the use of modified human BACs bearing specific mutations to produce humanized murine models of specific genetic diseases, such as thalassemias. BAC transgenic mice permit altering gene dosage, and mice overexpressing the transcription factor Tbx1 have been proposed to model the condition known as the velo-cardio-facial syndrome (DiGeorge syndrome) because these animals exhibit the full spectrum of defects observed in human patients.

BAC transgenic mice have also proved useful for mapping the location of a gene's regulatory elements. This approach stems from the concept that if a line of BAC-based transgenic mice can rescue a loss-of-function mutation, then the BAC used must contain all (or nearly all) of the appropriate regulatory elements, at least for the cell type(s) analyzed. If a BAC provides only a partial rescue, then that BAC probably contains a subset of the required regulatory elements. Therefore, by using different BACs, we can infer the location of different enhancer sequences that regulate expression in different cellular subpopulations. BACs have also been used to map the regulatory regions of a gene using enhancer-trap-based strategies, in which a reporter gene and associated minimal promoter are used to search for transcriptionally active regions. In this setting, a collection of overlapping BACs containing reporters are first generated and then used to produce lines of transgenic mice. Each line is then assessed for reporter expression.

Therefore, BACs that contain a specific gene and its associated regulatory regions can serve as promoters to drive the expression of inserted genes. This is currently one of the most beneficial features of BACs because it surmounts the problems associated with finding useful promoters. In instances in which the expression of a gene marks a specific subset of cells, a BAC containing that gene may function as a cell-type specific promoter.

How Do We Identify a BAC That Contains a Gene of Interest?

As a result of the tremendous increase in genomic sequence information, identifying a BAC useful for our experiment may be as simple as a quick look at the genomic locus containing our gene of interest. If we are working with an organism whose genomic sequence has been determined, such as mouse or human, the location of specific BAC clones is included as part of the annotation provided by the web-based genomic browsers (as at the National Center for Biotechnology Information (NCBI), University of California Santa Cruz genome, and Sanger Institute websites). The BAC clones are typically displayed as sets of overlapping clones that blanket virtually any genomic region. The annotation for a given BAC can be viewed by clicking on the name of a particular clone, which typically opens a new window containing the information on that entry. One quick shortcut is to use the NCBI BAC Clone Registry and the Find clones near a genomic feature tool to enter the gene name. A set of overlapping BACs for that gene will be displayed.

For organisms for which the genomic data are not available or are incomplete, it may be necessary to use polymerase chain reaction (PCR)- or hybridization-based methods to screen for BAC clones corresponding to a candidate gene. BAC libraries can be obtained as macroarrays spotted on to nylon filters. Library screening services are also available through the BACPAC resources and through commercial vendors.

The process of identifying a BAC that contains a gene along with its required regulatory elements is currently an empirical process because there are no systematic ways of finding these regions, which may be located on either side of the first or last exons or in the introns between. Therefore, unless a specific BAC has been previously shown to contain the requisite elements, selecting a candidate BAC clone carries a measure of uncertainty. It is therefore advisable to select a BAC with considerable (50 kb or more) 5′ and 3′ flanking regions, if possible. It should be noted, however, that there are examples of genes having regulatory elements located at a considerable distance (>100 kb) from the coding exons; thus, there will be instances when BACs will simply not be large enough to include all the necessary regulatory elements for an otherwise compact-appearing gene. Of course, as the size of the regions flanking a gene increases, there is also the chance that other genes will be present on the BAC. The expression of these unwanted genes can be inactivated using homologous recombination.

How Do We Obtain BAC Clones?

A quick web-based search has suggested that there appear to be at least 300 BAC genomic libraries now available for a rapidly increasing list of species ranging from *Anopheles gambiae* (African malaria mosquito) to *Zea mays* (Indian corn). A list of registered BAC libraries and a key to BAC nomenclature can be found at the NCBI clone registry. One frequently used source for obtaining BACs is the BACPAC Resources Center at the Children's Hospital Oakland Research Institute (CHORI), which provides commonly used libraries for mouse (RPCI-23 and RPCI-24), human (RPCI-11), and other species from the Roswell Park Cancer Institute (RPCI), Lawrence Berkeley National Laboratories (LBNL), and CHORI collections. The Caltech human BAC library D (CTD) can be obtained through the commercial supplier Invitrogen. The aformentioned libraries have extensive BAC end-sequencing data, which on a practical level means that these have been precisely located on the genome and are the ones displayed by the genome browsers. The sequencing of the BAC ends of a limited set of murine and human BAC libraries was originally undertaken to facilitate the mapping and sequencing efforts underlying the genome projects.

A partial list of academic and commercial sources for BAC libraries can be found at the NCBI clone registry. One vendor, Amplicon Express (Pullman, WA), currently offers a total of 97 BAC libraries ranging from the platypus to the pinot noir grape. Therefore, before a reseracher embarks on producing a BAC library of his or her own, it is useful to perform a thorough search; it is possible that a library for the organism either has already been made or is in the works.

Unlike small plasmids, which are typically provided as purified DNAs, BAC clones are usually provided within a suitable *E. coli* host strain (usually DH10B) in the form of bacterial stab cultures. Because BAC libraries are maintained in multiwell plates, the clonal purity of the BAC supplied may not be guaranteed, and it is the recipient's responsibility to verify the identity and integrity of the clone.

How Do We Modify These Very Large DNAs?

Because BACs contain very large inserted DNA fragments, it is not feasible to use conventional restriction endonuclease-based (cutting-and-pasting) cloning methodologies to manipulate these clones. Instead, recombination-based strategies have been devised that permit the targeted insertion of DNA fragments into these large BACs. The homologous recombination is performed *in vivo*, that is, within *E. coli* bacteria (see Figure 1). There are two basic types of systems, one using the *E. coli* recombinase recA and the other using bacteriophage-derived recombinases.

The recA-based system was developed by Nathaniel Heintz (Rockefeller University) and uses recombination substrates present in a circular DNA form (see Figure 2). Using this approach, the DNA fragment

Figure 1 Overview of homologous recombination in BACs. Homologous recombination occurs within *E. coli* bacteria that contain a BAC, typically at one copy per cell. In the case of recA-mediated recombination, the recombinase activity (recA) is provided on the same plasmid as the DNA to be inserted. In the case of the phage recombinase-mediated systems, the recombinases are either provided via the introduction of a plasmid or are encoded on a defective lambda prophage engineered into the *E. coli* genome (not shown). The DNA fragments to be recombined are introduced into the bacteria by either electroporation or transformation. Note that the recombination process also requires other host-provided enzymatic activities. Occasional nonhomologous recombination events occur, with insertion occurring into the *E. coli* genome (see Figures 2 and 3). BAC, bacterial artificial chromosome; Ori, origin of replication.

Figure 2 RecA-mediated homologous recombination in BACs. The DNA fragment to be inserted via homologous recombination (the cassette) is subcloned into a shuttle vector. The homology arms (A and B) are subcloned on each side of this cassette. In this system, the arms are typically 300–500 bp in length. The shuttle vector also contains an origin of replication, the gene encoding the recombinase recA, and markers permitting both positive and negative selection. On introduction into *E. coli* and under positive selection, the circular shuttle vector DNA may be inserted into the BAC using recombination with either homology arm A or B. Integration using arm A is depicted. The desired recombination product is obtained by selecting for the excision of the vector (negative selection) via recA-mediated recombination using homology arm B. Note that excision using arm A leads to the restoration of the original unmodified BAC. BAC, bacterial artificial chromosome; Ori, origin of replication. Reproduced from Heintz N (2001) BAC to the future: The use of BAC transgenic mice for neuroscience research. *Nature Reviews Neuroscience* 2: 861–870.

targeted for insertion into the BAC is first cloned into a shuttle vector. Two regions of homology (the homology arms) that flank this DNA fragment are also introduced. For recA-based recombination, arms of approximately 300–500 bp in length are used. The shuttle vector also contains a marker permitting positive selection and one permitting negative selection. In the first step of recombination, the circular plasmid is recombined into the BAC under positive selection. This can occur using either of the two homology arms and will lead to the insertion of the entire plasmid into the BAC. The desired recombination product is obtained under negative selection for the recA-mediated loss of the inserted plasmid, which can occur in two ways. In the first, recombination occurs using the same homology arm, returning the BAC to its initial state. In the second possibility, recombination occurs using the other homology arm, in which case the desired product remains in the BAC.

There are two systems derived from phage, one from bacteriophage lambda and the other from a lambdalike prophage, Rac. Unlike the recA-mediated system, the phage systems require a linear (as opposed to a circular) DNA as a substrate for recombination. A system using the recE and recT functions of

Rac, called ET cloning, was developed by Francis Stewart (Technische Universitat Dresden). In addition, the inclusion of the gam gene product increased the efficiency of recombination by protecting the linear DNA fragments from exonucleolytic degradation. These genes were provided on a plasmid permitting inducible expression of recE and the constitutive expression of recT and gam. The inducible expression of these activities was advantageous because there were concerns that prolonged expression of recombinase activity might lead to unwanted recombination events. Thus, this system was portable in that it could be transformed into bacteria containing a BAC. The selection for recombinants was accomplished by including selectable markers in the linear DNA to be introduced into the BAC. These markers were flanked by either loxP or frt sites, permitting their excision by either cre or flp recombinase, whose activities were introduced on plasmids. This strategy was developed to simplify the process of performing multiple independent recombination events on a BAC (see **Figure 3(a)**). For example, if a BAC contained more than one gene, it would be desirable to inactivate the other genes to avoid the unwanted expression of those gene products.

The original version of the system developed by Neal Copeland and Donald Court (NCI/NIH) used the bacteriophage lambda-encoded exo and beta gene products, which are similar in function to recE and recT. In this system, gam was also used to preserve the integrity of the linear DNA fragments. The Copeland lab system placed the expression of exo, beta, and gam under the control of a temperature-sensitive repressor, permitting inducible regulation. One advantage of this system was that it avoided the constitutive expression of gam, which reduced cell viability. These three genes were present on a defective lambda prophage, and, hence, this system was not portable. Therefore, BACs need to be introduced into these recombinogenic strains via electroporation. (Portable versions of this system have since been developed.) Two different strains were generated: one that permitted the arabinose-inducible expression of cre recombinase and one that permitted the inducible expression of flp recombinase. These activities were used to excise the selectable markers, which, as in the Stewart system, were incorporated into the linear DNA fragment. In both of the Stewart and Copeland lab systems, the linear DNAs targeted for insertion were introduced into the bacteria via electroporation.

The biggest advantage of the phage-derived systems is that the regions of homology can be quite small with useful recombination obtained with homology arms as short as 50 bp. This small size permits the introduction of these regions into the linear DNA substrates using PCR. One potential disadvantage of the phage systems has been the use of cre (or flp) recombinase to remove selectable markers because the excision events leave a single residual loxP or frt site. This is probably only an issue if the recombinant BACs are to be used for the production of transgenic mice, and then only a problem if these mice are to be mated with cre- or flp-expressing lines. In this regard, it should be noted that many of the commonly used BAC vectors also contain loxP sites; thus, BAC-based transgenic lines produced with circular BAC DNAs will probably contain these sites.

The issue of residual loxP sites has been eliminated in the most recent version of the recombination system from the Copeland lab (see **Figure 3(b)**). This approach features a strategy using a selectable marker, galactokinase (galK), for which there is both positive and negative selection. In the first step, a linear DNA fragment containing the galK gene is inserted via homologous recombination at the precise location to be modified (positive selection). In the second step, homologous recombination is used to replace the galK gene with the desired DNA element (negative selection).

The development of these homologous recombination systems has been a major advance because they have greatly facilitated the process of moving fragments of DNA from one vector to another, without the need for restriction endonucleases. Their use is not restricted to BACs; they can be used with higher-copy-number plasmids. It should be noted, however, that, if we wish to subclone very large DNA fragments, a moderate-copy-number (<20) plasmid should be selected to avoid exceeding the DNA synthetic capacity of *E. coli*. These recombination systems have proved to be of particular use in the assembly of targeting constructs used for the production of knockout or knock-in mice. Methods have also been devised that permit the introduction of point mutations; however, these are performed in the absence of a selectable marker, so an efficient screening process needs to be implemented.

The purification of BAC DNAs at both the small (miniprep) and large scale uses a modified alkaline lysis procedure. Because BACs are covalently closed supercoiled circular DNAs, they can be purified by CsCl density gradient centrifugation. Affinity-based column purification kits are also commercially available. The analysis of BAC DNAs and fragments derived by digestion with restriction endonucleases requires the use of pulsed-field gel electrophoresis (PFGE) because conventional agarose gel electrophoresis cannot easily resolve fragments >30 kb. Purified BAC DNAs can be introduced into *E. coli* using electroporation.

Figure 3 Two methods of homologous recombination mediated by phage recombinases: (a) homologous recombination using positive selection; (b) two-step method. In (a), the DNA fragment to be inserted (the cassette) is prepared as a linear DNA fragment. Homology arms (A and B) can be introduced using PCR as arms may be as short as 50 bp. Selection for recombinants is accomplished through the inclusion of a positive selectable marker that is flanked by either loxP or frt sites. The linear DNAs are introduced into the bacteria via electroporation. Using the Stewart lab system (ET cloning), the bacteria express recE, recT, and gam from the Rac prophage. Using the Copeland lab system, the phage lambda-encoded products exo, beta, and gam are used. Recombination of the linear DNA requires the use of both homology arms. On identification of homologous recombinants, the selectable marker can be removed by either cre or flp recombinase, giving rise to a residual loxP (or frt) site. The method shown in (b), a variant of (a) developed in the Copeland lab, eliminates the issue of the residual loxP or frt sites by using a two-step strategy. The selectable marker galactokinase (galK) is used, for which there is both positive and negative selection. In the first step, galK is inserted under positive selection. In the second step, galK is replaced by the desired cassette under negative selection.

Transgenic mice have been generated with both linear and circular BAC DNAs. Like smaller transgenes, it is thought that BAC transgenes may be present in tandem arrays in the genome. Although the insertion of such sizable segments of DNA leads to questions concerning the long-term stability of these elements, few data are available on the subject.

BAC Transfection into Mammalian Cells

BACs can be introduced into mammalian cells *in vitro*, although the efficiency of this process is hampered by the large size of the BAC DNAs. There has been moderate success in identifying condensing agents that facilitate BAC transfection, with efficiencies exceeding

50% in some cases. Because most BAC vectors do not permit replication in mammalian cells, it may be necessary to retrofit the BAC to include the appropriate origins of replication, selectable markers, and reporter genes.

BACs have been of particular use for those working with large double-stranded DNA viruses, such as herpesviruses or poxviruses. Due to their large capacity, it has been possible to clone entire viral genomes on to a single BAC and to generate altered forms using the aforementioned homologous recombination systems. The viral BAC clones can be re-introduced into mammalian cells, leading to the formation of recombinant viruses. To avoid possible interference by the BAC vector, systems have been developed that permit the cre recombinase-mediated excision of these sequences in mammalian cells. Although the use of BACs is in its early stages, it is evident that it should facilitate studies addressing viral biology, the generation of viral vectors for gene therapy, and the development of vaccines.

BACs

The nervous system contains a very large number of cell types, with estimates ranging from hundreds to thousands of different kinds of neurons and glial cells. This diversity of cell types poses a challenge for those attempting to understand the function of selected cellular subpopulations because the tools for manipulating gene expression in these subsets have, for the most part, not been generated. The use of BAC genomic clones as a source of functional promoter regions has expedited the development of transgenic lines exhibiting cell type-restricted gene expression. These lines should greatly facilitate our efforts to explore the diversity of neural cells and should provide the starting point for the development of animal models useful for the evaluation of their functional roles.

The utility of BACs for studying the nervous system has been underscored by the efforts of Nathaniel Heintz and colleagues, who have used them to produce hundreds of lines of transgenic mice expressing the enhanced green fluorescent protein (EGFP) in distinct subsets of neural cells. The primary goal of these efforts was to provide researchers with a high-resolution descriptive analysis of the cells in which specific genes are expressed in the nervous system. It was anticipated that these efforts would also lead to the identification of novel cellular subpopulations. The initial findings of this large-scale effort included the production of transgenic lines using BACs containing the gene encoding choline acetyltransferase (ChAT). The investigators had used two different ChAT BACs: one that included the entire gene plus flanking DNA and a clone that had considerable 5′ flanking DNA but that lacked the 3′ end of the gene. The BAC containing the entire ChAT gene yielded transgenic mice that appeared to express EGFP faithfully in cholinergic neurons. Although the other BAC line exhibited reporter expression in a subset of cholinergic neurons, EGFP was also detected in noncholinergic cells, suggesting that critical regulatory elements may reside in the 3′ region flanking the gene. These findings illustrate the importance of selecting the right BAC clone. Based on making several hundred BAC transgenic lines, the investigators reported that in situations in which genes were too large to fit on to a single BAC, the use of clones containing extensive 5′ flanking DNA regions (100 kb or more) was typically not sufficient to obtain proper expression of EGFP in transgenic mice, providing additional support for the concept that internal or 3′ sequences are often critical for the expression of many genes.

As additional examples of the utility of this collection of BAC transgenic mice, findings were presented for the goosecoid-like (Gscl) gene, whose expression profiles suggested that it may serve as a lineage marker for a subset of cells forming the interpeduncular nucleus. Also highlighted were the Semaphorin 3b (Sema3b)-EGFP mice, which have identified subpopulations of neurons projecting to the cerebellum, olfactory bulb, and superior colliculus. The observed patterns have helped to shape hypotheses concerning the role of this molecule in the establishment of these synaptic connections. And mice produced using a BAC containing the gene for phosphodiesterase 1C (Pde1c) appeared to contain a marked subpopulation of migrating cells that may correspond to the subpial granular layer.

The production of these mice should facilitate functional studies, such as electrophysiological analyses by permitting the direct visualization of discrete subpopulations of living cells. It is evident that the ability to mark cells should also help to identify potential synaptic partners and provide insight into their developmental origins. The data for these lines of mice are accessible through the Gene Expression Nervous System Atlas (GENSAT). These mice are being made available to other investigators, and the current status can be viewed on the GENSAT website.

The use of BACs to mark specific cell types has also been the goal of a team at Regeneron Pharmaceuticals, whose largely automated process, Velocigene, uses homologous recombination in bacteria to facilitate the rapid production of BAC-based constructs useful for recombination in embryonic stem (ES) cells. These constructs were designed to insert

the reporter gene β-galactosidase into a specific locus, leading the creation of a null allele. Although not specifically focused on the nervous system, their efforts have yielded a number of interesting patterns of gene expression in the brain.

The concept of using BACs as a source of gene-specific promoters useful for marking restricted populations of neural cells has also been exploited by other investigators. GAD67-EGFP mice have been produced and used to unravel how basket cell pinceau synapses on the Purkinje cell initial axon segment are formed. BAC transgenic glycine transporter 2 (GlyT2)-EGFP mice have also been developed and should facilitate the electrophysiological analyses of glycinergic neurons. The recent publication of regulator or G-protein-signaling-4 (RGS4)–GFP mice has also shown that, to validate that the BAC-transgenic mice exhibit faithful patterns of expression, the sites of reporter gene expression must be very carefully analyzed. Thus, one important consequence of the development of these transgenic lines is that our understanding of the sites of expression for many genes, including those considered to be well characterized, will be thoroughly reevaluated. BACs have also been used to make lines of mice expressing cre recombinase in genes expressed in Purkinje cells, retinal rod bipolar neurons, and in calmodulin-dependent protein kinase II (CaMKII)-α-expressing forebrain neurons.

A major dividend of these ongoing efforts has been the validation of specific BACs because one of the major risks when working with these clones is understanding whether a given BAC contains the regulatory elements required for the faithful expression of the gene contained therein. Thus, the identification of functionally useful BACs should facilitate the production of additional BAC-based lines. It is anticipated that these will include the production of additional cre recombinase-expressing lines, as well as those permitting temporally regulated gene expression using the tetracycline- or lac-based systems.

The development of BACs and the homologous recombination systems required to manipulate them can be viewed as key technological dividends stemming from the genome sequencing projects. Now that the genes have been identified, the goal is to understand how they function. BACs are playing a major role in this process in that they have provided a rapid way of manipulating gene expression in restricted subsets of cells, which is of particular relevance in the cell-type diverse nervous system. In addition, BACs are also being harnessed for the production of targeting constructs useful for the National Institutes of Health (NIH) Knockout Mouse Project (KOMP), whose goal is to produce null and conditional null alleles for essentially all genes. It also appears likely that BACs will continue to play a key role in defining the identity and location of a gene's regulatory elements. Thus, although BACs were first produced as a tool to expedite genomic mapping and sequencing, they are also playing a key role in the pursuit of gene function.

Advantages of Bacterial Artificial Chromosome Transgenic Mice

Bacterial artificial chromosome (BAC) transgenic mice are generated by the direct injection of a DNA fragment into a fertilized one-cell mouse embryo, which results in stable but random integration of multiple copies of the transgene. Unlike a gene-targeting approach in embryonic stem cells, which is aimed to manipulate the endogenous murine genes, the transgenic approach is often utilized to overexpress an exogenous transgene in order to assess the phenotypic consequences. A basic transgenic construct (Figure 1(a)) consists of a piece of genomic DNA that contains a eukaryotic promoter, associated regulatory elements (i.e., enhancers, suppressors, locus control regions, etc.), an open reading frame (ORF) that encodes the gene of interest (marker genes such as lacZ, green fluorescent protein, Cre recombinase, etc.), and a eukaryotic polyadenylation (polyA) signal. Traditional transgenic studies, using genomic DNA elements less than 20 kb, are often plagued by inconsistency due to positional effects, which refers to variable, ectopic, or frank failure of transgene expression when the same transgene is integrated at different genomic loci. Many empirical studies reveal that positional effects are due to the use of smaller genomic DNA fragments that lack critical transcriptional regulatory elements. An average mammalian gene size is about 27 kb, but the regulatory elements, which could be located in the regions flanking the gene and in the introns, could be located in genomic regions that are 100 kb or larger. Often, large genomic inserts are needed to ensure accurate, integration site-independent transgene expression *in vivo*.

The initial success with large genomic insert transgenesis was achieved with yeast artificial chromosomes (YACs), which contain an average of 500–600 kb genomic DNA and are propagated in yeast as linear artificial chromosomes. YAC transgenes provide the critical, initial proof of principle that large genomic inserts can confer integration site-independent and dosage-dependent transgene expression. However, there are several limitations, which include a high degree of chimerism (i.e., a clone contains genomic DNA from different genomic regions), clonal instability, difficulty isolating a relatively large quantity of intact YAC DNA, and a relatively high frequency of YAC transgene fragmentation, which hinders the more widely used applications of the YAC transgenic approach.

BACs are a circular, bacterial F element-based plasmid containing an average of about 180–200 kb of genomic DNA. The BAC system has several advantages over the YAC system, including clonal stability, low chimerism, and the ability to provide a large quantity of high-quality DNA. Since BACs have become the standard clones used for the majority of genome sequencing projects, the databases for the finished genomes contain not only the primary sequence and the densely annotated genes but also overlapping BAC contigs across the entire genome. To initiate an experiment involving BAC transgenesis, one can readily locate the appropriate BAC for a gene of interest by searching the public genome database and then obtaining the BAC clone from either the public or the private repositories. The ease with which one can map and obtain a BAC clone for transgenic studies greatly facilitates the use of this technology for large-scale transgenic studies.

One limitation for the BAC transgenic approach applies to the relatively small number of mammalian genes that are >200 kb in size. For these genes, the success rate of BAC transgenesis, as measured by the accuracy of transgene expression, becomes relatively low. In summary, the advantages of the BAC transgenic approach greatly outweigh its limitations, and it is for this reason that the BAC approach has become a preferred method for generating transgenic animals for neuroscience research.

Generation of the BAC Transgenic Mice

Selection of BACs for Transgenic Studies

The first step in a BAC transgenic experiment is selecting BACs that maximize the chance for accurate transgene expression *in vivo*. As a general rule, in order to recapitulate the expression pattern of a gene of interest on the BAC (termed target gene) *in vivo*, one should select BACs that contain at least 50 kb of both the 5′ and 3′ flanking genomic sequences, in addition to the genomic sequence spanning the coding region of the target gene. For mammalian genes that cover less than 100 kb, such BACs are relatively easy to locate in existing public databases such as the Genome Browsers at University of California at Santa Cruz, the Ensembl Genome Browser, or the Clonefinders at the National Center for Biotechnology. Appropriate BACs can be obtained from the public repository (BACPAC Resource Center at Oakland Children's Hospital) or from commercial sources (e.g., Invitrogen).

Figure 1 The advantage of BAC transgenic approach in mice. Traditional transgenic constructs, using genomic DNA elements less than 20 kb to drive the transgene expression, frequently result in low level or ectopic patterns of transgene expression (i.e., positional effects). BAC transgenes, with genomic sequence of 180–200 kb, can often confer accurate, transgene dosage-dependent, integration-site-independent transgene expression. (a, b) Examples of ectopic lacZ transgene expression in conventional transgenic studies for murine Ziprol gene. (c, d) Examples of lacZ transgene expression in a Ziprol BAC transgenic mice. Yang XW, Model P, and Heintz N (1997) Homologous recombination based modification in *Escherichia coli* and germline transmission in transgenic mice of a bacterial artificial chromosome. *Nature Biotechnology* 15: 859–865.

Figure 2 Two basic BAC transgenic construct designs. The first construct (CS-1) is designed to overexpress a transgenic open reading frame (Tg ORF), such as a marker gene or Cre, under the regulatory elements of the target gene on the BAC. A polyadenlyation signal (polyA) is inserted after the Tg ORF to terminate its transcription, which also ensures that the target gene itself is not overexpressed. The second construct (CS-2) is designed to overexpress the target gene and a Tg ORF, with the internal ribosomal entry site (IRES) allowing the translation of the two proteins from one messenger RNA.

Basic BAC Transgenic Construct Design

There are two basic BAC transgenic construct designs that are dependent on different utilities (Figure 2). The most common utility of BAC transgenesis is to selectively express an exogenous gene of interest (the ORF), such as the enhanced green fluorescent protein gene (EGFP) or Cre recombinase, under the regulatory elements of a target gene on the BAC. The target gene itself, however, should not be overexpressed in the transgene. In this case, the basic BAC transgenic construct consists of the ORF followed by a eukaryotic polyA signal (e.g., polyA signals from the human growth hormone or phosphoglycerate kinase), and the entire transgenic cassette is inserted in front of the translational start sequence for the target gene. Another common application for BAC transgenesis is to overexpress a target gene on the BAC and to simultaneously co-express an ORF to label the sites of overexpression. In this case, the most common BAC transgenic construct is to insert an internal ribosomal entrance sequence (IRES), followed by an ORF, after the translational stop sequence and in the last exon of the target gene. The IRES sequence permits translation of two proteins, one encoded by the target gene and one by the ORF, from the same mRNA message. These two basic BAC transgenic construct designs can satisfy the vast majority of BAC transgenic applications.

Engineering BACs by Homologous Recombination in *E. coli*

BAC transgenesis is greatly facilitated by the available set of highly efficient tools used to engineer BACs. There are two widely used homologous recombination-based methods to engineer BACs in *E. coli*: the RecA-based method and the recombineering method

Figure 3 Commonly used methods to engineer BACs by homologous recombination in *E. coli*. (a) Two-step RecA-based homologous recombination method to precisely place a target sequence (e.g., enhanced green fluorescent protein or EGFP) in between two chosen homologous sequences (A and B) on the BAC. Two steps of recombination called co-integration and resolution are required. The shuttle vector in this method includes an R6Kγ origin of replication (cannot replicate in BAC host bacteria but can replicate in other special bacterial strains (e.g., Pir2) that supports this origin of replication), RecA gene (supporting recombination in BAC host bacteria), ampicillin-resistant gene (Amp), and the recombination cassette (i.e., A-EGFP-B). (b) One-step RecA-based method to engineer BAC. In this case, a single homology arm (A) is needed, and RecA is supplied by a helper plasmid. This method is highly efficient and has been used for large-scale BAC engineering and BAC transgenic studies (i.e., GENSAT). (c) Recombineering method of BAC engineering. Transformation of the PCR-amplified linear DNA fragments containing two small homologous sequences (A and B) and *E. coli galK* gene into specialized BAC host bacteria that can inducibly express λ-Red recombinase. Induction of the recombinase allows the insertion of *galK* gene in between A and B sequences on the BAC by homologous recombination. Subsequently, transformation of a second PCR-generated sequence containing the recombination cassette (i.e., A-EGFP-B) into the BAC host bacteria allows the precisely replacement of *galK* gene on the BAC with the EGFP marker gene. (a) Yang XW, Model P, and Heintz N (1997) Homologous recombination based modification in *Escherichia coli* and germline transmission in transgenic mice of a bacterial artificial chromosome. *Nature Biotechnology* 15: 859–865; and Gong S, Yang XW, Li C, and Heintz N (2002) Highly efficient modification of bacterial artificial chromosomes (BACs) using novel shuttle vectors containing the R6Kgamma origin of replication. *Genome Research* 12: 1992–1998. (b) Gong S, Zheng C, Doughty ML, et al. (2003) A gene expression atlas of the central nervous system based on bacterial artificial chromosomes. *Nature* 425: 917–925. (c) Warming S, Costantino N, Court DL, Jenkins NA, and Copeland NG (2005) Simple and highly efficient BAC recombineering using galK selection. *Nucleic Acids Research* 33: e36.

(Figure 3). The first method developed to engineer BACs is the RecA-based method. The original RecA-based method, as well as its subsequent improved version, utilizes a shuttle vector that temporarily introduces the *E. coli* RecA gene into the BAC host bacteria to restore its recombination competence. In the shuttle vector, a recombination cassette is constructed so that two small stretches of homologous DNA sequences are subcloned by polymerase chain reactions (PCRs) from the BAC (each about 200–500 bp), and in between the two homologous sequences are the modifications to be introduced into the BAC (i.e., marker gene insertion, point mutation, or deletion). Once the shuttle vector is introduced into the BAC bacteria, two steps of homologous recombination can be sequentially selected to result in the precise placement of the desired modification in a chosen site on the BAC (i.e., between the two homology sequences; Figure 3(a)).

A variation of the RecA-based BAC engineering method, which is the one-step BAC modification method, permits relatively high-throughput engineering of BACs in a large-scale BAC transgenic project (Figure 3(b)). This method is designed to rapidly introduce a marker gene, such as EGFP or Cre, into many different BACs in order to study *in vivo* gene expression patterns and to label distinct neuronal types. In the one-step method, a minimized shuttle vector is constructed which contains a single homology sequence from the BAC (200–500 bp) followed

by a marker gene of choice and a eukaryotic polyA sequence. The BAC engineering step involves only one homologous recombination step, which is facilitated by RecA expressed from a helper plasmid. The modified BAC has the marker gene placed under the regulation of the target gene regulatory elements, and the extra sequence from the minimized shuttle vector does not interfere with the accuracy of transgene expression *in vivo*. The one-step BAC modification is a highly efficient procedure, with one experienced individual able to modify up to ten different BACs simultaneously over a 2–3-week period. Also this is the method used in the large-scale Gene Expression Atlas BAC transgenic project (GENSAT).

The second widely used method for BAC engineering is the recombineering method, in which the recombination is supported by the bacteriophage-encoded recombination enzymes *RecE* and *RecT* from a prophage or the *Red* genes (*gam*, *bet*, and *exo*) from λ phage. The latest and widely used version for recombineering is illustrated in Figure 3(c). First, the BAC is transformed into a specialized *E. coli* strain that can inducibly express the $\lambda-Red$ recombination enzymes and is deficient in a metabolic enzyme gene, *galK*. Second, a linear recombination cassette is generated using PCR, with two homology arms as short as 50 bp, each flanking the *galK* gene. This can serve as both a positive and a negative selection marker in an *E. coli* host that is *galK*-deficient. The cassette is then transformed into the BAC in the specialized recombination-competent bacteria, and subsequently, induction of recombination leads to precise integration of *galK* into the BAC. In the last step, a second recombination cassette containing the intended modifications (i.e., marker gene insertion, point mutation, or deletion), flanked by the same short homology arms as in the previous step, is introduced into the BAC. Induction of recombination allows the replacement of *galK* by the intended modifications, and the resulting $galK^-$ bacteria can be readily selected.

In summary, both the RecA-based and the recombineering methods are highly efficient and reliable methods to introduce mutations or marker genes into a BAC. These methods have both been applied successfully in large-scale BAC engineering projects.

Characterization and Preparation of BAC for Transgenic Microinjections

Once the BAC is correctly engineered, appropriate steps should be taken to ensure that the recombination procedures do not introduce any unwanted rearrangement or deletions. These unwanted introductions, however, should be a rather rare occurrence for the BAC modification methods described above. Analyses of modified BACS are often done by restriction enzyme fingerprinting on conventional or pulsed field gel electrophoresis.

The final critical step for generation of BAC transgenic mice is the purification of intact BAC DNA for pronuclear microinjection into fertilized mouse oocytes. There are two important issues here. First, one needs to purify intact BAC DNA away from the fragmented BAC DNA up to 100 kb, which is often present in the DNA preps. Transgenic integration of such fragmented DNA may introduce positional effects or the expression of unwanted truncated proteins that may confound the studies. Second, one must reduce impurity in the BAC DNA preps since impurity may reduce the viability of the injected oocytes and reduce the rate for generating the BAC transgenic founders. The most successful method, in terms of consistency in generating transgenic founders, is the large-scale cesium chloride centrifugation preps of BAC DNA.

Applications of the BAC Transgenic Approach in Neuroscience Research

Since the first demonstration of BAC engineering and the BAC transgenic approach by Yang, Model, and Heintz in 1997, tremendous strides have been made toward comprehensive and systematic applications of this powerful *in vivo* genetic tool in the direction of understanding the function and diseases of the mammalian brain. All these applications are based on the assertion that, for the majority of the genes in a mammalian genome (particularly for those that are $<$100 kb in genomic span), an appropriately designed BAC transgene has a very high probability of conferring accurate transgene expression *in vivo*. The confidence for such an assertion is greatly enhanced by the success of the GENSAT large-scale BAC transgenic project. In the GENSAT database, which contains several hundred BAC transgenic lines, the vast majority of them express the EGFP marker gene in the endogenous-like patterns in at least two independent mouse lines. The reproducibility and reliability of the BAC transgenic approach has inspired a myriad of *in vivo* applications affecting many facets of neuroscience, from molecular and cellular analyses to system and behavior studies and brain disease research.

Applications to Study Gene Expression and Gene Function

The BAC transgenic approach has several widely used applications centered on the analyses of expression and function of an individual mammalian gene.

Gene expression and regulation One of the most common applications of BAC transgenesis is to study the expression pattern of an individual gene in the

brain. For this purpose, a reporter gene, such as *EGFP*, *DsRed*, or *lacZ*, is introduced into a resident target gene in the BAC prior to generation of the transgenic mice. Transgene expression can be analyzed either by direct fluorescence or by immunohistochemistry. As a result, one can readily obtain high-resolution images of gene expression in the brain throughout development and into adulthood. The largest study of this kind is the GENSAT project, which has detailed analyses of central nervous system (CNS) BAC transgene expression for several hundred CNS genes. Since engineering a BAC is a very efficient process, one can sequentially introduce multicolor reporter genes into several genes on a single BAC transgene in order to simultaneously visualize the expression patterns of these genes *in vivo*.

Since the BAC contains an intact genomic locus for a gene of interest, another common application of BAC transgenesis is to dissect regulatory elements that are critical for gene expression *in vivo*, such as enhancers, suppressors, locus control regions, insulator elements, and imprinting elements. In these studies, mutant BACs (with the marker gene) carrying a mutation in the putative regulatory element are generated to assess its impact on transgene expression.

Dominant genetic studies Dominant genetic studies, such as overexpression of the wild-type or dominant-negative genes variants, can provide valuable functional insights into these genes. For example, the granule-cell-specific zinc finger transcription factor *Zipro1* has no apparent loss-of-function phenotypes, but BAC-mediated increase in *Zipro1* gene dosage reveals its critical role in controlling granule cell proliferation. One advantage of the BAC-mediated dominant genetic approach is that the transgene is expressed in an endogenous pattern and usually at relatively physiological levels (less than fivefold overexpression), thus avoiding the confounding effects of aberrant transgene expression.

BAC rescue of the loss-of-function mutants A classical application of BAC transgenesis is in the rescue of the loss-of-function mutants in mice, which facilitated the positional cloning of loss-of-function mutant genes. As a natural extension of the genetic rescue approach, one can also perform *in vivo* structure–function analyses of a target gene on the BAC by engineering specific mutations (e.g., mutating a protein domain or a phosphorylation site) prior to generating the BAC transgenic mice in order to evaluate whether the mutant transgene can rescue the null mutant phenotypes. Another potential utility for the BAC rescue approach is to study the functional differences of single-nucleotide polymorphisms (SNPs), which naturally occur among different individuals in a species and some of which may contribute to variations in brain function and/or brain disorders. To evaluate the differential functions of SNPs *in vivo*, one can generate BAC transgenes carrying the individual SNPs and then study the ability of these SNP transgenes to rescue the null phenotype. Such studies may facilitate the understanding of individual SNPs on brain function and brain diseases.

Protein tagging for *in vivo* proteomics An important venue to unravel gene function is through identification of interacting proteins. Although interacting proteins can be identified using biochemical purifications in stable cell lines or through yeast two-hybrid screening, a challenge remains to purify and identify the endogenous interacting protein complexes from the mammalian brains. Currently, such studies are limited to a few protein complexes for which excellent antibody reagents and/or purification schemes are available. With the advance in BAC transgenesis, small protein epitope tags (such as FLAG-, HA-, His-, or Myc-tags) or even larger protein tags (such as EGFP or Protein-A) can be readily engineered as an in-frame fusion to a target protein expressed from the BAC. Subsequent affinity purification of the epitope-tagged target proteins from the transgenic mouse brains can facilitate co-purification of interacting protein complexes, which can be identified by sensitive mass spectrometry techniques. Although this BAC-mediated protein tagging and *in vivo* proteomic method is still at its infancy, it represents an active area of research and may have great promise to advance understanding of CNS gene function.

Applications of BAC Transgenesis to Study Neurons and Neural Circuits

The second major area of application for BAC transgenesis is to selectively express an exogenous gene of interest (such as EGFP or Cre) in a particular neuronal type and/or a particular neural circuit defined by a driver gene on a BAC (i.e., *DAT* in dopaminergic neurons). In this case, the BAC transgene is used as a vehicle to provide genetic access to a specific cell type in the brain in order to study its roles in brain function or brain diseases. The success of the GENSAT project has already generated a rich data bank of BACs that can reproducibly target transgene expression in many different neuronal types, as defined by morphology, anatomic locations, or neurochemical characteristics. These BACs provide an immediate entry point for a variety of sophisticated *in vivo* analyses of these neurons and neural circuits.

Developing Cre/Flp recombinase mice BAC transgenesis has been widely used to develop mouse lines that express Cre or Flp recombinase in a given neuronal lineage (i.e., Purkinje cells in the cerebellum or

hair cells in the cochlea). These recombinase mice will facilitate the use of the conditional gene-targeting strategy to selectively delete or activate gene expression in a neuronal lineage in the brain.

***In vivo* electrophysiology and imaging** In many brain regions, different neuronal types are often intermixed and cannot be readily identified in live brain tissues or living organisms. BAC transgenic expression of fluorescent proteins such as EGFP facilitates detection of specific, genetically defined neuronal populations in live brain slices or living animals with an imaging window placed in the skull. Electrophysiological studies of these genetically labeled neurons in brain slices or in living animals (e.g., for striatal projection neuron subtypes and cortical parvalbumin-positive interneurons) has led to rapid advances in understanding the physiology of these neuronal types.

Recent rapid advances in genetically encoded fluorescent reporter genes have resulted in a rich repertoire of proteins that can be multicolored and can report in real-time neuronal activities, calcium signaling, receptor/channel function, and so forth. BAC transgenic delivery of these latest fluorescent reporters, combined with the latest *in vivo* imaging techniques such as two photon imaging, holds great promise in aiding the understanding of how different neuronal types function at a system level and/or in the intact behavior of animals.

Cell type-specific expression profiling A challenge in studying gene expression profiles in the mammalian brain with the microarray approach is the complexity of the brain tissues. One solution is to isolate relatively pure neuronal populations from the brain for extraction of RNA and microarray analyses. With the advent of BAC transgenesis, individual neuronal types can be labeled with fluorescent proteins while the neurons are still alive. Methods have been developed to physically dissociate and purify these genetically labeled neurons for gene expression profiling, one of which is called fluorescence-activated cell sorting (FACS)-array (Figure 4). In an example of this method, EGFP-labeled striatal projection neuron subtypes are enzymatically dissociated and subsequently purified using FACS. Only live EGFP (+) neurons are sorted since the dead neurons are labeled with propidium iodide and are sorted against. Subsequent RNA purification and microarray studies have led to identification and verification of a novel set of genes differentially enriched in these clinically important neuronal populations. Besides FACS, other approaches to purifying genetically labeled neurons, such as laser-captured microdissection or hand picking under fluorescent microscope, have been applied to perform cell type-specific gene expression profiling.

Transsynaptic genetic tracing of a neural circuit Traditional methods to map the neuronal circuitry rely on stereotactic injection of anterograde or retrograde

Figure 4 FACS-array procedure to profile genetically labeled neurons in the mouse brain. Striata from transgenic mice selectively expressing GFP in striatonigral or striatopallidal medium spiny neurons (MSNs) were dissected and enzymatically dissociated. The dissociated dead striatal neurons were labeled with propidium iodide (PI). The live GFP-labeled MSNs were isolated by Fluorescent Activated Cell Sorting (FACS) to select for GFP (+) and PI (−) neurons. The RNA purified from the sorted neurons was amplified *in vitro* to generate cRNA probes. The cRNA from two different MSN subtypes, labeled with either Cy-3 or Cy-5 fluorescent dyes, were hybridized onto the mouse microarrays. Adapted from Lobo MK, Karsten SL, Gray M, Geschwind DH, and Yang XW (2006) FACS-array profiling of striatal projection neuron subtypes in juvenile and adult mouse brains. *Nature Neuroscience* 9: 443–452.

chemical tracers into distinct regions in the brain. The injection sites usually have many different types of neurons, thus precluding the precise understanding of the connectivity of a single neuronal type (origin neuron) in a heterogeneous brain region. To overcome these problems, genetically encoded anterograde or retrograde transsynaptic tracers have been developed and can be delivered by BAC transgenesis to a precise neuronal type in the brain. For anterograde labeling of neurons that the origin neurons project to, one can use BAC transgenesis to express wheat germ agglutinin or barley lectin in the origin neuron. For retrograde labeling of neurons that synapse onto the origin neurons, one can express an engineered fusion protein called GFP-TTC in the origin neurons, which combines the GFP with a nontoxic, C-terminal fragment of tetanus toxin. An advantage of these genetically encoded tracers is that they can usually transfer across several synapses, thus providing an opportunity to elucidate a neural circuit either upstream or downstream of the origin neurons.

Another elegant approach has been developed to perform retrograde and transsynaptic mapping of the neuronal circuitry using a pseudorabies virus-based strategy. In this approach, BAC transgenic mice are used to express Cre in the origin neurons, and then genetically engineered pseudorabies viruses are stereotactically injected into the brain region containing the origin neurons. The virus expresses EGFP only on Cre-mediated excision of a transcription termination sequence in these neurons. Since the pseudorabies viruses can be transferred in a retrograde, transsynaptic fashion, the upstream neurons projecting to the origin neurons can be illuminated. Similar to the other approaches, the pseudorabies virus strategy can be transferred through multiple synapses to label the upstream circuits.

Inducible and/or reversible manipulation of neuronal function A powerful tool to understand how a specific neuronal type or neural circuit contributes to brain function is through inducible and/or reversible manipulations of these neurons or neural circuits, including inducible gene expression, cell ablation, or reversible activity silencing. Genetically encoded proteins have been developed to perform such sophisticated experiments. For inducible gene expression, the tetracycline-inducible system and inducible Cre or Flp recombinase systems have been developed. For cell-specific ablation, an immunotoxin-based strategy has been developed so that the interleukin-2 receptor α-subunit is selectively expressed in the target neurons. Subsequent stereotactic microinjection of an immunotoxin binding to this receptor leads to ablation of the neurons. Several genetic strategies using modified potassium channels, glycosylphosphatidylinositol anchor-tethered neurotoxins, bacterial chloride channels, and modified G-protein-coupled receptors responsive only to synthetic ligands have also been developed for ligand-induced, reversibly silencing neuronal types. Combining BAC transgenic delivery of these genetically encoded molecular switches with sophisticated physiological and behavioral studies may greatly advance understanding of how the brain functions on a system level.

Applications to Model Dominant Human Disorders and Study Disease Pathogenesis

An important application of BAC transgenesis is to develop mouse models of human disorders due to dominant genetic mechanisms. For a large number of such disorders, including several inherited neurodegenerative disorders such as familial Alzheimer's disease, familial Parkinson's disease, polyglutamine disease (i.e., Huntington's disease), and amyotrophic lateral sclerosis (ALS), transgenic mouse models have proven to be powerful tools to examine disease mechanisms and to test therapeutic strategies. Since large-insert genomic transgenes such as YACs and BACs often contain the intact genomic locus and direct accurate, endogenous-like expression of the disease-causing proteins, the phenotypes from these models are often more accurate and robust than conventional transgenic models. For example, YAC transgenic models of Huntington's and Alzheimer's disease and spinal and bulbar muscular atrophy all exhibit robust diseaselike features. As summarized above, the BAC transgenic approach is now being applied to develop human disease models. As an example, a robust new BAC transgenic mouse model of Huntington's disease (BACHD) has been developed and characterized. BACHD mice express full-length mutant human huntingtin under endogenous regulation and can rescue the lethality of the murine huntingtin loss-of-function allele. These mice develop progressive motor deficits and selective neuropathology, reminiscent of Huntington's disease patients.

Besides developing mouse models, BAC transgenesis is promising in the study of disease mechanisms and the testing of therapeutic strategies. One such potential application would be to test genetic modifiers of the disease. Potential genetic modifiers of disease pathogenesis can be readily identified in genetic model organisms suitable for a large-scale genetic screen, such as yeast, *Drosophila*, and *C. elegans*. A substantial number of these modifiers act through dominant genetic mechanisms and can therefore be tested in mice through BAC transgenic overexpression. Breeding modifier mice to the disease mouse models may reveal the disease suppression efficacy in the mammalian brain. Systematic application

of BAC transgenesis may enable rapid validation of a large number of genetic modifiers as potential therapeutic targets for brain disorders.

Summary

In summary, the BAC transgenic approach has emerged as a powerful *in vivo* genetic tool to study brain function at all levels, from the molecules and cells to the circuitry in an intact behaving animal. The advent of large-scale BAC transgenesis, particularly the GENSAT BAC transgenic project, has greatly enhanced the utility of the BAC approach for all facets of neuroscience research. The BAC approach has also been systematically applied to develop robust new animal models for human brain disorders and to develop novel therapeutic strategies. Therefore, it is safe to predict that a bright future is yet to come for the BAC transgenic approach in neuroscience research.

Balance and Posture Control

L M Nashner, NeuroCom International, Inc., Clackamas, OR, USA

© 2009 Elsevier Ltd. All rights reserved.

Balance: Definition

A person senses a state of 'balance' when perceptions of self-orientation in relation to the environment are in dynamic equilibrium. This expansive definition of balance combines conscious and automatic motor controls, conscious and unconscious brain processes, with sensory information from the visual, inner ear vestibular, and proprioceptive systems. The term balance more commonly describes the mechanisms maintaining stability during performance of daily life activities, with the majority of balance research being focused on mechanisms controlling gaze and postural stabilization. Clinical research provides a better understanding of the impact of sensory, musculoskeletal, and central nervous system diseases on gaze and posture.

Concepts for Understanding Gaze and Posture

Maintaining gaze and postural stability during daily life activities is complex and involves the coordinated actions of multiple biomechanical, sensory, motor, and brain processes. The gaze system positions the eyes relative to visual objects of interest in the environment during activities involving combinations of body, head, and object movement. The posture system positions the body center of gravity (COG) relative to the base of support during activities involving combinations of body, base of support, and visual surround movement.

Figures 1 and 2 illustrate the principal components of the gaze and posture systems, respectively. Both systems are composed of biomechanical, sensory, and motor components interconnected by afferent and efferent brain pathways. The two are organized similarly in that both combine information from multiple sensory sources, respond through the coordinated actions of multiple motor processes, and involve neural coordinating mechanisms of the brain. Both systems perform within varieties of sensory and mechanical environments by adaptively modifying how prior knowledge and current sensory information are mapped into coordinated motor actions. The two stabilizing systems are also interdependent. Gaze is difficult to stabilize unless the body is also stable. Stable gaze is necessary for accurate visual orientation information, which is in turn an important sensory component for maintaining postural stability.

Gaze System

Eye Movement Controls

To maintain visual accuracy during dynamic activities, the direction of gaze must be stabilized on visual objects of interest. Dynamic visual acuity is best when a visual object is stabilized on the fovea, a small area centered on the retina containing the highest density of cone receptor cells. Acuity degrades rapidly when the object is displaced more than a few degrees from the fovea or when the visual angle changes faster than a few degrees per second relative to the fovea. The following four movement systems are the principal components of gaze control:

1. *Vestibuloocular reflex (VOR)*. The VOR utilizes angular velocity information from the inner ear vestibular system to reflexively rotate the eyes in opposition to the rotational movements of the head. Moving the eyes in opposition to the head helps stabilize gaze when viewing a fixed object while the head moves. VOR movements commence within 15 ms of head movement and continuously move the eyes at velocities between approximately $20^\circ\,s^{-1}$ and $120^\circ\,s^{-1}$.
2. *Smooth pursuit*. The pursuit system maintains gaze on a moving visual object by driving the eyes with position feedback information derived from the conscious perception of the object. The system generates continuous movement commencing within 50 ms of object movement and maintaining the object on the fovea at velocities up to $20^\circ\,s^{-1}$. Unlike the VOR, the pursuit system requires the presence of a visual object.
3. *Saccadic*. The saccadic system generates rapid, discrete eye movements that position visual objects onto the fovea. In contrast to continuous VOR and pursuit movements, saccadic movements begin abruptly, move the eyes at velocities up to $300^\circ\,s^{-1}$, and then abruptly terminate when the object is centered on the fovea. The saccadic system can generate movements to both visualized and imagined objects, including those anticipating an object's appearance or movement.
4. *Head on trunk*. Coordinated movement of the head relative to the trunk is another important mechanism helping to maintain gaze stability. When the body moves backward, forward, and from side to side during standing and walking activities, the head rotates in the opposite direction, thereby minimizing

Figure 1 Principal components of the gaze stabilization system (VOR, vestibuloocular reflex).

Figure 2 Principal components of the posture stabilization system.

rotational motions of the head relative to the external environment. These head movements simplify the task of gaze control when the body is moving by providing a stable platform from which to launch eye movements.

The following examples illustrate common daily life interactions among the movement systems: When seated in a moving vehicle and reading a roadside sign through the windshield, the pursuit and VOR systems work together to maintain gaze at all velocities below $120\,^{\circ}s^{-1}$. When the vehicle moves more rapidly, the saccadic system intermittently intervenes to accelerate the eyes back onto the sign. When gaze is redirected into the vehicle to read a dashboard instrument, the brain automatically suppresses the VOR component, and the pursuit system stabilizes gaze on the instrument. When standing at curbside and reading a sign on the passing vehicle, the pursuit system continuously stabilizes gaze at vehicle velocities below $20\,^{\circ}s^{-1}$, and at higher velocities the saccadic system intermittently intervenes to accelerate the eyes back onto the sign.

Posture System

Biomechanics of Posture

Erect standing and walking activities require that the body's center of gravity be maintained vertically over the base of support. The COG is a theoretical point about which the forces of gravity appear to act, a point in humans located in the lower abdominal area of the trunk. In the absence of active controls, standing and walking postures are inherently unstable due to the influences of gravity and external disturbing forces. When the COG moves outside the base of support, the person falls unless a step or stumble rapidly repositions the base of support under the COG. Controlling postural stability is similar while walking. The placement of successive steps and the forward progression of the COG are coordinated to maintain their relative vertical positions.

The base of support is the area of contact between the feet and the support surface. The term 'limits of stability' (LOS) refers to a perimeter of positions within which the vertical projection of the COG falls within the base of support. An adult standing on a flat, firm surface with feet spaced comfortably apart can position the COG approximately 12.5° back to front, and 16° left to right, and remain within an elliptically shaped LOS area. Alterations in either foot placement or surface topography alter the LOS. Heel-to-toe and tiptoe walking dramatically reduce the width and length, respectively, of the LOS and make stability significantly more difficult to control in the dimensionally reduced directions. The LOS dimensions change randomly with individual steps while walking on an irregular surface such as large stones.

The position of the COG over the support base during stance and walking is influenced by the relative positions of the ankles, knees, hips, arms, and head. A variety of postures, not just erect stance,

position the COG over the base of support. Examples of nonerect, balanced postures include the squatting position and positions in which the waist is bent forward and the ankles are rotated backward. The latter postures are commonly used when bending down to retrieve objects from the floor.

Postural Movement Patterns

The earliest movement response with a functional impact on postural stability is termed the 'automatic postural movement.' Following an external disturbance, the automatic movement commences in leg muscles at 85–95 ms latencies when recorded by electromyography, and at 120–150 ms latencies recorded as force exerted against the support surface. Automatic movements are involuntary, triggered by muscle proprioceptive inputs, and are mediated by brain and subcortical pathways.

Automatic movements are coordinated into patterns of lower leg, thigh, trunk, and neck muscle responses. However, the pattern of an automatic movement elicited by the same external disturbance differs, depending on the prior experience and expectations of the person at the time of the disturbance. Figure 3 compares ankle, thigh, and lower trunk muscle electromyogram (EMG) patterns elicited by the identical backward and forward displacements of the support surface. Panels a and b illustrate responses following practice standing on a surface longer than the length of the feet (normal). Panels c and d illustrate responses of the same person, a few minutes later, after practicing stance on a support surface shorter than the length of the feet (short). The human stick diagrams illustrate the corresponding body movements. During initial practice trials on each surface, EMG and body movement patterns resemble combinations of these two patterns.

With sufficient practice balancing on a given surface, identical forward and backward translations of the surface elicit very different EMG and body movement patterns. The responses illustrated in Figure 3 are consistent with two biomechanically distinct patterns for moving the COG of a multisegmented body forward and backward. Given the existence of the distinct patterns, however, this does not rule out the use of hybrid combinations:

1. *Ankle strategy.* On the flat surface, the COG is moved by rotating the body as an approximately rigid

Figure 3 Postural movement strategies elicited by backward support surface translations (a, c) and by forward translations (b, d). Electromyogram traces are full-wave-rectified surface-electrode recordings of the gastrocnemius (Gast), tibialis anterior (Tib), hamstrings (Ham), quadriceps (Quad), paraspinal (Para), and abdominal (Abd) muscles of the leg and lower trunk. All electromyogram recordings were performed in the same test session with the same amplifier gains. In panels a and b, the person was well practiced at standing on a support surface longer than the length of the feet (normal). In panels (c) and (d), the person was well practiced at standing on a support surface shorter than the length of the feet (short). From Horak FB and Nashner LM (1986) Central programming of postural movements. Adaptation to altered support-surface configurations. *Journal of Neurophysiology* 55: 1369–1381.

mass about the ankle joints, hence the term 'ankle strategy.' This strategy rotates the body by exerting torque about the ankle joints while stabilizing the proximal knee and hip joints. However, because the feet are much shorter than the body height, the ability to generate torque about the ankles is limited. Hence, the ankle strategy is effective only when COG movements are relatively slow and the COG is positioned well within the LOS perimeter.

2. *Hip strategy.* On the narrow beam support surface, the COG moves by rapidly rotating the hip joints, hence the term 'hip strategy.' This strategy relies on the inertia of the trunk rapidly accelerating in one direction to generate a horizontal shear force against the support surface and move the COG in the opposite direction. Because there are no biomechanical limitations on the horizontal shear force, hip strategy is effective when standing on narrow support bases and/or the COG is positioned near the LOS perimeter. However, conditions that limit horizontal force, such as standing on ice, render the hip strategy ineffective.

Movement Control Theory

Movement control theory addresses the question: How can the brain, within less than 0.1 s, select the appropriate pattern and appropriately coordinate the actions of many muscles located throughout the body? One theory is that the brain simplifies the task by selecting in advance, from among a limited repertoire of discrete patterns, one or a combination of several patterns most appropriate to the task conditions. In other words, an automatic movement pattern is the expression of a 'postural set' reflecting recent experience with and expectations of the task. One approach to testing this theory used principal factors analysis to analyze the EMG patterns of leg muscles recorded during exposure to a variety of posture control challenges. Results supported the theory in that 80% of the EMG activity patterns were attributable to three principal factors, two resembling ankle and hip strategy patterns and a third involving vertical body movement.

Sensory Inputs to Posture

Sensing the position of the COG relative to the base of support requires combinations of visual, vestibular, and somatosensory (tactile, deep pressure, joint receptor, and muscle proprioceptive) inputs, as summarized in Table 1. When standing on firm surfaces and surrounded by fixed visible objects, information from the three senses is accurate and provides redundant information. However, postural stability cannot be maintained over the course of daily life activities using a single sense or combination of senses. Changes in environmental conditions eliminate or render inaccurate and inappropriate for postural control the orientation information derived from individual senses. This principle is illustrated by the following examples:

1. *Support surface*. Under fixed surface conditions, the somatosensory input derived from contact with the support surface provides a majority of the necessary orientation information. When the support surface is compliant, irregular, or moves, the somatosensory input is inaccurate for postural control, and visual and vestibular inputs are substituted. Dry beach sand, soft wet grass, and thick carpeting are examples of inaccurate surface conditions.

2. *Visual surround*. Objects moving within the visual surround disrupt the visual sense of orientation, because it becomes difficult to distinguish between self- and object motions. Under these conditions, visual information is de-emphasized, and greater reliance is placed on somatosensory and vestibular inputs. An example of a daily life activity is standing next to a large bus that suddenly accelerates forward, producing a momentary disorientation or unsteadiness until the brain determines that the bus is moving forward, and the body is not moving backward.

3. *Inertial–gravitational reference*. Maintaining stability is most challenging when both visual and somatosensory inputs are inaccurate or unavailable, because only the inertial–gravitational reference of the vestibular system is reliable. Under these conditions normal individuals can still maintain stability, but their sway is significantly greater. Individuals

Table 1 Utilization of the senses for balance

Property	*Sense*		
	Somatosensory system	*Vision*	*Vestibular system*
Orientation reference	Support surface	Surrounds	Gravity/inertial space
Conditions favoring use	Fixed, firm surface	Fixed visual surround	Irregular and/or moving support/visual surrounds
Conditions disrupting use	Irregular/compliant support surfaces	Moving surrounds/darkness	Unusual motion environments

with impaired vestibular function, by contrast, experience instability and frequent falls when simultaneously deprived of useful somatosensory and visual information.

Organization of Senses

The mechanisms used by the brain to organize sensory information for postural control have been studied by measuring the stability of a person exposed to conditions in which the support surface, the visual surround, or both are moved in direct relation to the spontaneous sway of the person. A technique, referred to as 'sway-referencing,' creates an orientation reference that, while perceptually correct, is functionally inappropriate for determining orientation relative to gravity. The complete protocol of six sensory conditions, including all combinations of sway-referenced conditions and eye closure, termed the sensory organization test (SOT), is illustrated in Figure 4. The person stands for three 20 s trials of each sensory condition. COG sway is recorded using a forceplate and a percentage equilibrium score calculated for each trial, with 0% indicating loss of balance and 100% indicating perfect stability. Under the first-three fixed-support SOT conditions, the person stands, eyes open in a fixed surround (condition 1), eyes closed (condition 2), and eyes open in the sway-referenced visual surround (condition 3). SOT conditions 4–6 repeat these three visual conditions in the same order, with the support surface sway-referenced.

Figure 5 illustrates the SOT results of a typical normal individual. The composite equilibrium score is a weighted average of scores for the six sensory conditions. The gray background area of the graph delineates the ranges of abnormal equilibrium scores for adults aged 20–59 years. With the support surface fixed (conditions 1–3), spontaneous COG sway motions are small and stability scores are correspondingly high. Neither elimination nor disruption of vision has significant effects on stability. With the support surface sway-referenced to eliminate useful somatosensory inputs (conditions 4–6), by contrast, all stability scores decline and vision plays a more significant role. With useful vision (condition 4), postural stability averages 80%, while closing the eyes (condition 5) reduces stability scores to 65%. Stability is similar with the eyes closed (condition 5) or open within a sway-referenced visual surround (condition 6), indicating that an inappropriate visual input is ignored.

Because the vestibular system is an inertial–gravitation reference, it is not readily manipulated by external conditions. One method used to quantify the influence of vestibular inputs and to verify that SOT condition 5 isolates vestibular control is to assess patients with clinically documented bilateral vestibular losses. As exemplified in Figure 6, a patient with compensated bilateral vestibular loss maintains balance approximately as well as do normal individuals under SOT conditions 1–4, but loses balance repeatedly under conditions 5 and 6. These results indicate that the vestibular input, while not critical for standing when functionally useful somatosensory and/or visual inputs are available, is critical when combinations of sway-referenced surface, sway-referenced visual, and eye closure (conditions 5 and 6) eliminate both alternatives.

Although the vestibular system plays a secondary role in controlling balance when accurate somatosensory and/or visual inputs are available, information from the vestibular system is essential when support surface and visual conditions unexpectedly change. Commonly occurring examples include walking on tilted, irregular, and/or compliant support surfaces, and moving in the dark and in environments containing independently moving objects such as a shopping mall or a heavily traveled street.

Accurate vestibular input is also required to coordinate 'head on trunk' movements and to perform independent head movements while maintaining postural stability, two processes critical to gaze stability. As described in the earlier section on postural movement patterns, coordination of head movements relative to the trunk stabilize the rotational orientation of the head within the environment. Vestibular loss patients, by contrast, fix the position of the head relative to the trunk rather than to the external environment, thereby limiting visual acuity during common daily life activities such as observing a moving person or vehicle while walking the opposite direction.

Sensory Organization Theory

A generally accepted theory of sensory balance control is that the brain responds to changes in the conditions of the task by adaptively reweighting the influence of individual sensory inputs to balance. Experimental evidence supporting the theory that contributions of visual and somatosensory inputs are adaptively reweighted in response to sway-referenced conditions has been provided by mathematical models simulating the performance of actual persons standing under SOT conditions.

Clinical Applications

Medical Necessity

Poor balance is a major medical problem, the principal reason for over 7 million clinic visits per year in

Figure 4 The six sensory organization test conditions. Anatomical symbols with each condition (eyes for vision, three overlapping circles for vestibular, and foot for lower extremity somatosensory) illustrate the senses available and appropriate for balance control under each condition.

the United States, and the reason for 3.2% of new visits to a primary care physician. Imbalance is the fourth most common neurological complaint of geriatric patients, and is the most common complaint of persons aged 85 years and older. Patients with balance disorders report a wide variety of symptoms, including inappropriate senses of self- and external environment motion (dizziness), light-headedness, postural instability, and jumpy and blurry visual images. In the elderly, the prevalence of chronic imbalance (present for greater than 1 month) is estimated to comprise between 13% and 38% of the total balance disorder population. Because good balance is critical to many daily life activities, chronic imbalance is a major cause of disability and loss of functional independence, and a major factor in increased risk for falls and fall injuries.

Historical Perspective

The traditional clinical approach to a balance disorder was to assume that a patient's problems were caused by a discrete pathology. The medical workup, including selection of diagnostic tests, was therefore structured to confirm and/or rule out the presence of the presumed localized disease. While the localized disease approach continues to be productive with many acute patients, it has proved ineffective in a majority of patients with chronic balance problems.

Figure 5 Sensory organization test result for a normal person. The gray background area outlines the equilibrium score falling below the range of age-matched normal persons for each sensory condition. The composite score is a weighted average of scores over the six sensory conditions. Green bars indicate individual trial scores within the normal range; N/S indicates a trial not performed.

Figure 6 Sensory organization test result for a patient with bilateral loss of vestibular function. In conditions 5 and 6, 'FALL' indicates a trial during which the patient lost balance. The red bar indicates a score falling below the range of age-matched normal persons.

In the typical chronic patient, a localizing diagnosis is either not established or, when established, includes multiple pathologies that alone cannot delineate the most effective treatment approach. When a discrete disease processes is identified, traditional pharmacological and surgical treatments can sometimes stabilize the disease progression. In most chronic cases, however, medical treatments cannot cure underlying diseases or resolve associated symptoms and stability problems.

Impairment Reduction

Clinical leaders now advocate that a chronic balance disorder is effectively managed as a 'syndrome' comprising the accumulated effects of impairments within multiple systems, impairments being the functional manifestations of pathology. When a balance disorder is managed as a syndrome, impairment reduction treatments target those impairments with the biggest impact on patient function. Clinical evidence has demonstrated that rehabilitation exercise is one of the most effective impairment reduction approaches for maximizing function in patients with balance disorders.

Diagnosis

Pathology The search for pathology is always necessary and must cover a wide range of body systems. If discrete pathology is identified, the patient will frequently present with gaze and postural stability impairments that correlate poorly with the pathology. This is because impairments are influenced not only by pathology but also by interactions among system components and the adaptive responses of the brain. The pathology diagnosis only partially documents the patient's gaze and postural stabilization problems, and therefore provides only a portion of the information needed to select the most effective combination of medical and rehabilitation treatments.

Impairment An understanding of the patient's gaze and posture control impairments, the functional manifestations of pathology, provides information that is essential to treatment planning and outcome documentation, especially when an impairment reduction approach is the best treatment option. Research has provided several new, objective assessment tools for isolating and quantifying sensory, motor, and central adaptive impairments of posture and gaze control:

1. *Computerized dynamic posturography.* Computerized dynamic posturography (CDP) is a series of computerized protocols designed to isolate and quantify sensory, motor, and central adaptive impairments affecting postural stability. The sensory organization test component of CDP has been described in Figure 4. The motor control test (MCT) assesses the effectiveness of automatic postural movements. The MCT exposes the freely standing patient to sequences of unexpected, brief forward and backward displacements of the support surface, thereby displacing the patient slightly off balance and eliciting automatic postural movement responses. MCT measurements include the latency and the amplitude of movement response in each leg, and the coordination of responses between the two legs. The adaptation test (ADT) assesses ability to suppress the influence of inappropriate automatic response components. The patient is exposed to unexpected toes-up and

toes-down rotations of the support surface that elicit inappropriate automatic postural responses. ADT measures the amount of sway activity required to recover from each perturbation.

2. *Dynamic visual acuity.* Dynamic visual acuity (DVA) is a computerized protocol designed to isolate and quantify VOR impairments affecting gaze stability when the patient moves the head and views a fixed visual object. In this test, the patient identifies optotypes displayed on a computer monitor while the computer records the patient's back and forth (as if saying 'No') or up and down (as if saying 'Yes') head rotations. When the head is moving at or above a prescribed minimum velocity, an optotype is displayed for a limited duration. The test is conducted in two formats – the first with the head velocity fixed and the optotype size progressively decreased, the second with the optotype size fixed and the head velocity progressively increased. In the first format, the smallest identifiable optotype size is compared to the smallest identifiable size with the head fixed. The difference between static and dynamic optotype size is termed the 'DVA loss.' In the second format, the maximum head velocity with the optotype correctly identified is reported.

Applications of Impairment Information

Disorientation and unsteadiness are characterized by varying combinations of impairments, including (1) lack of one or more sensory inputs critical to balance, (2) misinterpretation of one or more conflicting sensory inputs, (3) delayed, weak, or poorly coordinated movement responses, (4) inappropriate movement response patterns relative to the task conditions, (5) visual acuity loss at higher head velocities, and (6) large discrepancy between head-fixed and head-moving visual acuity. The following patient examples illustrate these impairments.

Uncompensated vestibular deficit An adult patient suffered a partial vestibular loss due to vestibular neuritis. The initial symptoms of dizziness and spinning resolved within a few weeks as expected, but the patient continued to report vague feelings of being 'off balance.' The patient's SOT results are shown in Figure 7. In contrast to the bilateral vestibular loss in Figure 6, this patient maintained balance under condition 5, suggesting that the vestibular input was sufficient to maintain stability. However, the patient was unstable in the presence of the sway-referenced visual surround (condition 6), indicating that the patient failed to suppress the conflicting visual input. Failure to suppress vision conflicts helped explain why symptoms were vague and difficult to describe. Since the vestibular system was medically stable, an impairment reduction approach was selected using rehabilitation exercises to enhance visual adaptation. The patient reported a resolution of symptoms within 4 weeks, and follow-up SOT results were normal.

Figure 7 Sensory organization test result for a patient with an uncompensated vestibular deficit; N/S indicates a trial not performed. The red bar indicates a score falling below the range of age-matched normal persons.

Intermittent imbalance of unknown origin A construction worker self-referred, complaining of a 6-month history of intermittent dizziness, mild unsteadiness, and visual blurring. He was concerned about the safety of performing as a construction worker. Medical history and traditional site of lesion testing provided no useful information. A traditional medical workup failed to identify vestibular and central nervous system pathology. The patient's DVA results are shown in Figure 8. The patient was able to maintain normal visual acuity at velocities up to 120 $^{\circ}s^{-1}$ while moving to the left. While moving to the right, acuity was lost above 80 $^{\circ}s^{-1}$, a level of performance judged insufficient to perform complex tasks. CDP test results, by contrast, were normal. Rehabilitation treatments therefore focused on improving the patient's gaze stability and visual acuity during active and passive head movement tasks, with emphasis placed on movements to the right. Posttreatment DVA results were within normal limits. The patient reported resolution of symptoms and returned to work.

Controlled-outcome studies The effectiveness of impairment reduction approaches, such as those discussed earlier, has been demonstrated in a number of controlled clinical outcome studies. The first study included 48 chronic balance disorder patients whose standard diagnostic workup was noncontributory.

Figure 8 Gaze stabilization test result for a patient with intermittent imbalance of unknown origin. The upper graph shows the maximum achieved head velocities (degrees per second) for left and right movement directions. The lower graph shows the percentage asymmetry between the left and right achieved velocities. The green bar indicates an achieved velocity consistent with dynamic visual acuity requirements for high-performance activity. The red bars indicate achieved velocity and velocity symmetry scores below those required for high-performance activity.

The traditional discrete pathology approach would be 'watch and wait.' One-half of the patients were randomly placed in a control group and 'watch and wait' continued. The other half were placed in an 'impairment reduction' group that received vestibular rehabilitation individualized to reduce the impairments identified by the patients' CDP findings. The impairment reduction group showed significant recovery of function, while the 'watch and wait' group showed no significant changes. In another study, the impairment reduction strategy was shown to decrease the incidence of falls in elderly adults with chronic unsteadiness. A cost-effectiveness study analyzed diagnostic technologies commonly used in working up dizzy patients to identify those having the greatest impact on outcome relative to cost. This study showed that tests combining impairment information with pathological information provided by traditional diagnostic tests designed to rule out and/or verify the existence (localize) pathology provided the highest clinical value.

Posture as a Fundamental Human Activity

Introduction

Human upright posture, traditionally defined as body segments' configuration at any given time, has been extensively studied but is still a poorly understood phenomenon. There are several reasons why existing models of posture (i.e., genetic, hierarchical, etc.) are unable to explain the enormous complexity of the mechanisms of human postural control. One reason is that there is still a strong influence of the dichotomy, similar to that of classical Cartesian dualism: "considering human posture as the genetically determined reference posture or integration of all stretch reflexes of the body in order to maintain equilibrium" versus "considering voluntary goal-directed movement as the activity of higher centers superimposed on the bodily mechanisms." There is still a debate in the literature as to whether a single central control process is responsible for both movement and its associated postures or whether there is a dual coordinated control system for voluntary movement and posture.

Human posture is a product of an extremely complex dynamical system with many degrees of freedom, which, like any other fundamental activity, undergoes dramatic changes throughout the life span. As such, the classical question of how the performer constrains the many degrees of freedom to preserve and coordinate the configuration of various body segments while performing a goal-oriented movement is still unanswered. In other words, the nature of the postural dynamic is extremely complex, since posture includes not only antigravity control (e.g., under static conditions, the center of gravity should remain within the support surface) but also the interface between perception and action via fine postural adjustments associated with suprapostural activity, stability control during locomotion, and the ability to assess the body's spatial–temporal orientation in the surrounding environment. Accordingly, a primary objective of the performer in upright stance is to explore the dynamical properties of the perceptual motor workspace and to avoid the actions that exceed its operational limitations.

Sources of Information for Postural Control

Considering posture as a complex dynamical assemblage, it is reasonable to assume that all sensory systems can contribute information relevant to the control of posture. It was hypothesized that processes within the postural control system involve organizing, integrating, and acting upon redundant visual, vestibular, and surface somatosensory inputs to provide orientation information. The contribution of sensory information to the maintenance of stable posture has been characterized as a hierarchical process in which the congruence of both support surface somatosensory and visual inputs is compared to an inertial–gravitational reference, established by vestibular reference inputs. Thus, balance is a multidimensional ability in which a range of factors such as eye–motor coordination, kinesthetic response, ampular sensitivity, and vertical semicircular canal function are crucial.

In cases of intersensory inconsistencies, inputs not congruent with vestibular reference inputs are suppressed, and greater perceptual significance is attached to those inputs in accord with vestibular sources. Overall, human upright posture is a product of a complex dynamical system that relies on integrating input from multimodal sensory sources, including (1) the visual system, (2) the vestibular system, and (3) a great number of sensory receptors embedded in the muscles, tendons, joint capsules, and skin that we commonly refer as proprioceptive systems.

Neural Basis for Multisensory Sources of Balance

A neural basis for the multisensory influences on postural motion and the whole body orientation has been proposed. Specifically, convergence of vision, audition, somatosensation, and proprioception at the cellular level in the vestibular nuclei has been shown. Also, cells have been identified in the vestibular nuclei where whole discharge rates were influenced by both body motion, as signaled by vestibular end organs, and visual motion. Recent evidence suggests that the cortex, in some way, plays a role in processing multisensory information and modifying human postural control. Moreover, it has been suggested that vestibular and somatosensory input may be integrated within a distributed cortical network, including the temporal–parietal cortex, supplementary motor area, and

prefrontal cortex, in order to process input related ego-motion and counteract a loss of balance. A more recent study with young controls has also identified functional magnetic resonance imaging (fMRI) correlates of self-perceived postural instability. Specifically, significant activation of several brain areas, including the parietal cortex, anterior cingulate, and cerebellum, was observed when young subjects visually recognized the gravitational vertical via a computer-animated model of stable versus unstable postures. Indeed, accumulated evidence from recent studies investigating the effects of human cerebral lesions on posture suggests that perception of the visual vertical involves the insula, thalamus, and superior parietal cortex. It was also shown that lesions of the temporal–parietal junction (a region of multimodal sensory integration) lead to poor equilibrium control on an unstable support.

Virtual Time to Contact

Recently, the notion of virtual time to contact (VTC), which specifies the spatial–temporal proximity of the center of pressure (COP) to the stability boundary, as an informational property in the regulation of posture was proposed. This new approach to understanding the nature of posture regulation places the emphasis on information for control not on departures from a stability point within the equilibrium region of the potential base of support, as in inverted pendulum models of posture, but rather on the temporal safety margin, as specified by the virtual time to collision with the stability boundary. A significant consequence of this approach is that the control variable for posture is defined over the organism–environment–task interaction, rather than as simply a product of the organism.

The newly created variable was called virtual time to contact, which is the instantaneous time to the functional stability boundary defined on the dynamics of each point in the time series. The word 'virtual' was used because the individual does not want to make contact with the stability boundary. Thus, VTC is an estimate of the time to the boundary should it occur, which would happen only in the case of a loss of stability, as in a fall. In this approach, a time series of the virtual time to contact can be determined that is based on the dynamics of the time to contact relative to the boundary, rather the relative position of the COP to the stability boundary. In a series of recent studies, VTC has been shown to be a more sensitive index of postural stability than other traditional COP-based measures in aged and traumatic brain-injured subjects. Clearly, further research is needed to examine the neurocognitive and physiological bases of VTC in control of human posture.

Upright Posture Control

Quiet Stance Domain

In the act of standing still, the body experiences small variations in its position. It oscillates in anterior–posterior (AP) and medial–lateral (ML) directions. This oscillation is quantified by different methods such as image recording, where whole body movement is recorded along the time dimension, or by the use of the force platform. By using a force platform one can record the time to time position of the COP. COP movements are commonly used to assess body oscillation during stance. Normally during stance the COP migrates approximately 0.4 cm in the AP direction and 0.18 cm in the ML direction, while center of mass (COM) displacements are somewhat smaller. The differences in migration of COP and COM in the AP direction have been associated with the generation of torques at the ankle joints, while ML displacements have been associated with activity of hip muscles. Several models have been suggested to explain and describe COP migration in quiet stance. Three of these models are now briefly described.

Models

Upright human posture has been frequently modeled as an inverted pendulum. Modeling the human body as an inverted pendulum is based on the assumption that joint motion occurs only at the ankle joints, body sway is very small, and the feet do not move. Since the stability of the system requires that the COM falls within the base of support, it is believed that the COM is the controlled variable of the unstable body system. COM is regulated through a continuous movement of the COP and is stabilized around a fixed reference point. In a single pendulum model, the difference between COM and COP is proportional to the acceleration of the body COM.

A two-process random-walk model was suggested in which the maintenance of vertical posture could be viewed as part of a stochastic process. This model assumed the movement of the COP as a correlated random walk and determined at which time intervals COP displacements are either positively or negatively correlated. It was found that for short time intervals (less than 1 s) COP displacements were positively correlated, that is, displacements of the COP in one particular direction were followed by displacements in the same direction. At longer timescales, negative correlations were found. Overall, it was suggested that these COP characteristics correspond to an open loop control at short timescales and a closed loop control at longer timescales.

A more recent model for the control of posture has been formulated and a new method of decomposing COP trajectories into two components, termed 'rambling' and 'trembling,' has been introduced. The decomposition first identified instant equilibrium points (IEPs). An IEP is the position of the COP at the instance when the horizontal forces are zero. At this moment the projection of the COM onto the base of support coincides with the COP position. The individual IEPs, connected through a spline fitting function, form the rambling trajectory, while the difference between the rambling and COP trajectories is called the trembling trajectory. The authors of this model suggest that the rambling trajectory describes the motion of a moving reference point with respect to which the body's equilibrium is instantly maintained, while the trembling trajectory describes body oscillation around the reference point trajectory.

Preprogrammed Reactions

A considerable body of research in human posture has focused on neural organization or muscular contraction synergy associated with postural control. Theoretical insights have suggested that a pattern of organization is preprogrammed by executive commands according to the particular motor task in order to constrain the large number of functionally related muscle synergy. Following the imposition of brief surface displacement, the automatic postural adjustments are recorded and characterized by relatively fixed temporal and structural patterns of ankle and thigh muscle activity. Preprogrammed reactions consist of a combination of muscle activation patterns specific for a given perturbation and act at a time delay of about 50–100 ms. They are different from simple reflexes in the sense that they depend on the instruction to the subject and that their magnitude can be independent of the length changes in the muscle. A vast literature exists on the regulation of posture under external perturbations and the modulation of preprogrammed reactions.

Anticipatory Posture Adjustments

It should be noted that Hess first pointed out that a proactive (i.e., anticipatory) postural stabilization is required for goal-oriented volitional movement producing an internal disturbance of equilibrium. It was shown that the ensemble of the sequential postural adjustments obeys certain rules (i.e., flexible postural synergy) that are modifiable in order to optimize the balance. The preparatory nature of postural responses is now considered to be centrally programmed and independent of any feedback from the moving limb. These preparatory (i.e., anticipatory) postural adjustments associated with volitional movement were intensively studied in relation to dynamic asymmetry and muscle forces generating movement that can perturb postural equilibrium. The disturbing effects of voluntary movement seem to be anticipated by the central nervous system (CNS). This anticipation is clearly demonstrated in studies revealing muscle activation about 50–150 ms prior to the movement initiation when no reflexes can be triggered (i.e., absence of external stimulus). Anticipatory postural adjustments have been described considering different movements performed by arm, leg, trunk, and head, including those for forearm loading and unloading tasks. It has been suggested that anticipatory posture adjustments (APAs) are generated by the CNS in a feed-forward fashion in an attempt to predict the upcoming postural perturbation and to generate approximate corrections.

Cortical Control of Human Postural Responses

The role of the cerebral cortex, in general, and the contribution of higher cortical functions in human postural control, in particular, have been less studied and are still controversial. Historically, the neuromuscular control of 'automatic' postural responses was thought to arise from the brain stem and spinal circuit with limited consideration for the role of the cerebral cortex. The original proposition that the whole righting apparatus is arranged subcortically in the brain stem, and in this way is made independent of direct voluntary influences, has persisted with time. The idea that postural responses are regulated subcortically was based upon the notion that postural responses are triggered automatically, without any voluntary intent, and therefore are initiated more quickly and with less variability than with cued voluntary movement. However, the onset of postural responses occurs at longer latencies than those of stretch reflexes, indirectly suggesting that postural responses exhibit greater potential for modulations and modifications by neural centers residing hierarchically higher along the neural axis. Moreover, unlike stretch reflexes, postural responses involve synergistic activation of muscle throughout the whole body, and these are also more context specific, flexible, and adaptable than spinal proprioceptive reflexes.

Behavioral Studies

There is considerable behavioral evidence suggesting the contribution of the cerebral cortex and higher cognitive functions in the control of upright posture. Indeed, postural response has been shown to be

modified by various cognitive-motor processes 'represented' in the cerebral cortex, including those involved in anticipatory postural adjustments. Postural responses are modified by (1) changes in cognitive load and attention when performing dual postural tasks, (2) changes in a subject's intentions to respond with a specific strategy, (3) learning and modification of postural responses with prior experience, and (4) changes in initial conditions. Considering that attention, mental calculation, and memory properties represent high-order cognitive functions, controlled by the cerebral cortex, it is reasonable to suggest direct cortical involvement in control of postural equilibrium.

Brain Imaging Studies

There are several lines of research that have directly demonstrated the involvement of the cerebral cortex in human postural control. Variation of slow negative potentials in the primary motor cortex preceding the onset of postural adjustment was observed in previous electroencephalogram (EEG) research. A more recent EEG study has also documented that the initiation of self-paced postural movement is preceded by slow negative direct current (DC) shift, similar to movement-related cortical potentials (MRCPs) accompanying voluntary goal-oriented movement. Also, a brief burst of gamma (40 Hz) EEG activity preceded the initiation of compensatory postural movement when balance was in danger. The spatial distribution of EEG patterns in postural actions approximated that previously observed during the postural perceptual tasks.

Changes in cortical excitability, revealed by slow negative DC potentials just prior to anticipated postural perturbations, have also been reported recently. Similar to DC potentials observed 1–2 s prior to a voluntary self-initiated postural movement, EEG readiness potentials with significant negative variation only in the cue condition were observed. The cue-related differences in the subjects' readiness potentials were highly correlated with the cue-related improved postural stability. Overall, this line of research supports the hypothesis that the cerebral cortex may play a role in optimization of postural responses to external perturbations thorough changes in the anticipatory central set. Therefore, the postural movement once considered to be automatic might be susceptible to voluntary cortical control.

There are several recent EEG studies examining the role of the cerebral cortex in triggered postural responses after a perturbation. These studies have shown that EEG potentials following postural perturbations (known as perturbation-evoke responses, PERs) become altered with changes in the central set, such as with changes in the predictability of a perturbation or with a secondary motor task. The PERs are thought to represent cortical processing of sensory input related to the balance disturbance that arises as an error- or conflict-related signal. Specifically, the first negative peak between 100 and 150 ms (N1) may represent sensory disturbance, and late PERs may be linked to the sensorimotor processing of balance correction, similar to the error-related negativity responses observed for incorrect responses in decision-making paradigms. These studies clearly demonstrate that the postural set influences the characteristics of the cortical contribution to the control of balance after perturbation.

Evidence suggests that the cerebellar–cortical loop is responsible for adapting postural responses based on prior experience and the basal ganglia–cortical loop is responsible for preselecting and optimizing postural responses based on current context. Thus, the cerebral cortex most likely influences longer latency postural responses directly via corticospinal loops and shorter latency postural responses indirectly via communication with the brain stem centers that harbor the synergies for postural responses, thereby providing both speed and flexibility of preselecting and modifying environmentally appropriate responses to a loss of balance.

Finally, the neural substrates for maintaining standing postures in human have been investigated recently using the mobile gantry positron emission tomography (PET) system. Interestingly, compared with the supine posture, standing upright with the feet together activated the cerebellar anterior lobe and the right visual cortex, while standing in tandem was accompanied by activation within the visual association cortex and cerebellar vermis. This finding is consistent with previous research suggesting that the human cerebellar vermis may coordinate the timing in keeping the center of gravity within the stability limits and therefore may provide control of postural scaling and central set in stance.

Concluding Comments

This article has presented a brief review of previous work with special emphasis on current research regarding the role of the cerebral cortex in human postural control. Considerable behavioral evidence clearly suggests the contribution of the cerebral cortex and higher cognitive functions in the control of upright posture. This was documented indirectly via modification of postural responses induced by various high-order cognitive functions and/or learning

that are thought to be represented in the cerebral cortex. There is also a growing body of more recent research that directly demonstrates the involvement of the cerebral cortex in postural movement, similar to many other voluntary movements under study. This was primarily documented via EEG patterns preceding self-initiated postural movement (MRCPs) and following postural perturbation (PERs). It should be noted, however, that this newly evolving understanding of the role of cortical processes in the control of posture in humans is still in its infancy. Future research implementing current advances in cellular recording and brain imaging techniques may be warranted to further explore the differential contribution and functional connectivity of various brain structures in the control of human posture.

Balint Syndrome

N L Denburg and D Tranel, University of Iowa, Iowa City, IA, USA

© 2009 Elsevier Ltd. All rights reserved.

'Balint syndrome' is an acquired disturbance of the ability to perceive the visual field as a whole, and traditionally, is considered to include three components: (1) 'visual disorientation' (also known as 'simultanagnosia'), (2) 'ocular apraxia' (also known as 'psychic gaze paralysis'), and (3) 'optic ataxia.' The key constituent in the syndrome, however, is visual disorientation, and there is considerable variability in the emphasis that is placed on the other components. There is recent evidence to suggest that body schema disturbances may frequently accompany Balint syndrome (i.e, the so-called Gerstmann syndrome involving right–left disorientation, acalculia, and finger agnosia).

Visual disorientation (simultanagnosia) can be conceptualized as an inability to attend to more than a very limited sector of the visual field at any given moment. The phenomenon is subjective. Patients report that they can see clearly in only a small part of the field, the rest being 'out of focus' and in a sort of 'fog.' The sector of clear vision, moreover, is unstable, and may shift without warning in any direction, so that patients experience a literal 'jumping about' of their visual perception. Such patients are incapable of constructing a spatially coherent visual field, and they cannot follow trajectories of stimuli or place stimuli in their proper locations in space. Perception of motion is often impaired, so that patients fail to notice objects that have moved about in their visual field or fail to recognize the meaning of movements they have otherwise perceived correctly. For example, patients may fail to recognize a familiar gait or stride or fail to understand pantomime. Isolated disturbances of motion detection, however, are quite rare (one of the few such cases was described by Zihl and colleagues in 1983). Patients with visual disorientation can perceive color and shape normally, so long as objects are appreciated within a clear sector of the visual field.

An example of simultanagnosia is illustrated with the picture in Figure 1. Here, a patient with Balint syndrome was presented with a simple line drawing of a wreath (item taken from the Boston Naming Test) and asked to respond to the question, "What is this?" The patient responded "bow" rather than "wreath," indicating that her sector of vision at that moment did not include the upper portion of the line drawing. Although simultanagnosia may impair object identification, as mentioned previously, the ability to identify an object is generally superior for animate objects, in which identification is frequently based on overall shape, than for inanimate objects, often identified by distinctive features.

Ocular apraxia (psychic gaze paralysis) is a deficit of visual scanning. It consists of an inability to direct gaze voluntarily toward a stimulus located in peripheral vision, so as to bring it into central vision. Thus, patients fail to direct saccades toward stimuli that have appeared in the panorama of their visual fields, or they produce saccades that are inaccurate and miss the target. Ocular apraxia is not necessary for the development of visual disorientation, although it always occurs together with visual disorientation or optic ataxia. Nyffeler and colleagues studied the natural course of oculomotor recovery in a 53-year-old woman who suffered biparietal lesions from cardiac arrest leading to hypoxia. Thirty-seven weeks after brain damage had occurred, ocular apraxia was markedly improved, as measured by an eye-tracking device, although her ability to read a clock, for example, remained impaired, indicating lasting functional deficits.

Optic ataxia is a disturbance of visually guided reaching behavior. Patients are not able to point accurately at a target, under visual guidance, e.g., they cannot point precisely to the examiner's fingertip or to items such as a cup or coin. Interestingly, pointing to targets on their own body does not pose a problem, as this can be accomplished on the basis of somatosensory information. Also, the patients have no difficulty pointing to sound sources. Optic ataxia can occur in isolation, particularly when lesions are at the border of the occipital and parietal regions or in the parietal region exclusively.

The full Balint syndrome is associated with bilateral occipitoparietal lesions (see Figure 2, a computed tomography (CT) scan of the brain which illustrates bilateral occipital involvement with more severe damage to the left parieto-occipital region), although unilateral lesions can also produce the syndrome, especially when they are on the right. Commonly, the lesions are caused by infarcts in the border zone (watershed) between the anterior and posterior cerebral artery territories. Severe and sudden hypotension is the main cause of this type of stroke, often in elderly patients who are vulnerable to systemic blood pressure drop. The Balint syndrome can also be caused by bilateral metastases in the occipitotemporal region.

Lesions causing the full Balint syndrome typically involve both the superior visual association cortices (dorsal areas 18/19) and a portion of the anteriorly adjacent parietal region (area 7 and sometimes

Figure 1 Stimuli used to demonstrate simultanagnosia.

Figure 2 Illustration of the neuroanatomic findings of a patient with Balint syndrome.

area 39). When lesions are confined to the superior occipital cortices without extension into the partial region, visual disorientation is likely to occur without associated ocular apraxia or optic ataxia. The defects in motion perception that are frequent in Balint patients are probably related to damage in the lower-parietal/lateral-occipital region, in the region formed by area 39. Many patients with Balint syndrome have an impairment of stereopsis, that is, the process of recovery of depth from visual information dependent upon binocular visual interaction, although complete astereopsis is seen only in the setting of bilateral lesions.

Figure 3 Illustration of the lateral view of the brain of a 50-year-old woman with probable VVAD causing Balint syndrome.

More recently, Balint syndrome has been associated with degenerative disease. Components of Balint syndrome, and particularly simultanagnosia, have been identified in patients with degeneration of the posterior cortices of the brain, referred to as visual variant of Alzheimer's disease (VVAD) or progressive visuospatial dysfunction, as well as a recent report of Balint syndrome in a patient with corticobasal ganglionic degeneration. Figure 3 illustrates the focal degeneration of the brain in a 50-year-old woman with probable VVAD.

Barrel Cortex Circuits

From Whisker to Cortex

While examining layer 4 of the rodent primary somatosensory cortex, Thomas Woolsey and Hendrik van der Loos discovered in 1970 that there are obvious cytoarchitectonic 'barrels' arranged identically to the whiskers on the snout (Figure 1(a)). This remarkable mapping has inspired many neuroscientists to turn their attention to the signaling pathway from whisker to cortex. Indeed, the entire sensory pathway is remarkably well delineated through stereotypical anatomical structures. The whiskers on the snout are laid out in a genetically determined pattern and the large posterior mystacial whiskers have been given a nomenclature such that all researchers can easily identify, for example, the C2 whisker (Figure 1(a)). These large posterior whiskers are actively moved at high frequencies during 'whisking' when a rodent is exploring its environment. This active movement of the whiskers is believed to enhance sensitivity and discrimination abilities of this sensory signaling pathway in the same way that humans would move their fingertips across a surface in order to gather textural information.

A whisker contact with an object during whisking or a passive deflection of a whisker evokes activity in trigeminal ganglion neurons. These sensory neurons innervate the whisker follicle and presumably express mechanogated ion channels, which have not yet been identified at a molecular level. Deflection of a whisker will induce mechanogated ionic currents, leading to action potential firing in the sensory trigeminal neurons. The sensory neurons respond to deflection of one and only one whisker, are highly selective to the direction of whisker deflection, and can be classified as rapidly adapting (RA) or slowly adapting (SA). Recently, it was proposed that different trigeminal sensory neurons might encode distinct aspects of tactile sensation, some being activated by object contact and others by whisking in free air. Quantitative analysis shows that the activity in the trigeminal ganglion neurons is extremely precise and highly reproducible, showing little trial-to-trial variability.

These action potentials in the sensory neurons accurately encoding whisker movement propagate to the brain stem, where they synaptically release glutamate onto brain stem neurons. The most important brain stem nucleus for processing of whisker information is the principal trigeminal (PrV) nucleus, which projects strongly to the ventral posterior medial (VPM) thalamus. The spinal trigeminal (SpV) complex of the brain stem also receives whisker inputs and these neurons project to the posterior medial (POM) thalamus, to the ventrolateral aspect of the ventral posterior medial (VPMvl) thalamus, and to the tectum, zona incerta, and other brain regions. Both the PrV nucleus and the SpV nuclei contain clear anatomical patterns termed 'barrelettes,' which are organized somatotopically. Data suggest that the PrV nucleus processes predominantly single whisker information, whereas the SpV nuclei process multi-whisker information.

The thalamic VPM and POM regions both receive input from the brain stem relating to whisker movement. The VPM thalamus, but not the POM thalamus, possesses somatotopically arranged 'barreloids.' Each barreloid processes information primarily related to movement of a single whisker. Within a barreloid there is a map of direction tuning such that more dorsal neurons respond better to forward and upward whisker deflection direction. The neurons in the VPM thalamus generally respond with short latency and high precision to a single whisker, in agreement with a key role of this thalamic nucleus in relaying reliable sensory information to the cortex. Much less is known about the POM thalamus, but under anesthesia it appears to be largely inhibited through inputs from the zona incerta. The physiological role of whisker information flowing through the POM region remains to be discovered.

The barreloid neurons of the VPM thalamus provide the major feed-forward excitation to the primary somatosensory barrel cortex. The principal target of innervation of the axons from a single barreloid is a barrel (Figure 1(b)). The barrels are laid out somatotopically in neocortical layer 4. The VPM neurons also project weakly to upper layer 6 of the primary somatosensory cortex. The POM neurons provide a complementary innervation of the primary somatosensory cortex, with little input to the layer 4 barrels, but with dense innervation of layer 1, layer 5A, and the layer 4 septal regions separating neighboring barrels. In contrast to the reliable encoding of sensory information at the periphery in the pattern of action potential firing of the trigeminal ganglion neurons, responses in the neocortex are highly variable, perhaps resulting from more complex context-dependent integration with spontaneous activity.

Figure 1 Long-range synaptic connections of the barrel cortex. (a) The whiskers (left) on the snout of the rodent are laid out identically to the barrels (right) in layer 4 of the somatosensory neocortex. The more posterior whiskers are longer, as indicated schematically for the C-row of whiskers. The C2 whisker is highlighted with a yellow follicle and a corresponding yellow barrel. (b) The ventral posterior medial (VPM) and the posterior medial (POM) nuclei are the two major thalamic inputs to the somatosensory neocortex. The VPM nucleus projects densely to the layer 4 (L4) barrels, with less prominent input to upper layer 6 (L6). The POM nucleus projects outside of the L4 barrels, innervating layers 1 (L1) and 5A (L5A) most densely. (c) The most prominent long-range corticocortical projections come from the contralateral primary somatosensory cortex (S1), secondary somatosensory cortex (S2), and primary motor cortex (M1).

Projections to the Primary Somatosensory Barrel Cortex

The primary somatosensory barrel cortex therefore receives major feed-forward input to the layer 4 barrels relating primarily to single whisker movement relayed by the VPM thalamic neurons. In addition to the thalamic input, which defines the primary somatosensory cortex, there are many other projections to the barrel cortex, which are likely to facilitate higher order associational and top-down processing (Figure 1(c)). The most obvious corticocortical inputs to the barrel cortex come from the surrounding dysgranular zone of the ispilateral primary somatosensory cortex, the contralateral primary somatosensory cortex (S1), the secondary somatosensory cortex (S2), and the primary motor cortex (M1).

The dysgranular zone surrounds the barrel field and is also involved in processing somatosensory information, but unfortunately little is known about response properties in this region. Anatomically it appears to provide and receive important synaptic input related to the barrel cortex. Inputs from the contralateral primary somatosensory cortex arrive via callosal axons, which target primarily this dysgranular zone and the septal regions between the barrels. Such callosal projections may signal information concerning ipsilateral multiwhisker deflection to layer 5 barrel cortex neurons.

The S2 located posterior and lateral to S1 is also extensively reciprocally synaptically connected to the barrel cortex. S2 has a more diffuse somatotopic arrangement with broader receptive fields. Little is known about the response properties of neurons in S2, how they contribute to perception, or how they interact with neurons in S1.

Input from M1 arrives primarily in layer 1 and layer 5 of barrel cortex. A surprisingly large part of M1 is involved in controlling whisker movement, although brain stem central pattern generators can evoke rhythmic whisking even in decorticate rodents. M1 is therefore more likely to be involved in fine regulation of whisker movements during tactile processing rather than in controlling each whisker cycle during whisking. The input to S1 from M1 might therefore signal fine-scale control of whisker movement, which might be important to relate to the sensory input evoked during object contacts.

In addition to these corticocortical glutamatergic inputs there are also inputs from modulatory neurotransmitter systems containing, for example,

acetylcholine, serotonin, or dopamine. The role of these neuromodulatory systems in somatosensory processing has not been clearly established.

Local Circuits in the Primary Somatosensory Barrel Cortex

A single whisker deflection will signal primarily through activity in the homologous thalamic barreloid projecting largely to a single layer 4 barrel. The layer 4 barrel neurons are therefore the first cortical neurons to become activated, but cortical processing of sensory information is distributed across the intricate synaptically connected cortical neuronal networks (Figure 2). Excitatory neurons in layer 4 can be classified as spiny stellate, star pyramidal, or pyramidal. These layer 4 neurons send their axons primarily to neurons within the same layer 4 barrel and to neurons in layer 2/3 within the same barrel column; recently, a projection to layer 5A was also described. The layer 2/3 neurons lying above a barrel receive their major input from layer 4 barrel neurons, but the layer 2 neurons lying above layer 4 septal regions receive a major input from layer 5A. In addition, all layer 2/3 neurons receive substantial intralaminar synaptic input from within layer 2/3. Since the axons of layer 2/3 pyramidal neurons can span large horizontal distances in layer 2/3, these synaptic connections are not necessarily from within the same barrel column. Layer 2/3 pyramidal neurons synapse onto layer 5 neurons, providing a major route for excitation of the infragranular layers. Excitatory layer 6 neurons are diverse and less well characterized, but projections have been reported to layer 4 and layer 5.

In addition to these excitatory neurons, there are heterogeneous populations of γ-aminobutyric acid (GABA)ergic interneurons, as found in other cortical areas. These GABAergic neurons are likely to provide a predominantly inhibitory role, preventing feed-forward explosive excitation and probably performing more subtle roles in governing excitatory neuron spike output and its precise timing.

Functional Activation of the Barrel Cortex

Whisker deflection evokes sequential action potential firing in trigeminal ganglion neurons, brain stem neurons, thalamic neurons, and cortical neurons. Sensory responses in all barrel cortex neurons consist of early depolarizing synaptic potentials, evoking action

Figure 2 Local synaptic circuits of the barrel cortex. The column on the left denotes with color-coded arrows the principal local inputs to a given cortical layer (L). The column on the right shows the most prominent excitatory synaptic outputs of a given layer.

Figure 3 Functional activation of the barrel cortex. (a) Schematic drawing indicating a likely laminar sequence of excitation of the primary somatosensory barrel cortex following a brief, single whisker deflection. Thalamic input arrives predominantly in a single layer 4 (L4) barrel (cyan outlines indicate barrels). The L4 excitatory spiny stellate and pyramidal neurons depolarize, firing action potentials which propagate through their axons to excite neighboring L4 neurons and layer 2/3 (L2/3) neurons within the same barrel column. The L2/3 neurons signal across barrel columns, allowing strong multiwhisker interactions, and in addition they excite infragranular neurons. (b) Viewed across the somatotopic map of the barrel cortex, excitation evoked by deflection of a single whisker initiates in a single barrel column, and over the next tens of milliseconds the excitation spreads across the entire barrel field. Even a brief deflection of a single whisker can therefore evoke activity in a large cortical area, which may be useful for correlating the sensory information arising from the entire whisker array.

potential activity in only a subset of neurons, followed rapidly or concomitantly with GABAergic inhibition. Cortical excitation evoked by a single whisker deflection begins within the layer 4 barrel corresponding to the stimulated whisker (Figure 3). Depending on the kinetics of the stimulus parameters and perhaps the brain state, the first responses occur with a latency of ~5 ms. It is clear that the sensory pathway for tactile information to reach the neocortex is extremely rapid. In the following milliseconds sensory information reaches layer 2/3 within the same barrel column. This excitation is likely mediated by the prominent axonal projection from layer 4 to layer 2/3 described previously. Within the first ~10 ms following whisker deflection, excitation is largely confined to a single barrel column, in agreement with expectations regarding cortical columnar architecture. However, over the next milliseconds, depolarizing potentials can be recorded across large areas of the barrel cortex. This lateral spread of excitation is likely mediated by the extensive horizontal arborizations of layer 2/3 pyramidal neurons. The lateral spread of excitation is also reflected in large multiwhisker receptive fields. Excitation of infragranular neurons is more complex, since they receive some input directly from thalamocortical synapses, as well as from neurons in layer 4 and layer 2/3. Layer 5 neurons begin to depolarize ~10 ms following whisker deflection, with relatively slow time to peak perhaps reflecting the complex integration of input from multiple layers. All cortical neurons respond to deflection of many individual whiskers, with the sharpest tuning in layer 4. These broad receptive fields indicate that a key element of cortical sensory processing is therefore likely to be the integration of whisker input from across the entire whisker array and probably the integration of information from other sensory modalities and from past experiences. The growing knowledge relating to the synaptic connectivity of neurons in the barrel cortex, together with the increasingly well-defined functional activation of the barrel cortex circuits by simple whisker deflections, should allow computational studies to reconstruct the synaptic basis of simple sensory coding in anesthetized animals.

Physiological Role of the Barrel Cortex

Behavioral analysis of the whisker system has gathered increasing attention, with a focus on determining how the barrel cortex contributes to perception and motor behavior. A major obstacle to these behavioral studies is that the rodent can also obtain somatosensory information using forepaws and nose. The whiskers, however, can reach further forward and further to the side than can the paw or the nose, and current behavioral studies rely on placing the tactile stimulus out of reach to all but the long mystacial whiskers.

The work of Hutson and Masterton in 1986 defined a whisker-dependent task that required intact primary somatosensory barrel cortex and that could be performed by rodents with just a single whisker (all other whiskers being trimmed). Hutson and Masterton's gap-crossing task (Figure 4(a)) begins with the rodent on an elevated platform from which it must reach out with its whiskers to touch another remote target platform. The location of the target platform is determined by whisker touch, because this is the only way for the rodent to touch the platform and vision is typically hindered through performing the task under infrared illumination. After touching the platform with its whisker, usually many times in succession during active whisking, the animal crosses to obtain a reward. Ablation of the barrel cortex prevents the rodent from performing the gap-crossing task. The results therefore suggest

Figure 4 Whisker-dependent behaviors. (a) In the gap-crossing task, a rodent must identify a target platform, which it can palpate with its whiskers across a gap. Upon determining the presence or absence and exact location of the platform, the rodent crosses the gap to receive a reward. (b) The size of an opening is likely to be important for a rodent to determine during natural behavior. The aperture-discrimination task tests the rodent's ability to discriminate between different opening sizes by associating different reward locations with wide or narrow apertures. (c) The rodent whiskers, like human fingertips, can discriminate textures. A rat can discriminate a smooth object from a similar object with finely spaced shallow grooves.

that a single whisker alone can be used to determine object location and that the perception depends upon activity in the primary somatosensory barrel cortex.

Another interesting behavioral paradigm involves the combined processing of somatosensory whisker input from left and right whiskers. In the aperture-discrimination task (Figure 4(b)) the rodent moves its head into an opening with a variable width. The rodent learns that wider openings are associated with rewards given at a different location to rewards associated with narrower apertures. This behavioral task is attractive since it is likely to be closely related to natural behaviors, when a rodent must judge whether it can squeeze through an opening or not. From a sensory processing perspective it is also interesting, since information must be compared between left and right whisker pads, perhaps involving callosal pathways.

Texture discrimination (Figure 4(c)) can also be performed using both the short whiskers surrounding the lips and the large mystacial whiskers. Psychophysical measures of performance indicate that the discrimination abilities of the rat whiskers are similar to those of the human fingertips. Recordings of neural activity during texture discrimination and aperture discrimination are beginning to give information relating sensory processing to perception.

Perspective

The rodent barrel cortex offers the opportunity to investigate the synaptic basis of a relatively well-defined sensory system. Over the next decades we hope that increasingly quantitative data combining results from awake behaving animals, from responses to well-controlled stimuli in anesthetized preparations, and from analyses of the anatomical and functional connectivity of the synaptic circuits will further our understanding of cortical processing.

Introduction

The basal forebrain (BF) refers to an extended continuum of subcortical nuclei with projections to diverse limbic and neocortical areas implicated in various aspects of cognitive function. Damage to the BF can result in cognitive impairments. For instance, aneurysms of the anterior communicating artery leading to neuronal death in the BF result in amnesia and impairments in executive function. Furthermore, cognitive deficits in both normal aging and age-related pathological conditions have been associated with the BF. The severity of cognitive impairment observed in Alzheimer's disease is correlated with the extent of deterioration of cholinergic neurons in the BF, and a similar relationship between cognitive impairment and alterations in BF cholinergic neurons is seen in normal aging.

Given that a large proportion of BF neurons synthesize and use acetylcholine (ACh) as a neurotransmitter, cholinergic neurons have been central to most explanations of the cognitive processes attributed to the BF. Recent work on the neurochemistry of the BF has focused on identifying the specific modulatory influences BF cholinergic neurons contribute to cognition. The use of nonhuman animals has been invaluable to such investigations, and as more selective lesion methods become available for experimental studies of this region, hypotheses regarding the involvement of the BF cholinergic system in global aspects of cognitive function have been gradually revised.

Such research suggests that BF cholinergic neurons do not play a specific role in memory processing *per se*, or a general role in sustaining the function of their cortical targets. For example, performance on many behavioral tasks that are impaired after ablation of cortical neurons remains intact after removal of cholinergic input to the same cortical regions. Instead, damage limited to BF cholinergic neurons produces highly restricted impairments in particular aspects of cognition, including sensory information processing, attention, and some aspects of associative learning and memory. The aim of this article is to provide a brief summary of what is known about the anatomy of the BF, to give a historical overview of experimental studies of BF function, and finally to discuss current work on the cognitive functions of this structure.

Anatomy and Connections of the Basal Forebrain

Cholinergic BF neurons are intermingled with a substantial population of noncholinergic neurons that share similar projection patterns. Estimates of the proportion of cortically projecting BF neurons that are cholinergic vary from study to study, but generally range from 30% to 50%. Many noncholinergic neurons in the BF may be local circuit neurons, receiving cortical input and modulating activity of cortically projecting cholinergic and noncholinergic neurons.

The BF can be divided into four groups of cells: the medial septum (MS), projecting primarily to the hippocampus; the vertical limb of the diagonal band of Broca (VDB), projecting primarily to the hippocampus and cingulate cortex; the horizontal limb of the diagonal band of Broca (HDB), projecting primarily to the olfactory bulb, piriform cortex, and entorhinal cortex; and the nucleus basalis magnocellularis (NBM), or substantia innominata (SI), projecting primarily to the neocortex and amygdala. These cholinergic nuclei have also been designated Ch1–Ch4; this nomenclature approximately corresponds to the anatomical divisions. The organization of the BF is similar in the primate and in the rat, although subdivisions of the nucleus basalis can be identified reliably in the primate but not in the rat. Some areas of the BF are reciprocally connected with their targets; anatomical experiments in rats have shown that the medial septum and diagonal band project to the hippocampus and medial prefrontal cortex and receive projections back from these structures. Similarly, the nucleus basalis is reciprocally connected with the amygdala and cortex. The BF also receives inputs from the hypothalamus, as well as the midbrain and upper pons. Inhibitory projections from the nucleus accumbens to the BF may play a particular role in regulating cortical ACh release.

Both nicotinic and muscarinic ACh receptors are important for cognition. However, the density of muscarinic receptors in the neocortical target sites of the BF is much greater than that of nicotinic receptors. Unlike nicotinic receptors, which are ionotropic in nature and thus fast-acting, muscarinic receptors are metabotropic and are thus slow to respond, but they have long-lasting effects, making them likely candidates for modulating the BF's cognitive processes.

The Basal Forebrain and Memory

A central tenet of the 'cholinergic hypothesis' has been that cholinergic dysfunction specifically is partially or wholly responsible for the memory deficits seen after damage to the BF. Thus, considerable research has been devoted to the magnocellular cholinergic neurons of the BF and their function in memory. Alzheimer's disease involves loss of the magnocellular cholinergic neurons of the BF. Postmortem examinations of the brains from Alzheimer's patients have found a marked cell loss in the BF relative to the brains of healthy controls. Brains of Alzheimer's patients show a loss of the enzymes choline acetyltransferase and acetylcholinesterase in the cortical targets of the BF; choline acetyltransferase synthesizes ACh. Once released from the presynaptic terminal, ACh is degraded by acetylcholinesterase. Cognitive impairment in patients with Alzheimer's disease is correlated with the extent of cholinergic loss. These findings suggest that the loss of cholinergic transmission in the BF contributes to the memory dysfunction observed in Alzheimer's disease.

Additional support for a memory role for the BF comes from patients with amnesia resulting from an anterior communicating artery aneurysm (ACoA). Infarcts associated with an ACoA do not typically damage the traditional cerebral areas implicated in amnesia (i.e., medial temporal and diencephalic structures). ACoA amnesic patients that sustained infarcts resulting in lesions confined to the BF, with no evidence of diencephalic or medial temporal involvement, have relatively intact immediate recall and intact implicit memory, but impaired delayed recall and an increased susceptibility to proactive interference. The increased susceptibility to proactive interference, the phenomenon whereby previous learning disrupts later learning, is hypothesized to be due to deficient attentional inhibitory mechanisms. This presumed decrease in attentional processing ultimately leads to poor integration of old and new learning. Accordingly, these patients have also shown reduced information processing speed and poor divided attention ability. The occurrence of sensory information processing deficits such as these, following BF damage, begins to shed light on a role for the cholinergic BF in more attention and information-processing aspects of cognitive function (to be discussed in the second half of this article).

The Alzheimer's and ACoA data suggest that the BF contributes to memory dysfunction, motivating the development of animal models of BF damage to further test the exact role of the cholinergic BF system in mediating memory dysfunction. In these models, the BF cholinergic system or its cholinergic targets are damaged and behavioral tests are performed to determine the pattern of memory function consequent to BF damage. The validity of these models depends on the similarity of the cognitive processes being tested in animals to those in humans, as well as on the anatomical homology between the BF in animals and the BF in humans.

To confirm the cholinergic hypothesis in an animal model, two challenges must be met: (1) any memory deficits observed must be due to a specific impairment in memory processes, as opposed to disruption of other cognitive or noncognitive processes; and (2) the deficits must not be attributable to destruction of other populations of noncholinergic neurons in the BF. Most initial studies of the cognitive functions of the BF used stereotaxic placement of electrolytic or excitotoxic lesions in different regions of the BF in rats. Interpretation of these studies was made difficult by the fact that electrolytic lesions damage mixed populations of neurons as well as passing fibers, and that excitotoxic lesions (e.g., ibotenic acid, kainic acid, quisqualic acid, and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)) preserve the passing fibers but still damage mixed populations of neurons, such as γ-aminobutyric acid (GABA) neurons. Excitotoxins work by inducing cell death through hyperstimulation of glutamate receptors. The nonspecific nature of excitotoxins makes it difficult to conclude whether any cognitive impairment found is solely due to cholinergic damage or rather to the combined damage of different cell types. Ibotenate and other excitotoxin-induced lesions of the NBM disrupt learning in working memory tasks (such as delayed alternation) and reference memory tasks (measuring spatial or conditional visual discrimination learning).

Although numerous studies involving ibotenic acid lesions of the BF have demonstrated deficits in spatial and conditional learning and memory in rats, lesions of the BF made with more selective excitotoxins (quisqualic acid and AMPA) resulted in greater destruction of cortically projecting cholinergic neurons of the NBM than that seen following ibotenate lesions, but they did not induce the majority of learning and memory deficits observed after ibotenate lesions. Consequently, many of the deficits induced by ibotenate lesions of the BF cannot be attributed to a primary destruction of cholinergic neurons. Histological examinations conducted following ibotenic acid injections into the BF have revealed substantial damage to the dorsal and ventral pallidum of rats, suggesting that basal ganglia damage may have contributed to the memory deficits found.

Because excitotoxic lesion techniques are not selective for cholinergic neurons and therefore the resulting behavioral deficits may be due in part to damage in some neighboring neuronal system, explicit tests of

the cholinergic hypothesis require a neurotoxin specific for BF cholinergic neurons. The immunoglobulin G immunotoxin, 192 IgG-saporin, provides a route for directly targeting the toxin, saporin, to cholinergic neurons *in vivo* in the rat, without damaging noncholinergic neurons at the lesion site. Immunotoxic lesions restricted to specific cholinergic nuclei of the BF have generally failed to produce memory deficits, suggesting that damage to noncholinergic neurons in the BF and surrounding regions of the basal ganglia may have been responsible for the excitotoxic-induced memory impairments previously found. Rats with saporin lesions of individual BF nuclei or even those with extensive lesions of the entire BF (MS/VDB, HDB, and NBM/SI) show little or no deficits in memory. For example, spatial learning in the water maze, working memory in the radial arm maze, and contextual fear conditioning, all tasks dependent on the integrity of the hippocampus, have been reported to be normal following extensive lesions of BF cholinergic neurons. It is noteworthy that the more specific the cholinergic lesion, the less dramatic the effects on learning and memory. The studies with less specific excitotoxic lesions underscore the importance of careful validation that BF lesions intended to be specific to cholinergic neurons actually spare noncholinergic neurons at the lesion site. Importantly, many experiments have used intracerebroventricular infusions of 192 IgG-saporin, which damage cerebellar Purkinje cells in rats in addition to cholinergic BF neurons. These experiments have revealed severe impairments in many spatial learning and memory tasks, although the extent to which this represents a more complete cholinergic lesion than can be achieved by site-specific injections, a primary effect of cerebellar damage, or some interaction of the two factors remains somewhat controversial. What is clear is that extensive loss of BF cholinergic neurons – as severe or more severe than that seen in late stages of Alzheimer's disease – does not result in a profile of memory impairment in rats that resembles dementia, or even the profile of cognitive impairment seen in normal aging in rats.

The foregoing experiments in rats that suggest a role for the BF in memory function, but not a specific role for cholinergic BF neurons in memory, are supported by experiments in nonhuman primates. Like humans, nonhuman primates have a more spatially distinct NBM, making generalizations between the cognitive deficits seen in monkeys and those seen in humans more convincing than generalizations between rats and humans. Investigations have been made into the effect of ibotenic acid lesions placed stereotaxically into the BF cholinergic nuclei of Old World (macaque) monkeys. A battery of tests (delayed nonmatch-to-sample, delayed response, concurrent visual discrimination, and a visuospatial attention task) revealed no memory deficits despite the presence of an impairment in visuospatial attention. Other experiments with ibotenic acid lesions of BF nuclei in macaque monkeys report an impairment in recognition memory assessed using delayed nonmatching-to-sample, but this impairment was not delay dependent, casting doubt on whether it represented an impairment of memory or some failure of attention or encoding on the sample trial. There is some contradiction between the findings of ibotenic lesions of the BF nuclei in Old and New World monkeys. Ibotenate lesions to the NBM led to impairments in retention of preoperatively learned visual discriminations and reversal learning of visual discriminations postoperatively in New World monkeys (marmosets). This was accounted for by possible nonspecific damage caused by the lesions made in New World monkeys. Administration of the putative cholinergic toxin ME20.4 IgG-saporin to the BF nuclei of marmosets led to perceptual impairments on retention and acquisition of visual discriminations, although sparing of noncholinergic neurons at the lesion site in these monkeys was not verified. Similar experiments on damage to the VDB in marmosets revealed impairments in retention and new learning of visuospatial conditional discriminations, similar to those resulting from damage to the hippocampus. Related experiments in rats have discovered similar effects in the absence of general impairments in hippocampal-dependent learning, suggesting that this may represent a specific contribution of ACh to resolving interference in memory rather than a general role for cholinergic input in enabling hippocampal function.

Aims to increase ACh levels in the clefts of the cholinergic synapse with acetylcholinesterase inhibitors, or to directly replace ACh with cholinomimetic drugs, have largely been unsuccessful in reversing cognitive deficits in Alzheimer's patients. This may be because direct enhancement of ACh levels may disrupt any remaining intact cholinergic transmission. Another complementary, pharmacological strategy to treat the cognitive deficits consequent to cholinergic loss has been to modulate the cholinergic system by transsynaptic mechanisms – for example, by affecting cholinergic transmission with GABA. Ultimately, this approach may be more effective in alleviating the associated cognitive deficits, since this acts to amplify the endogenous physiological cholinergic signal. However, given that loss of cholinergic neurons does not seem to be a primary cause of memory impairment in these conditions, even pharmacological treatments aimed at enhancing function of remaining cholinergic neurons by transsynaptic modulation might be expected to have little beneficial effect on memory.

In summary, many aspects of learning and memory proceed normally in the absence of cholinergic input from the BF. In contrast, BF cholinergic neurons do appear to play an essential role in regulating attentional processing capacity. We turn to specific evidence for the involvement of the BF in attentional processing in the following section.

The Basal Forebrain and Attention

Mechanisms of attention are thought to enable the efficient allocation of processing resources in order to respond to important events in the environment. There are different types of attentional processes: selective attention targets attentional resources on a restricted number of sensory stimuli and excludes other sensory stimuli; sustained attention reflects a state of readiness to detect and respond to unpredictable or rare events; and divided attention refers to simultaneous monitoring of several different channels of sensory information. Attention filters what sensory information is introduced into memory. The BF appears to regulate many of these attentional functions; recent studies of lesions of the cholinergic forebrain in rats and monkeys have suggested deficits the forms of attention. For example, the five-choice serial reaction time task, based on a human test of continuous performance, measures sustained spatial attention in rats. In this task, rats are required to monitor the occurrence of a light stimulus in one of five locations. With this paradigm, both excitotoxic (e.g., ibotenate acid, quisqualic acid, and AMPA) and saporin lesions of the NBM produce impairments in performance, which are ameliorated by increasing the duration or intensity of the stimuli. In support of the involvement of the cholinergic BF, this deficit is alleviated by an acetylcholinesterase inhibitor, physostigmine, an enzyme that boosts the availability of ACh.

A role for the NBM in attention has also been demonstrated in a temporal divided attention task, where at times rats are required to divide their attention between two simultaneous stimuli: rats with excitotoxic lesions of the NBM are specifically impaired in their ability to time two stimuli simultaneously. In a cross-modal divided-attention task, infusion of 192 IgG-saporin into the BF selectively increases the response latencies in a bimodal condition, without affecting the accuracy or the retrieval and execution of the stimulus–response action in either the visual or auditory modality.

BF neurons, including the cholinergic neurons, receive direct contacts from GABAergic afferents and are inhibited by GABA. Similar to the effects of cholinergic lesions, infusions of a benzodiazepine receptor agonist into the BF impair the performance of rats tested in a sustained-attention task without altering the efficacy of perceptual processes. Infusion of the $GABA_A$ receptor agonist, muscimol, directly into the BF both decreases the activity of the cortically projecting NBM neurons and impairs accuracy on the five-choice task. Two-lever vigilance tasks present the rat with successive trials of changes in the intensity of continuously delivered auditory (e.g., white noise) or visual (e.g., illumination) stimuli. One lever measures the 'hits' and the other lever measures the 'correct rejections.' In two-lever vigilance tasks for rats, 192 IgG-saporin lesions of the NBM and intra-NBM administration of $GABA_A$ benzodiazepine receptor agonists have impaired vigilance performance.

In a visuospatial attention task, Old World monkeys with BF lesions show impairments in shifting attention. A brief cue indicates the expected location of a target stimulus. The difference in response time to a target that appears at expected and unexpected locations is used as the measure of shifting of attention. A slower response time on invalid trials, in which the target appears at an unexpected location, compared to valid trials, in which the target appears at the expected location, indicates that a respondent has paid attention to the cue that is signaling the likely location of a target. Monkeys with BF lesions showed disproportionately longer response times on invalid trials, suggestive of an impairment in disengaging attention from the invalidly cued location. This was not due to a general impairment in motor skills, since the response to the target following the initiation of a response was comparable in both control and BF lesioned monkeys. A quite similar result has also been described in rats with selective lesions of cholinergic neurons in the NBM. It is important to note that this attentional impairment was quite selective; the monkeys with BF lesions were not impaired on tests of visual learning and memory, and rats with selective cholinergic lesions of the NBM were not impaired on a variety of cognitive tasks, including tests of spatial learning and memory.

In vivo microdialysis studies provide further support for an important role for the cholinergic BF in attention, showing that tasks placing both low and high demands on sustained attention result in significant increases in ACh efflux in the frontoparietal cortex of rats, one of the cortical targets of the NBM. However, bilateral saporin lesions of the NBM only impaired performance on high attentional-demand tasks, suggesting that cortical cholinergic neurotransmission is especially needed for tasks requiring high levels of attentional processing.

Experiments that examine the regulation of attentional processing in associative learning paradigms have identified dissociable roles for rostral (septal) and caudal (NBM) regions of BF cholinergic neurons.

Increases in conditioned stimulus processing, brought about by violations of learned contingencies, require the integrity of cholinergic neurons in the NBM, but not cholinergic neurons in the MS/VDB. Decreases in conditioned stimulus processing, which occur when conditioned stimuli are preexposed in the absence of reinforcement, or are consistent predictors of another event, require the integrity of cholinergic neurons in the MS/VDB, but not the NBM. The BF has reciprocal connections with the central nucleus of the amygdala, which has potential for widespread influences on cortical processing through direct projections to lower- and higher-order sensory areas and indirectly through projections to cholinergic neurons in the BF. Stimulation of the amygdala central nucleus has been found to influence BF electroencephalogram (EEG) patterns consistent with ACh release in rats and humans. Cortical ACh release stimulated by the amygdala is thought to induce a state of cortical readiness for processing sensory information. This suggests that the BF cholinergic system may provide an output pathway for the regulation of attention and cortical information processing by the amygdala. Indeed, evidence from crossed-lesion studies suggests that projections from the central nucleus to the NBM are critical for producing increases in conditioned stimulus processing: disconnection of the NBM from the central nucleus of the amygdala by crossed unilateral lesions also disrupts the ability to increase attentional processing in response to a violation of expectancy. Similarly, such lesions impair sustained visual attention in the five-choice paradigm.

As the cholinergic hypothesis shifts gears from a purely memory focus to one that encompasses attentional processes, the question of how the BF modulates attention has come to the forefront. ACh enhances the processing of incoming sensory information from a variety of modalities. For example, following training on a vigilance task in which rats were required to press a response lever located on the right when a visual signal was presented, and to press a response lever located on the left when no signal was presented, bilateral saporin lesions of the NBM significantly impaired the ability of rats to detect signals, but not their ability to correctly reject nonsignals. It has thus been proposed that ACh modulates attention by regulating the signal-to-noise ratio (SNR) of incoming sensory information. By minimizing the processing of irrelevant sensory signals as well as previously learned information, the encoding of important incoming sensory information can occur much more efficiently. Consistent with such a proposal, both pharmacological data and lesion-based research have implicated the BF cholinergic system in the encoding of new information, but not its subsequent retrieval. Consistent with such a model, Alzheimer's patients show normal rates of forgetting, but are impaired at the initial acquisition of information, suggesting an important role for the cholinergic BF in the encoding of sensory information.

A model has been proposed of how an active BF cholinergic system is conducive to the encoding of new information, while a hypoactive BF cholinergic system is conducive to the consolidation and retrieval of previously learned information. When there are high levels of cholinergic activity in the cortex, afferent input from external sensory stimuli is enhanced, while intrinsic processing within cortices is reduced. Intrinsic processing is associated with the reactivation of neural connections representing previously learned information, and a reduction in such processing would prevent the recall of previously learned information from interfering with the encoding of new information, thereby enhancing the SNR. This has been demonstrated by studies showing that systemic muscarinic cholinergic blockade with the muscarinic receptor antagonist, scopolamine, increased proactive interference from previously learned odor- and word-pair associations during the encoding of novel associations in nonhuman and human animals, respectively. A follow-up study has revealed BF contributions, as administration of a low dose of scopolamine resulted in increased proactive interference only in rats with bilateral saporin lesions of the NBM, not in sham-lesioned controls. Although not a direct measure of cholinergic activity, functional magnetic resonance imaging (fMRI) permitted investigation of underlying cholinergic brain systems involved in proactive interference resolution *in vivo* and confirmed that this BF contribution is conserved in humans.

This role of the BF cholinergic system in reducing SNR and minimizing interference from irrelevant sensory signals and previously learned information may account for the effect of BF cholinergic lesions in memory tasks, when they appear. The involvement of these neurons in reducing proactive interference has already been noted in discrimination learning paradigms in which interference is explicitly produced. This was also suggested to account for the effect of loss of MS/VDB cholinergic neurons on visuospatial conditional learning in rats; these lesions impair an environment–spatial conditional task in which local environmental cues signal the location of a reward when the two components of the conditional problem are learned simultaneously, but not sequentially. Neurophysiological experiments have shown that place fields of hippocampal neurons are resistant to remapping when local environmental cues are changed, providing a physiological mechanism for increased susceptibility to proactive interference.

Thus far, selective cholinergic lesions in the BF system appear to have limited effect on measures of learning and memory, but rather impair attentional processing and information processing. It is assumed that attentional processes are involved in the primary stages in information processing, so it is remarkable that no dramatic effects in various learning and memory tasks have been observed following damage to BF cholinergic neurons. If attentional processes are impaired, then a performance deficit would be expected in most learning and memory tasks, but it appears that this is not the case after selective cholinergic lesions. However, the statement that "BF damage impairs attention" is an oversimplification. Instead, the effects of these lesions might be better characterized as producing an impairment in the ability to regulate attentional processing appropriately, thereby reducing the efficiency of sensory information encoding. Indeed, the impairments observed in attentional tasks following damage to the BF cholinergic system may represent one instance of a general physiological involvement of ACh in reducing cortical SNR.

Conclusions

The BF is anatomically situated to regulate information processing in cortical and limbic structures involved in a wide array of cognitive functions. Indeed, extensive damage to the BF (to both cholinergic and noncholinergic components) results in a broad array of cognitive impairments. In contrast, damage limited to BF cholinergic neurons produces more restricted impairments in the regulation of attentional processing. Hence, BF cholinergic neurons appear to play a selective role in regulating cortical information processing, rather than a generalized function in supporting the functions of their target areas. This apparently restricted function of BF cholinergic neurons suggests that a loss of these cells is probably not the only factor in producing cognitive deficits in conditions like Alzheimer's disease, or in the amnesia consequent to aneurysms in the BF.

The characterization of BF cholinergic function as purely 'attentional' may fail to capture the array of cognitive contributions from these neurons. These neurons are likely involved in other aspects of sensory processing and representational plasticity in cortical areas. A general operating principle for the role of BF cholinergic neurons in cognition remains elusive, as does a role for the BF generally in cognitive function. The BF, particularly the cholinergic component, may be more broadly involved in the encoding and processing of sensory information, as well as regulating aspects of conscious experience; hence abnormalities in BF function could contribute to a wide variety of cognitive impairments in both neurodegenerative disease and in psychopathology. These recent hypotheses represent a useful guiding principle for future studies of BF function, both in animal models and in human clinical populations.

Basal Ganglia and Oculomotor Control

O Hikosaka, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Oculomotor Control by the Basal Ganglia

The basal ganglia control eye movements. This is illustrated by a variety of movement disorders caused by dysfunction of the basal ganglia, such as Parkinson's disease and Huntington's disease. A fixed, vacant facial expression of patients with Parkinson's disease, which is often called the Parkinson's mask, is due to the paucity of movements in the face, including the paucity of eye movements. Similar symptoms were observed in MPTP-induced dopamine deficient monkeys (Figure 1(a)). Most affected among various kinds of eye movements are smooth pursuit and saccades, which require voluntary control. Parkinsonian patients are often impaired in smoothly pursuing a moving object (deficit in smooth pursuit). They are also often impaired in shifting their gaze from one position in space to another (deficit in saccade). While their relation to smooth pursuit is still unclear, the basal ganglia are shown to play a critical role in the control of voluntary saccadic eye movement.

The impairment in saccadic eye movement in patients with basal ganglia disorders has been repeatedly demonstrated using more rigorous tests with accurate measurement of eye position. Typically, the subjects are required to fixate their gaze on a spot of light (target) on the screen and, if the target steps, follow it by quickly shifting their gaze. This is called a visually guided saccade task. Compared with age-matched control subjects, saccades of parkinsonian patients tend to be small in amplitude (i.e., hypometric), slow, and delayed (i.e., long latency). Curiously, the deficit in saccades is often more severe if there is no visible object and the saccades must rely on memory. In a memory-guided saccade task, a target appears briefly while the subject is fixating at the central spot and the subject has to make a saccade after a delay to the position where the target was presented. Parkinsonian patients are more impaired or selectively impaired in memory-guided saccades than in visually guided saccades. This phenomenon may illustrate the context-dependent movement deficits in Parkinson's disease, which are widely recognized among neurologists. Selective deficits in memory-guided saccades are observed in other basal ganglia disorders, including Huntington's disease. The similarity between Parkinson's and Huntington's diseases is noteworthy because they are caused by different mechanisms, the former by a loss of neurons in the substantia nigra (SN) and the latter by a loss of neurons in the caudate nucleus (CD). This suggests that the SN and the CD work together for the control of saccadic eye movements.

Neural Circuits in the Basal Ganglia for Oculomotor Control

How the basal ganglia might control eye movements has been studied by single unit studies using animals trained on the visually guided and memory-guided saccade tasks. Electrical activity of single neurons was recorded with microelectrodes and was correlated with saccadic eye movements. Saccade-related activity has been found in various nuclei in the basal ganglia, including the SN, CD, subthalamic nucleus (STN), and globus pallidus (GP). Such saccade-related neurons are clustered in a subregion of each nucleus: dorsolateral part of the pars reticulata of the SN (SNr), central-ventral part of the CD, ventral part of the STN, and dorsal part of the external segment of the globus pallidus (GPe). Anatomical studies have shown that these saccade-related parts are connected within the basal ganglia and with saccade-related regions outside the basal ganglia (Figure 1(b)). For example, the saccade-related part of the CD receives inputs from the frontal eye field and the supplementary eye field in the frontal cerebral cortex, whereas the saccade-related part of the SNr projects their axons to the superior colliculus (SC). Note that neurons related to skeletal movements are found in different subregions in the basal ganglia, such as the putamen (equivalent to the CD) and the internal segment of the globus pallidus (GPi) (equivalent to the SNr). These facts are consistent with the idea that there are functional subdivisions within the basal ganglia as well as in larger networks including the cerebral cortex and the cerebellum, each of which may form a closed-loop functional unit. Recent studies, however, indicate that such functional segregation is not perfect.

An important feature of the basal ganglia circuits is that they use inhibitory connections as a primary means to convey signals (Figure 1(b)). Each area contains projection neurons and interneurons. While cortical inputs to the CD are excitatory and use glutamate as a transmitter, projection neurons in all areas in the basal ganglia, except the STN, are thought to be GABAergic and inhibitory. This means that the polarity of a signal is reversed each time it passes

Figure 1 Abnormal eye movements in monkeys induced by basal ganglia dysfunctions. (a) Eye movements of a monkey while he was looking in a mirror before (top) and 31 days after (bottom) dopaminergic denervation of the left caudate nucleus by MPTP. Shown are the trajectories of eye movements superimposed on the view seen in the mirror by the monkey. (b) Basal ganglia neural network involved in the control of saccadic eye movement. CD, caudate nucleus; SNr, substantia nigra pars reticulata; SC, superior colliculus; SNc, substantia nigra pars compacta; GPe, globus pallidus external segment; STN, subthalamic nucleus; FEF, frontal eye field; SEF, supplementary eye field; DLPF, dorsolateral prefrontal cortex; LIP, area LIP in parietal cortex. Excitatory and inhibitory neurons and synapses are indicated by open and filled symbols, respectively. Gray symbol indicates dopaminergic neuron which exerts modulatory effects on CD neurons. The thickness of the line (axon) roughly indicates the level of spontaneous activity. The direct excitation of SC neurons by inputs from the cerebral cortex is gated by the inhibitory input from the SNr. (a) From Miyashita N, Hikosaka O, and Kato M (1995) Visual hemineglect induced by unilateral striatal dopamine deficiency in monkeys. *Neuroreport* 6: 1257–1260.

through projection neurons in one area. There are at least three parallel pathways in which saccade-related signals can be processed in the basal ganglia (Figure 1(b)): (1) direct pathway from the CD to the SNr; (2) indirect pathway from the CD to the SNr through the GPe and/or the STN; and (3) hyperdirect pathway from the STN to the SNr. Since the direct pathway consists of a series of two inhibitory connections (CD and SNr), the net effect is facilitatory. Since the indirect and the hyperdirect pathways consist of three and one inhibitory connection, respectively, the net effect is inhibitory. The basal ganglia thus could facilitate or inhibit motor processes by selectively using these pathways. The target area for saccadic eye movement is the SC.

With respect to saccadic motor control in general, the basal ganglia system is situated as a side path which has been added to the direct effect of the cerebral cortex on the SC (Figure 1(b)). Probably, the most important question is: how unique is the function of the basal ganglia, compared with the direct cortico-SC effect? The answers to this question should be found in the content of information carried by neurons in the CD and SNr.

Caudate Nucleus

The CD is a large structure in the basal ganglia and, together with the putamen, is called the striatum or the dorsal striatum. A majority of inputs to the basal ganglia is destined for the striatum which thus acts as the input station of the basal ganglia. The neural circuit in the basal ganglia related to eye movements originates in the CD and converges on the SNr which then projects to the SC (Figure 1(b)). In addition to the cortical inputs, the entire CD (together with the putamen and the ventral striatum) receives diffuse inputs from dopaminergic neurons in the SN pars compacta (SNc) and its surrounding regions. It is likely that particular combinations of these inputs create signals unique to CD neurons.

A majority of neurons comprising the CD are called medium-spiny neurons: neurons with medium-sized cell bodies and many dendrites thickly covered with spines. They are the projection neurons, neurons that project axons to the outside of the CD. They are GABAergic and inhibitory. The projection neurons are highly hyperpolarized in the resting state and emit action potentials only occasionally. A minority of neurons (less than 5%) in the CD consist of several types of interneurons. One conspicuous type is the cholinergic interneuron, which is characterized anatomically as large-aspiny neuron. They fire tonically and irregularly and are often called tonically active neurons (TANs).

Single unit studies using monkeys trained on saccade tasks have revealed that many CD projection neurons are clearly related to saccadic eye movements (Figures 2(a) and 2(b), top). Some of them respond to visual stimuli that potentially induce saccades to them. Other neurons become active before saccades. These visual-saccadic neurons have response fields which are usually centered in the contralateral field (Figure 2(c)). The responses are often highly dependent on the context. Visual responses may be enhanced if the animal attends to or memorizes the stimulus. Saccadic activity may be present only when the saccade is guided by memory or only when it is guided by visual stimuli. The neurons usually do not fire in relation to spontaneous saccades. Intermingled with such visual-saccadic neurons are found more complex neurons, such as those related to expectation of task-specific events or reward. Such complex nature of CD projection neurons appears to reflect the convergent inputs from the cortical eye fields (frontal eye field (FEF) and supplementary eye field (SEF)) and from the dorsolateral prefrontal cortex.

Figure 2 Oculomotor signal may be transmitted from caudate (Cd) to substantia nigra pars reticulata (SNr). Spike activities of a Cd neuron (top) and an SNr neuron were compared in two different modes of saccade: visually guided saccade (SAC/VIS) (a) and memory-guided saccade (SAC/MEM) (b). The spike activity, shown by spike rasters and histograms, were aligned on the onsets of the saccades, as indicated by the task schemes above: F, central fixation point; T, target point located with the movement fields of the neurons; E, schemetic eye position. (a) The target came on while the fixation point was still present, and the monkey was allowed to make a saccade after the fixation point went off. (b) The position of the target was indicated 2–3 s before the fixation point went off (not shown), and the monkey made a saccade to the remembered location of the cue stimulus. Short vertical bars in the spike rasters indicate the disappearence of the fixation point. (c) Movement fields of the Cd and SNr neurons. (d) Inhibition of the SNr neuron by stimulation (100 μA, single pulse) applied at the point close to the Cd neuron. Calibrations on the left of the histogram indicate 50 and 100 spikes s^{-1}. Reproduced from Experimental Brain Research, Vol. 95, 1993, pp. 457–472, Effects of Candate nucleus stimulation on subtantia nigra cell activity in monkey, figure 10, copyright Springer. Substantia Nigra Pars Reticulata

The SN is composed of two parts: pars reticulata (SNr), which contains GABAergic neurons, and pars compacta (SNc), which contains dopaminergic neurons. Saccade-related neurons are found in the SNr. The relation of the SNr to eye movements was first suggested by anatomical studies showing that the SNr project to the intermediate layer of the SC. The SC in mammals is known to be crucial for orienting of the eyes and head toward an object of interest. An equivalent structure, which is called the optic tectum, is universally present in other vertebrates and is under the control of the homolog of the basal ganglia. Thus, the role of the SNr (or the basal ganglia) in eye movements should be considered in a larger framework of animal behavior in which orienting is crucial for survival.

Neurons in the SNr are characterized by their rapid and tonic firing (Figure 3(a)). Their firing frequency is usually between 40 and 100 spikes s^{-1} in monkeys. Neurons in the GPi, many of which are related to skeletal movements, also fire rapidly and tonically. Thus, the high background activity is common to virtually all output neurons of the basal ganglia. Furthermore, virtually all of them are GABAergic. These facts indicate that neurons that receive outputs of the basal ganglia should be kept inhibited by them. The functional importance of the basal ganglia-induced inhibition can be demonstrated experimentally. The inhibition can be reduced or eliminated by injecting a small amount of a γ-aminobutyric acid (GABA) agonist (muscimol) into the SNr because SNr neurons have a high density of GABA receptors and therefore muscimol would inhibit their firing. After muscimol injection in the SNr, animals can no longer maintain stable eye position and make saccades continually and probably involuntarily (Figure 3(c)). This happens to all animals tested: monkeys, cats, and rats. Rats, compared with monkeys, exhibit a wider range of involuntary movements in addition to eye movements. A similar phenomenon occurs for skeletal movements when muscimol is injected in the globus pallidus internal segment. These findings may be relevant to the fact that patients with basal ganglia dysfunction usually exhibit some type of involuntary movements, such as tremor, dyskinesia, dystonia, ballism, and chorea. These involuntary movements may be caused by a reduction of the basal ganglia-induced inhibition. The reduction of inhibition could be sustained or phasic (possibly with rhythms).

However, the sustained inhibition alone can hardly be a motor control mechanism. Neurons in the SNr change (usually decrease) their firing rates in preparation for saccadic eye movement (Figures 2(a) and 2(b), bottom). Many SNr neurons stop firing in response to a visual stimulus if the animal is ready to make a saccade to it. Other neurons do so just

Figure 3 Basal ganglia mechanism for control of saccadic eye movement. (a) A cardinal saccade mechanism in the basal ganglia. The SC is normally inhibited by rapid firing of GABAergic neurons in the SNr. The tonic inhibition can be interrupted by GABAergic inputs from the caudate nucleus. This disinhibition, together with excitatory cortical inputs, allows SC neurons to fire in burst, which leads to a saccade to a contralateral location. (b) Simplified neural circuits in the basal ganglia for control of saccadic eye movement in a parasagittal view of the macaque brain. Red, blue, and green lines indicate excitatory, inhibitory, and modulatory connections. (c) Involuntary eye movement of a monkey after muscimol injection into right SNr, shown as trajectories of saccades during 2 s fixation periods. The monkey was unable to keep fixating at the central spot of light. From Hikosaka O and Wurtz RH (1985) Modification of saccadic eye movements by GABA-related substances. II. Effects muscimol in monkey substantia nigra pars reticulata. *Journal of Neurophysiology* 53: 292–308.

before the saccade. The inhibition of SNr neurons is caused, at least partly, by the GABAergic input from the CD. Electrical stimulation in the CD saccade-related region may elicit saccadic movements of the eye and the head to contralateral directions. If the electrical stimulation is short and weak, saccades are not evoked, but SNr neurons are inhibited and are occasionally facilitated (Figure 2(d)). The former is likely to be mediated by the direct CD–SNr inhibitory connection, while the latter is likely to be mediated by the indirect pathway through the GP (Figure 1(b)). Probably reflecting the powerful CD–SNr connection, many SNr neurons exhibit visual, saccadic, and memory-related activities with response fields centered in the contralateral field (Figure 2(c)). A group of SNr neurons are more strongly inhibited before memory-guided saccades than visually guided saccades (Figures 2(a) and 2(b), bottom).

Many of these SNr neurons project to the intermediate layer of the SC and have inhibitory synaptic contacts with saccadic burst neurons. This means that the SNr-induced tonic inhibition on SC neurons is removed or reduced before saccades (Figure 3(a)). Note that saccadic neurons in the SC receive excitatory inputs from many brain areas, especially saccade-related cortical areas: the FEF, SEF, and lateral intraparietal area (LIP). These excitatory cortical inputs, together with the SNr-induced disinhibition, would make SC neurons fire in a burst and the signal is sent to the brain stem saccade generators. Note, however, that SNr neurons may increase their activity before saccade. In such a case, the SC would be less likely to generate a signal to induce saccades.

To summarize, the SNr-induced inhibition on SC neurons acts as a gate for saccade generation (Figure 3(a)). SC neurons are constantly bombarded by excitatory inputs from many brain areas because there are so many objects that can attract our attention and gaze. However, these inputs are often incapable of inducing a burst of spikes in SC neurons due to the SNr-induced tonic inhibition. Only when the SNr-induced inhibition is reduced would SC neurons exhibit a burst of spikes reliably. This is probably a very efficient mechanism to select an appropriate action in a particular context.

Role of the Basal Ganglia in Reward-Oriented Eye Movement

Recent studies have revealed another striking feature of basal ganglia neurons: the relation to reward-oriented behavior. This feature has been investigated extensively in relation to saccadic eye movement. Typically, the amount of reward is biased depending on the direction of saccade: for example, rightward saccades are followed by a big reward and leftward saccades are followed by a small reward. This task has a strong behavioral impact: the saccade to the position associated with big reward is faster and earlier than that associated with small reward. The visual response of CD projection neurons is greatly enhanced and diminished if the saccade to the visual stimulus is expected to be followed by a bigger and smaller reward, respectively (Figure 4(a)). A minority of neurons exhibit the opposite reward modulation. The modulation is very common among visually responsive CD neurons (about 80%) and is often very strong such that the original directional tuning can be completed reversed. Similar reward-dependent modulation occurs for saccadic activity.

The relation of the CD to reward-oriented behavior is highlighted by a conspicuous group of CD projection neurons which cannot be classified as simply related to visual-saccadic processes. They exhibit growing activity while the animal is waiting for the go-signal for a saccade (Figure 5(a)). It appears to be related to saccade preparation. However, the activity occurs before the instruction is given to which position the saccade should be made. The activity is nonetheless spatially selective in that it is present only when saccades to a contralateral, rather than ipsilateral, position are followed by a big reward. If there is no positional bias in reward, the anticipatory activity is much weaker.

Further studies suggest that the reward-position-sensitive anticipatory activity is transmitted to the SC through the SNr (Figure 6). Suppose a bigger reward is associated with saccades to a right target than a left target, CD neurons on the left side would exhibit stronger anticipatory activity than those on the right side (according to the finding described above). Since a major effect of CD neurons on SNr neurons is inhibitory, SNr neurons on the left side would exhibit a stronger decrease in firing rates than those on the right side. This is actually observed experimentally. Since SNr neurons in turn inhibit SC neurons, the excitability of SC neurons on the left side would be elevated compared with those on the right side. This also has been confirmed experimentally. There is now a clear imbalance in excitability between the two sides of the SC: neurons on the left SC is more excitable than neurons on the right SC. This occurs before any instruction is given and far before a saccade is executed. This is an internal process based on the knowledge of the positional difference in reward amount. Under such a biased condition, a target that appears on the right side (i.e., associated with a big reward), which activates neurons on the left SC, would trigger a saccade more easily and more quickly than a target on the left side.

Figure 4 Responses of a right caudate neuron (a) and a left dopamine neuron (b) to visual cue in the memory-1DR and memory-ADR tasks. In one block of the memory-1DR task, only one particular direction was associated with reward. Since four target directions were used, the experiment was done in four blocks, which are shown in four left columns with different reward directions (indicated by R, U, L, D). In one block of memory-ADR task (indicated by ALL), all directions were associated with reward. Neurons were recorded from the right caudate and the left substantia nigra pars compacta (SNc). In the histogram/raster display (bin width: 20 ms), the neuronal discharge aligned on cue onset is shown separately for different cue directions; the cue directions were pseudorandomized. The reward direction is indicated by a dotted circle. The caudate neuron responded to the left (L) cue most strongly in ADR (ALL), but the response was greatly enhanced and depressed in 1DR when the cue indicated reward and no reward, respectively. The dopamine neuron showed no response to any cue in ADR. In 1DR, it responded to the cue with an excitation if it indicated an upcoming reward and with an inhibition if it indicated no reward. (a) From Kawagoe R, Takikawa Y, and Hikosaka O (1998) Expectation of reward modulates cognitive signals in the basal ganglia. *Nature Neuroscience* 1: 411–416.

In other words, the animal would make saccades more quickly to a more highly rewarded position (Figure 5(b)). Such a behavioral bias is consistently observed experimentally. These results suggest that the CD is a critical brain area for reward-oriented motivational behavior.

Dopaminergic Modulation of Information Processing in the Caudate Nucleus

Recent studies suggest that such strong reward-dependent modulation of CD neurons may be caused by dopaminergic inputs (Figure 1(b)). As mentioned above, CD projection neurons have dendrites with many spines on which both axons from cortical neurons and axons from midbrain dopaminergic neurons make synapses. A majority of cortical axons originate from the cortical eye fields and therefore are likely to carry spatial signals. In contrast, midbrain dopaminergic neurons are known to carry reward-related signals, but not spatial signals. They respond to reward which is given unexpectedly or, if reward is expected, to a sensory stimulus that predicts the reward. In the reward-biased saccade task, dopaminergic neurons respond by excitation and inhibition to sensory stimuli that predict a reward that is larger and smaller than what is expected, respectively (Figure 4(b)).

Figure 5 Pretarget activity of a caudate projection neuron selective for reward position. (a) Action potentials of a left caudate neuron (shown by dots in a raster display) while the monkey performed the visual-1DR task. The raster is aligned on the onset of the fixation point (fix on) and the onset of the target (target on). The changes in stimulus configuration are shown at top. After the fixation period of 1.5 s, a target came on at a right or left position pseudorandomly and the monkey had to make a saccade to it. In the first block of 20 trials (indicated by a pink bar), a reward (water) was given only if the target was presented on the right and the saccade was made to it. In the second block a reward was given only if the target was on the left (indicated by a green bar). These two types of blocks were repeated subsequently. The caudate neuron exhibited sustained activity before target onset while the monkey was fixating at the center spot, but the activity was much stronger when the reward was expected after saccade to the right target (which was contralateral to the neuron). (b) Correlated changes of pretarget activity of caudate neurons (top) and saccade latency (bottom). The mean pretarget activity of caudate neurons (top) was higher in the block of trials when the reward was expected on the contralateral position (indicated by blue dots) than on the ipsilateral position (red dots). The mean latency of contralateral saccades (bottom), which the caudate neurons would preferentially control, was shorter when they were preceded by higher pretarget activity and when they were followed by reward. From Lauwereyns J, Watanabe K, Coe B, and Hikosaka O (2002) A neural correlate of response bias in monkey caudate nucleus. *Nature* 418: 413–417.

How could dopamine influence activity of CD projection neurons? Dopamine does not exert fast excitatory or inhibitory actions, but is thought to modulate other synaptic inputs, especially glutamatergic inputs from the cerebral cortex. These findings led to the following hypothesis: the spatial signals from the cortical eye field are enhanced if dopaminergic inputs are increased (i.e., a bigger reward is expected) and depressed if dopaminergic inputs are decreased (i.e., a smaller reward is expected) (Figure 7). The interaction may occur within individual dendritic spines. This interaction might be mediated by long-term potentiation (LTP) or long-term depression (LTD). Recent studies have indicated that LTP indeed occurs if cortical inputs come in simultaneously with dopaminergic inputs and if the CD neuron fires. In support of this hypothesis, the reward-dependent bias in saccades is reduced if dopaminergic transmission in the CD is blocked by injecting dopamine D1 antagonist.

The role of interneuronal processing in the CD is less clear. TANs, which are thought to be cholinergic, respond to reward or reward predictor, similarly to dopaminergic neurons, but also respond to a sensory stimulus that predicts the absence of reward or punishment. It has been suggested that cholinergic interneurons indicate that the reward is not equal among actions to choose, but do not indicate which action is the best or the worst. The latter function would be carried out by dopaminergic neurons. Cholinergic interneurons might detect the condition in which rewards are unequal and guide dopaminergic neurons to fully operate. However, this hypothesis needs to be examined in future experiments.

Figure 6 A hypothetical scheme showing how pretarget activity of caudate neurons might determine saccade bias toward reward position. The caudate–SNr–SC connections in the right and left hemispheres are shown to visualize the contrast in their excitability. Red circles and lines with (+): excitatory neurons. Blue circles and lines with (–): Inhibitory neurons. The thickness of the line represents the firing rate of the neuron. The color saturation of the circle represents the excitability of the neuron. (Top) Pretarget period. If a reward is expected at a right position (shown by an apple), left caudate neurons become active and right caudate neurons are inactive. This occurs while the monkey is fixating. On the left side of the brain, SNr neurons are inhibited and hence SC neurons are disinhibited; on the right side, SNr neurons remain active and hence SC neurons are inhibited. (Bottom) Posttarget period. (Bottom-left) If a target then appears on the left, cortical areas on the right side are activated (indicated by yellow) and this signal is sent to right SC neurons with excitatory connections. Since the right SC neurons have been tonically inhibited by SNr neurons, cortical inputs can only slowly activate the SC neurons and hence the saccade to the left (nonreward position) is delayed. (Bottom-right) If a target appears on the right, cortical areas on the left side are activated and this signal is sent to left SC neurons. Since the left SC neurons have been freed from the SNr-induced inhibition, cortical inputs can quickly activate the SC neurons and hence the saccade to the right (reward position) is quickened. From Hikosaka O, Nakamura K, and Nakahara H (2006) Basal ganglia orient eyes to reward. *Journal of Neurophysiology* 95: 567–584.

Figure 7 A hypothetical scheme showing reward-dependent plasticity of corticocaudate synapses. In one condition of the memory-1DR task (1) the caudate neuron receives two kinds of visual input (L and R) from the cerebral cortex at dendritic spines (X and Y), (2) input L represents a left visual cue signal while input R represents a right visual cue signal, (3) input L indicates an upcoming reward while input R indicates no reward, and (4) L and R inputs come in randomly one at a time. Dopamine neurons in the SNc, which are presumed to make synapses on caudate neurons nonselectively, respond to input L with a burst of spikes (top-left) and respond to input R with a pause of spikes (top-right). After several trials the efficacy of the L–X synapse increases (bottom, indicated by a larger red circle) while the efficacy of the R–Y synapse decreases (bottom, indicated by a smaller red circle). Activation of caudate neuron in response to the same input L is now enhanced (bottom-left, indicated by thick blue line), while activation in response to input R is diminished (bottom-right, indicated by thin light-blue line). The bias persists for some trials due to the plasticity even when reward is associated equally with R and L inputs (bottom, indicated by thin green lines). The bias will be reversed in the next block when input R, not input L, indicates an upcoming reward. Red lines: excitatory connections. Blue circles and lines: inhibitory neurons. Green circles and lines: dopamine neuron which is modulatory. The thickness of the line represents the firing rate of the neuron, except that the dotted green line indicates a decrease in dopamine neuron firing. From Hikosaka O, Nakamura K, and Nakahara H (2006) Basal ganglia orient eyes to reward. *Journal of Neurophysiology* 95: 567–584.

Introduction: Cholinergic Neuromodulation in the Striatum

The clinical symptoms of Parkinson's disease (PD) were first described at 1817 by the English physician James Parkinson in his 'Essay on the Shaking Palsy.' At this time physicians and scientists had no clues as to the etiology, pathophysiology, or therapeutic options for this common disease. The first effective medical treatment of PD – with belladonna, an anticholinergic agent – was accidentally discovered in the second half of the nineteenth century. For more than 100 years, anticholinergic agents were the only efficient treatment for PD, and therefore, despite their limited therapeutic effects, were frequently prescribed. The critical role of dopamine (DA) depletion in the striatum (input stage of the basal ganglia networks) in the pathophysiology of PD was revealed through a series of heroic pathological, pharmacological, and neurochemical studies throughout the twentieth century. This series of discoveries eventually ended in the seminal finding by Cotzias et al. of DA replacement therapy for PD. Thus, effective treatments of PD involve the manipulation of DA and acetylcholine (ACh) in an opposing fashion, either by elevation of the extracellular level of striatal DA or by reduction of the ACh level. These clinical opposing effects led to the DA–ACh balance hypothesis, which states that the two transmitters act antagonistically in the striatum. The superiority of DA replacement over anticholinergic treatment for PD probably led to the recent escalation in research on the basal ganglia DA system and the relative neglect of the basal ganglia cholinergic system. This article revisits the cholinergic system of the basal ganglia and discusses its role in the physiology of the basal ganglia networks as well as the pathophysiology of their related disorders (e.g., PD).

Chemical transmission in the central nervous system (CNS) is usually classified into two main categories. Fast neurotransmitters carry information from one neuron to another. Fast neurotransmitters can be excitatory, such as glutamate, increasing the likelihood that the postsynaptic cell will fire, or inhibitory, such as γ-aminobutyric acid (GABA) in the adult animal, reducing the likelihood of postsynaptic discharge. Fast neurotransmission is predominant in the specific connections between neurons and therefore is usually limited in space as well as duration. On the other hand, several brain stem nuclei (e.g., the locus coeruleus, the raphe nuclei, and the substantia nigra and ventral tegmental area) form diffuse modulatory projections throughout the CNS. The respective modulatory neurotransmitters (noradrenalin, DA, and serotonin) affect the excitability and modify the responsiveness of their target neurons; however, these neurotransmitters usually do not directly affect their target neurons' ongoing discharge. Unlike fast neurotransmission, neuromodulation is characterized by a broad span of effects in both the spatial and the temporal domains. In the CNS, ACh projections arise mainly from the nucleus basalis of Meynert (NBM) and the pedunculopontine nucleus (PPN). These diffuse cholinergic projections play a critical role in the modulation of information processing by neocortical neurons, as well as in many other neuronal structures (e.g., brain stem and spinal cord).

Given the DA–ACh balance, it is not surprising that the striatum – the input stage of the basal ganglia – has very rich cholinergic innervation. In fact, the striatum has the highest density of cholinergic markers – such as the enzymes choline acetyltransferase and acetylcholinesterase – of all CNS structures. Nevertheless, the source of this rich cholinergic innervation of the striatum is not extrinsic, that is, from the central cholinergic structures such as the NBM or the PPN. Rather, striatal ACh is secreted by striatal cholinergic interneurons, which constitute 1–2% of the striatal neuronal population. The cholinergic interneurons are large aspiny cells with extensive and dense local axons. A few dendrites arise from the soma and branch in a radiating fashion, for distances of up to 0.75 mm from the soma. In the rodent, the dendritic tree of a single cholinergic interneuron may span about a third of the striatum; however, the dendritic domain of the cholinergic neurons is smaller in the primate. The axons of the cholinergic neurons originate from the dendritic trunks and branch repetitively. The resulting axonal arborization consists of a dense plexus of fine axonal branches that fill and go beyond the region of the dendritic field. Acute mapping of cholinergic interneurons reveals that they tend to lie at or close to the striosome–matrix border, suggesting an integrative role for these striatal interneurons.

Physiological Studies of Striatal Cholinergic Cells

Extracellular recording of the spiking activity of striatal neurons in behaving animals reveals two main populations of neurons. Phasically active neurons are characterized by a short-duration action potential, very low spontaneous activity (<1 spike s^{-1}), and a phasic increase triggered by movements and other relevant behavioral events. These neurons are believed to be the spiny projection cells of the striatum (95% of all striatal cells). Tonically active neurons (TANs) have a broader action potential and a spontaneous tonic irregular firing rate of 3–12 Hz and show strong and robust responses to reward related events. Recent studies indicate that TANs are the cholinergic interneurons of the striatum. Electrophysiological studies have confirmed that TANs cannot be antidromically activated by stimulation of the globus pallidus, thus supporting the identification of TANs as striatal interneurons.

Intracellular studies have shown that the striatal cholinergic interneurons discharge autonomously even under blockade of a variety of fast synaptic transmission and neuromodulators. The striatal cholinergic interneurons are characterized by a prolonged afterhyperpolarization (AHP) following an action potential and are highly sensitive to incoming excitatory inputs: Depolarization induced by only two or three synaptic potentials can drive them to fire action potentials. The sensitivity of cholinergic cells to synaptic excitation is due to the relatively depolarized membrane potential and high input resistance of these neurons. In brain slices, these neurons display a variety of firing patterns, including rhythmic single spiking, rhythmic bursting, and irregular firing. The persistent sodium current is responsible for destabilizing the resting potential of the neuron, and the hyperpolarization-activated, cyclic nucleotide-gated, inward cation current is responsible for depolarizing the cell from the variety of AHP states that the cell exhibits. The first of these is a medium-duration AHP (mAHP, ~200 ms) that follows each action potential during rhythmic single spiking The reduced input resistance during the mAHP diminishes the efficacy of depolarizing synaptic inputs and therefore places a ceiling on the firing rate of the TANs. Calcium entry via N-type voltage-activated calcium channels during the action potential is required for activation of the small-conductance, calcium-dependent potassium current which underlies the mAHP. The mAHP is essential for the tonic firing pattern of the TANs because pharmacological treatments which reduce the amplitude of the mAHP convert single (regularly or irregularly) spiking cells into burst-firing neurons. Activation of D1 DA receptors prolongs the TANs' interspike interval by enhancing the mAHP amplitude. The second and even longer (several hundred milliseconds to seconds) AHP of the cholinergic interneuron is termed the sAHP. Calcium entry via the L-type voltage-activated calcium channels triggers calcium release from intracellular stores, which in turn activates the current underlying the sAHP. It is the buildup of the sAHP that terminates the discharge during rhythmic bursting of these neurons. Finally, cholinergic interneurons exhibit an additional calcium-independent regenerative AHP because of the inwardly rectifying potassium current, which can induce all-or-none hyperpolarizations whose time course is mostly independent of the size of the stimulus that generated it. The sAHP and regenerative hyperpolarization are likely to participate in fashioning the pause response of the TANs.

TAN Encoding of Behavioral Events

The behaviorally triggered changes in the discharge of TANs, unlike the diversity of task-related activations exhibited by the phasically active population of striatal neurons, is stereotypic in terms of both the trigger events and the pattern of change. Many studies of these neurons have emphasized the homogeneity of the TAN responses across large parts and different territories of the striatum. Other studies have revealed that as in any biological system, not all TANs are born equal. However, compared with neurons of other neuronal structures (e.g., cortical, pallidal, and nigral cells) and even with the striatal projection neurons, the TAN population is very homogeneous. The next discussion outlines the main characteristics of this unique population of cholinergic interneurons, as well as its minor variants.

The behavioral events that tend to modify the tonic background discharge of TANs include primary rewards and stimuli that have acquired a reward value during associative learning. However, as with DA neurons, the TANs do not encode the hedonic value of the rewarding event; rather their responses are modulated by predictions about stimulus timing. In classical conditioning tasks, the responses are diminished or abolished in the presence of external cues that predict the time at which the rewarding events will occur. The critical role of the TANs in reward-related learning has been confirmed by the impairment of procedural learning by selective ablation with immunotoxin-mediated cell targeting of cholinergic neurons in the striatum.

The typical response of TANs involves a transient depression of their tonic firing. This depression is often followed by rebound excitation and may be preceded (or flanked) by increases in discharge rate. The pause in firing usually occurs 100 ms after the

behavioral trigger. The mean duration of the pause responses (~250 ms) is greater than the mean interspike interval of the same neurons (~180 ms, range 60–330 ms), suggesting that the pause represents an active suppression or modified intrinsic dynamics of TAN firing rather than a resetting of the TANs' ongoing discharge. Recent studies have revealed different response patterns for aversive events and reward-related events, as well as for putamen and caudate TANs. The functional significance of these variations is still under study. Bearing in mind the DA–ACh balance hypothesis and the therapeutic effects of anticholinergic agents in PD, it is not surprising that the pause of the TAN parallels the burst discharge of DA cells.

Network Properties of TANs

The strong resemblance across the temporal patterns of neuronal responses of widely distributed TANs led to the suggestion that the TANs form a distributed network with synchronized activity. Cross-correlation studies of simultaneously recorded TANs have revealed a significant degree of synchronized activity between TANs recorded by different electrodes, at distances of a few millimeters, for example.

In the normal monkey, only very few of simultaneously recorded TANs and pallidal neurons display significant synchronization. After treatment with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, many of these pairs display significant synchronous periodic oscillations. The low level of correlated activity in the normal state demonstrates that TANs have only a slight effect on pallidal activity during execution of familiar behavior. The high level of oscillatory correlated activity in the parkinsonian state further suggests that coherent oscillations of the whole basal ganglia circuitry underlie the clinical features of Parkinson's disease.

The Functional Organization of TANs' Synaptic Inputs

The observation that populations of TANs can exhibit synchronous pause responses, as well as their background synchronized activity, suggests that there may be a common synaptic or neuromodulatory input to the TANs which might underlie such synchronization. The major sources of inputs to the TANs include the cortex, the central complex of the thalamus (the centromedian (CM) nucleus), and midbrain dopaminergic neurons, as well as lateral GABAergic synapses arising either from GABAergic interneurons or from collaterals of the medium-spiny projection neurons of the striatum.

Neurochemical studies have documented inhibition of striatal ACh release by the nigrostriatal DA pathway. These neurochemical studies, as well as the synchronization of the DA burst with the TAN pauses, may suggest that DA is the main driver (or the brakes) of the TANs. Indeed, lesions of the dopaminergic projection to the striatum or local application of dopaminergic antagonists results in a loss of the pause response. However, these effects can be reversed by apomorphine (a postsynaptic DA agonist that therefore restores only the background level of DA), indicating that DA may gate, but not drive, the TAN pause. Recent *in vivo* intracellular recordings have revealed that high-frequency stimulation of the substantia nigra induces potentiation of the cortically evoked excitation of striatal cholinergic interneurons and prolongs the AHP of these neurons after cortical stimulation. These findings suggest that a substantia nigra-induced AHP produces cortical stimulus-associated firing pauses in cholinergic interneurons. On the other hand, inactivation of the CM complex in primates also results in a loss of the TAN pause response. Thus, dopaminergic inputs to the TANs probably have a gating function on the pause which follows the thalamic and/or cortical excitatory inputs. However, the hypothesis that the TAN pause is generated by a mechanism independent of a previous excitation, for instance by the lateral GABAergic connections in the striatum, has not yet been explored.

TANs' Effects in the Striatum

The release of ACh in the striatum affects the striatal neuronal elements through both muscarinic and nicotinic receptors. ACh secreted by the TANs can affect the excitability of striatal projections as well as the efficacy of corticostriatal synapses. These effects are mainly mediated through muscarinic receptors. Neurochemical studies have reported a reciprocal inhibition of striatal ACh release by the nigrostriatal DA pathway and of DA release by ACh. Nicotinic receptors are predominantly located at the synaptic terminals of the dopaminergic axons. Recent studies have shown that the effect of activation of nicotinic receptors is dependent on the discharge frequency of the DA neuron. Activation of nicotinic receptors enhances the probability of DA release by a single DA spike; however, it enhances short-term depression of DA release sites. Reducing ACh activity (e.g., during a pause) suppresses DA release by a single DA spike but facilitates the DA release by a burst of DA spikes.

Summary and Conclusions

This article has summarized recent advances in knowledge of the critical role of basal ganglia ACh in behavioral control, as well as its role in basal ganglia-related

disorders, such as PD. The clinical literature and practice emphasize the role of DA in the physiology and pathophysiology of the basal ganglia. However, the opposing relationships between the typical responses of DA and striatal cholinergic neurons, between the neurochemical levels of DA and ACh in the striatum, between their effects on corticostriatal transmission, and finally between their therapeutic actions, suggest that the striatal ACh–DA balance (e.g., the DA burst vs. the TAN pause) is a key process in the computational physiology of the basal ganglia. The TAN pauses are probably triggered either by feed-forward inhibition via the striatal fast-spiking GABAergic interneurons or by supra- or subthreshold excitation from the cortex or thalamic inputs to the cholinergic interneurons that induces a rebound AHP in these neurons. Many physiological studies indicate that the pause of the cholinergic interneurons informs the projection neuron of the striatum of salient events which deserve a shift of attention, and may facilitate learning at the cellular level. The functional role of the increases in discharge of the TANs is still being debated and should be clarified in the near future.

Basal Ganglia Divisions and Organization in Mammals

The basal ganglia (BG) are a group of nuclei located in the basal (subpallial) part of the telencephalon and involved in control of motor behavior (including planning and execution of movement), as well as in cognitive functions such as motivation, attention, and learning. The BG were classically involved in motor control based on the obvious movement disorders associated with BG lesions or abnormal activity. BG control of movement was thought to be done mainly by a pathway to the motor cortex by way of the thalamus. Evidence accumulated during the past 15 years indicates that the BG are closely associated not only with motor and premotor areas of the cortex but also with many other areas of the cortex/pallium, including the prefrontal, orbitofrontal, and cingulate cortices, which are thought to be important for controlling many aspects of cognitive functions such as planning, working memory, sequential behavior, visuospatial perception, and attention. Importantly, the BG appear to play an important role in selecting which action to perform, which depends on learning and experience, and participate in adaptive control of motor and cognitive behaviors. Moreover, the BG are involved in reward and anticipation of forthcoming reward, and the pallial amygdalar input to BG (involved in assigning biological/emotional significance to stimuli) appears to play a key role.

The BG of mammals consist of an input station called striatum and an output station called pallidum (Figure 1). Briefly, the striatum receives sensorimotor, cognitive, and viscerolimbic/emotional information primarily from most areas of the cerebral cortex/pallium (although it also receives input from the thalamus) and transmits this information to the pallidum. The pallidum in turn projects to effector centers in the thalamus and brain stem, thus acting on thalamocortical or descending pathways and influencing motor or cognitive behaviors. Therefore, the BG can be considered as an interface that connects the cerebral cortex with brain stem neural systems that effect specific aspects of behavior. The activity of principal striatal neurons is modulated by input from dopaminergic cells of the mesodiencephalic tegmentum (including the substantia nigra and ventral tegmental area) and by local circuit neurons of the striatum. When the dopaminergic input to the striatum fails, motor and cognitive dysfunctions are observed, producing parkinsonian symptoms, as well as cognitive and emotional deficits. In order to determine whether the BG exist in nonmammalian vertebrates, and whether they show the same (homologous) divisions and cell types and similar neurochemistry, connections, and functions, it is important to briefly consider the basic characteristics of mammalian BG.

Striatum and Pallidum Develop from Distinct Histogenetic Subdivisions of the Subpallium

The two major divisions of the BG originate in different sectors of the subpallium under the influence of distinct combinations of transcription factors (Figure 2). The striatum develops from the lateral ganglionic eminence, characterized by expression of the transcription factors Dlx1/2/5/6, Ghs1/2, and Mash1, among others, but not Nkx2.1/Titf-1. On the contrary, the pallidum develops from the medial ganglionic eminence, characterized by expression of Dlx1/2, Nkx2.1/Titf-1, Lhx6, and Lhx7/8, among others. It appears that Gsh1/2 and Nkx2.1/Titf-1 are important for specification of lateral or medial ganglionic eminences, respectively (LGE or MGE; also called striatal or pallidal subdivisions), whereas Dlx, Mash, and Lhx transcription factors play a role in the differentiation of neurons. Lack of function of Gsh1/2 produces severe malformation of the striatum, which is transformed into pallium/cortex. Lack of function of Nkx2.1 (as in Nkx2.1 knockout mice) produces severe malformation of the pallidum and transformation of the MGE into LGE. On the other hand, Dlx and Mash transcription factors appear to be involved in the acquisition of the GABAergic phenotype, which is typical of BG neurons, as well as their projections.

Dorsolateral versus Ventromedial Parts of the Basal Ganglia: A Gradient from Motor to Cognitive and to Motivational/Emotional Functions

The BG contain two main divisions: (1) a dorsal part mainly involved in motor and cognitive/executive functions and (2) a ventral part involved in cognitive and limbic/emotional functions such as motivation and attention. The division between the dorsal and the ventral parts of the BG is not sharp but, rather, gradiental from dorsolateral to ventromedial. Thus, from dorsolateral to ventromedial parts of the striatum, there is a gradient from motor to executive/cognitive to motivational/emotional functions.

Each BG part consists of a striatal portion and an associated pallidal portion (Figure 1). Thus, there is a

Figure 1 Schematic drawings of frontal sections through the telencephalon of a mammal (rat), a bird (pigeon), a reptile (lizard), and an amphibian (frog) showing the striatal (red) and pallidal (blue) subdivisions of the basal ganglia. Two different rostrocaudal levels are shown for each species. Ac, nucleus accumbens; Ap, pallial amygdala; As, subpallial amygdala; BST, bed nucleus of the stria terminalis; cc, corpus callosum; Cl, claustrum; CPu, caudoputamen complex (dorsal striatum); DC, dorsal cortex (reptile); DP, dorsal pallium; DVR, dorsal ventricular ridge; En, endopiriform nucleus; GP, globus pallidus; H, hyperpallium (dorsal pallium in birds); Hp, hippocampal formation; LC, lateral cortex (reptiles); LP, lateral pallium; LSt, lateral striatum (birds); M, mesopallium (lateral pallium of birds); MC, medial cortex (reptile); MP, medial pallium; MSt, medial striatum (birds); N, nidopallium (part of ventral pallium in birds); NdB, nucleus of the diagonal band (Broca); NCx, neocortex (dorsal pallium of mammals); Pa, pallidum; Pir, piriform cortex; S, septum; SAT, striato-amygdaloid transition area; St, striatum; Tu, olfactory tubercle; VP, ventral pallium; VPa, ventral pallidum.

dorsal striatum that includes the caudate nucleus and putamen in primates and carnivores (artificially separated by the fibers of the internal capsule) or simply the caudoputamen complex in rodents (CPu). The CPu projects to the globus pallidus (GP), which represents the dorsal part of the pallidum (Figure 3). In mammals, the GP shows two subdivisions called internal and external segments of the globus pallidus

Figure 2 (a–d) Digital images of frontal sections through the embryonic telencephalon of a mouse showing the expression of the transcription factors Dlx5 (a, b) or Nkx2.1 (c, d). Dlx5 is expressed in the entire subpallium, including the lateral and medial ganglionic eminences (LGE and MGE, respectively), most of the septum, anterior peduncular area (AEP), and part of the preoptic area (PO). Nkx2.1 is expressed only in part of the subpallium, in a domain that includes MGE (which gives rise to the globus pallidus), a pallidal part of the septum, AEP, and PO. In contrast, the LGE and its striatal derivatives (including the caudoputamen complex and nucleus accumbens) do not show nested expression of Nkx2.1. Nevertheless, the striatum contains dispersed cells expressing Nkx2.1, but these are immigrant interneurons that originate in the Nkx2.1-expressing domain. (e–g) Digital images of frontal sections through the telencephalon of the frog *Xenopus laevis* (adult animals) showing the expression of Distal-less-4 (xDll4, ortholog of Dlx2 of mouse (e) or xNkx2.1 (f and g). The expression patterns of these transcription factors in the telencephalon of *Xenopus* are comparable to those of the ortholog genes in mouse. The subpallium is rich in cells expressing xDll4 and includes most of the septum and the striatal and pallidal parts of the basal ganglia. The pallidal subdivision (but not the striatum) also expresses xNkx2.1. These data strongly support the homology of the striatal and pallidal parts of the basal ganglia between *Xenopus* and mouse. Ac, nucleus accumbens; BST, bed nucleus of the stria terminalis; CPu, caudoputamen complex (dorsal striatum); DP, dorsal pallium; GP, globus pallidus; LP, lateral pallium; MP, medial pallium; Pa, pallidum; Pir, piriform cortex; S, septum; St, striatum; Th, thalamus (dorsal thalamus); VP, ventral pallium.

Figure 3 Schematic drawings of lateral brain views of a mammal (rodent), a bird (pigeon), and a reptile (lizard) showing the main connections of the dorsal (somatomotor) basal ganglia (BG). Note the existence of similar BG pathways to the tectum (superior colliculus) by way of the substantia nigra pars reticulata (SNr) in all groups. In addition, reptiles and birds show BG pathways to the tectum by way of the pretectum. In all groups, the activity of the dorsal striatum is modulated by dopaminergic input from the substantia nigra pars compacta (SNc; the input is represented in green). These features possibly characterized the BG of ancestral amniotes. Moreover, dorsal BG pathways to the neocortex/dorsal pallium are observed in birds and especially in mammals. These BG–cortical/pallial channels include a direct pathway (red) and an indirect pathway (blue), and the latter involves a glutamatergic center called subthalamic nucleus (STN). The dorsal pallidum does not project to the thalamus (dorsal) in reptiles, suggesting that dorsal BG–neocortical/dorsal pallial loops evolved independently in birds and mammals. In mammals, the cholinergic pedunculopontine tegmental nucleus (PPN) receives dorsal BG input and is reciprocally connected with the SNr. By way of this nucleus, the BG are able to influence descending motor pathways (via the tectum/colliculus and medullary groups) and ascending activating pathways (via midline/intralaminar thalamic nuclei) that are involved in arousal and awareness (the cholinergic pathways are depicted in orange). The PPN is present in birds and reptiles, and apparently it gives rise to ascending activating pathways via the midline/intralaminar thalamic nuclei and to descending pathways via the tectum. However, the PPN of birds and reptiles appears to receive input mainly from the ventral BG and little or no input from dorsal BG. It is unknown whether a reciprocal connection between PPN and SNr exists in birds or reptiles. Ac, nucleus accumbens; Ap, pallial amygdala; Cb, cerebellum; CPu, caudoputamen complex (dorsal striatum); DC, dorsal cortex (reptile); DCN, dorsal column nuclei; DVR, dorsal ventricular ridge; GP, globus pallidus; GPe, globus pallidus, external or lateral segment; GPi, globus pallidus, internal or medial segment; H, hyperpallium (dorsal pallium in birds); Hp, hippocampal formation; IC, inferior colliculus; INT, intralaminar thalamic nuclei; LDT, laterodorsal tegmental nucleus; LoC, locus coeruleus; LSt, lateral striatum (birds); M1, primary motor cortex; M, mesopallium (lateral

(GPi and GPe, respectively). On the other hand, there is a ventral striatum that includes the nucleus accumbens and olfactory tubercle (its striatal part) and also an associated ventral pallidum (Figures 1 and 3).

The general features of the dorsal and ventral parts of the BG are similar. For example, the striatum typically shows a high acetylcholinesterase activity and is densely innervated by dopaminergic axons, which distinguish it from the adjacent telencephalic areas (i.e., the cortex/pallium and pallidum). However, the connections of the dorsal and ventral BG parts, although following a similar pattern, are different. Thus, whereas the CPu receives its main cortical input from widespread areas of the neocortex, including motor, premotor, and prefrontal areas, the nuclear accumbens (Acc) receives its main cortical input from limbic-related cortical/pallial areas, such as the hippocampal formation and the pallial amygdala (basolateral complex), as well as from the insular/perirhinal cortex and from parts of the prefrontal and cingulate cortex. In relation to the input from the prefrontal cortex, whereas the projections to the dorsal striatum originate in the areas involved in selective attention, working memory, decision making, and goal-directed behavior (dorsolateral prefrontal cortex of primates and prelimbic cortex of rodents), the projections to the ventral striatum primarily arise in areas involved in visceromotor and emotional behavior (orbitomedial cortex of primates and infralimbic cortex of rodents). Similarly, whereas the dorsal striatum is mainly modulated by dopaminergic input from the substantia nigra pars compacta (SNc; A9 catecholamine cell group), the ventral striatum is mainly modulated by dopaminergic input from the ventral tegmental area (A10 catecholamine cell group), SNc (A9 group), and retrorubral field (A8 group) and by noradrenergic input from the locus coeruleus (Figures 3 and 4). On the other hand, whereas the projections of the globus pallidus end on the motor, lateral part of the thalamus (ventral anterior/ventral lateral nuclei) and thereby influence motor/premotor, prefrontal, and other parts of the neocortex, the projections of the ventral pallidum target the medial (midline) thalamus (mediodorsal nucleus) which in turn projects to the prefrontal cortex (primarily the orbitomedial cortex of primates and infralimbic cortex in rodents). This part of the prefrontal cortex receives input from the hippocampal formation and pallial amygdala (basolateral complex), which are important for motivational/emotional functions (including assigning an emotional significance to stimuli).

However, there is no sharp boundary between dorsal (dorsolateral) and ventral (ventromedial) BG. In fact, the connectivity patterns of dorsal versus ventral BG change following a gradient from dorsolateral to ventromedial, as also noted previously for the functions. For example, the ventromedial part of CPu shows some connections similar to those of the adjacent core part of nucleus accumbens, such as input from the amygdala, which is typical of the limbic, ventromedial striatum.

Cell Types, Neurotransmitter Organization, and Connections

Both the striatum and the pallidum are characterized by having GABAergic neurons that show inhibitory, descending projections. In the striatum, the vast majority (approximately 90–95%) of the neurons are medium-sized, spiny neurons that project to the pallidum or brain stem. There are two major types of principal or projection neurons in the striatum: those that contain GABA and the neuropeptides substance P and dynorphin (GABA+/SP+/DYN+) and those that contain GABA and the neuropeptide enkephalin (GABA+/ENK+). Both cell populations are highly segregated in the dorsal part of the striatum (each type representing half of the total amount of projection neurons, with only 4% of co-localization) but less so in the ventral striatum. In the dorsal striatum, the two major cell types project to different targets: GABA+/SP+/DYN+ striatal neurons primarily project to the GPi (and only show a minor projection to the external segment) and to the substantia nigra (pars compacta and pars reticulata), whereas GABA+/ENK+ striatal neurons project heavily to the GPe.

In addition to projection neurons, the striatum also contains four subtypes of local circuit neurons (interneurons), which represent approximately 5–10% of all striatal neurons and modulate the activity of the principal striatal neurons. The four interneuron subtypes described in the striatum are (1) cholinergic interneurons; (2) interneurons containing GABA and parvalbumin; (3) interneurons containing GABA, nitric oxide, and the neuropeptides somatostatin and neuropeptide Y; and (4) interneurons containing

pallium of birds); MD, mediodorsal thalamic nucleus (midline thalamus); MSt, medial striatum (birds); N, nidopallium (part of ventral pallium in birds); OB, olfactory bulb; oc, optic chiasm; PFC, prefrontal cortex; Po, preoptic area; PrM, premotor cortex; PT, pretectal nucleus of the posterior commissure (it receives BG input); SC, superior colliculus; St, striatum; TeO, optic tectum; VB, ventrobasal thalamus; VTA, ventral tegmental area (A10 catecholamine cell group).

Figure 4 Schematic drawings of lateral brain views of a mammal (rodent), a bird (pigeon), and a reptile (lizard) showing the main connections of the ventral (viscerolimbic) basal ganglia (BG). Note the existence in all groups of similar ventral BG projections to the lateral hypothalamus, habenula (not shown), ventral tegmental area (VTA; A10 cell group), sustantia nigra pars compacta (SNc; A9 cell group), pedunculopontine tegmental nucleus (PPN), and locus coeruleus (LoC). In addition, the ventral BG projects to comparable midline/intralaminar thalamic nuclei, which in turn project back to the ventral BG in all groups. In birds and reptiles, the midline thalamus also projects to the ventrolateral pallium, including the pallial amygdala. These were possibly basic features for ventral BG pathways in ancestral amniotes. In mammals, the midline thalamic nucleus that receives ventral BG input shows a projection to the prefrontal cortex, and this appears to represent a newly evolved connection. In all groups, the ventral striatum is modulated by dopaminergic input from the A8–A10 cell groups and by noradrenergic input from LoC (the catecholaminergic input to the ventral striatum is depicted in green). By way of the PPN, the ventral BG in all groups may influence descending motor pathways (through the tectum) and ascending activating pathways (through the midline/intralaminar thalamus) (the cholinergic pathways are depicted in orange). Cb, cerebellum; CPu, caudo-putamen complex (dorsal striatum); DC, dorsal cortex (reptile); DCN, dorsal column nuclei; DVR, dorsal ventricular ridge; GP, globus pallidus; GPe, globus pallidus, external or lateral segment; GPi, globus pallidus, internal or medial segment; H, hyperpallium (dorsal pallium in birds); Hp, hippocampal formation; IC, inferior colliculus; INT, intralaminar thalamic nuclei; LDT, laterodorsal tegmental nucleus; LHy, lateral hypothalamus; LSt, lateral striatum (birds); M1, primary motor cortex; M, mesopallium (lateral pallium of birds); MD, mediodorsal thalamic nucleus (midline thalamus); MSt, medial striatum (birds); N, nidopallium (part of ventral pallium in birds); OB, olfactory bulb; oc, optic chiasm; PFC, prefrontal cortex; Po, preoptic area; PrM, premotor cortex; PT, pretectal nucleus of the posterior commissure (it receives dorsal BG input); SC, superior colliculus; SNr, substantia nigra pars reticulata; St, striatum; STN, subthalamic nucleus; TeO, optic tectum; VB, ventrobasal thalamus; VPa, ventral pallidum.

GABA and calretinin. It appears that the striatum of rodents and primates also contains a small subpopulation of neurons containing tyrosine hydroxylase/dopamine. This appears to represent another interneuron subtype, without clear relation to the four interneuron subtypes mentioned previously. However, although most striatal interneurons appear to originate outside the striatum (in the MGE or basal to it), it is likely that the striatal neurons containing tyrosine hydroxylase/dopamine originate in a dorsal subdivision of the lateral ganglionic eminence (dLGE), which is known to be the source of the dopaminergic interneurons of the olfactory bulb.

Pallidal neurons are typically large and the majority contain GABA, the neuropeptide LANT6 (a neurotensin-related hexapeptide), and parvalbumin. The dendrites of these cells show a typical flat-disk arrangement and are contacted by striatal axons while passing through. However, the cellular composition of the pallidum is more complex. For example, in the GPe, although the majority of the neurons (approximately two-thirds) are the typical large cells containing GABA, LANT6, and parvalbumin and primarily show descending projections to the subthalamus and substantia nigra pars reticulata (SNr), there is an important subpopulation of neurons (representing approximately one-third) that contain GABA, calbindin, and ENK and project back to the striatum (in addition to the subthalamus/SNr). Moreover, it appears that the GPe also contains a minor interneuron subpopulation containing calretinin.

The pallidum receives its major input from the striatum and projects to the brain stem and to the thalamus (influencing thalamocortical circuits). Due to the mostly segregated striatal input to GP, the GPi is characterized by dense SP+ innervation, whereas the GPe is characterized by dense ENK+ innervation. The ventral pallidum (VP) is densely innervated by both SP+ and ENK+ fibers. As noted previously, the projections of VP differ from those of GP (Figures 3 and 4). In the thalamus, while VP targets the mediodorsal nucleus (midline thalamus), GP projects to the motor part of the ventrobasal complex (ventral anterior and ventral lateral nuclei), thus influencing different thalamocortical circuits. Both VP and GP also project to intralaminar thalamic nuclei (including the parafascicular nucleus). Similarly, whereas GP projects to the subthalamic nucleus (STN), VP primarily projects to the medial aspect of STN and adjacent lateral hypothalamic area. In the tegmentum, whereas GP projects to the SNr, VP mainly projects to the ventral tegmental area, SNc, retrorubral area (A10, A9, and A8 catecholamine cell groups, respectively) and locus coeruleus. These differences in connectivity between GP and VP underlie the functional differences described for dorsal and ventral BG. On the other hand, the projections of GPe and GPi differ and are related to separate circuits that have opposite functions for BG control of movement. The organization of these circuits is explained in more detail in the following section.

Functional Circuits

In mammals, the BG influence motor, cognitive, and emotional functions by way of either BG-thalamocortical recurrent (re-entrant) pathways or descending outputs to the brain stem (e.g., the BG outputs to tectoreticulospinal pathways). The activity of BG is modulated by dopaminergic, serotonergic, and noradrenergic input.

Parallel cortico-basal ganglia-thalamocortical loops for control of motor, cognitive–executive, and emotional/motivational functions One interesting aspect of BG connections with the cortex is that they are organized in parallel, mostly segregated circuits. These were first proposed when comparing ventral versus dorsal BG, which by way of distinct connections (distinct input from the cortex and output to different thalamocortical circuits) could influence either motivational/emotional or motor behavior (Figures 3 and 4). Later, the existence of multiple parallel, segregated circuits was observed, channeled through different parts of the dorsal or ventral BG. Thus, it appears that each functional area of the cortex is related to a specific, functionally equivalent part of the BG, and that there are multiple parallel cortico-BG-thalamocortical loops or channels, each involved in control of a specific aspect of motor behavior or cognition. Each cortico-BG-thalamocortical channel reaches the same cortical area that gives rise to the circuit; that is, these are mostly closed channels. Distinct circuits influence distinct cortical areas and can control different aspects of motor, cognitive–executive, or emotional/motivational behavior. However, there is evidence that some BG-thalamocortical loops are partially open. For example, the ventral putamen of primates gives rise to a circuit that ultimately targets the primary motor cortex, which does not project to that part of the putamen. In contrast, this part of the ventral putamen receives amygdalar input, thus providing a route for limbic/emotional influence on motor output.

The lateral, motor thalamus (ventral anterior and ventral lateral nuclei) that mediates BG pathways to the cortex also receives cerebellar input, mostly mediated by the dentate nucleus. For this reason, it used to be thought that motor information from both BG and cerebellum converged on the same thalamic nuclei that project to the motor cortex. However, it is now clear that BG and cerebellar targets in the motor

thalamus are mostly segregated. Evidence indicates that although the BG and cerebellum reach the same cortical areas of the frontal or prefrontal cortex mostly by way of parallel thalamocortical channels, they target different sectors of each cortical area.

Direct, indirect, and hyperdirect pathways for release and inhibition of movement The BG-thalamocortical circuits consist of direct and indirect pathways, which have opposite roles on control of motor/cognitive functions. These are better known for the dorsal BG, which show segregated projections through the substantia nigra and primarily distinct parts of GP (Figures 3 and 5). The GPi and the SNr receive their major input from GABA+/SP+/DYN+ cells of the CPu and project to the motor thalamus (ventral anterior/ventral lateral nuclei of the ventrobasal thalamic complex). This striato-GPi/SNr-thalamic circuit constitutes the so-called direct pathway for BG control of movement (red color in Figures 3 and 5). Since the striatal, pallidal, and SNr projections are GABAergic, and the thalamocortical projection is excitatory, the activation of this pathway by the cortex or thalamus produces a disinhibition of the motor thalamus and ultimately produces activation of the motor cortex and a release of movement. This direct pathway is controlled by an indirect circuit, which originates in the GABA+/ENK+ cells of the CPu (blue color in Figures 3 and 5). The GABA+/ENK+ striatal neurons project to the GPe, which in turn projects to an excitatory hypothalamic center called the STN that projects to the GPi and SNr. Activation of this indirect pathway produces disinhibition of the STN and thus excitation of GPi and SNr. This ultimately inhibits the motor thalamus and blocks movement. It appears that the combined activation of both direct and indirect pathways releases desired movement while blocking unwanted movement.

In addition to the direct and indirect pathways for movement release and inhibition, there is a hyperdirect pathway that produces movement inhibition by way of a fast, direct motor cortical input to the STN.

Basal ganglia pathways to the brain stem In addition to the cortico-BG-thalamocortical reentrant loops, the BG also influences motor or cognitive behavior by way of descending projections to the brain stem. These projections are better known for the dorsal BG, which project to the SNr that in turn projects to the midbrain tectum (superior colliculus) (Figures 3 and 5). This pathway targets tectoreticulospinal cells located in deep layers of the tectum. The apical dendrites of these cells receive visual input from the retina, and this BG pathway is important for controlling eye, head, and neck movement and thus for control of visuomotor and orientation behavior. In addition, the SNr projection to the midbrain tectum targets ascending tectocortical cells, providing another mechanism for visuomotor control.

Figure 5 Diagrams representing basal ganglia (BG) functional models in mammals (top) and birds (bottom). Based on the similarity of cell types, neurotransmitters, and connections, it appears that the BG of birds and mammals use mostly similar mechanisms for control of motor behavior. These involve similar pathways to the midbrain tectum (superior colliculus), which are very prominent in birds, and similar pathways to the frontal cortex/dorsal pallium, which are extremely well developed in mammals. The BG projections involve direct and indirect pathways that are involved in either the release or inhibition of movement, respectively. The direct pathway (red) originates in SP+ cells of the striatum and is going to produce disinhibition of either thalamocortical projections or tectoreticulospinal projections, thus producing release of movement. Activation of the indirect pathway (blue) originates in ENK+ cells of the striatum and produces disinhibition of a glutamatergic center, the subthalamic nucleus (STN), that in turn projects to the direct pathway, producing the opposite effect. For simplicity, only a few centers and connections are included in the scheme (the pedunculopontine tegmental nucleus, which plays an important role in mammals, has been omitted but is discussed in the text). DA, dopamine; GP, globus pallidus; GPe, globus pallidus, external or lateral segment; GPi, globus pallidus, internal or medial segment; PT, pretectal nucleus of the posterior commissure (it receives BG input); SNc, substantia nigra pars compacta (A9 catecholamine cell group); SNr, substantia nigra pars reticulata; VB, ventrobasal thalamus.

On the other hand, the ventral BG and the adjacent parts of the dorsal BG project to the pedunculopontine tegmental nucleus (PPN) and laterodorsal tegmental nucleus (LDT) in the reticular formation of the rostral hindbrain (Figures 3–5). The PPN and LDT are cholinergic cell groups that belong to an ascending activating system that reaches widespread areas of the cortex and striatum mainly by way of the intralaminar/midline nuclei of the thalamus. Through these projections, the PPN and LDT appear to play an important role in arousal and awareness. Thus, through projections to the PPN/LDT, the BG are able to influence this important aspect of cognition. Moreover, the PPN projects to the SNc and globus pallidus, and it is reciprocally connected with the SNr and STN. The PPN is able to influence BG-thalamocortical recurrent circuits and has been proposed to be an important actor for BG control of motor behavior.

In addition, the PPN projects to the midbrain tectum (which has been related to orienting behavior and initiation of saccades) and also shows descending projections to medullary systems (Figures 3–5). These pathways through the PPN constitute additional links for BG modulation of tectal outputs and other descending systems involved in motor control.

Modulation of basal ganglia activity As noted previously, activity of striatal principal neurons is modulated by ascending projections from dopaminergic, serotonergic, and noradrenergic groups of the brain stem (A8–A10 cell groups, raphe nuclei, and locus coeruleus, respectively) (Figures 3–5). The best known of these is the modulatory input from dopaminergic cells of the ventral tegmental area (A10), the substantia nigra pars compacta (SNc, A9), and the retrorubral field (A8). In the striatum, dopamine activates GABA+/SP+/DYN+ neurons while inhibiting GABA+/ENK+ (Figure 5). Depletion of the dopaminergic innervation of the striatum (as in Parkinson's disease due to gradual death of SNc neurons) produces movement abnormalities. This releases the indirect pathway from inhibition, producing unwanted movements (tremor) at rest during initial stages. This also produces loss of excitation of the direct pathway, gradually leading to bradykinesia (slowness of movements), postural instability, akinesia, and muscular rigidity at later stages. In addition, depletion of dopaminergic innervation leads to cognitive/emotional deficits. This is also observed in Parkinson's disease, which is partially due to loss of dopaminergic innervation in the striatum and prefrontal cortex, as well as cell loss in the locus coeruleus (and consequently loss of noradrenergic innervation in the ventral striatum) and in the PPN.

Whereas the dopaminergic input to the CPu mainly arises in the SNc (A9) and is important for movement control and cognition, the input to the ventromedial striatum (including the nucleus accumbens) mostly originates in the A8–A10 groups and appears important for motivation and reward.

The Basal Ganglia in Nonmammals

Conservative Evolution of the Basal Ganglia in Tetrapods

The BG have also been described in the basal (subpallial) telencephalon of birds, reptiles, and amphibians, suggesting that they are present in all tetrapod vertebrates (a group that includes mammals, birds, reptiles, and amphibians) (Figure 6). Similar to the BG of mammals, in these vertebrates the BG show striatal and pallidal subdivisions and also similar neurochemical characteristics and basic connections (Figure 1). This suggests that many of these features were present in the first tetrapod vertebrates, and that BG evolution has been highly conservative. However, important divergence in BG evolution appears to have occurred in the transition from stem tetrapods to amniotes (including birds, reptiles, and mammals; Figure 6) and later in the lineages to birds or mammals.

Developmental evidence supports basal ganglia homology The most important evidence supporting the homology of the BG across different tetrapod

Figure 6 Cladogram showing the phylogenetic relationship between different groups in vertebrates.

groups comes from developmental studies and expression of transcription factors. First, the BG in both mammals and nonmammalian tetrapods develop from the same (homologous) histogenetic division of the telencephalon, the subpallium, characterized by expression of Dlx/Distal-less family transcription factors and lack of pallial marker genes such as Emx1/2 and Tbr1/2 (Figure 2). Second, the subpallium of mammals and nonmammalian tetrapods contains the same two major subdivisions, namely striatal and pallido-pedunculo-preoptic subdivisions (Figure 2). The striatal subdivision (called LGE in mammals) expresses Dlx/Distal-less but not Nkx2.1/Titf-1 and gives rise to the striatum. The pallido-pedunculo-preoptic subdivision expresses Dlx/Distal-less, Nkx2.1/Titf-1, Lhx6, and/or Lhx7/8 and gives rise to the pallidum proper (called MGE in mammals), a pallidal part of the septum (septal pallidum), the anterior peduncular area (AEP), and a subpallial (anterior) part of the preoptic area (POa) (AEP–POa are related to part of the extended amygdala and the cholinergic cell groups of the basal telencephalon). Thus, the BG in all tetrapods consist of the same (homologous) two subdivisions, striatum and pallidum, which are formed from homologous histogenetic fields, located in the same topological position (same relative position within the brain), under the influence of the same transcription factors. Moreover, evidence indicates that these transcription factors play the same role in BG development in mammals and nonmammals. For example, Nkx2.1/Titf-1 is involved in specification of the pallidal subdivision in both mammals and nonmammals, and lack or depletion of function of this transcription factor produces severe malformation of this territory.

Comparable cell types, neurotransmitter organization, and connections Similar to mammals, the BG of birds, reptiles, and amphibians are rich in GABAergic neurons and typically show GABAergic, inhibitory projections (in contrast to the cortex/pallium, which shows glutamatergic, excitatory projections). As in mammals, the striatum of birds, reptiles, and amphibians is characterized by high acetylcholinesterase activity and dense dopaminergic innervation that originates in comparable cell groups of the mesodiencephalic tegmentum (A8–A10 cell groups). The striatum is the major input station (receiving input from both pallium/cortex and thalamus), and the pallidum is the major BG output center to the hypothalamus/subthalamus, thalamus, pretectum, and brain stem. The striatum, especially in amphibians and also in reptiles and birds, also contributes to some of the BG outputs.

Based on their relative position in the subpallium and connections, dorsal (dorsolateral) and ventral (ventromedial) parts of the striatum have been identified in amphibians, reptiles, and birds. As in mammals, the striatum projects to the pallidum in nonmammalian tetrapods, and each striatal division has an associated pallidal part.

Similar to the CPu of mammals, the dorsolateral striatum of birds and reptiles contains two major types of projection neurons: (1) GABA+/SP+/DYN+ neurons projecting to the pallidum and substantia nigra and (2) GABA+/ENK+ neurons mainly projecting to the pallidum (red or blue, respectively, in Figure 3). Although the dorsal pallidum in nonmammals shows no subdivisions, the dorsal striatopallidal projections from either SP+ or ENK+ cells end on different pallidal cells, and the pathways remain segregated at least in birds. The ventromedial striatum of birds and reptiles, and the striatum of amphibians, also contain ENK+ and SP+ GABAergic neurons projecting to the nigra and ventral tegmental area, although the segregation of both cell types is less clear. Regarding the interneurons, the striatum of birds and reptiles possesses at least the same three major interneuron subtypes described in mammals: acetylcholine, GABA/parvalbumin, or GABA/neuropeptide Y/somatostatin (the latter also contains nitric oxide synthase and shows NADPH-diaphorase-positive activity). Cholinergic and nitrergic/somatostatin-containing cells are also present in the striatum of amphibians, suggesting the presence of at least two interneuron subtypes (which were possibly present in the striatum of stem tetrapods). As in mammals, it appears that the striatal interneurons in nonmammalian tetrapods originate outside the striatum, in the histogenetic domain expressing Nkx2.1/Titf-1 (which includes the pallidal subdivision).

Similar to mammals, the dorsolateral striatum of birds and reptiles receives widespread cortical/pallial input (including from the dorsal pallium but also from other parts of the pallium) and projects to the dorsal pallidum (globus pallidus) (Figure 3). The ventromedial striatum of birds and reptiles, on the other hand, receives input from limbic parts of the pallium (including the pallial amygdala and the medial pallium) and projects to the ventral pallidum (Figure 4). The pallial input to the striatum is much more modest in amphibians and originates in limbic areas such as the medial pallium (hippocampal-like), the ventral pallium (pallial amygdalar-like), and a rostral pallial area reciprocally connected to olfactory areas (Figure 7). It seems that the striatum does not receive input from the dorsal pallium in amphibians. As in mammals, the whole striatum of birds, reptiles, and amphibians receives midline/intralaminar-like thalamic input. In addition,

Figure 7 Schematic drawings of lateral brain views of an amphibian (a frog) showing the main afferent (top) or efferent pathways (middle and bottom) of the dorsal and ventral basal ganglia (BG). All or most of these connections are also present in reptiles, birds, and mammals and were likely present in ancestral tetrapods. Ac, nucleus accumbens; Ap, pallial amygdala; DP, dorsal pallium; Hy, hypothalamus; INT, intralaminar thalamic nuclei; LDT, laterodorsal tegmental nucleus; LoC, locus coeruleus; MD, mediodorsal thalamic nucleus (midline thalamus); MP, medial pallium; OB, olfactory bulb; PPN, pedunculopontine tegmental nucleus; PT, pretectal nucleus of the posterior commissure (it receives BG input); PTh, prethalamus (ventral thalamus); Ra, Raphe nuclei; SNr, substantia nigra pars reticulata; STN, subthalamic nucleus; Str, striatum; TeO, optic tectum; Th, thalamus (dorsal thalamus); ToS, torus semicircularis (comparable to the inferior colliculus of mammals); VPa, ventral pallidum.

the striatum of amphibians receives important input from sensory thalamic nuclei. As a whole, in amphibians the thalamic input to the striatum is more important than the pallial input (Figure 7), and this was possibly similar in stem tetrapods.

On the other hand, in birds, reptiles, and amphibians the pallidum contains GABA+/LANT6+ neurons that project to the hypothalamus/subthalamus, thalamus, and brain stem in a pattern that partially resembles that in mammals (Figures 3, 4, and 7). Thus, the dorsal pallidum of nonmammals projects to the subthalamus and SNr, which is typical of the mammalian globus pallidus (Figures 3 and 7). The ventral pallidum of nonmammals projects to the lateral hypothalamus (adjacent to the subthalamus), the A8–A10 catecholamine cell groups (including the

ventral tegmental area and SNc), the cholinergic pedunculopontine/laterodorsal tegmental nuclei, and the locus coeruleus (Figures 4 and 7).

The ventral and dorsal pallidum of birds also show projections to distinct thalamic nuclei (midline- or ventrobasal-like) that project to either limbic or somatomotor telencephalic areas, respectively (including the dorsal cortex/pallium) (Figures 3 and 4). In addition, the ventral and dorsal pallidum of birds show projections to intralaminar-like thalamic nuclei (including the dorsointermediate nucleus, comparable to the parafascicular nucleus of mammals), which in turn show widespread projections to the striatum and pallium. These pallido-thalamo-telencephalic projections of birds partially resemble those described in mammals. However, in reptiles and amphibians only the ventral pallidum, but not the dorsal pallidum, projects to the dorsomedial thalamus (Figures 3, 4, and 7). The available data suggest the existence of similar ventral BG-thalamo-striatal pathways in all tetrapods (by way of midline/intralaminar-like thalamic nuclei). However, the BG-thalamo-pallial connection appears to be different between mammals and nonmammals. The BG-thalamo-telencephalic circuits are explained in more detailed in the next section.

In addition to the projections to the thalamus (dorsal), the pallida (dorsal and ventral parts) of mammals, birds, reptiles, and amphibians do share similar projections to the prethalamus (ventral thalamus), which involves an indirect BG influence on the thalamus (dorsal thalamus) and on thalamo-telencephalic projections (Figure 7). This BG projection to the prethalamus was likely present in the origin of tetrapods.

On the other hand, the dorsal pallidum of amphibians, reptiles, and birds projects to a pretectal nucleus characterized by the presence of GABA+/ENK+ cells that project to the tectum (Figures 3 and 7). Evidence suggests that the presence of a pallido-pretectal-tectal pathway was the primitive condition in tetrapods, but this BG pathway to the tectum through the pretectum has undergone a great reduction in the mammalian lineage and is apparently absent in rodents, carnivores, and primates. It would be interesting to analyze the presence of a BG-pretecto-tectal pathway in noneutherian mammals.

Functional circuits: Evidence for conservation and divergence Based on available data on neurotransmitters and connections, the BG of mammals, birds, reptiles, and amphibians share some basic circuits and appear to be involved in similar basic motor and limbic functions. However, some differences exist, indicating divergent evolution of some BG circuits in the avian and mammalian lineages.

Data on the dorsal BG are more abundant and suggest the existence of several pathways to the midbrain tectum in nonmammals, some of which are comparable to those of mammals (Figures 3, 5, and 7). For example, the dorsal BG of mammals and nonmammals show a comparable projection to the tectum by way of the SNr. This pathway appears to be present at least in all amniotes (mammals, birds, and reptiles). In addition, the dorsal BG of birds, reptiles, and amphibians possess another pathway to the midbrain tectum by way of the pretectum (through the nucleus of the posterior commissure in reptiles or its homolog in birds and amphibians). This BG-pretecto-tectal pathway shows great development in reptiles and especially in birds. As in mammals, these pathways to the midbrain tectum of nonmammals are suggested to be involved in BG control of eyes, head, and neck movement and in orientation responses. The involvement of nonmammalian BG in motor behavior has been evidenced in birds and reptiles by the observation of movement disorders following destruction of the dopaminergic innervation of the striatum.

There is evidence in birds indicating the existence of direct and indirect pathways in the BG projection to the tectum (red or blue in Figures 3 and 5). Thus, the dorsal BG projection to both SNr and pretectum comes directly from SP+ neurons of the striatum and indirectly through the pallidum by way of the ENK+ striatopallidal projection. Since striatal, pallidal, SNr, and pretectal cells involved in these projections are GABAergic, activation of the SP+ striatal cells will likely produce disinhibition of tectoreticulospinal neurons and release of movement, whereas activation of the ENK+ cells likely produces the opposite. Moreover, birds, reptiles, and amphibians appear to have a glutamatergic subthalamic center comparable (homologous) to the subthalamic nucleus of mammals (Figures 3, 5, and 7). The subthalamic nucleus of these vertebrates receives input from the dorsal pallidum (via the ENK+ striatopallidal pathway) and shows an excitatory projection to the SNr and pretectum, thus providing another indirect mechanism for BG movement control. Moreover, the subthalamic nucleus projects back to the dorsal pallidum and, possibly as in mammals, may influence the direct pathway (i.e., subthalamic axons contact pallidal cells receiving SP+ striatal input), providing another indirect mechanism for BG movement control (Figure 5).

In addition to the previously mentioned pathways to the midbrain tectum, birds have a dorsal BG pathway to a somatomotor area of the dorsal pallium/cortex by way of a dorsal thalamic center (ventrointermediate area of birds, comparable to the motor part of the ventrobasal complex of mammals)

that resembles in many respects the well-known BG-thalamo-motor cortical circuit of mammals (Figures 3 and 5). Similar to mammals, this pathway in birds shows a direct, SP+ striatopallidal circuit and an indirect ENK+ striatopallidal circuit that controls the direct channel through a glutamatergic center of the subthalamus. As in mammals, based on their similar neurotransmitters and connections, it is likely that activation of the direct circuit produces release of movement, whereas activation of the indirect circuit produces inhibition of unwanted movements.

The striking similarity of avian and mammalian dorsal BG pathways to dorsal pallium suggests that they are homologous. In addition to the specific dorsal BG pathway to the dorsal pallium by way of a ventrobasal-like thalamic nucleus, the dorsal BG of birds and mammals show comparable projections to an intralaminar-type thalamic nucleus (dorsointermediate nucleus or DIP in birds, comparable to the parafascicular nucleus of mammals) that projects to the telencephalon (to both striatum and cortex/pallium). However, it seems that such dorsal BG pathways to the cortex/pallium by way of the thalamus do not exist in reptiles since the dorsal BG does not project to the dorsal thalamus in any reptilian species analyzed. Therefore, the most parsimonious interpretation is that mammals and birds evolved dorsal BG-thalamo-pallial pathways independently.

On the other hand, the pallido-thalamo-dorsal pallial pathway in birds is meager and likely has only a minor influence on motor control. Thus, in contrast to mammals, the BG of birds, reptiles, and amphibians exert their control on movement mainly (if not only) by way of pathways to the midbrain tectum.

Regarding the ventral BG, evidence indicates that they show many similar connections between mammals, birds, reptiles, and amphibians (Figures 4 and 7). This suggests that they are involved in similar basic functions by way of similar circuits. For example, in amphibians, reptiles, birds, and mammals, the ventral or ventromedial striatum receives input from the limbic cortex/pallium, including the medial (hippocampal) pallium and the pallial amygdala, and is reciprocally connected with the dopaminergic cells of the ventral tegmental. This suggests that, as in mammals, the ventral (ventromedial) striatum of birds, reptiles, and amphibians may be involved in functions such as motivation/reward, attention, and learning, and this has been shown in birds.

In addition, the ventral BG in birds, reptiles, amphibians, and mammals show comparable projections to the reticular formation of the rostral hindbrain, where the PPN and LDT tegmental cholinergic nuclei are located (Figures 4 and 7). Considering the high similarity in the cholinergic systems among reptiles, birds, and mammals, it is likely that the BG projection to the PPN/LDT is a gateway for general activation of the telencephalon (pallium and subpallium) by way of intralaminar/midline thalamic nuclei (Figure 4). Thus, this may represent a BG pathway for control of arousal and awareness, which appears to be present at least in all amniotes. As in mammals, the cholinergic tegmental nuclei that receive BG input in nonmammals appear to represent a link for influencing descending tectoreticulospinal pathways (Figures 4 and 7) and perhaps for controlling some aspects of visuomotor and orientation behavior in nonmammals.

On the other hand, amphibians, birds, reptiles, and mammals show ventral BG projections to medial thalamic nuclei that project to the telencephalon (Figures 4 and 7). In mammals and birds, the relay in the medial thalamus includes both midline and intralaminar nuclei (Figure 4). The midline thalamic relay (mediodorsal nucleus of mammals and dorsomedial thalamic nuclei of birds) projects to the limbic-related ventral striatum and to specific areas of the pallium involved in cognitive tasks (prefrontal cortex in mammals and nidopallium in birds). The midline thalamic relay in birds also projects to the pallial amygdala. In birds and mammals, there is a closed cortico/pallio-BG-thalamocortical/pallial loop by way of the midline thalamus. However, the loop of birds is not comparable to that of mammals since it involves a pallial region (nidopallium, which derives from the ventral pallium) different from the neocortex (a dorsal pallial derivative). On the other hand, the intralaminar-like thalamic relay (e.g., the parafascicular nucleus of mammals and its putative avian homolog, the dorsointermediate nucleus) shows relatively wider projections to both striatum and pallium/cortex in both birds and mammals.

In reptiles and amphibians, the ventral BG projects to the dorsomedial thalamus, and this dorsomedial thalamic area projects back to the ventral BG (ventral striatum) (Figures 4 and 7). Based on its position and reciprocal connection with ventral BG, the dorsomedial thalamic nucleus receiving BG input of amphibians and reptiles resemble the midline and intralaminar nuclei of mammals and birds. The dorsomedial thalamus of reptiles that receives ventral BG input also projects to the pallium, including the ventrolateral pallium (posterior dorsal ventricular ridge (DVR) and pallial amygdala), resembling the projections of the midline thalamic nuclei of birds. A similar ventral BG-thalamo-ventrolateral pallial circuit is also present in amphibians (Figure 7) and may have been present in the brain of ancestral tetrapods. It appears that this basic pathway underwent a great elaboration especially in birds (most prominently in songbirds). In mammals, the midline thalamus has

also become very complex and includes nuclei (distinct from the BG-recipient mediodorsal nucleus) that project to the pallial amygdala and hippocampal formation. Perhaps all of these midline thalamic nuclei of mammals evolved from a basic cell group present in stem amniotes or stem tetrapods, similar to those of the dorsomedial thalamus of modern reptiles or amphibians (receiving ventral BG input and projecting to the pallial amygdala). On the other hand, based on the lack of projections from the midline thalamic relay to the dorsal pallium, reptiles, amphibians, and birds do not possess a circuit comparable to the ventral BG-thalamo-prefrontocortical loop of mammals.

Divergence and Novelties of the Basal Ganglia in Tetrapods

As noted previously, the BG share many features (in terms of development, subdivisions, cell types, neurotransmitter organization, and connections) across amphibians, reptiles, birds, and mammals, indicating a highly conservative evolution in tetrapods. However, as also noted, there are some differences between groups denoting the existence of divergent evolution and the appearance of novel features in the BG in some lineages within tetrapods. The major divergent steps apparently occurred in the transition from stem tetrapods to amniotes and later in the evolutionary lineages of birds and mammals.

Expansion of thalamus and cortex/pallium drove the evolution of basal ganglia-thalamocortical pathways The transition from a semiaquatic habitat, such as that used by amphibian tetrapods, to a fully terrestrial habitat, such as that used by reptiles, was accompanied by dramatic changes in the locomotor (musculoskeletal) system, sensory organs, and related centers of the central nervous system. This apparently drove the expansion of the dorsal thalamic centers involved in sensory processing and also the expansion of their telencephalic targets, especially in the pallium. Of particular relevance was the expansion of the pallium, with the appearance of specific areas involved in sensory processing, association, and sensorimotor integration. Within this framework, the pallium/cortex displaced the subpallium as the major center for processing and integrating the complex and fast-changing information of the new habitat and as the major executing center in terms of response. This task was done in conjunction with the subpallium and was accompanied by great development and elaboration of cortico/pallio-BG projections. This is the pattern observed in modern reptiles, as well as in birds and mammals, with a large to huge expansion of the thalamus and cortex/pallium, and, with respect to amphibians, a large expansion of the thalamocortical/pallial and cortico/pallio-BG projections. The richer and more elaborated information that reaches the BG in reptiles (as well as birds and mammals) mainly through the pallium/cortex suggests that in these animals, this structure plays a more sophisticated role in motivation, learning, and motor control than in amphibians.

The thalamus, the cortex/pallium, and the associated BG, as well as their projections, have continued to expand in the evolutionary lineages of birds and mammals. This has been accompanied by the evolution of additional direct BG projections to the dorsal thalamus, by the elaboration of preexistent BG-thalamocortical/pallial pathways, and by the appearance of novel BG-cortical loops (e.g., the dorsal BG-thalamo-dorsal pallial/neocortical pathways). Since the dorsal BG pathways to the neocortex/dorsal pallium via the thalamus are not present in modern reptiles, it seems that these circuitries evolved independently in birds and mammals.

An interesting aspect of this evolution is that birds and mammals have expanded different sectors of the thalamus and associated pallium. Thus, birds show the greatest expansion in the collothalamus (part of the thalamus receiving sensory input from the colliculus/tectum) and in the ventrolateral pallium (which gives rise to a large pallial structure, the DVR, that includes the nidopallium of birds; at caudal levels it includes the pallial amygdala). In contrast, mammals show the greatest expansion in the lemnothalamus (part of the thalamus receiving sensory input directly from the lemniscus or from the retina) and associated dorsal pallium (neocortex). As a consequence, the nature of the pallial input that primarily reaches the BG differs between mammals and birds. This is explained in more detail later.

The medial striatum of songbirds and budgerigars: Specialization in song/vocalization learning and plasticity A major medial part of the medial striatum of birds (previously called lobus paraolfactorius) shows cellular and connectivity patterns that resemble the ventral (ventromedial) striatum of mammals, such as the nucleus accumbens. This includes input from the medial (hippocampal) pallium and pallial amygdala; reciprocal connection with the dopaminergic ventral tegmental area; input from noradrenergic cells of the locus coeruleus; and projections to the ventral pallidum, hypothalamus, habenula, and pedunculopontine tegmental nucleus. This part of the striatum has been shown to be involved in reward and also in learning and memory formation. This part of the avian medial striatum appears to represent the viscerolimbic striatum (together with the olfactory tubercle), and it

appears to be involved in functions similar to those described for the mammalian nucleus accumbens, including motivation, reward, and cognitive functions such as learning and memory. The most lateral part of the avian medial striatum gradually shows features more typical of the mammalian CPu and is involved in motor control. As in mammals, there is no sharp boundary between the 'limbic' striatum and the 'somatomotor' striatum, and the transition from one to the other is gradual.

In oscine songbirds and budgerigars (e.g., the parrot), the medial striatum includes a specific area that is involved in song or vocalization learning and plasticity. This area of the medial striatum is called area X in oscine songbirds and the magnocellular nucleus of the medial striatum in budgerigars. Both striatal areas are part of highly elaborated pallio-BG-thalamopallial circuits, which together with other pathways and forebrain centers specific to songbirds or budgerigars control different aspects of song or vocalization (from learning to production) (Figure 8). These circuits of oscine songbirds and budgerigars are suggested to have evolved independently. Nevertheless, these circuits and the specific brain centers may have evolved from basic, less-elaborated pathways and centers present in the origin of the avian radiation. Supporting this, a number of studies indicate that area X shows many features typical of the surrounding medial striatum, including a majority of small spiny GABAergic neurons containing SP or ENK, cholinergic, and GABAergic interneurons; glutamatergic input from the ventrolateral pallium (including a nidopallial center called LMAN); and a reciprocal connection with the ventral tegmental area (among others). An interesting aspect of area X is that it contains a pallidal-like cell type that projects to a specific nucleus the thalamus (medial part of the dorsolateral nucleus) that in turn projects to LMAN (thus closing the loop) (Figure 8). The physiological properties of this cell type are similar to those of typical pallidal cells, including being spontaneously active and capable of sustained high-frequency firing. This has led to the suggestion that area X is a mixed striatopallidal area. Interestingly, the pallidal-like cell type of area X receives input from the spiny neurons of this area (which are typically striatal and receive direct pallial input), indicating that area X contains the basic elements for a typical striato-pallido-thalamic direct pathway (the striatal and pallidal cells are depicted in pink or purple, respectively, in Figure 8). Moreover, not all pallidal-like cells of area Xproject to the thalamus. There is a subpopulation of pallidal-like cells that project to other pallidal-like neurons of area X projecting to the thalamus, thus providing an indirect BG route to the thalamus. All of this evidence raises the possibility that the pallidal-like cells of area X are truly pallidal (i.e., they originate in the pallidal subdivision of the subpallium). However, these cells do not appear to express the transcription factor Nkx2.1 (at least in adult animals, although this may be due to downregulation). On the other hand, these cells contain the neuropeptide ENK (typical in striatal cells). However, the globus pallidus in mammals also contains a subpopulation of ENK+ neurons, and this projects back to the striatum. Therefore, the exact nature of the pallidal-like cells of area X is unclear. Nevertheless, the majority of the features of area X (except the presence of the pallidal-like cells projecting to the thalamus, which represent a minority) are typically striatal and resemble the adjacent areas of the avian medial striatum. Interestingly, the medial striatum of non-songbirds, such as the chick, also contains pallidal-like cells and projects to the thalamus. Moreover, in chicks there is a ventral BG-thalamo-nidopallial loop that resembles that through area X in songbirds (Figure 4). This supports the view that area X of songbirds evolved from a striatal field showing some basic neurochemical and connectivity features that are common to most (if not all) birds.

Figure 8 Schematic drawing of a lateral view of a songbird brain showing circuits related to song production and learning. Note the existence of a basal ganglia–thalamocortical/pallial loop that plays a role in song learning and plasticity, which involves a specific nucleus of the medial striatum called area X. This nucleus appears to include spiny striatal neurons (pink) as well as pallidal-like neurons (purple). Cb, cerebellum; DLM, dorsolateral thalamic nucleus, medial part; HVC, high vocal center; LMAN, nidopallial nucleus of songbirds (lateral magnocellular nucleus of the anterior nidopallium; part of the ventral pallium); MSt, medial striatum; RA, nucleus robustus of the arcopallium (part of ventral pallium).

Limbic versus motor parts of the basal ganglia: Evidence suggests that the limbic part is prevalent in amphibians, reptiles, and birds As noted previously, the BG in tetrapods includes a ventromedial portion involved in motivational/emotional (viscerolimbic-like) functions and a dorsolateral part involved in

executive and motor functions. Both parts are also involved in cognitive functions such as learning. In mammals, the transition between both parts is gradual rather than sharp, and this also appears to be the case in birds and possibly other tetrapods.

The motor/executive BG part shows the greatest development in mammals, and this is related to the development of the cerebral cortex (particularly the neocortex) and the sensorimotor lemnothalamus. In birds, however, a large part of the striatum (perhaps most of the avian medial striatum in songbirds and at least half of it in chicken or pigeon) appears to show viscerolimbic-type features and is involved in motivation, reward, and learning. This specific striatal part includes area X of songbirds, which has been proposed to be a specific part of the viscerolimbic BG specialized for song. This is related to the fact that in many birds, and especially songbirds, the ventrolateral pallium (including the nidopallium, mesopallium, and arcopallium) shows the greatest development, but the dorsal pallium (called hyperpallium or Wulst) shows a relatively moderate to small size (owls are an exception to this general rule since they show major development of the dorsal pallium). A large part of the medial striatum of birds receives input from the ventrolateral pallium (particularly from the pallial amygdala and nidopallium, which in songbirds includes LMAN and the high vocal center; **Figure 8**). In mammals, the homologous ventrolateral pallium – based on both embryological and molecular criteria – gives rise to the claustrum, pallial amygdala, piriform cortex, and perhaps the agranular part of the insular cortex, but not the neocortex. The latter derives from the dorsal pallium. The avian dorsal pallium (called hyperpallium) projects only to the lateralmost part of the medial striatum and to the lateral striatum, which appear to represent the somatomotor striatum. The lateral striatum (as the dorsal pallium) is particularly small in songbirds and budgerigars and, as a whole, the somatomotor striatum is relatively small compared to the viscerolimbic striatum. The situation may be different in owls, which possess a highly developed dorsal pallium (hyperpallium). This does not undermine the role of the BG and the pallium in birds. Birds do show a large and highly complex telencephalon which is involved in highly complex behaviors (e.g., song and vocalization learning and production; most mammals are unable to do this). The development of the ventrolateral pallium in birds has involved the appearance of numerous sensory, associative, and even motor centers without precedent in the ventral pallium of vertebrates and that cannot be functionally compared to the claustrum or pallial amygdala of mammals. This has involved the evolution of complex systems and pathways through the BG, which are involved in highly sophisticated functions such as song/vocalization learning. Birds therefore comprise a vertebrate group useful for studying BG evolution and its role in complex behaviors such as song and vocalization.

The telencephalon of modern reptiles shows an organization relatively similar to that of birds, with a large ventrolateral pallium (DVR) and a small dorsal pallium. This is also the case in amphibians, although the pallial and subpallial structures are much smaller in these animals than in reptiles. It is therefore likely that the reptilian and amphibian BG are mostly devoted to viscerolimbic functions.

The Basal Ganglia of the First Vertebrates: Evidence from Fish

Genetic embryological evidence, together with neurochemistry evidence and some connectivity patterns in adult teleost and cartilaginous fish, suggests the existence in jawed fish of BG comparable (homologous) to those of tetrapod vertebrates. The BG of jawed fish appear to contain striatal and pallidal subdivisions, expressing either only Distal-less or both Distal-less and Nkx2.1/Titf-1. The genetic evidence argues against the proposal of a mixed striatopallidal field in these animals. The striatal division is the so-called dorsal part of the ventral telencephalic area (Vd), whereas the pallidal division appears to be the ventral part of the ventral telencephalic area (Vv) (**Figure 9**). Supporting this, Vv is rich in cells containing parvalbumin (which is typical of the pallidal projection neurons in tetrapods). However, the pallidal field of jawed fish – derived from the Nkx2.1/Titf-1-expressing domain – appears to include mixed features of ventral pallidum, pallidal septum, and more basal telencephalic areas of tetrapods (all of which derive from the Nkx2.1-expressing domain).

Some neurochemical and connectivity features of the striatum of jawed fish resemble those of the tetrapod striatum. For example, the striatum of jawed fish (Vd) possesses GABAergic neurons containing SP or ENK that project to the pallidum (Vv). It also projects to pretectal and tegmental nuclei that, in turn, appear to project to the tectum. This suggests the existence of BG pathways to the tectum in jawed fish comparable to those described in tetrapods. Moreover, the striatum is reciprocally connected with a dopaminergic center of the diencephalic tegmentum comparable to a rostral part of the ventral tegmental area–substantia nigra (A10–A9 catecholamine groups) of tetrapods and also receives noradrenergic input from the locus coeruleus. This suggests that at least these basic aspects characterized the BG of the first jawed vertebrates. In addition, the striatum receives input from the pallium (from the field that appears comparable to the ventrolateral

Figure 9 Schematic drawing of a frontal section through the telencephalon of zebra fish (a teleost fish) showing the striatal (Vd) and putative pallidal (Vv) subdivisions. As in tetrapods, these two divisions derive, respectively, from subpallial domains expressing either Dlx1/2 or both Dlx1/2 and Nkx2.1/Titf-1 transcription factors. Similarly to mammals, the subpallial derivatives of zebra fish are rich in GABAergic cells. The striatum (red) contains peptidergic cells that project to the pallidum, and it is reciprocally connected with a dopaminergic cell group comparable to the A9–A10 catecholamine cell groups of tetrapods (substantia nigra and ventral tegmental area). The pallidum is rich in parvalbumin-containing cells but shows mixed connections, resembling the ventral pallidum (perhaps the dorsalmost aspect of Vv; blue) and pallidal septum of tetrapods. Dc, dorsal telencephalic area (pallium), central part; Dl, dorsal telencephalic area (pallium), lateral part; Dm, dorsal telencephalic area, medial part; Dp, dorsal telencephalic area (pallium), posterior part; Vl, ventral telencephalic area (subpallium), lateral part.

pallium of tetrapods, which includes the pallial amygdala and olfactory areas), thalamus, and several sensory areas in the hypothalamus and brain stem (including gustatory and visceral areas). The pattern of connections suggests that the BG in these animals may primarily be involved in viscerolimbic functions. Nevertheless, data suggest a role in motor functions (e.g., the observation of 'parkinsonian symptoms' following lesion to the dopaminergic systems).

In addition, the striatum of jawed fish shows direct projections to the pallium, which is not typical of the tetrapod striatum. This raises doubts about the homology of this striatal field of fish with the BG striatum of tetrapods, and it opens the possibility of homology with the striatal part of the septum (known to project to the pallium in tetrapods). However, evidence indicates that the striatum in reptiles and birds shows scarce direct projections to the pallium (including the ventrolateral pallium). This raises the possibility that perhaps such direct striatopallial projections were common in ancestral jawed vertebrates but were gradually lost during evolution within the tetrapod radiation.

The pallidum: A novelty of jawed vertebrates Comparative genetic embryological evidence from zebra fish (a teleost fish) and lamprey (a jawless fish close to the origin of vertebrates) indicates a major difference with regard to subpallial development and divisions, which have important implications for understanding the organization of the BG in the first vertebrates and for understanding their evolution. The subpallium of zebra fish, like that of tetrapods, has two major subdivisions: a subdivision expressing Dlx/Distal-less family genes that gives rise to the striatum and a subdivision expressing Dlx/Distal-less and Nkx2.1/Titf-1 homeobox genes that gives rise to the pallidum proper (in addition to a pallidal part of the septum and other cell groups of the basal telencephalon). In contrast, Nkx2.1/Titf-1 is not expressed in the telencephalon in lamprey, meaning that this jawless fish lacks a pallidal subdivision in the subpallium (Figure 10). This is in agreement with the apparent absence of a pallidum in adult lampreys based on neurochemical and connectivity studies. This suggests that the BG of the first vertebrates was only striatal-like, and the pallidum appeared during or after the transition from jawless to jawed vertebrates. This was apparently related to the appearance of a novel expression domain of Nkx2.1/Titf-1 in the basal telencephalon. An important question that remains to be answered concerns what factor(s) triggered this new expression in the telencephalon, although evidence suggests that this may partially be related to sequence changes in the regulatory region (promoter/enhancer) of Nkx2.1/Titf-1.

No pallidum, no immigrant interneurons in the striatum? In tetrapods, the Nkx2.1-expresssing domain of the basal telencephalon (including the pallidal and other basal subdivisions) appears to be the source of the interneurons of the striatum. This has been shown for the striatal interneurons containing acetylcholine, parvalbumin, and nitric oxide/somatostatin/neuropeptide Y. The absence of a domain expressing Nkx2.1/Titf-1 in the basal telencephalon of lamprey suggests that the striatum in this jawless fish lacks immigrant interneurons comparable to those of tetrapods. These may have started to appear after the evolution of the Nkx2.1-expressing pallidum, involving a tangential migration of some cells from the pallidal subdivision into the striatum. However, this may have been a gradual process since, of the three major interneuron subtypes present in the striatum of amniotes (mammals, birds, and reptiles), only two subtypes are present in the striatum of amphibians (cholinergic and nitrergic/somatostatin-containing cells), and only one subtype (possibly nitrergic/somatostatin-containing cells) appears to be present in the striatum of jawed fish. In contrast to this view, one study has shown the presence of extremely few cholinergic neurons in the striatum of lamprey, raising questions

Figure 10 Schematic drawings of the embryonic brain (lateral view) of different vertebrate groups showing the striatal (St) and pallido-pedunculo-preoptic (Pa-AEP) domains in the subpallium, based on the expression of either Dlx/Distal-less family genes or both Dlx/Distal-less and Nkx2.1/Titf-1. Note that Nkx2.1/Titf-1 is not expressed in the embryonic telencephalon of lamprey, which is correlated with the apparent absence of a pallidum in adult animals. Ha, alar hypothalamus; Hb, basal hypothalamus; MB, midbrain; P, pallium; Pt, pretectum; PTh, prethalamus (ventral thalamus); Sp, subpallium; Th, thalamus (dorsal thalamus).

about the origin of these cells. On the other hand, the striatum of fish contains TH+ cells, and at least some of these may be native striatal interneurons.

The case of TH+ cells in the striatum of fish: Do they come from a dLGE-like subdivision? A striking feature of the striatum of teleost and cartilaginous fish is that it contains neurons expressing tyrosine hydroxylase (TH; the rate-limiting enzyme of catecholamines) and dopamine (DA). This is a feature that has not been observed in the striatum of amphibians, reptiles, or birds. In recent years, however, with the development of *in situ* hybridization techniques for mRNA detection, it has been possible to identify a subpopulation of TH+/DA+ cells in the striatum of rodents and primates which appear to represent interneurons. As such, it would be interesting to reinvestigate their existence in other vertebrate groups. In

mammals, the dLGE is known to produce TH+/DA+ interneurons that migrate tangentially to the olfactory bulb. It is likely that this same embryonic subdivision is the origin of the striatal cells containing TH and DA. Could the TH+/DA+ cells of the fish striatum originate in an embryonic dorsal striatal subdivision comparable to dLGE of mammals? To answer this question, it would be necessary to analyze the expression of transcription factors typical of that subdivision, such as Pax6, and to study experimentally whether this would produce the striatal TH+ neurons. In the meantime, it is worth noting that the striatum of cartilaginous fish appears to have two main subdivisions, and the dorsal one is rich in TH+ cells and shows a close relationship to the olfactory bulb, resembling the relation between dLGE and the rostral migratory stream into the olfactory bulb observed in mammals.

Functional Anatomy of the Basal Ganglia

General Circuit Overview

The term 'basal ganglia' encompasses the striatum, the external and internal segments of the globus pallidus (GPe and GPi, respectively), the pars compacta and the pars reticulata of the substantia nigra (SNc and SNr, respectively), and the subthalamic nucleus (STN). These structures are components of larger cortico–subcortical reentrant pathways (see Figure 1). Anatomical and physiological studies have shown that the basal ganglia, thalamus, and cortex are linked to form a system of segregated parallel circuits, which permit the basal ganglia to simultaneously participate in different functions, such as movement, reward, and procedural learning. Five major circuits have been identified, and were named after the presumed functions of the cortical areas they involve: a 'motor' circuit, centered on the precentral cortical motor fields; an 'oculomotor' circuit, originating from the frontal and supplementary eye fields; two prefrontal circuits, involving the dorsolateral prefrontal and lateral orbitofrontal cortices; and a 'limbic' circuit, centered on the anterior cingulate and medial orbitofrontal cortices. Each of these circuits may be composed of several subcircuits.

Although these circuits originate and terminate in different cortical areas, and occupy different domains in the basal ganglia and the thalamus, they share certain anatomical features, which are outlined in the simplified schemes shown in Figures 1 and 2. Each circuit arises from a separate cortical area and passes through different portions of the striatum, GPe, GPi, SNr, and STN, and parts of the ventrolateral, ventral anterior, and mediodorsal (VL, VA, and MD, respectively) thalamus. In each of these loops, the striatum and STN serve as 'input' stages of the basal ganglia, whereas GPi and SNr serve as 'output' stages, sending inhibitory projections to thalamus and brain stem. The thalamus projects back to the cortical areas of origin of the respective circuit to complete the reentrant loops.

Motor Circuit

Of the different circuits passing through the basal ganglia, the motor circuit has received the most attention, because abnormalities in this circuit may play a major role in the development of the motor abnormalities in Parkinson's disease and other movement disorders. The motor circuit arises from the precentral motor fields and engages the putamen, the 'motor' portions of GPe, STN, and GPi/SNr, as well as parts of the VL thalamus. The circuit is organized into somatotopic regions that contain groups of neurons which discharge either in conjunction with the preparation for or the execution of limb movements. The motor circuit may also play a role in motor functions, ranging from the scaling of kinematic parameters such as the amplitude or velocity of movement, the initiation or execution of internally triggered movements, the sequencing of movements, and the switching between movements or motor programs, to a role in procedural learning.

Direct and Indirect Basal Ganglia Pathways

Two major projection systems link the striatum to the output structures of the basal ganglia (Figure 2, left panel): a monosynaptic inhibitory (γ-aminobutyric acid (GABA)ergic) 'direct' pathway between striatum and GPi/SNr, and a polysynaptic 'indirect' pathway which involves GPe and STN. In the indirect pathway, the projections between the striatum and GPe, and between GPe and the STN are inhibitory (GABAergic), while the STN–GPi/SNr pathway is excitatory (glutamatergic). In addition, a reciprocal inhibitory connection between both segments of the globus pallidus which circumvents the STN is also considered as part of the indirect pathway.

The striatal neurons that give rise to the direct and indirect pathways differ in several ways which may strongly affect their functions. One difference is that in rodent experiments the two populations of striatal neurons appear to receive inputs from different populations of cortical neurons. Furthermore, direct pathway neurons receive stronger inputs from the intralaminar nuclei of the thalamus (the centromedian and parafascicular nucleus; CM/Pf), relative to indirect pathway neurons. Inputs from other thalamic nuclei (such as feedback circuits emanating from VA/VL) target direct and indirect neurons alike.

There are also biochemical differences between direct and indirect pathways. Although both groups of neurons are GABAergic, the direct pathway neurons express substance P as a cotransmitter, while indirect pathway neurons express enkephalin instead. Another important difference is that the activity of the direct and indirect pathways appears to be differentially modulated by dopamine, released from terminals of the nigrostriatal projection. Dopamine has been shown to inhibit the activity of striatal neurons

Figure 1 Schematic view of the large-scale anatomic organization of related areas of cortex, basal ganglia, and thalamus. All three structures form reentrant circuits which occupy anatomically distinct areas.

that give rise to the indirect pathway via activation of dopamine D2 receptors, and to facilitate the activity of direct pathway neurons via activation of D1 receptors.

Activation of the direct pathway by cortical inputs would inhibit the activity of the output nuclei GPi and SNr, and thereby disinhibit thalamocortical projection neurons. In contrast, activation of striatal neurons that give rise to the indirect pathway would have a net excitatory effect on GPi/SNr activity and would thereby act to inhibit thalamocortical neurons (Figure 2, left panel). Dopamine may have a substantial effect on the balance of activity between direct and indirect pathways. Through its differential effects, exerted via activation of different dopamine receptor types, a reciprocal relationship may exist between striatal dopamine levels and basal ganglia output. Increased release of dopamine may activate the direct pathway and inactivate the indirect pathway so that basal ganglia output from GPi/SNr to the thalamus is reduced. Conversely, reduced release of dopamine would result in disinhibition of the indirect pathway and reduced facilitation of the direct pathway, leading to increased basal ganglia output. There is also evidence that dopamine may be released at extrastriatal sites, including the pallidum, STN, and SNr. For instance, dopamine released from local dendrites of SNc neurons may activate D1 receptors on terminals of the striatonigral projection. This may then result in increased local GABA release in the SNr and subsequent inhibition of the activity of SNr neurons.

The anatomic model described here can be applied to generate a description of the involvement of the basal ganglia in the control of movements. According to this model, movements are initiated at the cortical level. Cortical inputs to the basal ganglia may then transiently activate both direct and indirect pathways. A phasic increase of inhibition of GPi via the monosynaptic direct pathway may lead to a brief disinhibition of thalamocortical neurons, which may then allow increased activity in thalamic neurons projecting to specific cortical areas, thus facilitating the movement. Activation of the indirect pathway may increase GPi/SNr output and may thereby have the effect of inhibiting or stabilizing the activity in the thalamus and brain stem. This may suppress potential competing movements, or terminate ongoing movements.

While such models are attractive due to their simplicity, several new findings suggest that views based purely on the anatomic connections are not accurate. For instance, while in the older models the overall effect of phasic activation of corticostriatal projection neurons would entirely depend on the interplay between the direct and indirect pathways,

Figure 2 Activity in the basal ganglia–thalamocortical circuitry (normal) and overall activity changes occurring in parkinsonism and hemiballism. The basal ganglia circuits include striatum, external and internal globus pallidal (GPe, GPi, respectively) segments, substantia nigra pars reticulata and pars compacta (SNr, SNc, respectively), and subthalamic nucleus (STN). Cortical input reaches the basal ganglia via the corticostriatal and the cortico–subthalamic connections. Basal ganglia output is directed toward the centromedian (CM) and ventral anterior/ventral lateral (VA/VL) nucleus of thalamus, as well as the pedunculopontine nucleus (PPN). Excitatory connections are shown in gray, inhibitory pathways in black. In the parkinsonian state, loss of dopamine in the striatum results in activity changes throughout the basal ganglia (represented by the thickness of the connecting arrows), leading to increased basal ganglia output to the thalamus. In hemiballism, damage to the STN results in reduced excitatory input to the basal ganglia output nuclei, leading to a cascade of other changes throughout the entire circuitry.

it now seems that basal ganglia output may also be shaped by nonlinear effects that go beyond straight excitation or inhibition. For example, recent studies of the interaction between GPe and STN have shown that release from GABAergic inhibition does not simply allow STN neurons to return to their baseline activity, but may also result in significant transient rebound excitation of such neurons. Similarly, glutamatergic inputs to basal ganglia neurons may not only lead to activation of recipient neurons, but may also alter firing patterns, such as burst firing or oscillatory discharge. The impact of these transient changes on the overall functioning of the basal ganglia is not clear at this time.

At a yet higher level of complexity, recent work has suggested that some of the basal ganglia functions can only be understood in terms of coordinated interactions of large neuronal ensembles in cortex and basal ganglia. For instance, there is emerging evidence that ensemble activity involving large populations of basal ganglia neurons may play a prominent role in the transmission and processing of cortical oscillatory activity.

Pathophysiology of Motor Hypo- and Hyperkinetic Movement Disorders

Most movement disorders of basal ganglia origin are believed to arise from dysfunction of the 'motor' circuit, resulting in alterations of GPi and SNr output. Clinically, these disorders are dominated by either poverty of movement (hypokinetic disorders) or an excess of movement (hyperkinetic disorders). Hypokinetic disorders (e.g., Parkinson's disease) feature an impairment of movement initiation (akinesia) and reductions in the amplitude or velocity of voluntary movements (bradykinesia). By contrast, hyperkinetic disorders (e.g., chorea or ballism) are characterized by involuntary movements.

Hypokinetic Disorders

The most common hypokinetic disorder is Parkinson's disease, which is characterized by akinesia, bradykinesia, a 5 Hz tremor at rest, and muscular rigidity. The most salient pathological sign is the finding of degeneration of the SNc neurons that give rise to the dopaminergic nigrostriatal projection. The earliest and most prominent dopamine loss is found in the motor portion of the striatum, the putamen. Studies of the neuronal activity in the basal ganglia in primates which were rendered parkinsonian by treatment with the dopaminergic neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) have suggested the pathophysiological changes that are shown in Figure 2 (middle panel). According to this model, loss of dopamine in the striatum appears to have the opposite effect on the activity in the indirect and direct pathways, eventually leading to an overall increase in activation of GPi and SNr via the indirect

pathway, and reduced inhibition of GPi and SNr via the direct pathway.

Perhaps related to striatal dopamine loss, there are also morphological changes in striatal neurons in the Parkinsonian brain. These changes may further influence the balance between direct and indirect pathways. Thus, in postmortem tissue from patients with Parkinson's disease, the overall size of the dendritic tree of striatal cells and the number of specialized dendritic membrane compartments (spines) on striatal projection neurons that receive cortical and other inputs were significantly reduced. Similar changes, particularly affecting the indirect pathway, have also been documented in rodent models of the disorder.

The activity of indirect pathway neurons downstream from the striatum is also altered. For instance, GPe activity is reduced in MPTP-treated animals, whereas discharge rates in STN and GPi/SNr are increased. An important piece of evidence in favor of the hypothesis that STN overactivity directly contributes to the development of parkinsonism is that lesions of this nucleus ameliorate all of the major parkinsonian motor signs.

Imaging studies of cortical function have shown that the activity changes in the basal ganglia in parkinsonism are accompanied by reduced activity in related cortical motor areas. In addition, there is a task-dependent increase of activation in some cortical areas which are normally not activated under these circumstances. The aberrant activation of these areas may be the product of compensatory mechanisms which may add to the inefficiencies of movement generation in parkinsonism.

In addition to the rate changes, a variety of changes in discharge patterns may also play a role, ranging from increased synchronization between neighboring neurons to oscillatory burst patterns (Figure 3). Recent reviews of the pathophysiology of parkinsonism have emphasized synchronized oscillations in the basal ganglia, based largely on recordings of local field potentials (LFPs) in patients with Parkinson's disease undergoing functional neurosurgery. These recordings have suggested that abnormal beta-range oscillations develop throughout the entire basal ganglia–thalamocortical circuitry, and these may play a major role in the production of parkinsonian signs. At the same time, 'prokinetic' normal oscillations in the gamma range appear to be suppressed in the parkinsonian state. Several mechanisms have been described that may account for oscillatory and non-oscillatory changes in phasic discharge properties, including pacemaker mechanisms that result from the interaction of different nuclei (for instance, GPe and STN), membrane properties of individual basal ganglia neurons that may predispose these cells to the development of recurring bursts, or altered cortical activity patterns that may directly drive basal ganglia neurons.

Figure 3 Raster displays of spontaneous neuronal activity recorded in the internal segment of the globus pallidus in normal (a) and Parkinsonian (b) primates. Shown are 20 consecutive 1000 ms segments of data in each panel. Each of the short vertical lines in the figure represents a single action potential. In addition to an increase in activity, there are also obvious changes in the firing patterns, with a marked prominence of bursts and oscillatory discharge patterns in the parkinsonian state.

The link between abnormal network activity in the basal ganglia–thalamocortical circuitry and parkinsonian motor signs has not been firmly established. It appears that some aspects of akinesia and tremor are due to abnormal oscillatory bursting in the basal ganglia output nuclei. Bradykinesia may result from more specific disturbances of cortical processing by excessive phasic inhibition of thalamocortical circuits. Recent evidence indicates that damage to sites which are anatomically linked to the basal ganglia, but have historically not been considered to be part of these structures (in particular, the pedunculopontine nucleus), may also play a role in the development of akinesia.

Parkinsonism is also associated with nonmotor abnormalities, such as oculomotor disturbances, autonomic dysfunction, depression, anxiety, sleep disturbances, impaired visuospatial orientation, and cognitive abnormalities. It is likely that some of these impairments are due to abnormal discharge in nonmotor circuits of the basal ganglia, which may be affected by dopamine loss in much the same way as is the motor circuit. In addition, degeneration of neurons outside of the basal ganglia has been described to occur in Parkinson's disease. Thus, in addition to nigral damage, postmortem examinations of brains from parkinsonian patients show substantial damage in pigmented brain stem nuclei, the olfactory tubercle, and cortex.

Hyperkinetic Disorders

In contrast to hypokinetic diseases, hyperkinetic disorders appear to be associated with abnormally low basal ganglia output from GPi and SNr. Reduced basal ganglia output may arise from a shift of the balance of activity between direct and indirect pathway activity toward the direct pathway. Thalamocortical neurons under such conditions may become more responsive to cortical inputs or exhibit an increased tendency to discharge spontaneously, thus leading to involuntary movements. The involuntary movements seen in ballism and Huntington's disease, as well as those induced by dopaminergic drugs, may all arise from this mechanism.

The term 'hemiballism' refers to involuntary proximal limb movements on one side of the body; these are most frequently due to damage restricted to the contralateral STN (see Figure 2, right panel). The STN damage, in turn, is thought to lower the STN's excitatory drive on GPi. These changes have been directly demonstrated in primate and rodent experiments, in which STN lesions result in a significant reduction of tonic discharge in GPi and a decrease in the phasic responses of GPi neurons to limb displacement.

In early stages of Huntington's disease, degeneration of striatal neurons that give rise to the indirect pathway is thought to result in excessive inhibition of STN neurons and abnormally low GPi activation. This, in turn, may result in proximal and distal involuntary movements. In later stages of the disease, the degeneration spreads to involve direct pathway neurons, and the associated phenotype changes in many patients are reminiscent of parkinsonism. Perhaps as a consequence of extensive neuronal degeneration of nonmotor circuits, most patients also develop cognitive and emotional disturbances.

Dystonia, a movement disorder which is often associated with basal ganglia lesions, is dominated by abnormal twisting movements and postures. The pathophysiology of dystonia is poorly understood, most likely due to the fact that dystonia can be a symptom of a variety of diseases with very different pathophysiologic backgrounds. Recordings in dystonic patients suggest that discharge rates in GPi are reduced, likely due to overactivity along the direct pathway. Similar to parkinsonism, however, the level of synchrony of spiking activity of neighboring neurons is increased in dystonia, and there is increased bursting throughout the basal ganglia. Recently, oscillatory LFP changes have also been identified in this condition.

Surgical Treatments

As a result of the better understanding of the pathophysiologic abnormalities that may underlie movement disorders such as Parkinson's disease, neurosurgical interventions in the basal ganglia have been reintroduced as effective treatments for these conditions. Initially, neurosurgeons performed almost exclusively ablative procedures as treatments for movement disorders, including procedures such as pallidotomies or thalamotomies. In the meantime, however, the focus has shifted to deep brain stimulation therapy in which electrical leads are implanted into the basal ganglia or thalamus and are used for chronic high-frequency stimulation. Conceivably, both types of procedures work through elimination of disruptive basal ganglia outputs. While therapeutic lesion effects in Parkinson's disease are perhaps understandable in terms of a reversal of the described rate changes in the basal ganglia, deep brain stimulation may target predominately firing pattern abnormalities of the stimulated circuitry.

Nonmotor Symptoms Related to Basal Ganglia Dysfunction

Pathology in the nonmotor circuits of the basal ganglia may be important not only for the development of some of the nonmotor signs accompanying Parkinson's disease and other movement disorders, but also for several unrelated behavioral and psychiatric disorders. Because anatomical and functional details regarding these circuits and the disease associated with their dysfunction are not completely worked out, they are only briefly mentioned here.

The dorsolateral prefrontal circuit originates in Brodmann areas 9 and 10 of the cortex, and its subcortical route involves the head of the caudate nucleus, the dorsomedial portion of GPi, and the rostral SNr, as well as portions of the VA and MD nuclei of the thalamus. This circuit has been implicated

broadly in 'executive functions' – for instance, the organization of behavioral responses to complex problems or the use of verbal skills in problem solving. Damage to portions of this circuit is associated with a variety of behavioral abnormalities related to these cognitive functions.

The dorsolateral orbitofrontal circuit involves the lateral prefrontal cortex, the ventromedial caudate nucleus, and associated areas of GPi/SNr and thalamus. This circuit appears to play a role in the mediation of empathetic and socially appropriate behaviors. Consequently, damage to this area is associated with irritability, emotional lability, failure to respond to social cues, and lack of empathy.

The limbic circuit arises in the anterior cingulate gyrus of cortex and involves the ventral striatum (which also receives 'limbic' input from hippocampus, amygdala, and entorhinal cortices). The ventral striatum then projects to the ventral and rostromedial GPi and rostrodorsal SNr. From there the pathway continues to neurons in the paramedian portion of the MD nucleus of the thalamus, and back to the anterior cingulate cortex. This circuit may be important in motivated behavior and may convey reinforcing stimuli to diffuse areas of the basal ganglia and cortex.

In a general sense it appears that the psychiatric disorders resulting from dysfunction of the nonmotor circuits parallel those seen in the motor circuit. One of the best studied psychiatric disorders in this regard is obsessive–compulsive disorder. Functional imaging studies have demonstrated abnormalities in the activity of limbic basal ganglia–thalamocortical projection systems in patients with this disorder. Reminiscent of the situation in Parkinson's disease, patients with obsessive–compulsive disorder appear to access 'unusual' brain regions (such as portions of the temporal cortices) when they are confronted with stimuli that call for recruitment of corticostriatal systems.

Tourette syndrome, a disorder in which obsessive–compulsive symptoms occur in combination with vocal or motor tics, is likely associated with abnormalities in the limbic and motor basal ganglia–thalamocortical circuitry. Not unexpectedly, the motor symptoms in this disease are reflected in additional changes in brain activation, particularly in the sensorimotor cortices and supplementary motor area.

Finally, the basal ganglia may also be involved in the development of depression, even in the absence of motor dysfunction. Thus, positron emission tomography studies in patients with major depression have shown reduced metabolic activity or blood flow in cortical portions of the limbic system, especially the orbitofrontal cortex and prefrontal cortices, in conjunction with similarly reduced activity in related areas of the basal ganglia, particularly the ventral striatum and caudate nucleus. In addition, stimulation of the limbic portion of the STN, or the SNr in parkinsonian patients who are treated with deep brain stimulation, can induce dramatic mood changes, ranging from depression to mania.

Conclusion

Our understanding of the role of the basal ganglia in normal movement remains very limited. Much more is known about abnormalities associated with basal ganglia disorders. By contributing to the reemergence of neurosurgical and other interventions as treatments for movement disorders, models of basal ganglia dysfunction have already had a major impact in the treatment of diseases such as Parkinson's disease or dystonia.

The models described herein continue to evolve. Gradually, the view of the basal ganglia as a set of nuclei by which cortical activity is simply relayed back to cortex is replaced by more general organizational schemes in which single-cell spiking and large-scale oscillatory and nonoscillatory activities of local or spatially distributed ensembles of neurons play a role.

Basal Ganglia: Habit

A M Graybiel, Massachusetts Institute of Technology, Cambridge, MA, USA

Introduction

The study of habits has a long and distinguished history in the field of psychology and has now emerged as a dynamic field of interest in neuroscience. Habits are familiar to all of us as repetitive behaviors that we have acquired and that we can perform almost without thinking. Habits considered in this everyday sense are usually unobtrusive and helpful parts of our daily behavior. Examples range from how we comb our hair or put on our shoes to how we drive to work or how we interact with friends. A wide range of behaviors that are variously called mannerisms and rituals also fall into this category and are justifiably linked to the study of habits. These behaviors bring the study of habits close to work on the effects of social and emotional factors on behavior. Under many circumstances, habits can become urgently repeated, dominant parts of our behavior and as such can be undesirable, maladaptive, or even destructive. Habits related to taking drugs of abuse (typically called 'habit forming' drugs) fall into this category, and so do some of the other repetitive behaviors that we to varying degrees lack control of. In psychology, this broad set of behaviors have all been considered as reflecting a degree of automatization of behavior and have been contrasted with conscious, flexible behaviors in pursuit of goals and projects.

All these behaviors have in one or another way been linked with activity in the basal ganglia and the neural circuits of which the basal ganglia are a part. This link to the basal ganglia has in turn generated interest in the possibility that the brain circuits underlying habit formation are also implicated in the genesis of the repetitive behaviors that characterize a range of neurologic and neuropsychiatric disorders, such as Tourette's syndrome and obsessive–compulsive disorder. Before considering these circuits, it is important to consider how scientists have tried to sharpen the definition of habits.

Definitions of Habit in Cognitive Neuroscience

Most definitions of habit in cognitive neuroscience begin with habit learning. In studies of humans, a major approach has been to consider habits as behaviors that can be learned and performed with no or low levels of awareness ('implicitly'), in contrast to the facts and episodes that are acquired with conscious awareness ('explicitly'). In this view, habits result from the activity of basal ganglia-based procedural learning and memory circuits, and these are contrasted with circuits for explicit learning and memory, represented by the hippocampus and medial temporal lobe. Hippocampal damage, resulting in amnesic syndromes, leaves motor learning relatively intact, along with many automatic, habitual behaviors. By contrast, damage to the basal ganglia (most often damage to the striatum) leaves explicit learning relatively intact but makes implicit learning difficult or impossible. This contrast is based on studies of patients with focal brain damage and also on observations of patients with disorders including Alzheimer's disorder and Parkinson's disease. The famous patient H.M., with massive hippocampal/medial temporal lobe damage, lost the ability to store new 'fact' memories but was able to learn new procedures – for example rotor pursuit. Such an amnesic patient can learn a probabilistic (implicit learning) task, and yet can have absolutely no awareness of having learned it. Such a clean-cut division of labor of hippocampal and basal ganglia functions is probably overdrawn, as some studies emphasize, but nonetheless makes the point that habits are mostly below the level of high-level attention and conscious representation. Human brain imaging studies have confirmed differential activation of these two systems and have emphasized their complementary, if not competitive, functions.

Definitions of Habits in Psychology

In parallel with this work on human explicit and implicit learning systems, studies in animals have shown a rather similar dissociation between the animal's remembering explicitly where it went on a previous trial and its robotlike going to the same place regardless of the previous choice. These studies, mainly employing navigational tasks in mazes learned by rats, have suggested a similar division between behaviors dependent on the striatum and behaviors dependent on the hippocampus or temporal lobe. But these studies, like those with humans, have pointed out that the division between explicit and procedural (habit) learning may not just follow anatomic subdivisions. For example, basal ganglia (striatal) regions anatomically linked to the hippocampus exhibit some of the characteristics of hippocampal (explicit learning)

circuits, not implicit (stimulus–response; S-R) learning circuits. An influential attempt to define habits operationally in experimental animals rests on the basic idea that the animals can either act in a purposeful way, orienting their activity toward an outcome or goal, or can act without regard to the goal. If goal directed, the behavior was called action–outcome (A-O). But if the behavior became automatic to the point that the outcome was no longer guiding it, the behavior was considered to occur automatically in an S-R, reflexive way, regardless of outcome.

The advantage of this way of defining habits is that behavioral tests can be devised to determine the degree to which outcome matters. If reward is devalued (e.g., by pairing the reward with malaise-inducing treatments out of the task, or by simple satiation), a habit should continue, but an A-O behavior should be sensitive to the devaluation and decrease or cease. The reward devaluation paradigm can thus be used in lesion studies to determine which brain regions are responsible for the sensitivity to reward devaluation and which are not, the latter being candidate sites in 'habit circuits.'

Procedural Learning and Skill Learning

Work on habit learning directly intersects with the large field of work on procedural learning, which focuses on the transition from novice to expert behavior that occurs as a procedure is practiced repeatedly. In experimental studies, reaction times (simple and serial) are a principal behavioral measure: When responses are made repeatedly to a sequence of stimuli, the reaction times fall even if the participant is unaware of the repeating sequence and the sequence is learned implicitly. To the degree that skill learning produces a highly repeatable motor behavior – as in riding a bicycle or hitting a good backhand in tennis – there is much commonality with habit learning. However, would riding a bike with skill be called a habit? Probably not, unless the behavior were triggered in a context, repeatedly, as though with a goal in mind (e.g., riding around the park every morning for exercise before going to work).

The acquisition of skills and procedures engages a large set of neural circuits, including motor and premotor regions of the neocortex, the cerebellum, and the basal ganglia. Careful study of the patterns of activation of these regions during the course of skill learning has demonstrated a characteristic progression of activity from anterior to more posterior parts of these cortical networks and related regions of the striatum and cerebellum. This signature of learning bears many similarities to the patterns of changing activity observed in attempts to study habit learning, although direct comparisons are hampered by the fact that most of the habit learning studies have been performed in rodents, and with notable exceptions, most of the motor skill learning studies have been done in humans and other primates.

Emotional Habits, Social Habits, and Rituals

The field of habit learning naturally links up with the study of emotional behavior and with social and cultural practices, as so many of these are ritualized. This broad field cannot be covered here, but it is important to emphasize that the acquisition of habits occurs not only for sensorimotor behaviors, but also for behaviors that require only modest skill but engage the emotional and social sides of behavior. The customs and practices of societies, groups, clubs, and individual couples can be as dominant as idiosyncratic habits can be in an individual. Imaging studies are beginning to open up this field to neuroscience. Of interest are findings suggesting that some of the basal ganglia-based pathways engaged in habit learning are also engaged in these social contexts, and thus that the social contexts may be fundamental to the process of habit learning in many situations. This work ranges from the study of courtship and mating behaviors to the appreciation of art. At the same time, models of reinforcement learning and neuroeconomics are increasingly being applied to behaviors that are social in nature, further tying together these lines of work.

Lesion Studies and Attempts to Define a 'Habit Circuit' in the Brain

Lesion studies have long implicated the striatum in the performance of habits. Lesions that damage the striatum disrupt habit performance, but lesions that damage the hippocampus or amygdala disrupt such habits to a lesser degree or not at all. Early studies did not distinguish clearly the different parts of the striatum, but it has been established progressively that the lateral (sensorimotor) striatum is involved in the performance of habits, whereas more medial (associative) parts of the striatum are engaged in cue-based, conditional learning and performance. In the past 5 years, direct attempts have been made to use reward devaluation and related training schedules in experiments on rats to determine whether these anatomically defined striatal regions can also be distinguished in terms of differential involvement in A-O and S-R behaviors. The results suggest that they can be. Lesions of the medial striatum in rats disrupt A-O behavior. Specifically, if an animal has learned a behavior in a reward-based training paradigm and reward is then devalued, the animal's

sensitivity to the reward devaluation is reduced with medial striatal lesions (i.e., the animal repeats the habit). By contrast, lesions of the lateral striatum disrupt S-R behavior: the animal's lack of sensitivity to reward devaluation (defining habit) is decreased by lateral striatal lesions, so that now the animal does not repeat the habit.

These findings have been interpreted as indicating that the striatum, and particularly the lateral striatum, is critical for habit learning and that habits are 'stored' there. But much evidence suggests that this is not so. The basal ganglia are embedded in larger brain circuits that interconnect them with brain stem nuclei and with regions of the cerebral cortex. Even on anatomical grounds, then, it is preferable to think of the functioning of the striatum and related basal ganglia nuclei as parts of these larger circuits. For habit learning and habit memory, evidence from lesion studies supports this broader view. For example, regions of the frontal cortex of the rat modulate these A-O and S-R modes of behavior. If the infralimbic region of the frontal cortex is damaged, rats that otherwise would perform a task in the habit mode (regardless of outcome) now are sensitive to outcome. The relative dependence of behavioral performance on the striatum probably strongly depends on the particular behavior, as well as on specializations of different regions of the striatum for particular sensory, motor, and other behavioral contexts. For example, the ventral striatum is strongly and directly interconnected with regions of the limbic system, olfactory system, and parts of the hippocampus and may serve specialized functions. It is interesting that this region is critical for courtship behavior, a form of instinctual behavior closely related to learned habits and rituals. A part of the dorsolateral striatum is essential for the expression of the highly ritualistic grooming behavior called syntactic grooming. In some songbirds, a specialized part of the basal ganglia forms the core of a circuit necessary for song learning. Altogether these results suggest that the basal ganglia participate in both the learning of habits and the performance of acquired habits, even if the template for the behavior is not stored in a given part of the striatum.

Computational Framework for Studies of Habit Learning

The field of research on reinforcement learning is making a strong contribution to the study of habit learning. The fundamental concept is that an animal (or, more generally, an agent) with a goal to achieve explores the environment in pursuit of the goal receives feedback from the environment as he acts, and decides on which actions to take depending on this feedback. The animal needs to explore, but it also needs to exploit (i.e., select or avoid an action), and the balance between whether to explore or to exploit exists in the context of uncertainty, which exploring can reduce. But precipitous exploitation can be costly. The animal thus works probabilistically, estimating the values of subgoals, forming a policy to follow, and judging the value of particular actions in the context according to that policy. There is considerable interest in determining whether parameters in such reinforcement learning models – for example, sub-goal value, action value, and policy – are represented by activity in the brain, and evidence suggests that such parameters are indeed recognizable. The best examples of this congruence between experiment and theory are in relation to the firing of the dopamine-containing neurons of the midbrain and the striatal neurons that receive these projections. The firing of the dopamine-containing neurons suggests that these neurons correspond to the reward prediction error postulated by some reinforcement learning theories, notably the temporal difference algorithm. These neurons may also code uncertainty and action value. Action value and aspects of reward prediction are, in turn, congruent with the firing patterns of neurons in the striatum. These findings have prompted the view that basal ganglia circuits are active in relation to the exploration–exploitation balance in behavior and to the development of the best policy for obtaining reward. Some authors cast the development of a habit as establishing a fixed value for actions, and they contrast this aspect of basal ganglia (striatal) activity with a more flexible control of behavior in which fixed values are not assigned to behaviors. There are clear ties between these model-based views and the experimentally derived views of A-O and S-R behavior.

Addictions as Habits

When people or experimental animals are exposed repeatedly to addictive drugs, especially by intermittent exposure, many become addicted to the drug or drug class. This addiction is manifest by their seeking to take the drug repeatedly and by their extreme motivation to have and to take the drug. In humans, these behaviors can occur despite conscious awareness that the drug use is 'bad' (antisocial, dangerous, or even life-threatening) in the long or short run. The dopamine-containing neurons of the midbrain and their targets in the striatum and cortex are central to the acquisition and expression of such drug-induced habits. The induction of an addictive behavior requires the midbrain dopamine-containing neurons in the

ventral tegmental area, and the expression of the addictive behavior requires the ventral striatum (and allied circuits), principally including the nucleus accumbens. Studies have probed the relationship between these behaviors and the behaviors of nonaddicted animals performing habits. There are many similarities. A key aspect of the study of addiction is that the molecular and cellular bases of these behaviors can be studied in experiments by administering these drugs to animals or by having the animals self-administer the drugs. This work has great potential to uncover mechanistic bases of such extreme habits and perhaps of habit circuit functioning in general.

Chunking of Action Repertoires

These various views of the process of acquiring a habit – or a learned procedure or sequential behavior – have deep commonalities. One indication of this comes from studies in which chronic recordings have been made in the striatum as animals go through the process of acquiring a new behavior. This work suggests that there is a form of 'neural exploration' early in training, when the population of neurons fire in relation to virtually all aspects of the procedure, followed by a phase of 'neural exploitation,' in which the firing patterns of the neurons become tuned to selective aspects of the procedure. In the sensorimotor part of the striatum, the population of neurons eventually tend to fire the most at the beginning and end of the entire procedure, suggesting that they may help bracket or chunk the behavior after exploitation. Insofar as this part of the striatum helps to release or to inhibit actions, this chunking function could help to encode behaviors that are accepted as part of behavioral policy through a process of reinforcement-based learning. The explore–exploit framework has the added appeal that it is applicable also to the learning of behaviors such as singing in birds, in which the behavior goes through a prolonged period of babbling (exploration) before exploitation (the crystallized adult song).

Introduction

The basal ganglia are a group of subcortical nuclei involved in a variety of processes, including motor, associative, cognitive, and mnemonic functions. The dorsal division of the basal ganglia consists of the striatum (divided into the caudate nucleus and putamen by the internal capsule in primates and other species), the external segment of the globus pallidus (GPe; simply globus pallidus in rodents), the internal segment of the globus pallidus (GPi; entopeduncular nucleus (EP) in several species, including rodents and cats), the subthalamic nucleus (STN), and the substantia nigra (SN). The latter structure is divided into two main parts, the dorsal pars compacta (SNc), in which the dopaminergic nigrostriatal neurons are located, and the more ventral pars reticulata (SNr). In addition to these structures that are associated with motor and associative functions of the basal ganglia, there is a ventral division of the basal ganglia (ventral striatum or nucleus accumbens; ventral pallidum, which is equivalent to GPe and GPi; and the ventral tegmental area, which is a medial continuation of the SNc). The ventral division of the basal ganglia is primarily associated with limbic functions. The nomenclature of divisions of the basal ganglia can be particularly confusing to a reader new to the field. For this reason a table (Table 1) of commonly used terms and their synonyms or homologous structures is included.

The main transmitter used by neurons of the basal ganglia is γ-aminobutyric acid (GABA); as many as 99% of all basal ganglia neurons are GABAergic. The only exceptions are glutamatergic neurons of the STN, dopamine neurons of the SNc, and one population of interneurons in the striatum that utilizes acetylcholine. The major inputs to the basal ganglia are glutamatergic and are derived from the cerebral cortex and the thalamus. The main point of entry of the cortical and thalamic information to the basal ganglia is the striatum, although there are also significant projections to the STN (Figure 1). Virtually the entire cortical mantle projects onto the striatum. The corticostriatal projection is derived from several classes of cortical pyramidal neurons that predominantly innervate the ipsilateral striatum but also the contralateral striatum. The corticosubthalamic projection is derived from more restricted regions of the cortex (see below). The corticostriatal and thalamostriatal projections are highly topographically organized and impart functionality onto the striatum and, consequently, other divisions of the basal ganglia. The main synaptic targets of the cortical and thalamic inputs to the basal ganglia are the medium-sized densely spiny projection neurons of the striatum (Figures 2 and 3).

In what is now considered the classical view of basal ganglia circuitry, the functional organization is such that cortical and thalamic information is processed within the striatum and integrated with the many other inputs that reach the basal ganglia (e.g., from amygdala, hippocampus, and dorsal raphé), which primarily innervate the striatum, and then the 'processed information' is transmitted to the output nuclei of the basal ganglia, that is, the GPi (or EP) and the SNr, by two routes, the so-called direct and indirect pathways. In the direct pathway, cortical and thalamic information is transmitted directly from the striatum to the output nuclei. In the indirect pathway, cortical and thalamic information is transmitted indirectly to the output nuclei via the complex network interconnecting the GPe and STN. The basal ganglia then influence behavior by projecting, via the output nuclei, to the thalamus (mainly the ventral anterior and ventral lateral nuclear complex, mediodorsal nucleus and the intralaminar nuclei) that in turn projects back to the cortex or by projecting to subcortical regions that are involved in movement, including the superior colliculus, the pedunculopontine nucleus (PPN), lateral habenula, and reticular formation (Figure 1).

Overlying this feed-forward organization of the basal ganglia are many feedback pathways. The major one of these is the dopaminergic projection from the SNc that predominantly innervates the striatum but also innervates the STN and GPe. This projection modulates the flow of cortical and thalamic information through the basal ganglia. Loss of these dopamine neurons in Parkinson's disease leads to an imbalance of the flow of cortical information through the basal ganglia in favor of the indirect pathway and the motor symptoms associated with this disorder. Other feedback systems include the serotonergic projection from the dorsal raphé and the projection from the GPe to striatum (see later).

Table 1 Nomenclature

Commonly used name for a particular structure	*Homologous structure and/or synonyms*
Striatum	Neostriatum, caudate-putamen
Globus pallidus (rat)	External segment of globus pallidus (GPe; primate)
	Lateral globus pallidus (GPl; primate)
Entopeduncular nucleus (rat)	Internal segment of globus pallidus (GPi; primate)
	Medial globus pallidus (GPm; primate)
Ventral striatum	Nucleus accumbens

Striatum

The principal neurons of the striatum, the medium-size densely spiny neurons (MSN; Figure 3), give rise to the direct and indirect pathways. The MSNs have a perikaryon about 15 μm in diameter and give rise to several dendrites that are initially spine free but then become densely laden with spines after the first bifurcation. They account for up to 97% of striatal neurons in rodents but a smaller proportion in primates. They utilize GABA as their major neurotransmitter and are subdivided into two major subpopulations on the basis of their projection region, pattern of axonal collateralization, and neurochemical content. One subpopulation gives rise to the direct pathway, they preferentially project to the output nuclei of the basal ganglia (but also send a collateral to the GPe), and selectively express the neuropeptides, substance P and dynorphin, and D1 dopamine receptors. The other subpopulation gives rise to the indirect pathway, they exclusively project to the GPe and express enkephalin and D2 dopamine receptors. Both populations also give rise to local axon collaterals, the principal target of which are other MSNs. Axon terminals derived from MSNs form symmetric synapses (Gray's type 2) and their morphological features are similar in all their target regions (Figure 4(a)). Their spines are the main target of corticostriatal afferents and at least part of the thalamostriatal projection; both projections form asymmetric synapses (Gray's type 1; Figure 2). An individual cortical axon gives rise to only very few synapses with an individual MSN; since MSNs possess in the region of 10 000–15 000 spines, the implication is that there is a massive convergence of cortical axons (and possibly thalamic axons) on an individual MSN. The MSNs are also the principal target of the dopaminergic feedback from the SNc (spine necks, dendrites, and perikarya; Figure 2).

Figure 1 Simplified block diagram of the basal ganglia and their principal connections. The nuclei of the basal ganglia are included in the light blue box and consist of the striatum, the external segment of the globus pallidus (GPe), the subthalamic nucleus (STN), the substantia nigra pars reticulata and the internal segment of the globus pallidus (SNr/GPi), and the substantia nigra pars compacta (SNc). The two major inputs to the basal ganglia are from the cortex and the thalamus (mainly the intralaminar nuclei). The SNr and GPi constitute the output nuclei of the basal ganglia. The basal ganglia influence behavior by the output nuclei (SNr/GPi) projecting to the thalamus and thence back to the cortex, and projections to the superior colliculus (SC), the reticular formation (RF), the pedunculopontine nucleus (PPN), and the lateral habenula (HBN). Dopamine neurons of the SNc provide a massive feedback projection to the striatum and to the GPe and STN, which modulates the flow of cortical and thalamic information through the basal ganglia. In the now classical description of the organization of the basal ganglia, the output from the striatum to the output nuclei is referred to as the 'direct pathway' of information flow through the basal ganglia. This pathway leads to a disinhibition of basal ganglia targets and is considered to be associated with basal ganglia behavior. The 'indirect pathway' consists of the projection from the striatum to the GPe and the projection of the GPe to the STN and thence to the output nuclei. However, recent evidence suggests that the indirect pathway is much more complicated, involving a complex network interconnecting the GPe and the STN and the output nuclei. Furthermore, the STN receives input from both the thalamus and cortex. Activity in the indirect pathway is believed to underlie, at least in part, the resting inhibitory output from the GPi/SNr, and activation of the indirect pathway leads to a greater inhibition of basal ganglia targets and is considered to be associated with the attenuation of basal ganglia behavior. Dark blue indicates structures that are principally GABAergic, red indicates structures that are principally glutamatergic, yellow indicates structures that are dopaminergic, and green indicates structures with variable neurochemistry.

Figure 2 Synaptic connections of cortical, thalamic, and dopamine terminals in the striatum. (a) Electron micrograph of a section immunolabeled to reveal the vesicular glutamate transporter 1 (VGLUT1) as a marker of glutamatergic corticostriatal terminals and tyrosine hydroxylase (the rate-limiting enzyme in the synthesis of catecholamines; TH) as a marker of dopaminergic nigrostriatal axons and terminals. The VGLUT1 immunoreactivity was revealed by means of an immunogold method (electron-dense particles, which appear as dense black blobs), and the TH was revealed by an immunoperoxidase method (amorphous, electron-dense reaction product giving the labeled structure an overall dark appearance). The majority of cortical terminals typically form asymmetric synapses (Gray's type 1; arrowheads) with dendritic spines (sp) of the principal neuron of the striatum, the medium-size densely spiny neuron (MSN; see **Figure 3**). Note that cortical terminals make synaptic contact with the dendritic shafts of MSNs to a much lesser extent and also make synaptic contact with the dendritic shafts of interneurons. The TH-immunoreactive axon makes symmetric synaptic contact (Gray's type 2; small arrows) with the neck of the spine that receives the input from the cortical terminal. This spatial relationship between cortical terminals and nigrostriatal terminals has been considered the principal site of interaction between dopamine and glutamate in the striatum and, indeed, the basal ganglia as a whole. Note that dopaminergic terminals also contact the dendritic shafts and perikarya of MSNs and of interneurons. (b) Electron micrograph of a section of striatum immunolabeled in a manner similar to (a) except that the vesicular glutamate transporter 2 (VGLUT2) was used as a marker of thalamostriatal terminals. Axon terminals derived from the thalamus make synaptic contact with a higher proportion of dendritic shafts than do corticostriatal terminals, although the relative proportions of spines and shafts varies with the thalamic nucleus of origin. In this micrograph, one VGLUT2-positive terminal forms an asymmetric synapse (arrowheads) with a spine (sp; top left). A second VGLUT2-positive terminal forms asymmetric synaptic contact (arrowheads) with a dendritic shaft (den; lower right). Both the postsynaptic spine and the postsynaptic dendritic shaft receive synaptic input (small arrows) from TH-positive terminals, indicating that, at least in qualitative terms, the spatial relationship between glutamatergic thalamostriatal terminals and dopaminergic terminals is similar to the relationship between corticostriatal and dopaminergic terminals. Scale bar = 200 nm (a, b). From Moss J and Bolam JP (unpublished).

The striatum also contains at least three populations of GABA interneurons: (1) fast-spiking, parvalbumin (PV)-positive interneurons; (2) those that express nitric oxide synthase (NOS); and (3) those that express calretinin. The PV-positive neurons receive major inputs from the cortex, thalamus, and neurons of the GPe (see the next section) and provide an inhibitory input to the MSNs. The striatum also contains a population of large cholinergic interneurons that receive input from the cortex, thalamus and MSNs, and in turn innervate MSNs. The interneurons are also targets of the dopaminergic input from the SNc. The interneurons account for only a small proportion of striatal neurons (~3–10%, depending on species). In addition to its functional division into the direct and indirect pathways, the striatum possesses subcompartments, the striosomes (or patches), matrix, and matrisomes, which possess different neurochemical markers and have different input/output characteristics.

GPe

The main extrinsic synaptic target of MSNs that give rise to the indirect pathway are the neurons of the GPe. All GPe neurons are GABAergic and differentially express the calcium-binding proteins PV or calbindin. They are arranged in such a way as to expose

Figure 3 Golgi-impregnated medium-size densely spiny neuron (MSN) in the rat striatum. This is the principal neuron of the striatum, accounting for up to 97% of all striatal neurons. They are GABAergic, give rise to the output from the striatum, and give rise to local axon collaterals. The cell body is approximately 15 μm and in this focal plane gives rise to four primary dendrites. The dendrites are initially spine free and then become densely laden with spines, usually after the first bifurcation. An individual MSN possesses 10 000–15 000 spines, each of which receives a glutamatergic input at its head (see **Figure 2**). The axon is not visible in this micrograph, but segments of Golgi-impregnated axons (much finer structures), presumably derived from other neurons, are present in the field. At this anatomical level, the MSNs giving rise to the direct and indirect pathways are indistinguishable, as are MSNs from different species.

the maximum extent of their dendritic arbor to the incoming striatal afferents. Thus their principal input is from the striatum; pallidal neurons are ensheathed by striatal terminals in a manner similar to neurons of the GPi (**Figure 4(a)** and see below). However, GPe neurons also receive prominent inputs from the STN (**Figures 4(e) and 4(f)**) and from the local axon collaterals of other pallidal neurons. Individual GPe neurons in turn give rise to projections to functionally related territories of the STN, the output nuclei of the basal ganglia, and the SNc (**Figure 5**), where they form symmetric synapses predominantly with the cell bodies and proximal dendrites of their target neurons (**Figures 4(b), 4(c), and 6**). In addition, all GPe neurons give rise to local axon collaterals that underlie a complex and structured microcircuitry within the GPe (**Figure 5**). About a quarter of GPe neurons give rise to collaterals that innervate the striatum in addition to the projections described above (**Figure 5**). Their principal synaptic targets within the striatum are the proximal regions of the PV-positive and NOS-positive GABAergic interneurons. Because the main synaptic targets of the PV-positive GABAergic interneurons are the MSNs, and an individual interneuron can innervate several hundred MSNs, GPe neurons can theoretically control the activity of every neuron in the striatum. Thus, by virtue of their extensive axon collaterals, GPe neurons are in a position to influence the activity of neurons at every level of the basal ganglia. The strategically important placement of their synapses on the proximal regions of their target neurons (**Figure 6**), their GABAergic nature, and their high resting discharge imply a critical role in the modulation of the flow of information through the basal ganglia.

STN

The STN is a small nucleus located below the thalamus; it consists of a relatively homogeneous population of neurons that extend their dendrites in the principal plane of the nucleus. The most distinguishing characteristic of this nucleus is that, unlike the majority of neurons in the basal ganglia (99%), neurons of the STN use glutamate as a neurotransmitter and thus exert excitatory influences on their targets. Traditionally, the principal inputs of STN neurons have been considered to be derived from the GPe, and indeed these neurons provide the major inhibitory input to the STN (**Figure 4(c)**). In fact, the STN is reciprocally connected to functionally related regions of the GPe. Two other major inputs to the STN are derived from the cortex and intralaminar thalamic nuclei. The glutamatergic corticosubthalamic input is mainly derived from the motor, premotor, and prefrontal cortices and is exclusively ipsilateral and, at least in part, is derived from collaterals of cortical neurons innervating the striatum. The corticosubthalamic axon terminals form asymmetric synapses principally with small-diameter dendrites, and this pathway is the fastest route by which the cortex can influence the STN and, through the projections of STN neurons, the output neurons of the basal ganglia. The thalamic input to the STN is also glutamatergic, gives rise to asymmetric synapses with small-diameter dendrites, and is derived from those thalamic nuclei that also innervate the striatum. The STN also receives input from

Figure 4 Characteristic features of synaptic terminals of neurons of the basal ganglia. A series of electron micrographs illustrating typical ultrastructural features, synaptic specializations, and neurochemistry of synaptic terminals derived from the striatum (a), the external segment of the globus pallidus (GPe) (b,c), and the subthalamic nucleus (STN; (d–f)). The sections illustrated in (a), (c), and (f) were labeled by the postembedding immunogold method to reveal γ-aminobutyric acid (GABA) immunoreactivity, and the section illustrated in (e) was processed to reveal glutamate (GLU) immunoreactivity. (a) A striatal terminal (farthest to the left) in the internal segment of the globus pallidus (GPi) labeled following an injection of the anterograde tracer biotinylated dextran amine (BDA) in the putamen of a squirrel monkey. The terminal is identified by the electron-dense reaction product formed by the histochemical reaction to reveal the BDA. It is in symmetric synaptic contact (arrow) with a dendrite (den) and is immunoreactive for GABA (as indicated by the high density of immunogold particles overlying it). Two neighboring boutons (b1 and b2), which also possess the morphological features of striatal terminals, are also immunoreactive for GABA. These terminals are derived from the striatal medium-size densely spiny neurons. Contrast these with bouton b3, which forms an asymmetric synapse (arrowhead) and does not display GABA immunoreactivity. This bouton possesses morphological features of a terminal derived from the STN. (b, c) Terminals derived from the GPe forming symmetric synaptic contacts (arrows) with a dendritic shaft (den) in (b) and a perikaryon (peri) in (c). The terminal in (b) is in the rat entopeduncular nucleus (equivalent to GPi) and was labeled after an injection of the anterograde tracer *Phaseolus vulgaris* leucoagglutinin in the GP of the rat. The bouton in (c) is in the STN and was labeled after an injection of BDA in the GPe of the squirrel monkey. This section was incubated to reveal GABA immunoreactivity, and the labeled bouton displays a high concentration of immunogold particles overlying it, indicating that it is enriched in GABA. Note the similarity in the morphological characteristics of the pallidal boutons despite the fact that they are from different species and in different nuclei. (d) A terminal derived from the STN. This terminal is in the rat substantia nigra pars reticulata and was anterogradely labeled following the injection of the anterograde tracer biocytin in the STN. It forms an asymmetric synapse (arrowhead) with a dendrite (den) that contains retrogradely transported horseradish peroxidase (HRP) from the ventromedial thalamic nucleus, thus identifying it as a dendrite of a basal ganglia output neuron. (e,f) Adjacent sections of the same anterogradely labeled STN bouton in the GPe of squirrel monkey that forms an asymmetric synapse (arrowheads). The bouton is enriched in glutamate immunoreactivity (in (e)) but is not immunoreactive for GABA (in (f)). Note the similarity in the morphological features of the subthalamic terminals in different species and in different nuclei. Scale bar = 0.5 μm (a–f). From Smith Y, Bevan MD, Shink E, and Bolam JP (1998) Commentary: Microcircuitry of the direct and indirect pathways of the basal ganglia. *Neuroscience* 86: 353–387.

dopamine neurons of the SNc, serotonergic neurons from the dorsal raphé, and cholinergic inputs of the PPN.

The main outputs of the STN are to functionally related regions of the output nuclei of the basal ganglia, that is, the SNr (Figure 4(d)) and GPi (or EP). Individual STN neurons also innervate the GPe (Figures 4(e) and 4(f)), the PPN, and the dopamine neurons of the SNc. In each target, the terminals of STN neurons form asymmetric synapses, and at least some have been shown to be enriched in glutamate (Figure 4(e)). The placement of STN terminals is mainly on the proximal regions of their targets. The glutamatergic nature of STN neurons, their relatively high resting discharge rate, and their responsiveness to excitatory inputs from the cortex and thalamus underlie a critical role in setting the level of activity in basal ganglia output neurons.

SNr and GPi

The SNr and the GPi (or EP in rodents) represent the major output nuclei of the basal ganglia, sending their axons to the thalamus and thence back to the cortex or to subcortical structures involved in the control of behavior, including the superior colliculus, parvicellular reticular formation, lateral habenula, and the PPN (Figure 1). The relative importance of the two output nuclei in the control of behavior varies among species of different orders. Thus, output to thalamus from the GPi in primates is probably more important than the output from the SNr whereas in rodents, the output from the SNr is probably more important than that from the EP.

Basal ganglia output neurons are large GABAergic neurons with long, infrequently branching, aspiny

Figure 5 Individual neurons of the rat globus pallidus (GP) innervate multiple regions of the basal ganglia. Partial reconstructions of individual neurons from the rat GP that were labeled with neurobiotin *in vivo* by the juxtacellular method following electrophysiological characterization. These neurons were reconstructed from serial sections using a camera lucida drawing tube. The cell bodies and dendrites are shown in red, and the axon in black. In both cases the drawing of the axon has been cut in two; the ends of the axons marked 'a' connect with the ends marked 'b'. The upper neuron gave rise to local axon collaterals within the GP, and the main axon traveled through the internal capsule to the entopeduncular nucleus (EP), subthalamic nucleus (STN), and substantia nigra pars compacta (SNc) and pars reticulata (SNr). In addition to local axon collaterals and clear projections to the STN, SNc, and SNr, the lower neuron gives rise to two collaterals that innervate the striatum (STR). About a quarter of labeled GP neurons gave rise to collaterals that innervated the STR. Observations similar to these have been made in the external segment of the primate GP. The neuron of origin of those structures shown in gray could not be distinguished beween the two neurons. Scale bar = 300 μm. From Bevan M, Booth P, and Bolam JP (unpublished neurons).

dendrites. In the GPi at least, they are similar to GPe neurons in that their dendrites are arranged in such a way as to expose their maximum surface to the incoming striatal afferents. Their major input is from the MSNs of the striatum that give rise to the direct pathway; thus dendrites and perikarya are ensheathed in afferent terminals, most of which are derived from the striatum (Figure 4(a)). They also receive a prominent afferent input on their perikarya and proximal dendrites from the GABAergic neurons

Figure 6 Globus pallidus (GP) neurons form multiple contacts with the proximal regions of their target neurons. Light micrograph of the substantia nigra pars reticulata (SNr) of a rat, in which anterograde tracer was deposited in the GP and revealed by a peroxidase method. The perikarya of two SNr neurons are present in the center of the field (peri) and are apposed by many anterogradely labeled large axonal boutons (some indicated by small arrows) derived from the GP. This 'basket-like' innervation is typical of the manner in which GP neurons innervate their target neurons. Note that this section was taken from an animal that also received an injection of anterograde tracer in the striatum; the brown-labeled structures are thus of striatal origin. Scale bar = ~20 μm. From Smith Y and Bolam JP (unpublished).

of the GPe (Figure 4(b)) and glutamatergic neurons of the STN (b3 in Figures 4(a) and the labeled boutons in Figures 4(d)–(4f)). Individual basal ganglia output neurons thus receive synaptic input from both the direct pathway and the indirect pathway. The high resting discharge rate of neurons in the GPi and SNr underlies a tonic inhibition of neurons in the target regions of the basal ganglia under resting conditions. Increased activity of striatal afferents to these neurons leads to a reduction in their firing rate and hence reduced inhibition (i.e., disinhibition) of the targets of the basal ganglia. This disinhibition is considered to be a key factor in the way the basal ganglia influence behavior.

SNc

The SNc consists principally of dopamine neurons although some evidence suggests it also has a population, albeit small, of GABAegic neurons. The dopamine neurons lie in a densely packed band with the majority of dendrites following the plane of the compacta (Figure 7). Some dendrites, particularly of those neurons located in the ventral part of the compacta, also descend into the SNr (Figure 7). Dopamine neurons receive a dense innervation from GABAergic terminals derived from the striatum and the GPe and also receive glutamatergic input from the STN, cholinergic terminals from the PPN, and serotonergic terminals from the dorsal raphé. The axon emerges from the cell body or primary dendrite (and, rarely, a secondary dendrite). Dopamine neurons do not give rise to local axon collaterals within the SN, although it is evident that the dendrites can release dopamine and thus influence neighboring neurons. The main target of the axon is the striatum, but the GPe and the STN also receive a significant dopaminergic input via collaterals of the main axon. Individual dopamine neurons give rise to a remarkable number of synapses. Estimates vary between about 250 000 and 330 000 synapses at the level of the striatum, plus any additional synapses arising from collaterals in the GP and STN. The axon terminals of dopamine neurons give rise to symmetric synapses. The major targets in the striatum are the spines, dendritic shafts, and perikarya of MSNs (Figure 2). Synaptic contact on spines generally occurs at the neck, and the spine invariably receives a glutamatergic terminal derived from the cortex or thalamus, forming an asymmetric synapse (Figure 2). This spatial relationship underlies the modulatory role of dopamine on the excitatory influence from cortex and thalamus.

Concluding Remarks

For the sake of clarity, this description of the internal organization of the basal ganglia has been simplified, omitting many of the less well understood (but probably still important) synaptic connections. Furthermore, the description relies heavily on data derived from the dorsal division of the basal ganglia. Nevertheless, the basic principles of the connections

Figure 7 Micrographs and a digital reconstruction of an individual dopamine neuron in the rat substantia nigra pars compacta (SNc), recorded *in vivo* and then labeled with neurobiotin by the juxtacellular method. The neurobiotin, together with immunoreactivity for tyrosine hydroxylase (TH), were revealed by fluorescence methods ((a), inset). In this section the TH immunoreactive elements were revealed by a green fluorescent marker and the double labeling for TH and the neurobiotin by the yellow fluorescence. The labeled neuron was thus confirmed to be dopaminergic by the presence of immunoreactivity for TH. After neurochemical characterization, the neurobiotin and immunoreactivity for TH were localized by peroxidase reaction products, and the main panel in (a) shows the labeled neuron in the dense layer of TH-positive neurons in the SNc. The digital reconstruction in (b) shows the typical arrangement of the majority of dendrites of dopamine neurons that follow the plane of the SNc, with some dendrites descending into the SN pars reticulata (SNr). The axon of this neuron was followed to the globus pallidus, where is gave rise to a cluster of boutons, and then to the striatum. Scale bar = 25 μm; (a, inset) 500 μm (b). From Brown MTC, Bolam JP, and Magill PJ (unpublished).

described here also apply to the ventral division of the basal ganglia. One can thus conclude from the study of the functional organization of the basal ganglia that the complex functions of the basal ganglia are underpinned by an equally complex cellular and synaptic architecture.

Basal Ganglia: Motor Functions

M E Anderson, University of Washington, Seattle, WA, USA

© 2009 Elsevier Ltd. All rights reserved.

Although James Parkinson described the motor signs of the disorder that bears his name in 1817, the association between lesions of the basal ganglia and movement disorders was not really established until the clinico-pathological reports of Wilson and the Vogts in the early part of the twentieth century. Identification of this relationship led to a focus on the role of the basal ganglia in movement. In spite of recent evidence that the basal ganglia are involved in cognitive as well as motor function, abnormalities of movement are still the most visible and easily identified signs of basal ganglia dysfunction.

Anatomical Circuits: Skeletomotor and Oculomotor Systems

The basic connectivity from the cerebral cortex through the basal ganglia is shown in Figure 1. This type of circuit is repeated for many cortical areas, including the several motor areas of the frontal and parietal lobes. Cortical inputs to the basal ganglia are primarily to the striatum (both the putamen and the caudate nuclueus) and to the subthalamic nucleus. Output from the basal ganglia is entirely inhibitory, with γ-aminobutyric acid (GABA) as the neurotransmitter, and it originates from neurons in the internal segment of the globus pallidus (GPi) or the reticular portion of the substantia nigra (SNr).

The inhibitory output of GPi is largely destined for the ventrolateral and intralaminar nuclei of the thalamus and for the pedunculopontine region of the midbrain (PPN). That from SNr projects primarily to more medial and rostral areas of the ventral thalamus and caudally to the superior colliculus, as well as to the PPN. Anatomical tracing studies using viruses that are injected into various areas of cerebral cortex and then transported retrogradely and transsynaptically to the GPi or SNr showed that the basal ganglia origins of input to different cortical areas via the thalamus are segregated; that is, they are parts of parallel circuits. Furthermore, these parallel circuits form closed loops, with the basal ganglia output returning to an area of the cortex from which the cortical input is derived, via the striatum. For example, striatal neurons in the loop that connects the basal ganglia with the supplementary motor area also receive input from the supplementary motor cortex. In addition to these closed loops, a circuit may also be influenced by input from other cortical sources. Some of these are direct cortico-cortical connections (e.g., the primary motor cortex receives input from the supplementary motor area), and some are via the thalamus (e.g., from areas of thalamus that are connected to the prefrontal cortex). This allows the areas involved in the execution of motor output to be influenced by areas whose signals relate more to working memory, sequential order, or motor planning, in addition to the terminal kinematic or kinetic variables.

Some of the inhibitory output from the SNr is directed to the superior colliculus, which largely influences oculomotor and neck muscles and, hence, the eye and head position (see Figure 1). Another target of nigral inhibitory output is the pedunculopontine region of the brain stem, which especially affects posture and locomotion.

Additional elements in each circuit through the basal ganglia include the subthalamic nucleus, which provides glutamatergic excitatory synaptic input to both the pallidal segments and to the SNr (Figure 1), and the nigrostriatal dopaminergic system, which provides a modulatory action at several points in the basal ganglia, but most obviously at the putamen and caudate nucleus.

Thus, the loops through the basal ganglia that are relevant in the production of controlled movement may include those that originate from each of the areas of the frontal lobe, with individual areas contributing short-term memory, motor planning, sequencing of movement, or the speed and amount of force generation or displacement. The final consequence of signal processing in any of the loops through the basal ganglia is a change in inhibitory output for that circuit from GPi or SNr.

The Basal Ganglia Act by Varying Tonic Inhibition

Activity of Output Neurons in the Absence of Movement

Even when the animal is stationary, the inhibitory output neurons of the GPi and SNr are among the most active cells in the nervous system, with tonic discharge rates in the range of 50–100 Hz (see Figure 2). This tonic inhibition of neurons in the thalamus, superior colliculus, and PPN seems to provide stability to the system because transient suppression of activity in arm-related areas of GPi by local injection of muscimol, a $GABA_A$ receptor agonist, results in drift of the arm away from the hold position (Figure 3(b)). This drift can be corrected when something, such as a

change in the target light color, brings the error to the animal's attention. A similar instability occurs in the oculomotor system when muscimol is injected into the SNr, except that the eye movements off and back on the target are both rapid, producing what is called a saccadic jerk.

Figure 1 Basic connectivity from the cerebral cortex through the basal ganglia. GPe, external segment of the globus pallidus; GPi, internal segment of the globus pallidus; PPN, pedunculopontine region of the midbrain; SC, superior colliculus; SNc, compact portion of the substantia nigra; SNr, reticular portion of the substantia nigra; STN, subthalamic nucleus; VA/VLo, ventral anterior/ventrolateral nucleus of the thalamus.

Basal Ganglia Inhibition Changes During Movement

When a movement is to be made, activity changes in a select group of neurons in the SNr or GPi, cerebral cortex, superior colliculus, and presumably PPN. If the eyes are to produce a rapid movement (a saccade), the change is a decrease in SNr discharge, resulting in a disinhibition of the collicular neurons that are activated to produce saccade initiation. This pause in nigral activity occurs primarily when saccades are made to visual targets in the contralateral visual field and is enhanced when the target location must be remembered from a visual target presented briefly before a go cue. This rather simple reduction in inhibitory activity is adequate to facilitate movement in the oculomotor system, in which a rapid change in activity in agonist motor neurons drives the eye to the new location, but the movement is stopped by the viscoelastic properties of the eye and associated tissues.

When an arm movement is made, the changes in activity of the GPi neurons are more complicated, as is the spatiotemporal pattern of activity in the muscles used to control the multisegmented arm. When arm movements are tested in several movement directions, there is usually at least one for which the pallidal neuron's activity is at least initially reduced below the resting rate, although often followed by enhanced discharge, as shown in Figure 2. For the majority of movements, the GPi cell might actually have an increase in discharge. The reduction in GPi inhibitory activity facilitates the appropriate circuits to produce

Figure 2 Pallidal discharge during hold and perimovement periods. (a) Thick line, average position; thin lines, extreme position of the hand; dots, potential targets. (b) Discharge of a neuron in GPi. Lower rasters: time of action potential (each dot) in each trial (line of dots), centered in time around the beginning of the hold time (time 0, left panel) or around the beginning of hand movement (time 0, right panel). Upper histogram, average discharge rate. (c) Hand speed; thick line, average across trials; thin line, extremes of hand speed.

Figure 3 Instability of hand position induced by intrapallidal injection of muscimol. (b) Reproduced from Inase M, Buford JA, and Anderson ME (1996) Changes in the control of arm position, movement, and thalamic discharge during local inactivation in the internal globus pallidus of the monkey. *Journal of Neurophysiology* 75: 1087–1104, used with permission from The American Physiological Society.

muscle contraction in a select set of muscles, but the facilitation of GPi activity results in enhanced inhibition of thalamocortical neurons and reduced thalamic drive to selected areas of the motor cortices.

It has been proposed that the mixed pattern of suppression and activation of pallidal inhibitory output during limb movements is appropriate to produce a focused facilitation (disinhibition) of desired motor activation while suppressing undesired motor activity via the pallidal neurons whose discharge increases. This complicated change of activity in the GPi is appropriate to enhance the complicated spatiotemporal patterns of activation in agonist/antagonist groups of muscles associated with a variety of limb movements and to deal with changes in load encountered by the limbs.

Basal Ganglia Output Reflects Both Kinematic Variables and Movement Conditions

Basal Ganglia Output and Kinematic Variables

If basal ganglia output is to influence movement, we might predict a relationship between the kinematic variables of the movement, such as its direction, amplitude, or velocity, and the activity or change of activity in the basal ganglia output neurons during movements. On the other hand, changes in basal ganglia activity might reflect conditions under which the movement is made, such as with external sensory guidance, memory guidance, or a trigger for the next step in a sequence of movements.

The activity of movement-related GPi neurons, like that of neurons in motor areas of the cerebral cortex, is directionally tuned. That is, movement-related changes in activity are most pronounced for movements in a particular direction (referred to as the preferred direction). This preferred direction is consistent across movements of different speed and extent and does not vary when movements are made to remembered versus visible target locations.

Pallidal activity does vary with changes in the speed and/or extent of arm movements, especially in the preferred direction. This relation has been shown both by electrophysiological recordings of GPi activity in normal monkeys and by functional imaging studies in humans.

The importance of basal ganglia output to the control of arm movement can also be tested by examining the kinematics of movement when pallidal output neurons are temporarily inhibited with the $GABA_A$ agonist muscimol. In normal monkeys, this reversible inhibition generally results in slowed and hypometric movements. This could represent a failure both to inhibit antagonist muscles via enhanced pallidal activity in their circuit and to facilitate agonists via the temporally timed pause in activity in other circuits.

Task-Dependence of Motor-Related Changes in Basal Ganglia Activity

Beyond the kinematic aspects of movement that may be affected by the basal ganglia, it has been suggested that the basal ganglia are especially important in (1) controlling movements made under internal guidance,

such as those made to remembered target locations that are not indicated at the time the movement is to be made; (2) learning or combining movements into motor sequences; and (3) chunking activities, grouping them in a way that underlies habits or automatic behaviors.

Basal ganglia involvement in internally versus externally guided movements The magnitude of changes in pallidal activity is modified in different behavioral conditions, even if the movement direction, amplitude, and velocity are constant. When arm-related pallidal discharge is compared in normal monkeys under sensory-guided and memory-guided conditions, the activity of individual neurons is markedly influenced by the spatial or temporal memory demands of the task, although the sample as a whole may have no preferential difference in sensory- versus memory-guided conditions. This means that, although a group of neurons may have preferential changes for particular movement conditions, a range of movement conditions may be facilitated by selected groups of pallidal neurons.

The basal ganglia and movement sequences Several studies have indicated the importance of the basal ganglia in learning or implementing sequences of movements. Although other areas of the brain, including the cerebellum, may also play important roles in learning or implementing sequential movements, the basal ganglia consistently show activation during sequence learning and performance.

The locus of activation may change in the basal ganglia, however, as the sequence is learned. In functional imaging studies, the anterior dorsal (associative) portions of the striatum are active during initial explicit learning of a motor sequence, whereas the posterior ventral (sensorimotor) portion is more active when the sequence is overlearned. Furthermore, there is evidence that accuracy is positively correlated with the early signal in the anterior dorsal striatum, whereas reaction time is correlated (negatively) with the later signal in the posterior ventral putamen. In monkeys trained for varying amounts of time on different complex reaching sequences, the neurons in the caudate nucleus and putamen anterior to the anterior commissure are more activated while new motor sequences are learned, whereas neurons in the more posterior, sensorimotor putamen are more involved in the production of already learned sequences.

The basal ganglia and automatic movements or habits When movements – including complex sequences – are repeated sufficiently, they may be performed automatically. Experimentally, an automatic movement can be defined as one that is not disturbed by a concurrent cognitive or second motor task. The increase in errors produced during the concurrent performance of the second task may be used to evaluate automaticity.

Although several studies have suggested that the basal ganglia play a special role in the automatic phase of a learned task, these nuclei certainly are not uniquely active during automatic movements. Functional imaging studies, for example, show that the basal ganglia, like several other structures, are activated during both the acquisition and the automatic phases of a complex finger press task. In normal subjects, the high level of activation present in select areas of both the basal ganglia and the cortex during early stages of sequence learning may actually decrease and become more focused when task performance reaches an automatic stage. However, no new areas – cortical or subcortical – are uniquely activated when sequence performance becomes automatic.

The Influence of Dopamine on the Basal Ganglia and Movement

The role of dopamine in the basal ganglia is of special interest because it is primarily the dopaminergic nigrostriatal neurons that degenerate in Parkinson's disease. The major action of dopamine in the basal ganglia is on the striatal neurons, and the available data suggest that dopamine may influence both their intrinsic membrane properties and mechanisms of synaptic plasticity, such as long-term potentiation (LTP) and long-term depression (LTD).

In operant task conditions, dopaminergic neurons are active when animals receive an unexpected reward and briefly fall silent when an expected reward is absent. When the probability of reward differs for different targets in a task, the activity of primate midbrain dopamine neurons shifts based on the expected reward value for the target. Moreover, the gain of their stimulus-evoked responses reflects the variance of the reward value. And the activity of striatal neurons, which are known to receive dopaminergic input, also changes with target reward probability.

Pallidal neurons may show activity that is co-modulated with both movement direction and reward prediction. Furthermore, the predictive power of the pallidal activity changes dynamically during the course of a trial. It predicts reward more accurately at the beginning of the trial and is linked more closely to movement direction by the end of the trial. Such a combination of reward and kinematic signals could reflect both the cortico-basal ganglia-thalamocortical circuit in which the pallidal neuron participates and a synaptic weighting signal modified by dopamine on the basis of the reward. Thus, dopamine could

influence synaptic plasticity that couples reward or motivation to the activity of striatal neurons and, eventually, to the movement-related output of the basal ganglia.

Parkinson's Disease and Movement

The classic motor signs of parkinsonism include bradykinesia (slowed movement); a tremor at rest or during a static contraction; and rigidity, a tonic contraction of motor units, commonly resulting in flexion-biased postures of the trunk and limbs. Associated with these signs are deficits in balance, gait, and speech production. In general, patients do not demonstrate a strict weakness, nor do they report sensory loss. On more careful testing, the bradykinesia is usually linked to hypometric movements. Reduced movement amplitude, may, in part, be related to erroneous proprioception, which has been well-documented in parkinsonian subjects. Abnormal coupling of proprioceptive information with a motivational signal could lead to abnormal movement amplitude and velocity (the latter two usually covary).

The degree to which the basal ganglia are important for automaticity and habit learning also has been addressed in parkinsonian subjects, in whom usually automatic motor behaviors such as arm swing and postural adjustment commonly are depressed. Using the dual task already described to determine the degree to which sequential finger movements could be performed automatically (without disturbance from a concurrent task), parkinsonian subjects could achieve automatic performance of a four-step learned sequence. What most could not do, however, was to perform a longer sequence (12 steps) automatically, a task that most normal subjects performed successfully. Furthermore, functional imaging during automatic performance of the four-step task continued to show widespread activation in both the cortex and the basal ganglia of parkinsonian subjects, even when it was performed automatically, whereas the activation of these areas was more focused in normal subjects, who performed the four-step sequence automatically. Again, no new areas were activated in the basal ganglia of the parkinsonian subjects to achieve automaticity.

This continued widespread activation of cortical and subcortical areas, including the basal ganglia, during experimentally defined automatic motor performance of the short sequence in parkinsonian subjects is similar to that in normals during initial learning of either a short or a long task. Activity of the basal ganglia is not uniquely related to automaticity, but it is a part of a distributed network of activity that commandeers more of the brain when the task is novel and difficult and becomes more focused when the task is performed automatically.

Involuntary Movements after Levodopa Treatment

Since the early 1970s, the standard treatment for symptoms of Parkinson's disease has been oral administration of levodopa (L-DOPA), the precursor of dopamine that can cross the blood–brain barrier and be available in the brain parenchyma. Although this treatment (usually as Sinamet, in which L-DOPA is combined with a peripheral decarboxylase inhibitor to increase the central action) may be effective for several years, its effectiveness gradually diminishes and dyskinesias develop. These involuntary movements, which may sometimes appear similar to normal, puposeful movements, cannot be suppressed, and they markedly disrupt normal motor function.

During periods of dyskinesias, the tonic activity of the inhibitory basal ganglia output neurons in the GPi is unusually low and is interrupted by bursts. The absence of tonic pallidal inhibitory activity seems to leave the system unstable, with resulting uncontrollable movements.

One mechanism proposed to underlie the dyskinesias induced by chronic L-DOPA treatment is based on abnormalities in synaptic plasticity that appear in animal models after long-term treatment with L-DOPA. A rodent model of Parkinson's disease can be produced by destruction of the dopaminergic nigrostriatal system using 6-hydroxydopamine (6-OH DA). After chronic treatment with L-DOPA, abnormal involuntary movements appear in some animals but not in others. (This variability is also characteristic of L-DOPA-induced dyskinesias in parkinsonian subjects.) Slices from animals with and without dyskinesias are then used to compare synaptic plasticity in the two groups. LTP of the corticostriatal synapse, which can be produced in normals by high-frequency stimulation of the corticostriatal fibers, can be produced in slices from animals with or without dyskinesias if dopamine is present in the bathing medium. However, if the stimulus train is switched to low frequencies (1–2 Hz) in slices from animals without dyskinesias, the LTP is reversed (depotentiation), whereas in those from animals that developed dyskinesias, LTP cannot be reversed. It is as if the corticostriatal synapses in animals with dyskinesias become stuck in the potentiated state. Potentiated activation of striatal neurons, which have a net inhibitory action on the inhibitory GPi output cells, reduces their stabilizing tonic activity, and this could lead to the involuntary movements.

The failure to reverse LTP involves a D1-receptor-mediated mechanism, which is consistent with the fact that dopamine agonists that act primarily via the D2 receptor and are used to treat symptoms of Parkinson's disease do not tend to induce dyskinesias. Thus, although dopamine clearly is required to induce synaptic potentiation in the striatum, over the long term its rather nonspecific chronic action may lead to unwanted changes in synaptic plasticity and abnormal movements.

Summary

A combination of electrophysiological, anatomical, imaging, and lesion studies show that some of the circuits through the basal ganglia carry signals that are related to the kinematics of movement. Disruption of the output of these circuits leads to instability in motor control and abnormalities in the amplitude and velocity of targeted movements. Dopamine acts in the basal ganglia to modulate the signals of these circuits, and in Parkinson's disease, in which dopaminergic nigral neurons degenerate, movements are slowed and hypometric. Because dopamine release is related to the probability of success/reward, the basal ganglia are a site where motivational and kinematic signals can be integrated to scale synaptic strength, as must occur during motor learning.

Basal Ganglia: Physiological Circuits

Composition of the Basal Ganglia

The basal ganglia are composed of four nuclei (see Figure 1(a)):

1. The striatum, which comprises the caudate nucleus, putamen and ventral striatum (including the nucleus accumbens).
2. The globus pallidus, which consists of the external segment (GPe) and internal segment (GPi).
3. The subthalamic nucleus (STN).
4. The substantia nigra, which is divided into the pars reticulata (SNr) and pars compacta (SNc).

The basal ganglia receive inputs from wide areas of the cerebral cortex. Information processed in the basal ganglia returns mainly to the cerebral cortex, especially to the frontal lobe, via the thalamus (Figure 1(b)). Thus, the basal ganglia and the cerebral cortex form a loop circuitry (cortico-basal ganglia loop). Through this loop, the basal ganglia control cortical activity. Some output of the basal ganglia also descends to the brain stem. The basal ganglia can be grouped functionally into four categories:

1. Input nuclei: striatum and STN, which receive cortical inputs.
2. Output nuclei: GPi and SNr, which project outside the basal ganglia to the thalamus and the brain stem.
3. Connecting nucleus: GPe, which connects the input nuclei to the output nuclei.
4. Modulatory nucleus: SNc, which modulates the activity of the basal ganglia.

The caudate nucleus and putamen can be considered as a continuum in that they share similar cellular morphology and firing patterns. In rodents, they form a single entity. The striatum of primates and carnivores is separated by dense fiber bundles of the internal capsule into the caudate nucleus and putamen. The caudate nucleus receives inputs mainly from the prefrontal cortex, and the putamen from the motor cortices. The GPi and SNr can also be considered as a continuum separated by the internal capsule. In dolphins, the internal capsule runs more dorsally, and the GPi and SNr are fused together. In rodents and carnivores, the GPi is small and buried in the fibers of the internal capsule, thus classically named the entopeduncular nucleus, and the GPe is sometimes called simply the globus pallidus.

Circuitry of the Basal Ganglia

The striatum as the input nucleus receives excitatory glutamatergic inputs from the cerebral cortex. Striatal projection neurons can be classified into two groups on the basis of projection sites and neurotransmitters. Information in the striatum is transferred to the output nuclei, GPi/SNr, via two different pathways (Figure 2(a)): (1) the 'direct pathway,' in which striatal neurons containing γ-aminobutyric acid (GABA), substance P, and dynorphin project monosynaptically to the GPi/SNr and (2) the 'indirect pathway,' in which striatal neurons containing GABA and enkephalin project polysynaptically to the GPi/SNr by way of sequential connections with the GPe (composed of GABAergic neurons) and STN (composed of glutamatergic neurons). On the one hand, signals through the direct pathway have inhibitory effects on GPi/SNr neurons. On the other, signals through the indirect pathway have excitatory effects on GPi/SNr neurons because both striato-GPe and GPe–STN projections are inhibitory and STN–GPi/SNr projections are excitatory.

In addition to the canonical basal ganglia circuitry, the STN receives direct inputs from the cerebral cortex in a somatotopically organized manner and can thus be considered another input nucleus of the basal ganglia, suggesting a third pathway, the 'hyperdirect pathway,' in which STN neurons receiving cortical inputs project monosynaptically to the GPi/SNr (Figure 2(a)). The hyperdirect pathway conveys strong excitatory signals from the cortex to the GPi/SNr with faster conduction velocity than is possible via the direct or indirect pathway.

The output nuclei of the basal ganglia, GPi/SNr, are composed of inhibitory GABAergic neurons, and they fire at high frequency (40–100 Hz). Thus, neurons in the target nuclei, that is, the ventral anterior and ventral lateral nuclei (VA/VL) of the thalamus and brain stem nuclei, such as the pedunculopontine tegmental nucleus (PPN) and superior colliculus, are strongly tonically inhibited. VA/VL thalamic neurons project to the frontal cortex.

Dopaminergic neurons in the SNc project to the striatum and modulate differentially the activity of striatal projection neurons in the direct and indirect pathways (Figure 2(a)). Dopamine excites striatal neurons in the direct pathway through the dopamine D1 receptors, whereas it inhibits striatal neurons in the indirect pathway through dopamine D2 receptors.

The motor loop controlling movements of forelimbs and hindlimbs is well studied among the cortico-basal ganglia loops. This loop starts from the motor cortices (such as the primary motor cortex (MI), supplementary motor area (SMA), and premotor cortex (PM)), goes

Figure 1 Basal ganglia. (a) Human basal ganglia shown in a coronal section and in a lateral view (inset). (b) The basal ganglia receive cortical inputs and return processed information to the cerebral cortex through the thalamus (cortico-basal ganglia loop) and to the brain stem.

through the somatomotor territories of the basal ganglia, and finally returns to the original cortices through the VA/VL of the thalamus. The somatomotor territories of the basal ganglia include the caudoventral putamen, the caudoventral GPe/GPi, and the dorsal STN, and each territory shows somatotopic organization (Figure 2(b)). In addition to the motor loop, the oculomotor loop, prefrontal loop (composed of dorsolateral prefrontal and lateral orbitofrontal loops), and limbic loop connect the cerebral cortical areas (the frontal eye field/supplementary eye field, prefrontal cortex and limbic cortex, respectively) with corresponding parts of the basal ganglia and thalamic nuclei and form multiple parallel, segregated, and functionally distinct but homologous loops (Figure 2(a)). Through these multiple loops, the basal ganglia control eye movements, higher brain functions, and emotions, as well as limb movements.

The aforementioned basal ganglia circuitry may be oversimplified. Other significant projections exist:

1. It is supposed that striatal neurons projecting to the GPe and GPi belong to different groups. However, tracing studies of a single neuron have shown the existence of neurons projecting to both the GPe and the GPi. It has also been reported that some striatal projection neurons express both D1 and D2 receptors. Moreover, electrophysiological experiments have failed to show the expected effect of dopamine on striatal projection neurons.
2. Thalamic neurons, such as in the VA/VL and centromedian-parafascicular complex (CM/Pf), project also to the striatum, suggesting a short circuit of the striato-GPi-thalamo-striatal loop (Figure 2(a)).
3. The cortico-basal ganglia loops are considered to be composed of several segregated and parallel loops. However, the projections overlap partially. Thus, these loops should be viewed more as a continuum than as subdivisions with strict boundaries.
4. The GPe gives rise to GABAergic projections to the GPi/SNr, striatum, and GPe itself through local axon collaterals. Thus, the GPe may be viewed as a center nucleus projecting to multiple sites of the basal ganglia.
5. The STN projects to the GPe as well as to the GPi, using axon collaterals. The STN and GPe have intimate interconnections, and interconnected groups of neurons in the GPe and STN innervate the same population of neurons in the GPi.

Striatum: One of the Input Nuclei of the Basal Ganglia

The striatum receives excitatory glutamatergic inputs from wide areas of the cerebral cortex. Cortical inputs maintain functional topography; for example,

the motor and sensory cortices project to the caudal part of the putamen, and the prefrontal cortex projects to the caudate nucleus and the rostral part of the putamen. Hindlimb, forelimb, and orofacial areas of the MI project to the dorsal to ventral part of the caudal putamen in a somatotopically organized manner (Figure 2(b)). Corticostriatal afferents arise from small to medium-size pyramidal neurons located mainly in the upper half of layer V, with some being distributed in layer III. Some of corticostriatal afferents are axon collaterals of corticospinal neurons. During behavior, corticospinal neurons show muscle-like movement-related activity. However, corticostriatal neurons show more-selective activity to the parameters of behavioral tasks. Thus, both kinds of information are conveyed to the striatum. The striatum also receives excitatory glutamatergic inputs from the CM/Pf and VA/VL of the thalamus, dopaminergic inputs from the SNc, and serotonergic inputs from the dorsal raphe nucleus.

The striatum is composed of projection neurons that are the majority in number (80–95%) and interneurons (Figure 3). Projection neurons are inhibitory GABAergic medium-size neurons, and their dendrites are covered with numerous spines. Medium spiny projection neurons are usually silent and fire when they receive inputs, so they are described as phasically active neurons in *in vivo* unit recording. Projection neurons can be divided into two groups on the basis of the transmitters and projection sites, as described above. Interneurons lack spines and are classified into at least three groups: (1) cholinergic large aspiny neurons, (2) GABAergic aspiny neurons that contain parvalbumin, and (3) GABAergic aspiny neurons that contain somatostatin/nitric oxide synthase. Interneurons, as well as projection neurons, receive inputs from the cerebral cortex, thalamus, and SNc and finally project to projection neurons and control their activity (Figure 3). Cholinergic large aspiny neurons fire spontaneously at 2–10 Hz and are described as tonically active neurons in

Figure 3 Circuitry within the striatum and its outputs. Spiny projection neurons receive cortical inputs directly and indirectly through interneurons and project to the external segment of the globus pallidus (GPe), internal segment of the globus pallidus (GPi), and substantia nigra pars reticulata (SNr). in vivo unit recording. The *in vivo* activity patterns of other interneurons remain to be elucidated.

Although the striatum looks very homogeneous, it can be divided anatomically into the μ-opiate receptorrich 'patch' compartment ('striosome') and the surrounding 'matrix' compartment. However, the functional significance of the compartmentalization is not fully understood.

GPe and STN: Two Strongly Interconnected Nuclei of the Basal Ganglia

Striatal neurons containing enkephalin and GABA project to the GPe (Figures 2(a) and 3). The GPe is composed of GABAergic neurons and fires spontaneously at high frequency (40–100 Hz). The GPe projects to the STN and GPi. It also projects to the GPe itself by local axon collaterals. The STN is composed of excitatory glutamatergic neurons and fires at medium rate (20–40 Hz). The STN receives excitatory inputs from the frontal lobe, including the motor cortices, in a somatotopically organized manner, and it receives inhibitory inputs from the GPe, and projects to the GPe, GPi, and SNr (Figures 2(a) and 2(b)). Thus, the STN can be considered an input nucleus of the cortico-STN–GPi/SNr hyperdirect pathway, as well as a relay nucleus of the striato-GPe–STN–GPi/SNr indirect pathway. The GPe projects to the GPi/SNr, suggesting another striato-GPe–GPi/SNr indirect pathway. Interconnections between the STN and GPe/GPi

form a fiber bundle called the subthalamic fasciculus (Figure 4).

GPi and SNr: Output Nuclei of the Basal Ganglia

Information processed in the basal ganglia reaches the GPi/SNr. The majority of output information returns to the cerebral cortex through the thalamus, while a minority descends to the brain stem. The pallidothalamic projections arise from the GPi as two fiber bundles, ansa lenticularis (from the lateral or rostral portion of the GPi) and lenticular fasciculus (from the medial or caudal portion of the GPi), merge at Forel's field H, form the thalamic fasciculus, and finally reach the thalamus (Figure 4). This projection terminates at the oral part of the ventral lateral nucleus (VLo), the parvicellular part of the ventral anterior nucleus (VApc) of the thalamus, and the lateral habenular nucleus, and gives axon collaterals also to the CM. The VLo and VApc project to the motor cortices including the MI, SMA, and PM; thus, wide areas of the motor cortices are under the control of the basal ganglia (the motor loop). The neurons projecting to the lateral habenular nucleus are located in the ventromedial border of the GPi and are different from those projecting to the thalamus. The lateral habenular nucleus projects to the raphe nuclei, ventral tegmental area, and SNc through the fasciculus retroflexus. The descending fibers depart from the ascending fibers in Forel's field H and project to the PPN (Figures 2(a) and 4). The PPN projects down to the spinal cord through the brain stem reticular formation and controls locomotion and posture.

Figure 4 Output pathways of the internal segment of the globus pallidus (GPi) shown in a coronal section. CM, centromedian nucleus; GPe, external segment of the globus pallidus; H, Forel's field H; PPN, pedunculopontine tegmental nucleus; STN, subthalamic nucleus; VApc, parvicellular part of ventral anterior nucleus; VLo, oral part of ventral lateral nucleus; ZI, zona incerta. Reproduced from Parent A, Cossette M, and Lévesque M (2000) Anatomical considerations in basal ganglia surgery. In: Lozano AM (ed.) *Movement Disorder Surgery: Progress in Neurological Surgery,* vol. 15, pp. 21–30. Basel. Karger, with permission from S Karger AG.

The nigrothalamic projections terminate more rostrally than the pallidothalamic projections at the magnocellular part of the ventral anterior nucleus (VAmc), the medial part of the ventral lateral nucleus (VLm), and the paralaminar part of the medial dorsal nucleus (MDpl) of the thalamus. These thalamic nuclei project to the prefrontal cortex, frontal eye field, and supplementary eye field, forming the prefrontal and oculomotor loops. The SNr also projects to the superior colliculus (nigrotectal projection) and PPN (nigrotegmental projection).

On the one hand, ascending projections from the basal ganglia to the cerebral cortex through the thalamus control the learned movements of hands and the higher brain functions. On the other, descending projections to the motor centers in the brain stem control the innate motor functions, such as eye movements, trunk movements, locomotion, mastication, and vocalization.

The cerebellar nuclei project to the oral part of the ventral posterolateral nucleus (VPLo) and the caudal part of the ventral lateral nucleus (VLc) of the thalamus, which are more caudal than the pallidothalamic terminal fields. Thus, the SNr, GPi, and cerebellar nuclei project to different thalamic subnuclei, from rostral to caudal part of the thalamus. In the motor loop, the outputs from the GPi and cerebellar nuclei finally project to the motor cortices.

SNc: Modulatory Nucleus of the Basal Ganglia

The SNc is composed of dopaminergic neurons and projects widely to the basal ganglia and frontal cortex, especially to the striatum. Dopamine receptors are one of the G-protein-coupled receptors, identified as subtypes D1 through D5. They are classified into the D1 group (comprising D1 and D5), which activates adenylate cyclase, and the D2 group (D2, D3, and D4), which inhibits adenylate cyclase. Among striatal projection neurons, neurons in the direct pathway express mainly D1 receptors, and neurons in the indirect pathway have D2 receptors. Thus, dopamine has differential effects on these two different neuronal groups (Figures 2(a) and 3).

Functions of the Basal Ganglia

Physiological functions of the basal ganglia are not yet fully understood; the most probable hypothesis

Figure 5 Spatial and temporal distributions of basal ganglia activity during behavior based on the focused selection model. Signals through the direct pathway inhibit internal segment of the globus pallidus/substantia nigra pars reticulata (GPi/SNr) neurons, activate thalamic neurons by disinhibition, and release a selected motor program. On the other hand, signals through the hyperdirect and indirect pathways have broad excitatory effects on GPi/SNr neurons in temporal and spatial domains, clearly initiate and terminate the selected motor program, and inhibit other unnecessary competing motor programs. STN, subthalamic nucleus. Reproduced from Nambu A (2007) Globus pallidus internal segment. In: Tepper JM, Abercrombie ED, and Bolam JP (eds.) *GABA and the Basal Ganglia: From Molecules to Systems: Progress in Brain Research*, vol. 160, pp. 135–150. Amsterdam: Elsevier, with permission from Elsevier.

of basal ganglia functions is the focused selection of intended movements. Neurons in the output nuclei of the basal ganglia are inhibitory GABAergic and fire at high frequency; thus, neurons in the target structures, such as the thalamus, are inhibited continuously (Figure 5). When striatal neurons are activated by cortical inputs, the striatal neurons inhibit GPi/SNr activity through the striato-GPi/SNr direct pathway. The continuous inhibition from the output nuclei to the target structures is temporally removed (disinhibition), and neurons in the target structures, including thalamic and cortical neurons, are activated, resulting in the release of a selected motor program. These mechanisms have been investigated in saccadic eye movements.

On the other hand, signals through the hyperdirect and indirect pathways have excitatory effects on the GPi/SNr and thus have inhibitory effects on thalamic neurons. Considering the conduction velocity, signals through the hyperdirect pathway first actively inhibit thalamic neurons, then those through the direct pathway disinhibit them, and finally those through the indirect pathway inhibit them again (Figure 5). Thus, signals through the hyperdirect and indirect pathways clearly control initiation and termination of the selected motor program.

In addition to this temporal aspect, the enhancement by differential inputs through the hyperdirect, direct, and indirect pathways may work in the spatial domain as well. Anatomical studies have shown that STN–GPi fibers arborize more widely and terminate on more proximal neuronal elements than do striato-GPi fibers. Signals through the hyperdirect and indirect pathways activate GPi/SNr neurons extensively, thereby inhibiting large areas of the thalamus, whereas signals through the direct pathway disinhibit thalamic neurons only in the center area (Figure 5). Thus, signals through the hyperdirect and indirect pathways inhibit thalamic neurons in the surrounding area, which are related to unnecessary, competing motor programs.

Because of the temporal and spatial inputs to the target structures through the hyperdirect, direct, and indirect pathways, only the selected motor program is executed at the selected timing, and other competing motor programs are canceled. The oculomotor, prefrontal, and limbic loops control the activity of corresponding cortical areas in a similar manner.

Summary and Conclusions

The basal ganglia circuitry can be summarized as follows: (1) The basal ganglia control not only voluntary movements but also other higher brain functions through the multiple and parallel cortico-basal ganglia loops. (2) The output of the basal ganglia is controlled differentially by the direct, indirect, and hyperdirect pathways. (3) The basal ganglia are proposed to be involved in the focused selection of intended movements.

During two decades, accumulated knowledge of the basal ganglia has revolutionized our understanding on this structure. It also has suggested new therapies for movement disorders. However, we still do not have

the complete answer to the simplest question: What is the primary function of the basal ganglia? We need more studies focused on the information flow through the cortico-basal ganglia loop to answer additional questions concerning what kind of information each pathway conveys and how such information is processed in each nucleus.

Bayesian Cortical Models

Introduction

A fundamental challenge faced by the brain is to act on the basis of noisy sensory information and incomplete knowledge about the world. For example, a mouse seeking food in a natural environment must combine information about its current location estimated from sensory information such as whisker movements, sight, and odor with prior knowledge about places, paths, and potential food locations in the environment. Similarly, a tennis player must integrate prior knowledge about where her opponent tends to hit the ball with visual information about the current trajectory of the ball before deciding on her next stroke. A driver on a highway must integrate visual information about other cars and his own self-motion with prior knowledge about the dynamics of the car being driven, lane-changing rules, and typical driving patterns of other drivers. In each of these cases, the central problem that the brain needs to solve is one of inferring task-relevant attributes about the world in the presence of noisy and uncertain sensory information. Bayesian inference provides a mathematically rigorous way to combine noisy sensory information with prior knowledge, leading to revised beliefs about the current state of the world. Considerable evidence exists from psychophysical studies that the brain may indeed be employing Bayesian inference for perception and sensorimotor integration. These studies typically rely on Bayesian models formulated at an abstract mathematical level. The challenge is to understand how such models can be implemented by networks of neurons. This article reviews some recently proposed models for implementing Bayesian inference in cortical circuitry.

Bayesian Inference

Bayesian inference is based on a 240-year-old result known as Bayes' theorem, named after Reverend Thomas Bayes (1702–61), who first proposed a special case of the theorem. The theorem can be derived from the definition of joint probability of two random variables, say X and I:

$$P(X, I) = P(X|I)P(I) = P(I|X)P(X) \qquad [1]$$

The second equality implies that

$$P(X|I) = \frac{P(I|X)P(X)}{P(I)} \qquad [2]$$

which is Bayes' theorem for the two random variables X and I. To see how the theorem can be used for inference, suppose that X represents a task-relevant attribute such as the anticipated location of the ball in the tennis example above. Let I denote new visual information based on observing the opponent hit the ball. $P(X)$ is the prior distribution over locations, representing prior knowledge about where the opponent tends to hit the ball based on past experience with this opponent. With Bayes' theorem, a new distribution over possible ball locations can be inferred that takes the new visual input I into account: this is the posterior $P(X|I)$, which combines the prior $P(X)$ and the input likelihood $P(I|X)$ according to the above equation (the term $P(I)$ is a normalization constant which can be computed by integrating or summing the numerator $P(I|X)\ P(X)$ over all locations X). Bayes' theorem is useful because in most cases, it is easier to estimate $P(I|X)$ (e.g., by gathering statistics about I for a fixed X) than to estimate directly $P(X|I)$.

Bayesian inference is extremely versatile because it can be applied in myriad different situations. For example, one can generalize the example above to sequential Bayesian inference given inputs evolving over time: if I_1 is the input received at time step 1, then $P(X|I_1) = k_1 P(I_1|X)P(X)$, where k_1 is the normalization constant. Now if a new input I_2 is received at time step 2, the new posterior is given by

$$\begin{aligned} P(X|I_1, I_2) &= k_2 P(I_1, I_2|X)P(X) \\ &= k_2 P(I_2|X)P(I_1|X)P(X) \\ &= kP(I_2|X)P(X|I_1) \end{aligned} \qquad [3]$$

where it was assumed that the inputs are independent given X and where k and k_2 are normalization constants. Thus, the new posterior can be computed recursively by multiplying the new input likelihood with the posterior from the previous time step. Similarly, consider the problem of estimating a quantity X (e.g., location of a stimulus) from inputs from two different modalities (e.g., audition and vision). If I_a and I_v are the two inputs, the posterior can once again be estimated as

$$P(X|I_v, I_a) = k_3 P(I_v|X)P(I_a|X)P(X) \qquad [4]$$

assuming the inputs are independent given the source X. Note that this equation predicts a multiplicative interaction between the two input modalities and the prior distribution over X, a prediction that has received support from several psychophysical studies.

The above examples involved a few random variables and dependencies between them. The world that animal brains must cope with requires large

numbers of random variables to describe it with complex dependencies between them. Researchers in the fields of artificial intelligence and statistics have developed general algorithms for Bayesian inference over any set of random variables given 'evidence' (input information) regarding a subset of random variables. These algorithms are typically based on describing the domain of interest in terms of a 'graphical model' wherein the nodes of a graph denote random variables and the connections between the nodes represent dependencies between the random variables as characterized by conditional probabilities. A prominent algorithm for Bayesian inference is the belief propagation algorithm, which works by passing 'messages' (probability distributions) between the nodes of a graphical model. Messages received at each node are combined to yield the posterior probability distribution of the random variable associated with that node in the light of given input data or evidence. The challenge faced by computational neuroscientists is to understand how probabilities could be represented in the brain and how general Bayesian inference algorithms such as belief propagation can be implemented in neural circuits. Three classes of models addressing this issue are reviewed below.

Log Probability Models

One of the earliest suggestions regarding neurons representing probabilities was made by Barlow in 1969. Barlow proposed that neurons in the retina represent the certainty that a particular trigger feature (e.g., increase in light intensity) is present in the input stimulus. Specifically, Barlow suggested that the neurons signal the negative logarithm of the probability of the null hypothesis that the trigger feature is absent. Thus, a low response indicates a high degree of certainty that the trigger feature is present. Such a model generates responses that bear similarities to the responses of cat retinal ganglion cells.

Several recent cortical models for representing probabilities with neurons can be seen as variants of Barlow's retinal model. In these models, cortical neurons are assumed to represent the logarithm of probabilities or logarithm of ratios of probabilities. The reason for a logarithmic representation is that such a representation converts multiplication and division of probabilities to addition and subtraction, respectively, operations that can be implemented readily using conventional models of neurons (such as integrate-and-fire models).

Inspired by data from decision-making studies in humans and monkeys, Gold and Shadlen have proposed a model for neurons in cortical lateral intraparietal and frontal eye field areas that interprets their responses as representing the log likelihood ratio between two alternatives. Their model is based on the observation that the responses of neurons in these areas exhibit a behavior similar to a random walk to a fixed threshold. The neuron's response increases given evidence in favor of the neuron's preferred hypothesis and decreases when given evidence against that hypothesis, resulting in an evidence accumulation process similar to computing a log likelihood ratio over time. Gold and Shadlen developed a mathematical model to formalize this intuition. They have shown that under reasonable assumptions, the difference in responses between pools of neurons preferring opposing stimuli (e.g., leftward vs. rightward motion) is proportional to the log likelihood ratio between the two alternatives represented by the stimuli (**Figure 1**). Thus, downstream neurons, such as those in the lateral intraparietal area, need only add up these differences over time for their responses to be proportional to the log likelihood ratio between two alternatives. Decision making is accomplished by comparing the evolving neural response (denoting log likelihood ratio) to a decision threshold.

An extension of the Gold and Shadlen model to the case of spiking neurons has been proposed by Deneve. In this model, each neuron is assumed to represent the log 'odds' ratio for a preferred binary-valued state, that is, the logarithm of the probability

Figure 1 Relationship between neuronal response and log likelihood ratio according to the Gold–Shadlen model. The graphs illustrate that the difference in spike rates from two appropriately chosen neurons (or neural ensembles) can approximate the log likelihood ratio favoring one hypothesis over another. (Left, top plot) The red and blue curves are probability density functions (PDFs) that describe the hypothetical distributions of responses x from a sensory neuron when either hypothesis h_1 or h_2, respectively, is true (h_1, red; h_2, blue). Note that this neuron responds best when h_1 is true (red curve). The PDFs for a second neuron with responses y are shown below. This 'antineuron' responds best when h_2 is true (blue curves). The PDFs are assumed to be normal distributions with means μ_1 and μ_2 as shown and variance σ^2. (Right) The green curve represents the log likelihood ratio computed from the firing rates x and y of the neuron–antineuron pair. Note that the log likelihood ratio is proportional to the difference ($x-y$) in the firing rates. Knowledge of the PDFs is not required to interpret this difference: a positive value indicates support for h_1; a negative value indicates support for h_2. Adapted from Gold JI and Shadlen MN (2001) Neural computations that underlie decisions about sensory stimuli. *Trends in Cognitive Sciences* 5(1): 10–16.

that the preferred state is 1 over the probability that the preferred state is 0, given all inputs seen thus far. To promote efficiency, each neuron fires only when the difference between its log odds ratio and a prediction of the log odds ratio (based on the output spikes emitted thus far) reaches a certain threshold.

A potential drawback of a log probability ratio representation is that it can become cumbersome when the number of hypotheses being considered is large, given the large number of ratios, corresponding to different combinations of hypotheses, that need to be represented. An alternative approach is to explicitly represent the probability (or log probability) of a hypothesis or random variable using a single neuron. For example, if the random variable is direction of motion, a population of neurons, each preferring one particular direction of motion, could be used to represent the probability distribution over directions of motion. The firing rate of each neuron in this model is proportional to the probability (or log probability) of the direction of motion preferred by that neuron. The distribution of firing rates over the population can be regarded as a sampled representation of the probability distribution over the continuous space of motion direction. A model for Bayesian inference based on such a representation was proposed by Rao. A recurrent network of leaky integrator neurons was shown to be capable of implementing a simple form of the belief propagation algorithm over time. Recurrent connections between neurons encode the transition probabilities between the states represented by the neurons while the feedforward connections from the input neurons encode the likelihood function. Bayesian inference was approximated by implementing the belief propagation equations in the logarithmic domain; this allows the equations to be implemented by leaky integrator neurons, causing the output response of each neuron to become proportional to the log posterior probability of the state encoded by the neuron (Figure 2). This model was later extended to the case of exact inference in spiking neurons and hierarchical networks (see the section titled 'Hierarchical models').

Population Coding Models

A second class of models for representing and performing inference using probability distributions is based on the idea of population coding. Whereas the models discussed above utilize single neurons to directly represent probabilities or probability ratios, population coding models assume that probability distributions are implicitly represented by populations of neurons. For example, one class of models uses basis functions (or 'kernels') to represent probability distributions within neuronal ensembles. In this approach, a distribution $P(X)$ over stimulus X is represented implicitly in neural responses as a linear combination of basis functions:

$$P(X) = \sum_i r_i b_i(X) \qquad [5]$$

where r_i is the normalized response (firing rate) and b_i the implicit basis function associated with neuron i in

Figure 2 Responses from a log probability model for Bayesian motion detection. The plots depict responses from a log probability model for belief propagation proposed by Rao. A network of 30 neurons receives inputs from a one-dimensional model retina. Inputs consist of bars moving rightward or leftward. The receptive field of each neuron is localized to one particular spatial location on the retina using a Gaussian spatial filter. The input likelihood function for a neuron is proportional to the product of its spatial filter and the current image. The recurrent synaptic connections between neurons represent the transition probabilities of rightward and leftward motion in such a way that the first 15 neurons are selective for rightward motion and the other 15 are selective for leftward motion. Left, log likelihood, log posterior, firing rates, and posterior probabilities computed by the model network for a rightward moving stimulus when it arrives at the central image location. Note that the log likelihoods are the same for the left and right selective neurons, but their outputs correctly reflect the direction of motion due to recurrent interactions in the network. Right, the same plots for a leftward moving bar as it reaches the central location. From Rao RPN (2004) Bayesian computation in recurrent neural circuits. *Neural Computation* 16(1): 1–38.

the population. The basis function of each neuron is typically assumed to be linearly related to the tuning function $f_i(x)$ of the neuron as measured in physiological experiments. A limitation of the basis function approach above is that due to its additive nature, it cannot represent distributions that are sharper than the component distributions. A more recent model proposed by Jazayeri and Movshon combines the above idea with a log probability representation. In this model, the firings rates of neurons are assumed to be governed by an exponential distribution (such as Poisson), and the log probability distribution over stimulus X is assumed to be represented as

$$\log P(X) = \sum_i r_i \log f_i(X) \qquad [6]$$

A second class of population coding models is based on the use of a Bayesian decoding strategy to estimate the stimulus X (or its distribution), given a set of responses r_i. For example, in the distributional population coding (DPC) model of Zemel, Dayan, and Pouget, the responses are assumed to depend on general distributions over X, and a maximum *a posteriori* probability distribution is computed from possible distributions over X (Figure 3). The best estimate in this method is not a single value of X but an entire distribution over X, which is assumed to be represented by the neural population. The underlying

Figure 3 Distributional population coding (DPC) model. A set of firing rates **r** (topmost plot) may be interpreted as implicitly encoding a probability distribution $P(\mathbf{x}|\mathbf{w})$ over a variable **x** (the variable **w** represents any information that **x** depends on). Given a set of rates **r**, one can use Bayesian methods to obtain a probability distribution over possible implicit distributions, $P[P[\mathbf{x}|\mathbf{w}] \mid \mathbf{r}]$. The final decoded distribution $\hat{P}^r(x)$ is the maximum *a posteriori* distribution, obtained from the peak of this distribution over distributions. The error bars in the plot capture the variances in the firing rates of the units. From Zemel RS, Dayan P, and Pouget A (1998) Probabilistic interpretation of population codes. *Neural Computation* 10(2): 403–430.

goal of representing entire distributions within neural populations is common to both the DPC approach and the log probability models described above. However, the approaches differ in how they achieve this goal: the DPC method assumes prespecified tuning functions for the neurons and a sophisticated decoding operation to extract probability values whereas log probability models rely on exponential or linear decoding operations.

Many of the above models cannot disambiguate between cases in which there are multiple peaks in the decoded distribution due to uncertainty about a single stimulus or due to simultaneous multiple stimuli present in the input. A more recent model proposed by Sahani and Dayan, the doubly distributional population coding model, handles this problem by encoding probability distributions over a function $m(x)$ of the input x rather than distributions over x itself. The greater representational capacity of this method, however, comes at the expense of more-complex encoding and decoding schemes.

The distributional coding models discussed above were geared primarily toward representing probability distributions. More recent work by Zemel and colleagues has explored how distributional codes could be used for inference as well. In their approach, a recurrent network of leaky integrate-and-fire neurons maps an input population of spikes $R(t)$ to an output population of spikes $S(t)$. The network is trained to capture the probabilistic dynamics of a hidden random variable $X(t)$. This is done by adapting the weights of the neural network in such a way that the output decoding distribution $Q(X(t)|\mathbf{S}(t))$ is as close as possible to the input distribution $P(X(t)|\mathbf{R}(t))$, where $\mathbf{R}(t)$ and $\mathbf{S}(t)$ are vectors representing the input and output spike trains, respectively. The advantage of this approach is that the decoding process may allow a higher-fidelity representation of the output distribution than direct representational schemes such as the log probability models above. On the other hand, since the probability representation is implicit in the neural population, it becomes harder to map mathematically derived inference algorithms such as belief propagation to neural circuitry.

A different model by Ma and colleagues addresses the problem of inference using probabilistic population codes. In this model, the posterior distribution of a stimulus X given a population response vector of firing rates $\mathbf{r}$ is given by Bayes' theorem:

$$P(X|\mathbf{r}) = kP(\mathbf{r}|X)P(X) \qquad [7]$$

where k is a normalizing constant, $P(\mathbf{r}|X)$ is the firing rate distribution given X, and $P(X)$ is the prior distribution over X. Thus, the variability in neuronal

responses to a fixed stimulus is advantageously used to represent a posterior distribution over the stimulus. Assuming that this variability is captured by independent Poisson statistics (or other Poisson-like distributions from the exponential family), Bayesian inference can be performed by simply adding population responses on a neuron-by-neuron basis (Figure 4). For example, going back to the problem of estimating a quantity X (e.g., location of a stimulus) using inputs $\mathbf{r}_1$ and $\mathbf{r}_2$ from two different modalities (e.g., vision and audition), the posterior $P(X|\mathbf{r}_1, \mathbf{r}_2) \propto P(\mathbf{r}_1|X)\, P(\mathbf{r}_2|X)\, P(X)$ can be computed by a third population of neurons whose firing rate vector $\mathbf{r}_3$ is given by $\mathbf{r}_3 = \mathbf{r}_1 + \mathbf{r}_2$ (assuming a uniform prior distribution over X). This property, which is similar in spirit to the additive properties of log probability models, is a consequence of working with the exponential family of distributions (a related idea was explored by Hinton and Brown in their restricted Boltzmann machine model).

Hierarchical Models

There has been considerable interest in the neural implementation of hierarchical models for inference. Part of this interest stems from the fact that hierarchical models often capture the multiscale structure of input signals such as images in a very natural way (e.g., objects are composed of parts, which are in turn composed of subparts, etc.). A hierarchical

Figure 4 Probabilistic population codes. The figure depicts Bayesian inference with probabilistic population codes for Gaussian probability distributions and Poisson variability in neural responses. The left plots show population activity (firing rates) in response to two cues C_1 and C_2 (e.g., audition and vision) related to a stimulus s. Each of these implicitly encodes a Gaussian probability distribution with variances σ_1^2 and σ_2^2 inversely proportional to the gains g_1 and g_2 of the population codes (K is a constant depending on the width of the tuning curves of neurons and the number of neurons). r_1 and r_2 denote firing rates. Adding these two population codes leads to the population activity shown on the right. This output also encodes a probability distribution with a variance inversely proportional to the gain, which is equal to $g_1 + g_2$. Since g_1 and g_2 are in turn inversely proportional to σ_1^2 and σ_2^2 respectively, the inverse variance of the output code is the sum of the inverse variances associated with C_1 and C_2. This is the variance expected from optimal Bayesian inference using Gaussian distributions in eqn [4] in the text (assuming a uniform prior distribution). Thus, taking the sum of two population codes is equivalent to taking the product of their encoded distributions. From Ma WJ, Beck JM, Latham PE, and Pouget A (2006) Bayesian inference with probabilistic population codes. *Nature Neuroscience* 9: 1432–1438.

decomposition often results in greater efficiency, both via parsimony of representation (e.g., a large number of objects can be represented by combining a small set of parts in many different ways) and by speeding up learning. A second motivation for hierarchical models has been the evidence from anatomical and physiological studies that cortical areas are reciprocally connected via feedforward and feedback connections, and many regions of the primate cortex appear to be hierarchically organized (e.g., visual cortex and motor cortex).

Dayan, Hinton, and colleagues investigated a hierarchical model network called the Helmholtz machine that uses feedback connections from higher to lower levels to instantiate a probabilistic generative model of its inputs. An interesting proposed learning method with the suggestive name of 'wake–sleep' algorithm involves learning the feedback weights during a 'wake' phase based on inputs and the feedforward weights in the 'sleep' phase based on 'fantasy' data produced by the feedback model. Although the model employs feedback connections, these are used only for bootstrapping the learning of the feedforward weights (via fantasy data). Perception involves a single feedforward pass through the network.

A hierarchical network that does employ feedback for inference was explored by Lewicki and Sejnowski. In this model, each unit encodes a binary state, and the probability that a unit's state S_i is equal to 1 depends on the states of its 'parents' (units sending connections to unit i), denoted by $pa[S_i]$, via

$$P(S_i = 1|pa[S_i]; \mathbf{W}) = h\left(\sum_j w_{ji} s_j\right) \qquad [8]$$

where $\mathbf{W}$ is the matrix of synaptic weights, w_{ji} is the synaptic weight from S_j to S_i, and h is the noisy OR function $h(x) = 1 - \exp(-x)$ $(x \geq 0)$. Bayesian inference is performed using a procedure known as Gibbs sampling, which involves sampling the value of a particular unit in the network given previously sampled values for the rest of the units and repeating this process for different units. After several iterations, these values will be typical samples from the posterior distribution of states in the network.

A different hierarchical cortical model based on the idea of predictive coding was suggested by Rao and Ballard. In this model, feedback connections convey predictions of expected activities at lower levels while the feedforward connections carry the residual errors between the predictions and actual activities; these errors are used to correct the state estimates at each level (Figure 5(a)). The state estimate at each level can be regarded as the mean of a Gaussian distribution over states at that level. The model can be viewed

Figure 5 Hierarchical predictive coding and particle filtering models. (a) Schematic depiction of the hierarchical predictive coding model of the visual cortical pathway comprising lateral geniculate nucleus, V1, V2, ... At each hierarchical level, feedback pathways carry predictions of neural activity at the lower level, while feedforward pathways carry residual errors between the predictions and actual neural activity. These errors are used by the predictive estimator at each level to correct its current estimate of the input signal and generate the next prediction. The predictive estimators allow each level to maintain a Gaussian distribution over the features encoded by that level. (b) Schematic diagram of the hierarchical particle filtering model of the visual cortex. The $x_i^{(j)}$s denote 'particles' or sampled values for the features encoded by visual cortical area i. Each particle has a weight $w_i^{(j)}$ such that the weighted sum of all particles is a discrete approximation to the full posterior distribution over the feature x_i. B_1 and B_2 denote bottom-up and top-down 'beliefs' that reflect probabilistic information from lower and higher areas, respectively. The ϕs denote feedforward or feedback synaptic weights between cortical areas chosen to facilitate hierarchical inference. * denotes multiplication. as an approximate neural implementation of the Kalman filter, a well-known algorithm for state estimation used in engineering and control theory. A related hierarchical model of the visual cortex based on an approximate inference method known as particle filtering was suggested by Lee and Mumford. The particle-filtering-algorithm can be viewed as a generalization of the Kalman filter to nonlinear dynamics and non-Gaussian distributions. Inference involves message passing between different levels of the network in a manner similar to belief propagation but using sampled values for the random variables (Figure 5(b)). The actual neural implementation of particle filtering was left open. The Lee–Mumford model shares similarities with log probability models

in that both utilize sampled representations of probability distributions over continuous spaces.

A hierarchical cortical model based on belief propagation, with a possible neural implementation, was suggested by Rao. In this model, lower-level neurons represent specific image features (such as edges) at specific locations while higher-level neurons factor these features into more abstract attributes such as locations (irrespective of features) and features (irrespective of locations; Figure 6). Noisy leaky integrate-and-fire neurons are used to implement the belief propagation equations for a hierarchical network, under the assumption that the dendrites of neurons approximate a logarithmic transformation of their inputs. Under these conditions, the spiking probability of a neuron becomes proportional to the posterior probability of the feature (or location) being encoded by the neuron. The probabilistic integration of top-down prior information with bottom-up image likelihood information, as prescribed by Bayesian inference, is shown to account for several attentional effects in the visual cortex such as multiplicative modulation of tuning curves, restoration of neural responses in the presence of distracting stimuli, and influence of attention on neighboring unattended locations. A related model, proposed by Yu and Dayan, is based on a five-layer neural architecture and a log probability encoding scheme. This model explains both reaction times in a spatial attention task and multiplicative response modulation in the visual cortex.

Conclusion

Bayesian models have been used to explain a surprisingly wide range of perceptual phenomena in recent years. These models demonstrate how particular choices for the prior distribution of stimuli yield posterior distributions that can help explain a variety of psychophysical data. Most of these models are, however, formulated at an abstract mathematical level, leaving open the question of their neural implementation. Computational neuroscientists are beginning to investigate ways in which cortical circuits may implement Bayesian inference.

Figure 6 Hierarchical Bayesian cortical model of visual cortical areas. (a) Probabilistic generative model that factors images into spatial locations and features. (b) Three-level network for implementing Bayesian inference for the generative model in (a). Circles represent neurons, arrows represent feedforward connections, and lines represent bidirectional connections. The intermediate representation neurons are assumed to correspond to visual cortical areas V1/V2. The location-invariant feature-coding neurons (F) are assumed to reside in V4 while the feature-invariant location-coding neurons (L) are assumed to reside in areas of the parietal cortex. The location-coding neurons compute the posterior probability P(L|I) while the feature-coding neurons compute the posterior probability P(F|I). (c) Each bar graph represents the responses of three feature-coding model neurons, the first coding for vertical features (V), the second for horizontal features (H), and the third for the null (blank) stimulus (N), when the input image I contains a vertical bar flashed at three different locations (dark inset images). Note that the vertical feature-coding neuron's firing rate, denoting the posterior probability of the vertical feature, remains high and invariant to bar location. On the other hand, as shown in (d), information about the vertical bar's current location is captured by the location-coding neurons. From Rao RPN (2005) Bayesian inference and attentional modulation in the visual cortex. *NeuroReport* 16(16): 1843–1848.

This article reviewed three classes of Bayesian cortical models: log probability models, population coding models, and hierarchical models. Log probability models typically assume that a given cortical neuron encodes a particular preferred stimulus, the responses of the neuron reflecting the posterior probability of this stimulus (or, alternatively, the log posterior or log posterior ratio between the presence and absence of the stimulus). Population coding models assume that probability distributions are implicitly encoded in the responses of a population of neurons, and these models rely on a decoding function to recover the probability distribution from a given set of responses. Population coding models are typically more efficient in representing distributions than are log probability models: for example, the basis function model can represent distributions over continuous variables efficiently whereas the log probability approach can only represent such distributions as sampled distributions using a set of discrete values (preferred stimuli of the neurons). On the other hand, because they represent probabilities directly rather than implicitly, log probability schemes lend themselves more easily to implementing sophisticated Bayesian inference algorithms such as belief propagation. Finally, motivated by the hierarchical structure of the cortex, numerous models have been suggested for implementing hierarchical Bayesian inference. Whether such models can provide a unified account of the neurobiological properties observed across different cortical areas remains an interesting open question. Also intriguing is the question of whether known mechanisms of synaptic plasticity, such as Hebbian and spike timing-dependent plasticity, facilitate Bayesian inference in cortical networks.

Bayesian Models of Motor Control

M Berniker and K Kording, Northwestern University Institute of Neuroscience, Chicago, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Motor control is fundamental to the nervous system: only through our movements do we interact with the world. Many models of motor control assume that of all the ways we could move, we typically choose one of the best. This implies that we can have a 'notion' of how bad one movement is in comparison to other possible movements. Within the framework of decision theory, this notion is formalized by a cost function that assigns a numerical value to every possible movement. The right movement decision seems simple: choose the action a^* that has the lowest associated cost. This decision process can be compactly described by the equation,

$$a^* = \arg\min_a (\text{cost}(\text{a})) \qquad [1]$$

For example, several studies have proposed that people move their hand from one position to another in a fashion that is as 'smooth' as possible. Thus, the cost function penalizes movements that are not smooth. It was found that many properties of human reaching movements, such as the velocity profiles, can be well predicted by such cost functions.

This framework assumes that we can deterministically choose a movement and be sure of its outcome. Yet, most motor outcomes are affected by uncertainty. To illustrate, if we aim at the center of a dartboard, we are not certain to hit the bullseye with the dart (even if we are a seasoned champion). If we continue to aim at the center and throw many times, we will end up with a distribution of dart positions. This distribution, $p(x|a)$, characterizes the likelihood of each outcome, the dart position x, given that we chose action a, the aiming point. This affects how we should choose the best action, the one that minimizes our likely cost:

$$a^* = \arg\min_a \left(\sum_{\substack{\text{possible}\\ \text{outcomes}}} \text{cost}\,(\text{outcome})\; p(\text{outcome}|a) \right) \qquad [2]$$

In other words, we should choose the action that minimizes our expected cost. In the example of playing darts, the best aiming point is a point where we will receive high scores even if we make large mistakes. Indeed, both amateur and world-class players are known to adopt a strategy that is well predicted by this approach.

While playing darts, the errors largely stem from motor noise (Figure 1(a)). However, there are many sensory sources of uncertainty as well. For example, our visual system is noisy and the location of the dartboard relative to our body is thus uncertain (Figure 1(a)). Moreover, our proprioceptive system is noisy as well; the exact configuration of our body as we release the dart is uncertain (Figure 1(a)). These sources of uncertainty combine to produce uncertainty in the movement outcome given our movement decision.

The difficulty in treating these movement decisions is that the probability of an outcome given our action decision ($p(x|a)$) is generally difficult to compute. The problem is that computing this distribution requires the specification of information that is generally uncertain. This includes information about our body as well as the external world. Bayesian inference specifies how such pieces of information should be combined. It thus predicts how pieces of information should be integrated to allow for motor control that minimizes our cost.

Bayesian Integration

Combining uncertain information to produce a coherent and accurate estimate of the world is a central problem faced in motor control. A number of psychophysics studies have analyzed how people integrate multiple sources of uncertain information to make sensorimotor decisions.

Combining Prior Knowledge with New Evidence

As an example of how we integrate uncertain information to estimate the world, consider the game of tennis. When playing tennis, it is helpful to estimate where the ball will land. Vision does not provide perfect information about the ball's trajectory or velocity, and we are thus uncertain where the ball will land. The visual system, although noisy, still provides us with an estimate, or likelihood, of where the ball will strike the court. This likelihood is the probability of having a particular sensory input for each possible location the ball may land (Figure 1(b)). This knowledge may be combined with information obtained from experience: the locations where the ball may land are not uniformly distributed over the court. The locations are usually concentrated within the confines of the court and may be highly peaked near the baselines where it is most difficult to return the ball. This distribution of positions is called the prior (Figure 1(b)). Bayes' rule defines how to combine the prior and the likelihood to make an optimal estimate of the location where the ball lands (Figure 1(b)).

Figure 1 (a) Possible sources of noise in the motor system. Visual and proprioceptive senses contain inherent uncertainties. Motor commands also possess noise and result in uncertain movements. (b) Bayesian integration in tennis: we view a ball traveling toward the court floor and estimate the location where it will land, a likelihood (red). Experience from many such instances tells us that the ball usually lands close to the baseline, a prior (green). From these two pieces of information, we produce an updated estimate of where we believe the ball will land, a posterior (blue ellipses). (c) Bayesian integration of a prior and likelihood. The prior, denoted with the green curve, represents the probability of a state, *x*. The likelihood, denoted with the red curve, represents the probability of observing the data, *o*, given *x*. The posterior is the probability that *x* is the state, given our observation, *o*. (d) Bayes' rule applied to cue combinations.

Bayes' rule states that the probability of the ball landing at position x given our observation o is the product of the prior probability of the ball at x, with the likelihood of the observation o given the position x, divided by the probability of the observation:

$$p(x|o) = p(x)p(o|x)/p(o) \qquad [3]$$

The distribution produced by eqn [3] is shown graphically Figure 1(c). We can also interpret Bayes' rule as the 'optimal' means of combining a prior and a likelihood as it produces an estimate with the minimum uncertainty. A few studies have shown that when people combine prior and new information, their behavior is close to that predicted by Bayes' rule. Peoples' ability to integrate priors and likelihoods in a manner that is close to the optimal prediction by Bayes' rule has been shown in many modalities.

A typical study will let people use a motor task to indicate their estimate of the location of a target. In every trial, this location will be drawn from a Gaussian probability distribution (the prior). One group of subjects experience a narrow target distribution and thus have a narrow prior. A different group of subjects will experience a wide target distribution, thus having a wide prior. Bayesian statistics predicts how subjects should combine the likelihood with the prior. These predictions are then compared to human performance.

Such paradigms have been applied to numerous estimation problems. Sensorimotor integration, force estimation, timing estimations, speed estimations, the interpretation of visual scenes, and even cognitive estimates are examples. These studies jointly demonstrate that people are very good at combining prior knowledge with new evidence in a way predicted by Bayesian statistics.

Cue Combination

In many cases, it is not prior knowledge that is combined with a likelihood but, rather, two different cues that are combined into a joint estimate. For example, we may see and feel an object at the same time. We can then use what we saw and what we felt to infer the properties of the object. Bayesian statistics allows us to also solve these problems and the posterior is simply the product of the likelihoods (Figure 1(d)). Some studies have found that people are also optimal at this combination.

As a typical study, we consider an analysis of how people combine visual and auditory information to estimate the position of a target. In such a study, the precision of visual and auditory perception is

measured for each subject (unimodal). Subsequently, the precision and accuracy of perception is measured when subjects can use both modalities (bimodal). The performance in the bimodal trials can be predicted from the unimodal trials using Bayesian statistics.

As with studies investigating prior–likelihood integration, such a paradigm has been applied to numerous cue combination problems. It has been applied to the combination of visual and auditory information as well as tactile and visual information. It has also been applied to several cases in which two pieces of knowledge from the same modality are combined. For example, texture and stereo disparity are both cues for estimating the depth of a visual object. In all tested cases, cues are combined by the subjects in a manner that is close to the optimum prescribed by Bayesian statistics.

Bayesian Integration over Time

The state of the world and our information about it are continually changing. We thus constantly need to integrate this new information with our current beliefs to inform our estimates of the world. This implies that Bayesian integration should take place in a continuous manner.

This approach is extensively taken in modern applications of control theory. Many of these applications are built on the idea of Kalman filtering, which is a method for using an error in our prediction of the world to continuously update our beliefs (Figure 2(a)). This technique, although not usually described as such, is equivalent to a sophisticated application of Bayesian statistics. At every time step, a Kalman filter combines its estimate of the world's state (the prior) with a measured observation (the likelihood) to update the prediction of the world's current state, represented by a posterior (Figure 2(b)). This formalism is well developed and used in a wide range of applications from aeronautics to humanoid robotics. Indeed, even the motor control problems of two applications as disparate as controlling a jet and controlling our bodies share many computational analogies. In both cases, continuously incoming information needs to be assessed to move precisely (albeit on different timescales). Only recently has this methodology of Kalman filtering been applied to make quantitative predictions of human movement behavior.

A number of studies have examined how subjects integrate information in a continuous fashion. These studies have compared the way in which subjects move with the predictions of optimal Bayesian models. They have found close agreement between the predictions of the optimal theory and the way movements are actually executed.

As an example of this problem, we consider a recent theory of motor adaptation. The properties of our muscles change continuously throughout our lives. Over several timescales, muscles change – fatigue over the course of hours, disease over the course of weeks, and aging over many years. This means that we must estimate the strength of our muscles if we are to move precisely. The error in our estimate of the strength of our muscles will translate into a movement error. We can use this error to obtain a likelihood function characterizing the strength of the muscles. According to Bayesian statistics, we need to combine the newly obtained information, our motor error, with our prior belief. We can thus infer a new and improved estimate (Figure 2(c)). Often, adaptation is probed using a target jump paradigm. In these paradigms, an experimental manipulation is used to change subjects' perception of the strength of their limb. In these circumstances, Bayesian statistics predicts that

Figure 2 (a) Typical procedure for optimally estimating the world's state in modern control theory. A model of the world, combined with a motor command, is used to estimate a predicted state, or prior distribution (green). Observations of the world dictate the likelihood of a particular observation given the current world state (red). A Kalman filter is used to make a Bayesian update of our belief in the world's current state (blue). (b) This process of Bayesian inference repeats itself at each time step. (c) Motor adaptation can be framed as an analogous update procedure. Our prior belief of muscle strength (green) is integrated with our observed motor error (red) to update a belief of our muscle's strength.

subjects should adapt over time. The way subjects adapt in this setting is then compared to the adaptation profile predicted by optimal Bayesian adaptation.

It has been found that motor adaptation over time can be well understood from the predictions of Kalman filtering. It has also been found that the way people estimate the position of their hand in the dark is well predicted by the same methods. As another example, when people balance a pole on their hand, they also seem to use such strategies. These studies highlight that when people integrate information over time, they seem to do so in a manner that is consistent with the optimal Bayesian solution.

Bayesian Inference of Structure

We previously discussed how people combine two cues into a joint estimate using Bayes' rule. The application of these models implicitly assumed that we are certain that both cues have a common source: if we hear a tone while seeing a flash, we assume that both of the cues originate at the same position and have a common cause. This idea has been used very successfully for describing human behavior in cue combination experiments.

Although successful as implemented thus far, these probabilistic models have obvious shortcomings. For instance, we know from experience and experimental studies that if two cues are very dissimilar our perception of unity breaks down. If we see a flash far to our right while perceiving a tone far to our left, we perceive two independent events. We infer the structure of events; we estimate if two events have a common cause or if they just randomly co-occur. This implies that if two events are perceived as having a common cause, they should influence the perception of each other. On the other hand, if they are perceived as not having a common cause, the perception of each should be independent of the other. In some circumstances, the cues can create an illusion of a common cause, the so-called ventriloquist effect.

Traditional Bayesian models of psychophysical behavior are unable to explain this range of phenomena. Indeed, experiments that tested these models used cues that were close to coincident. For example, the position of a visual stimulus was close to the position of an auditory stimulus.

Other studies have tested subject performance in situations in which two cues are dissimilar from one another. A typical study will present a visual stimulus at a random position within the visual field and simultaneously present an auditory stimulus at a different random position. Subsequently, subjects are asked where they perceive the stimuli.

These studies have found that when two stimuli are near coincident, people tend to infer a common cause and use each cue to guide estimation of the other. With increasing disparity between the cues, subjects' belief in a common cause decreases (Figure 3). Traditional Bayesian models predict that in the case of Gaussian likelihoods the estimate of the value of one cue should be linearly influenced by the value of the other cue. In sharp contrast to these predictions, experiments have found nonlinear cue interactions. These interactions are well predicted if we assume that on each trial the subjects infer a common or distinct cause for both cues.

These effects are found in a wide range of experimental situations. They have been found in position estimation using visual and auditory stimuli, in the estimation of depth from several cues, and also in number estimation using visual, tactile, and auditory stimuli. Evidence suggests that subjects integrate not only priors and likelihoods but also the causal structure underlying a set of sensory stimuli.

The statistical problem that subjects solve in cue combination implicitly involves an inference about the causal structure of the stimuli. In these studies, people are uncertain about the identity and number of relevant variables; for example, did the flash of light cause the auditory tone, did the tone cause the flash, was there an unknown cause for them both, or were they simply coincidental? The problem faced by the nervous system is thus similar to cognitive problems that occur in the context of causal induction. Many experiments demonstrate that people interpret events in terms of cause and effect. The results presented here show that sensorimotor integration exhibits some of the factors that make human cognition difficult to understand. Carefully studying and analyzing seemingly simple problems such as cue combination may provide a fascinating way of studying the human cognitive system in a quantitative manner.

Future Directions for Bayesian Inference

The Bayesian models reviewed so far do well at predicting the results from many experimental studies of motor control. Whereas in theory Bayesian statistics' applicability is rarely limited, in practice there are many cases in which this technique is hindered.

Most of the previously discussed Bayesian models assume that noise sources are Gaussian and that the interactions between the subject and the world are linear. Recent approaches in Bayesian statistics allow the application of powerful framework well beyond these simple assumptions. For instance, the structure inference problem is a simple case of non-Gaussian

Figure 3 (a) Two structural beliefs of the world. If two cues are adequately coincident, subjects perceive them as having a common cause (green box), a phenomenon typified through ventriloquism. If the cues are disparate in time or space, subjects perceive them as having independent causes (red box). (b) Subjects' belief of common cause. Because the spatial disparity of two cues, a light flash and a tone, is experimentally controlled, the belief in a common cause can be manipulated.

probability distributions. The techniques that may be applied to such problems range from linearization techniques such as extended Kalman filters over variational techniques to particle-filtering methods. The specialized Bayesian literature deals extensively with such computational difficulties.

Bayesian inference allows us to estimate the present state of the world given all the sensory observations we have obtained from the past until now. If the problem we are faced with requires making only one decision at a single point in time (static problem), then decision theory (see eqn [2]) readily allows us to decide optimally. Yet, movement is fundamentally a sequential decision (dynamic) problem. Any motor command we produce in the present influences the situations in which we will find ourselves in the future. This implies that motor commands are not independent from each other but, rather, each command must be viewed in the context of all possible future situations it may direct us.

Optimal control theory is the systematic study of problems of this class. Often utilizing a Bayesian framework, it employs analytical and numerical techniques to solve the motor control problem. For the set of problems in which dynamics are linear, noise is Gaussian, and cost functions are quadratic, optimal control provides efficient solutions. Much research addresses ways of extending the approaches to more complicated problems. Typical applications involve the control of humanoid robots and the control of aircraft. The theory is complex and beyond the scope of this article. Advances in optimal control coupled with advances in Bayesian methods hold promise for allowing progressively more complicated movement behaviors to be analyzed and predicted.

Discussion

Much if not most of neuroscience is driven by postulates regarding the problems the nervous system is

attempting to solve. For example, researchers recording from the visual system may assume that visual features such as edges are of importance to the object recognition problem. When researchers study the motor system, they may decide that efficient movements are the intended goal. This way of thinking is called normative: a description of the problem being solved is converted into predictions of how the nervous system 'should' work. Models that predict behavior from such descriptions are especially informative and make precise quantitative predictions of experimental data.

Normative models prescribe how the nervous system should behave, as opposed to neural modeling, which describes how the nervous system behaves. To clarify the distinction, models derived from meaningful descriptions of the problem to be solved should be considered normative or prescriptive. For example, some theories of movement assume that people try to move as smoothly as possible, and these models explain a large amount of experimental data. However, there is no explicit reason why smooth movements would be better than similar but less smooth movements. Perhaps more to the point, these models do not yield insight on why subjects move the way they do. In the case of smooth movements, research demonstrated that a different cost function, clearly tied to the movement problem, could also predict the data; optimizing movements for precision naturally leads to smooth movements – a cost function that is of obvious importance.

A different way of modeling the properties of the nervous system is the so-called 'bottom-up' approach. Numerous measured or inferred properties of neurons are used to run comprehensive computer simulations of neurons within expansive networks, the results of which are meant to mimic the actual nervous system. This approach relies on the accurate knowledge of many system parameters – a formidable requirement. Furthermore, in large, complex systems such as these, small deviations in parameters can result in gross and qualitative differences from the actual system being emulated – in this case the nervous system. Even in areas where bottom-up modeling is practical, such as action potential propagation in squid giant axons, normative models may contribute to an understanding of the system. It has been conjectured that the density of sodium channels is optimally adapted to maximize the speed of action potential conductance, very possibly the result of evolutionary pressures to minimize the flight response time. This is of obvious normative reasoning because fleeing fast from approaching predators can mean the difference between life and death. Normative modeling of low-level cellular properties is possible and in close analogy with the normative 'top-down' modeling of behaviors made by decision theory.

Bayesian integration offers a computational framework for combining various sensory information, from multiple modalities and different points in time, into a joint estimate of the world. Consistent with these ideas, unimodal brain regions are known to be affected by uncertainty. For example, primary visual cortex is influenced by the statistics of a stimulus. Multimodal regions that combine information are similarly influenced by probabilities. Prefrontal, temporal, and parietal cortices are likely to exhibit similar statistical principles. Crucial in the timing of motor behaviors and motor learning, the cerebellum's function can also be explained in Bayesian terms. Interestingly, however, even cortical regions traditionally thought of as unimodal, such as primary visual and auditory cortices, have been shown to be responsive to multiple sensory modalities and receive projections from multiple sensory regions. Taken together, the functional and anatomical connectivity of the brain is consistent with the multimodal computations necessary for Bayesian inference. Considering how salient the problem of uncertainty is, numerous, if not all, brain regions can be expected to utilize Bayesian statistics to reduce uncertainty.

Bayesian statistics and normative modeling hold promise for many areas of neuroscience because they formalize the problems the nervous system needs to solve while addressing the inherent uncertainties. Normative models have few free parameters in comparison to neural models – radically simplifying their application. Moreover, normative modeling is synergistic with neural modeling; combining the two techniques will provide models that not only predict but also explain neural behavior. By quantitatively predicting behavior from these normative–neural models, we can develop a deeper understanding of the problems being solved by the nervous system. This will also allow us to ask better, more informed questions in future neuroscientific experiments.

BDNF in Synaptic Plasticity and Memory

N H Woo and B Lu, National Institutes of Health, Bethesda, MD, USA

© 2009 Published by Elsevier Ltd.

Introduction

Among members of the neurotrophin family, brain-derived neurotrophic factor (BDNF) stands out for its ability to regulate synaptic plasticity and various cognitive functions of the brain. A Medline search with the terms 'BDNF' and 'synaptic' yields more than 700 research articles, mostly published in the last 7 years. Given that neurotrophins were initially defined as secretory factors that promote neuronal survival and differentiation during development, the role of BDNF in synaptic modulation was not recognized until late 1990s. A number of observations have aided in the realization that the primary function of BDNF is to regulate synaptic transmission and plasticity, rather than neuronal survival. One is that BDNF is widely distributed in many regions of the adult brain, with levels much higher than any other neurotrophins. The other is that the expression of BDNF can be rapidly enhanced by neuronal activity under conditions relevant to synaptic plasticity. Because neuronal activity is known to be crucial for synaptic plasticity, it was hypothesized that activity-dependent synaptic modulation is mediated by BDNF. Indeed, early studies demonstrated that BDNF mimics neuronal activity in altering the number and/or strength of synaptic connections. Subsequent studies revealed a much more complex and interesting picture. On the one hand, BDNF regulates various forms of synaptic plasticity, leading to changes in neuronal circuitry subserving complex behaviors. On the other hand, many aspects of BDNF cell biology, such as transcription and secretion, are tightly controlled by neuronal activity. Complex interactions between BDNF and neuronal activity may offer a plethora of means to control sophisticated cognitive functions of the mammalian brain.

Cell Biology of BDNF

All neurotrophins arise from their precursors as a result of proteolytic cleavage of the prodomain. Proneurotrophins have long been thought to be inactive precursors. However, this view was challenged a few years ago when proneurotrophins were shown to promote apoptosis via p75 neurotrophin receptor (p75NTR). This is opposite to the cell survival effect by mature neurotrophins, which act via their preferred tropomyocin-related receptor tyrosine kinase (Trk) receptors. Similarly, proBDNF and mature BDNF (mBDNF) have been shown to elicit opposite effects on synaptic plasticity (Figure 1). In recognition that proneurotrophins are biologically active, cleavage of proneurotrophins becomes an important regulatory mechanism that controls the direction of neurotrophin regulation.

Signal Transduction

The biological functions of BDNF are mediated by two receptor systems: TrkB and p75NTR. It is well established that mBDNF binds TrkB with high affinity. Upon binding, BDNF triggers TrkB dimerization resulting in tyrosine phosphorylation in its cytoplasmic domain. These autophosphorylation events recruit a series of intracellular proteins that primes subsequent activation of several signaling pathways. Three classical signaling pathways have been identified: phosphatidylinositol-3-kinase (PI3K) pathway, phospholipase C-γ (PLC-γ) pathway, and Map-Erk Kinase (MEK)-MAPK pathway (Figure 1). The majority of BDNF actions described thus far are attributed to signaling cascades activated by TrkB. In addition to cell surface signaling, BDNF induces the endocytosis of TrkB. Rather than simply inactivating TrkB, the endocytosis of BDNF-TrkB complex results in the formation of BDNF-TrkB signaling endosomes, triggering signaling cascades different from those initiated from cell surface TrkB. This process is required for translation-dependent long-term functions, and is involved in retrograde propagation of BDNF signal from axonal terminals to cell body.

All neurotrophins including proBDNF bind p75NTR, which triggers signaling events distinct from those by Trk receptors. The cytoplasmic domain of p75NTR lacks intrinsic catalytic activity. Upon ligand binding, several intracellular signal transduction cascades are activated, including nuclear factor kappa B (NF-κB), Jun kinase, and sphingomyelin hydrolysis (Figure 1). Notably, p75NTR activation is associated with the initiation of apoptosis. For many years, p75NTR was considered a 'low affinity' neurotrophin receptor. Recent studies indicate that preferred ligands for p75NTR are proneurotrophins, with binding affinities just as high as that between mature neurotrophins and Trk receptors. Current data support a model that pro- and mature neurotrophins induce very different functions through two distinct receptor-signaling systems. An added complexity is the newly discovered coreceptor sortilin. The prodomain of proneurotrophins bind sortilin, whereas the mature domain binds p75NTR. The formation of

Figure 1 Synthesis, trafficking, and receptor-signaling of BDNF. Initially synthesized in the endoplasmic reticulum (ER) as a precursor protein, proBDNF is properly folded in the ER and Golgi network and packaged into secretory vesicles. Subsequently, BDNF is sorted into either the constitutive or regulated secretory pathway, and transported to the appropriate site of release. The prodomain can be cleaved intracellularly by furin or protein convertases, resulting in the secretion of mature BDNF (mBDNF). Alternatively, proBDNF can be secreted and cleaved extracellularly by the tPA/plasmin cascade or metalloproteinases to yield mBDNF. Once secreted, proBDNF and mBDNF elicit diverse and often opposing biological actions via two distinct receptor-signaling systems. mBDNF binds TrkB, leading to the autophosphorylation of tyrosine residues in the tyrosine kinase domain. Consequently, three major signaling cascades can be activated by mBDNF-TrkB, including the PI3K pathway, ERK/MAPK pathway, and PLCγ pathway. In contrast, proBDNF binds p75NTR, resulting in the activation of several signaling molecules, including NF-κB, JNK and RhoA.

the sortilin–proneurotrophin–p75NTR triplex may be necessary for p75NTR signaling.

Activity-Dependent Controls

A cardinal feature of BDNF is that its expression is regulated by neuronal activity. It is now recognized that a multitude of physiological stimuli can alter BDNF expression. For example, visual input and sensory stimulation of the whiskers control BDNF expression in the visual cortex and barrel cortex, respectively. In the superchiasmatic nucleus and amygdala, expression of BDNF is regulated by circadian rhythm and fear emotion. Remarkably, learning or exercise can also enhance BDNF expression in the hippocampus. Moreover, BDNF levels are also affected in a variety of pathological conditions associated with altered neuronal activity in the brain including seizure, Alzheimer's, depression, and stress. In addition to regulation of BDNF gene expression, a new theme emerging from recent studies is that neuronal activity also controls many cellular processes of BDNF, including intracellular trafficking, secretion of BDNF, and perhaps cleavage of proBDNF.

Transcription The genomic structure of BDNF is quite complex. In rats, there are at least four promoters controlling four short 5′ exons. Each 5′ exon is alternatively spliced onto a common 3′ exon (exon V) encoding the pre-proBDNF protein. In humans, the latest study reported seven promoters and eight exons, with exon VIII being the common exon coding for pre-proBDNF. It has long been a puzzle why nature has designed multiple BDNF transcripts that encode exactly the same protein. Cumulative evidence now indicates that these transcripts are distributed in different brain regions, different cell types, and even different parts of the cells (soma vs. dendrites). Importantly, their expression can be altered in response to different physiological stimuli. For instance, exon III transcript is detected only in cell bodies, whereas exon IV transcript is present both in cell bodies and dendritic processes of neurons in the visual cortex. During cerebellar development, thyroid hormone treatment selectively primarily enhances the expression of exon II mRNA.

Emerging evidence indicates that BDNF promoters are differentially involved in various neurological and psychiatric disorders. Promoter II-drive transcription can be suppressed by a neuronal silencer, and such suppression is removed by huntingtin, which binds and sequesters the silencer in the cytosol of cortical neurons. This is important for the survival of cortical neurons that projects to the striatum. In Huntington's disease, the mutant huntingtin can no longer bind the silencer, resulting in the translocation of the silencer into the nucleus and suppression of BDNF promoter II. Another striking example of BDNF promoter specific regulation involves MeCP2, which is a methyl-CpG-dependent transcriptional repressor that binds methylated DNA BDNF promoter III. Neuronal depolarization dissociates MeCP2 from promoter III, leading to the expression of exon III transcript in hippocampal neurons. Mutation in MeCP2, which occurs in 80% of Rett syndrome patients, abolishes this activity-dependent form of regulation. Promoter IV has been implicated in stress and is the major target of glucocortical and mineralocortical receptors. In clinical studies, a human single nucleotide polymorphism (SNP) in the exon IV has been associated with epilepsy and late-onset Alzheimer's.

Among all the promoters, promoter III has received much attention because it is by far the most effectively regulated by neuronal activity in the amygdala, hippocampus, and cortex. An increase in promoter III-driven transcription has been associated with long-term potentiation (LTP) and memory. Early work showed that BDNF gene expression was dependent on a rise in intracellular calcium and that application of high K^+ to cultured cortical neurons selectively enhanced exon III expression. Based on these observations, three elements in promoter III were characterized to be involved in Ca^{2+}-dependent expression of BDNF: the Ca^{2+} responsive sequence 1 (CaRE1) that binds Ca^{2+} responsive transcription factor (CaRF), the E-Box that binds upstream stimulatory factor (USF), and the classic cAMP responsive element (CRE) that binds cAMP responsive element binding (CREB). In addition, the transcription through promoter III is regulated by NF-κB and MeCP2. Taken together, transcription of BDNF exon III is tightly regulated by several mechanisms that couple neuronal activity with gene transcription.

Processing and trafficking Like all neurotrophins, BDNF mRNA is translated into a precursor protein, pre-proBDNF, which enters into the endoplasmic reticulum (ER) lumen through its N-terminal 'pre' sequence (signal peptide). After the removal of the pre-sequence by signal peptidases in the rough ER, the protein is folded in the trans-Golgi network and then packaged into secretory vesicles. Once folded correctly, BDNF is sorted into one of two principal pathways, the constitutive (i.e., spontaneous release) or regulated (i.e., release in response to stimuli) secretory pathway (Figure 2). The BDNF-containing vesicles are trafficked to the appropriate subcellular compartment. In neuronal dendrites and spines, BDNF appears to be stored in a special type of

Figure 2 Regulation of distinct forms of hippocampal synaptic plasticity by BDNF. (a) mBDNF facilitates E-LTP in neonatal hippocampus in which BDNF level is low. Application of tetanic stimulation to neonatal slices (p12-p13) induces only short-term potentiation (STP), which can be converted to E-LTP by exposure to exogenous BDNF. (b) mBDNF facilitates E-LTP by promoting vesicle docking. (c) mBDNF is also involved in L-LTP. Strong theta-burst stimulation (TBS) induces robust L-LTP in wild-type (WT), but not in BDNF +/− mice hippocampal slices. (d) ProBDNF → mBDNF conversion by tPA/plasmin is required for L-LTP. Strong TBS triggers the secretion of tPA, which cleaves plasminogen to form plasmin. Plasmin subsequently cleaves proBDNF to yield mBDNF, which binds TrkB and permits L-LTP expression. (e) proBDNF promotes hippocampal LTD. Slices from p75NTR−/− mice fail to exhibit NMDA receptor-dependent LTD, whereas treatment with cleavage-resistant proBDNF enhances LTD in wild-type slice. (f) proBDNF binds to p75NTR to facilitate LTD, possibly through the regulation of NR2B, a distinct NMDA receptor subunit implicated in hippocampal LTD. secretory granules that lack chromogranin A (CGA), a marker for large dense core vesicles (LDCV). In contrast, conventional BDNF-containing LDCVs have been found in axons and terminals, possibly through anterograde axonal transport. Nonneuronal cells such as fibroblasts and Schwann cell secrete neurotrophins constitutively, whereas principal neurons and neuroendocrine cells secrete neurotrophins in response to depolarization and a rise in intracellular calcium.

The dendritic trafficking and synaptic localization of BDNF appear to be influenced by its own prodomain. This was implicated in a study that examined a SNP in the pro-region of the human BDNF gene. This SNP, located at nucleotide 196, produces a valine-to-methionine substitution at amino acid 66 (Val66Met). In cultured hippocampal neurons, fluorescence-tagged val-BDNF is distributed in cell body, as well as dendrites. A fraction of val-BDNF is also located at synapses, as revealed by their co-localization with synaptic markers. In marked contrast, met-BDNF is largely located in cell body and proximal dendrites. Met-BDNF was rarely localized at distal dendrites and was absent at synapses. These results suggest that the prodomain, particularly the region containing Val66, is critical for dendritic trafficking and synaptic localization of BDNF.

A long-held view is that proneurotrophins, particularly proNGF and proBDNF, are processed by intracellular proteases including the serine protease furin in the trans-Golgi network and the prohormone convertases (PC1/3) in the secretory granules. Recent studies have shown that a large fraction of BDNF in the brain is secreted in the proform, which is converted to mBDNF by extracellular proteases including plasmin or metalloproteinases (MMP3 or MMP7). Because proBDNF and mBDNF elicit distinct and often opposing biological actions through different receptors, proteolytic cleavage has now emerged as a new mechanism that determines the function of BDNF. Of particular interest is tissue plasminogen activator (tPA), an extracellular protease that converts the inactive zymogen plasminogen to plasmin. tPA is secreted from axonal terminals in response to neuronal activity. It is conceivable that neuronal activity could control proBDNF → mBDNF conversion by triggering tPA secretion.

Secretion BDNF is perhaps the only neurotrophin indisputably secreted in response to neuronal activity. In fact, majority of BDNF is sorted into the regulated, rather than the constitutive, secretory pathway. Experiments using green fluorescent protein (GFP)-tagged BDNF revealed that BDNF can be secreted from either pre- or postsynaptic sites. The amount of BDNF secretion depends on the pattern of neuronal activity. Generally, tetanus such as those used to induce LTP is more effective in inducing BDNF secretion than low-frequency stimulation. This has been demonstrated in cultured neurons as well as in slices that underwent different forms of plasticity.

Studies of Val66Met SNP have drawn attention to the role of prodomain in activity-dependent BDNF secretion. In neurons transfected with met-BDNF, depolarization-induced secretion was selectively impaired while constitutive secretion remained normal. Subsequent studies demonstrate that proBDNF is co-localized with the neurotrophin coreceptor sortilin intracellularly in secretory granules, and that sortilin interacts specifically with the prodomain in a region encompassing Val66Met. Remarkably, inhibition of the interaction between the prodomain and intracellular sortilin attenuates secretion of BDNF induced by depolarization, suggesting that this interaction is critical for regulated secretion. However, sortilin could interact with the prodomain of other neurotrophins incapable of regulated secretion, making it less likely to be a specific mechanism for sorting. On the other hand, a sorting motif was recently identified in the mature domain of BDNF, but not nerve growth factor (NGF), that interacts with a well-known sorting receptor, carboxypeptidase E (CPE). Such an interaction was deemed essential for sorting proBDNF into regulated pathway vesicles for activity-dependent secretion. Given that the prodomain promotes proper folding of neurotrophins, it is conceivable that interaction between the prodomain and sortilin may hold proBDNF in a correct configuration, exposing the mature domain to the sorting receptor CPE, which sorts proBDNF into the regulated secretory pathway.

Roles of BDNF in Synaptic Plasticity

The ability of the mammalian brain to adapt or modify itself in response to experience and/or environment depends on the plasticity of synaptic connections. Substantial evidence indicates that the number and strength of synapses is readily altered by neuronal activity. This process, known as synaptic plasticity, displays several physiological properties that substantiate its role as a cellular correlate for multiple cognitive processes, including learning and memory. These include the activity dependence and associative nature of induction as well as the input specificity of expression, all of which endow the vast storage and processing capacity of the mammalian brain. Remarkably, BDNF is involved in many of these features. An emerging theme is that BDNF plays a

critical role in regulating several forms of synaptic plasticity in distinct regions of the brain, including the hippocampus and visual cortex.

Input Specificity

Most activity-dependent forms of synaptic plasticity expressed in the brain are input specific, namely modifications at one synapse are not spread to synapses nearby. Experiments have shown that BDNF elicits its actions in a local and synapse-specific manner, with particular preference to active synapses. This unique property may be attributed to several key characteristics of BDNF signaling.

First, secretion of BDNF is activity dependent and is likely to occur at synaptic sites. The control of BDNF secretion occurs relatively fast, usually in a timescale of seconds. Imaging studies demonstrate that BDNF is often co-localized with pre- and postsynaptic markers in hippocampal neurons, suggesting the synaptic localization of BDNF. Application of high-frequency stimulation (HFS) induces a rapid decay of GFP-tagged BDNF, indicating BDNF is secreted in an activity-dependent manner at synapses. Due to its negative charge, BDNF is thought to have a limited capacity for diffusion, and therefore constrains the actions of BDNF at or near its site of secretion.

Second, there is good evidence that BDNF exon II and IV transcripts can be targeted into the dendrites of hippocampal neurons, and neuronal activity enhances such targeting. Recent studies have shown that dendritic BDNF mRNA can be translated locally into BDNF protein. Taken together, a possible scenario is that local synaptic activity triggers dendritic translation of BDNF and may serve as an alternative mechanism to ensure synapse-specific modulation by BDNF.

Finally, local synaptic activity may ensure a better response of target synapses to BDNF by regulating TrkB trafficking. High-frequency neuronal activity has been shown to promote the insertion of TrkB into the surface membrane of hippocampal neurons. This process appears to be ligand independent and requires calcium influx and activation of Ca^{2+}/calmodulin-dependent kinase II (CaMKII). BDNF secreted from active synapses/neurons recruits TrkB from extrasynaptic sites into lipid rafts, microdomains of membrane enriched at synapses. This lateral movement requires TrkB tyrosine kinase activity. Synaptic activity often induces a rise of postsynaptic cAMP. This local increase in cAMP concentration at active synapses facilitates translocation of TrkB into the postsynaptic density, and functions to gate synapse-specific effects of BDNF by controlling TrkB tyrosine phosphorylation locally. Finally, neuronal activity promotes BDNF-induced TrkB endocytosis, a signaling event important for many long-term BDNF functions. All of these could contribute to a more efficient response to BDNF at active synapses.

Early Phase Long-Term Potentiation

It is well established that BDNF plays a key role in LTP, a persistent enhancement of synaptic strength. LTP can be divided into an early phase (E-LTP) and a later phase (L-LTP). E-LTP is relatively short-lasting (1 h) and depends on protein phosphorylation, while L-LTP lasts many hours and requires new protein synthesis. Early work has focused on BDNF regulation of E-LTP in the hippocampus. In neonatal hippocampus in which BDNF levels are low, exogenous BDNF facilitates E-LTP induced by HFS (**Figure 2(a)**). In addition, exogenous BDNF facilitates LTP induced by subthreshold tetanus that normally induces weak potentiation. Conversely, in the adult hippocampus, a stage where endogenous levels of BDNF are relatively high, inhibition of BDNF activity either by function-blocking BDNF antibody or BDNF scavengers, TrkB immunoglobulin G (IgG), attenuates the expression of E-LTP.

In agreement with pharmacological studies, genetically modified mice with mutation of either BDNF or TrkB gene exhibit severe impairments in E-LTP. Interestingly, heterozygous mice (BDNF+/−) with only half of the BDNF gene dosage show a similar degree of impairment as homozygous mice (BDNF−/−), arguing that a critical level of BDNF is important for hippocampal LTP. The impairment of LTP in BDNF-mutant mice is reversed by acute application of recombinant BDNF or by virus-mediated BDNF gene transfer. Deletion of BDNF gene selectively in the adult forebrain by inducible knockout approaches confirms that the effects of BDNF on E-LTP are not due to developmental abnormalities.

The effects of BDNF on hippocampal E-LTP result primarily from alterations of presynaptic function (**Figure 2(b)**). Exogenous BDNF enhances synaptic response to HFS and paired pulse facilitation (PPF), two indicators of presynaptic function. In mice lacking BDNF, posttetanic potentiation (PTP) and PPF are significantly reduced. Electron microscopy reveals a reduction in the number of vesicles docked at presynaptic active zones in these mutant mice. Moreover, biochemical experiments using hippocampal synaptosomes indicate that BDNF modulates the levels or phosphorylation of synaptic proteins involved in vesicle docking and fusion, such as synapsin, synaptophysin, and synaptobrevin. Taken together, the presynaptic role of BDNF for the mobilization and/or docking of synaptic vesicles to presynaptic active

zones may allow hippocampal synapses to follow tetanic stimulation more effectively, resulting in the facilitation of hippocampal LTP.

It is important to note that the biological effects of BDNF are not exclusively the result of its presynaptic actions. In the dentate gyrus, the induction of LTP requires postsynaptic BDNF signaling. A series of studies have demonstrated that BDNF can exert postsynaptic modulatory effects by modulating α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type and *N*-methyl-D-aspartate (NMDA)-type glutamate receptors in neuronal cultures, and some potassium channels in hippocampal slices. In this respect, TrkB receptors have been observed to localize in the postsynaptic density of isolated synaptosomes prepared from cortical neurons. However, whether these postsynaptic modulatory effects of BDNF directly participate in LTP remains to be established.

Late Phase Long-Term Potentiation

Several early studies suggest that BDNF may also play a role in late phase long-term potentiation (L-LTP). L-LTP-inducing tetanic stimulation selectively enhances the expression of BDNF and TrkB mRNAs in the hippocampus. BDNF transcription is regulated in part by CREB, a transcription factor required for L-LTP expression. The delayed and sustained enhancement of BDNF synthesis correlates well with the time course of L-LTP, which increases 2–4 h after L-LTP induction. More direct evidence comes from electrophysiology experiments showing a significant reduction in L-LTP recorded from slices treated with TrkB-blocking antibody, or those from BDNF +/− mice (Figure 2(c)). However, BDNF only regulates L-LTP induced by theta-burst stimulation (TBS) or application of the adenylate cyclase activator forskolin, but not by four spaced trains of HFS, a more standard protocol used to induce L-LTP. These results suggest that strong tetanic stimulation may induce signaling downstream of BDNF, bypassing the requirement of BDNF in L-LTP.

Recent experiments have provided more in-depth insights as to the role of BDNF in L-LTP. In the presence of BDNF, weak tetanus that normally induces only E-LTP resulted in robust L-LTP. Moreover, perfusion of BDNF to hippocampal slices rescued L-LTP that is normally absent when protein synthesis is inhibited. It appears that BDNF is secreted largely in its precursor form (proBDNF), which is converted to mBDNF by extracellular proteases. Biochemical and genetic experiments indicate that this conversion is mediated by an enzymatic cascade that involves tPA and plasmin, two secreted proteases found at hippocampal synapses. tPA has long been implicated in L-LTP, but the precise downstream effector(s) of tPA was not established. The current data support the notion that tPA cleaves the inactive zymogen plasminogen to form plasmin, which in turn cleaves proBDNF to generate mBDNF. Application of mBDNF, but not cleavage-resistant proBDNF, completely reversed the L-LTP deficit observed in tPA and plasmin knockout mice. Thus, conversion of proBDNF to mBDNF by the tPA/plasmin system is critical for L-LTP expression (Figure 2(d)).

Two key cellular events associated with long-term synaptic plasticity are synaptic growth and *de novo* protein synthesis, both of which are regulated by BDNF. In addition to stimulating axonal growth, chronic application of BDNF to hippocampal slices increases the dendritic spine density of CA1 pyramidal neurons. This is particularly relevant since dendritic spines and protrusions are enhanced during L-LTP. In cell cultures, BDNF has been shown to increase mammalian target of rapamycin (mTOR)-dependent translation of a panel of synaptically expressed transcripts including GluR1 and homer2 mRNAs in the dendrites of hippocampal neurons. However, exogenous BDNF applied immediately after strong TBS rescues L-LTP in hippocampal slices in which protein synthesis was blocked for the entire course of the experiments. This provocative result, together with the finding that gene expression of BDNF is stimulated by L-LTP-inducing tetanic stimulation, implies BDNF is a key protein synthesis product required for long-term modifications necessary for L-LTP expression.

Long-Term Depression

In addition to its role in LTP, BDNF regulates long-term depression (LTD), a persistent reduction in synaptic strength induced by prolonged low-frequency stimulation. Expression of LTD is developmentally regulated and exists in several forms mediated by different glutamate receptors. The best-known form of LTD is the NMDA receptor (NMDAR)-dependent form, which is robustly expressed in young animals. mBDNF inhibits LTD in the visual cortex and hippocampus. Collectively, these observations point to a general theme that BDNF facilitates synaptic strengthening, but attenuates synaptic depression.

Analogous to the survival and apoptosis effects of mBDNF and proBDNF, respectively, in the periphery, an important advance is that proBDNF, if uncleaved, enhances NMDAR-dependent LTD via p75NTR in the CNS. Compared to TrkB, the role of p75NTR in synaptic plasticity has not been studied until

recently. In p75NTR mutant mice (p75NTR−/−), NMDAR-dependent LTD was completely absent while other forms of plasticity including NMDAR-dependent LTP and NMDAR-independent LTD were intact. Biochemical experiments indicate that NR2B, a specific NMDAR subunit uniquely implicated in LTD, was significantly reduced in the mutant hippocampus. Whole-cell recordings revealed a severe reduction in NR2B-mediated synaptic currents in CA1 neurons of p75NTR−/− mice. More importantly, application of cleavage-resistant proBDNF increased NR2B-mediated synaptic currents and enhanced LTD in hippocampal slices derived from wild-type mice but not in p75NTR−/− mice (Figure 2(e)). These findings suggest that proBDNF is an endogenous ligand of p75NTR during development, which acts to enhance LTD via modulating NR2B function (Figure 2(f)).

Learning, Memory, and Other Cognitive Functions

Given its central role in synaptic plasticity, numerous studies have examined how BDNF regulates the acquisition (learning) and retention (memory) of new information. Thus far, the strongest correlation is observed between BDNF and hippocampal-dependent forms of memory, which include declarative or episodic and spatial memory. During contextual learning, BDNF expression is rapidly and selectively upregulated in the hippocampus. When BDNF signaling is disrupted either by inhibitors or by genetic knockout, spatial learning is significantly impaired, as reflected by poor performance in the Morris water maze. In many cases impairments in memory were also mirrored with LTP deficits. For instance, deletion of BDNF or TrkB gene in the adult forebrain results in a significant attenuation of contextual fear or spatial memories, as well as hippocampal LTP.

A major advance came from a study on a SNP, which converts a valine (val) to a methionine (met) in the prodomain of the human BDNF gene. This SNP occurs with a frequency of approximately 19–25% in the Caucasian. Human subjects with the met allele exhibit lower hippocampal *N*-acetylaspartate (NAA), a putative measure of neuronal integrity and synaptic abundance. Functional imaging reveals an association of the met allele with abnormal hippocampal activation (Figure 3(a)). Most remarkably, subjects with the met-BDNF allele performed poorer in a hippocampal-dependent episodic memory task, but not in hippocampal-independent working memory and semantic memory tasks. In cultured neurons derived from rodent hippocampus, BDNF (val-BDNF) is packaged in secretory granules that are distributed as puncta throughout cell body and dendrites, with some localized at synapses. In contrast, significantly less met-BDNF-containing granules are localized to dendrites and synapses. Moreover, regulated secretion of met-BDNF induced by neuronal depolarization, but not constitutive secretion, is significantly reduced. Thus, impairments in trafficking, synaptic targeting, and/or regulated secretion may explain the specific memory deficits seen in human subjects with the met allele (Figure 3(b)). These results represent the first demonstration of a role for BDNF in human hippocampal function and of a single gene affecting human episodic memory.

Figure 3 Impact of a SNP in the BDNF gene on cognitive brain function and intracellular trafficking of BDNF. The SNP converts a valine to a methionine in amino acid 66 located in the prodomain of BDNF (val66met). (a) Differences in fMRI responses between val/val and val/met subjects during a memory task. Subjects with val/met genotype exhibit abnormal hippocampal activation (shown in red). The met/met subjects also exhibit deficits in hippocampus-dependent episodic memory. (b) Cellular phenotypes associated with the BDNF val66met SNP. Val-BDNF is distributed throughout a typical hippocampal neuron including distal dendrites and synapses. In contrast, met-BDNF is rarely localized at distal dendrites or synapses and fails to undergo depolarization-induced secretion. Failure of intracellular trafficking and activity-dependent secretion of BDNF may underlie the cognitive deficits observed in subjects with the met allele. (a) Reproduced from Egan MF, Kojima M, Callicott JH, et al. (2003) The BDNF val66met polymorphism affects activity-dependent secretion of BDNF and human memory and hippocampal function. *Cell* 112: 257–269, with permission from Elsevier.

Genetic analyses in mice show that genes affecting memory performance often impact other cognitive functions. It is now recognized that deficits in BDNF may contribute to neurological and psychiatric disorders. In studies of drug addiction, LTP and LTD have emerged as candidate mechanisms for drug-induced alterations in the nucleus accumbens and ventral tegmental area. Several reports have demonstrated that BDNF modulates behavioral sensitization to cocaine. Substantial evidence also points to its role in depression. There is reduced BDNF expression in the hippocampus of animal models for depression; chronic treatment with antidepressants increases its levels. However, it is unclear whether antidepressants achieve their clinical effects on depression by upregulation of BDNF.

Conclusion

Stemming from the multidisciplinary approaches used in present-day research ranging from cellular systems to behavior, BDNF is now recognized as a key regulator for synaptic circuits underlying many cognitive functions. New and unidentified role(s) of BDNF in plasticity and cognition will undoubtedly continue to surface and will provide abundant intellectual stimulation to drive future advances. Ultimately, understanding the actions of BDNF will aid in the development of therapeutic interventions that will alleviate a wide spectrum of neurological and psychiatric disorders derived from BDNF dysfunction.

Behavioral Hierarchies

Introduction

Nikolaas Tinbergen wrote the following in 1951:

> It is of great importance for our understanding of instinctive behaviour as a whole to realize that the various instincts are not independent of each other. We have rejected the reflex hypothesis of behaviour and we have seen that each instinctive mechanism is constantly primed, that is to say, prepared to come into action. Such a system can only work because blocking mechanisms prevent the animal from performing continuous chaotic movements.

The term 'behavioral hierarchy' is used to describe the structural organization of behavioral expression. It reflects that certain behaviors can take precedence over others when appropriate stimuli for the multiple behaviors coincide in time. Healthy animals are generally configured for three basic functions: acquisition of nutrient resources, avoidance of debilitating injury and death, and reproduction. Each function subsumes a suite of behavioral subroutines of a size commensurate with the animal's lifestyle complexity, and the expression of the behavioral elements within and between those functions tends to be fractionated. That is, in general behaviors are expressed in a unitary way, so that conflicting behaviors are not expressed together, and the organism may concentrate its attention on achieving its goals efficiently.

The concept of the behavioral hierarchy formalizes the common observations that animals tend to devote themselves rather single-mindedly to affairs at hand that serve motives of goal satisfaction, defense, or simple avoidance of harm. In it, expression of an animal's behavioral repertory is organized to serve the competitive natures of reproduction and resource acquisition. Humans appreciate this intuitively and express it in literature and art extensively founded on interlocking themes of social dominance, reproductive success, and resource acquisition.

Tinbergen's simple and elegant scheme for the organization of behavior derived from assiduous observations of behavioral transitions and the conditions under which they occurred. It resonated with an appreciative audience of behavioral researchers in both field and lab because it had much explanatory and predictive power and because in retrospect it was so obvious. However, one of the most exciting aspects of his work was that he formulated neural hypotheses from his behavioral observations that were testable in the laboratory. While he considered his model as an overly simplified, beginning attempt at explaining the origin of behavioral hierarchies, he well realized its explanatory power.

He conceived of animal behavior as a hierarchical organization of behavioral modules, of suites in which antagonistic components lay within reciprocally inhibitory relationships (Figure 1). Thus, when one component was expressed as a result of excitation by an appropriate sign stimulus, or an internal motivational component, the incompatible behavior would be actively suppressed. His conclusions came from observations such as when the male stickleback was in reproductive condition and actively engaged in nest building, the threshold for releasing aggression against a male conspecific was markedly higher than when not so engaged. He and his contemporaries appreciated the influence of hormonal state on behavioral thresholds, auguring the present understanding of the role of plasticity in behavioral hierarchies.

Tinbergen's work happily coincided with early decades in which emerged appreciation of the nature of the nerve action potential and the integrative power of the synapse. He was also aware of contemporary views that the nervous system was organized in a somewhat hierarchical fashion, such that elements of simpler behaviors often emerged from pattern-generating 'centers' in the spinal cord and were integrated appropriately by specific sensory inputs and descending influences.

Coupled with early demonstrations that simple neural circuits could be deduced in the laboratory as pattern generators for simple behaviors in invertebrates, these proposals gave rise to the field we now recognize as comparative neuroethology, in which a basic premise has been that accurate observations of behavior can generate testable neural hypotheses regarding neural mechanisms. How have the past 60 years of neuroethological investigations refined and modified the concept of behavioral hierarchy?

Early Neural Models of Behavioral Choice

Some of the earliest investigations of arthropod model systems found that simple repetitive behaviors, such as rhythmic swimmeret beating in crayfish and lobster, could be preserved in semi-intact preparations deprived of sensory inputs. This led to the concept of the central pattern generator (CPG), a neural circuit that could generate appropriately patterned outputs by itself, and for which the patterned output could be sculpted by sensory and other inputs to adapt to specific situations; for instance, unevenness of terrain during locomotion. From this it was evident

Figure 1 Tinbergen's concept of the hierarchical system of centers underlying an instinct, here shown as for reproduction in the stickleback. Centers, represented as circles at different levels, stand for behavioral suites such as the elements of fighting, nesting, and so forth at the second level. Reciprocal arrows between the centers indicate mutual inhibitory relationships such that behaviors tend to be expressed singly, without conflict. From Tinbergen N (1951) *The Study of Instinct*. Oxford, UK: Clarendon.

that basic outlines of much behavior could be generated centrally and modified by continuous sensory feedback from the environment, a concept that lent a great deal of impetus to neurophysiological inquiry into locomotion and other rhythmic behaviors in invertebrates and vertebrates.

The early probing of the swimmeret and other CPGs employed extracellular electrodes for stimulating and recording; these yielded exact documentation of the phenomenology attending motor output and control, but they could not easily extract detailed integrative mechanisms. Eventually, in a number of instances it, was found that distinct, patterned behaviors (such as swimmeret beating in semi-intact preparations), or their fictive motor output in isolated nervous systems, could be elicited by simple trains of electrical shocks to certain areas of the nerve cord. Moreover, by careful dissection, single nerve fibers could be separated which when stimulated could drive the entire behavior, but with unique effects on frequency or phase coordination that suggested their actions in combination to achieve normal behaviors. Such observations led to the concept of the command neuron, which seemed to fit in well with the putative neural organization of a behavioral hierarchy.

Evolving Perspectives of Behavioral Choice

The command neuron concept borrowed momentum from early ideas of the existence of 'centers' in the brain responsible for distinct behavioral suites. One early and attractive interpretation was that command neurons acted as integrating centers for the excitatory and inhibitory effects of sensation, internal needs, and memory, and that when behavioral thresholds were reached, their activity would command that behavior. Soon commandlike neurons in several different preparations were reliably identified and recorded with intracellular electrodes, allowing their roles in driving motor outputs and integrating sensory influences to be studied in some detail. At one point a forum of neuroethologists convened to discuss their nature, from which emerged the idea that 'command neurons' could be defined as cells "both necessary and sufficient" to drive a patterned motor output. That is, they would be active during the behavior, they could drive it they were when stimulated, and the behavior would be blocked or diminished when those cells were hyperpolarized into silence.

One type of command neuron both necessary and sufficient to its behavior was identified in a number of small rhythmic networks, including those for molluskan feeding, escape swimming in certain sea-slugs, and leech swimming. Spiking in these neurons driven by tonic intracellular current injection drove appropriate motor output of the CPG with an important sequel: rhythmic, alternating excitatory and inhibitory synaptic feedback from the oscillating CPG entrained the command neurons themselves into rhythmic activity locked to one phase of the CPG rhythm. Thus, these neurons were actually intrinsic elements of the CPGs they drove.

The finding of these commandlike neurons invited assessment of their roles in the neural organization of behavioral hierarchies. Detailed studies in mollusks and leech showed that these neurons acted as passive positive-feedback elements in the feeding CPGs, where they acted to provide the degree of excitation necessary to bring the feeding motor network over the threshold for active expression of rhythmic motor output (swimming, biting, and swallowing). The immediate relevance of these command neurons to behavioral hierarchies was that, at first glance, they seemed to be critical sites in the neuronal circuitry where specific motor expression could be suppressed, allowing expression of alternative responses to stimuli (such as active avoidance of food in the mollusk, or shortening vs. swimming in the leech).

The view of command neurons as critical sites where CPG expression could be suppressed was well in line with Tinbergen's predictions of reciprocal inhibition between incompatible behaviors. However, this view is still not the same as the notion that command neurons act as sites where **go, no-go** decisions are made by directly integrating external inputs from both sensory lines and other CPGs. Where they are presently known, those functions appear to lie presynaptic to the command neurons, within the CPGs where they both reside and act.

Neuronal Bases of Behavioral Hierarchies

For Tinbergen and his colleagues, the behavioral hierarchy of the male stickleback in reproductive season was especially clear, and this made the animal a useful model system for investigations that have spanned seven decades. The stickleback studies emphasize both the importance of the apparent roles of inhibition between temporally dominant behaviors, such that the sensory thresholds for expression of subordinate behaviors are increased, and the importance of correct routing of sensory stimuli in expression and sequencing of behavioral elements. They led to the question, how are these regulatory mechanisms actually mediated at the level of the responsible neural networks? This experimental question has been addressable in animals with simple brains and behavior.

Nutrition and reproduction are the major influences on the marked plasticity observed in behavioral hierarchies of most animals. Thus, high levels of nutrient appetite tend to be manifested in arousal and goal-directed activities. These are most notable in motile foragers, and in particular in active predators.

The medicinal leech provides a vivid example of the general types of behavioral changes attending changing hunger and reproductive states that happen in many animals. Marked hunger is manifested in heightened sensitivity to water vibrations and reduced swim thresholds. Immediate plasticity in the hierarchy is mediated by sequential reactions to sign stimuli. For instance, should oriented swimming to a vibration source lead to the lucky find of a bathing mammal, both attachment to the skin substrate and the heat of the warm-blooded animal inhibit further swimming. Crawling may lead to finding a site where warmth, appetitive odors, and thigmotaxic coziness may summate to inhibit crawling and initiate active feeding. Satiation in the leech, after imbibing up to eightfold its weight, completely changes its behavioral responses. Feeding inhibited by gut distention, the leech drops off and, if lucky enough to be back in a lake or stream, heads for the bottom and a safe niche under a rock or sunken log, completely ignoring the appetitive stimuli formerly so attractive. There, the blood meal is digested over weeks to months and converted to reproductive resources, the eggs. During this time the leech is entirely unresponsive to the appetitive influences that drove its predatory behavior, first in the short term because of the gut distension from its meal and then second probably by the reproductive hormonal influences triggered by permissive signals from the nutrient resource.

For vertebrates, detailed mechanisms of the switching mechanisms underlying behavioral hierarchies remain for the most part unknown, due to the relative difficulty of precisely specifying neuronal circuitry. However, a great deal is becoming known about the involvement of peptides and hormones. In mammals appetite and major aspects of behavioral arousal in mammals are organized around peptidergic hormones and transmitters. The satiety mechanisms in mammals are diverse. The mammalian brain keeps an account of its nutrient resources in terms of blood glucose, glycogen stores, fat stores, and digestive activity. Glucose sensor neurons abound in hypothalamic areas regulating appetite. The hormones leptin, secreted from adipose cells proportionate to mass, and ghrelin and other peptides secreted from the stomach act at the hypothalamus on the peptidergic

neuron circuits driving appetitive arousal and behavior. Neurons in the hypothalamus also produce leptin and ghrelin, among other potent peptide neuromodulators, and exert effects on neurons producing orexin and neuropeptide Y peptides that promote appetite and cortical arousal. Orexins are key peptides in stimulation of both appetitive behavior and the arousal side of sleep and wakefulness. Receiving inputs from all nutrient stores, orexin neurons couple behavioral arousal to energy balance and appetite. Behavioral decisions can therefore be made on a long-term cost–benefit basis, in which risk assessment and resource valuation can be estimated in terms of need.

Studies of simpler model systems with both uncomplicated behavioral repertories and accessible nervous systems have cast light on the interactions between motor networks for different behaviors that can organize them into specific priority sequences for expression. For active predators in foraging mode, such as the leech and the California sea-slug *Pleurobranchaea*, feeding behavior dominates most other behaviors. For instance, a sensitive withdrawal reflex is normally stimulated by a rough prod to the anterior region. However, expression of active feeding behavior in the presence of food stimuli actively suppresses the withdrawal in both species. Moreover, most ongoing behaviors can be shut down rapidly and completely by initiation of an escape or startle reaction.

Studies of behavioral hierarchies in gastropods and annelid drew schemes for the organization of behavioral priorities. For the most part, they represented an apparent central position of feeding behavior in the animals' hierarchies: feeding could suppress copulation, reflex withdrawal, and even righting responses that normally occurred when the animal was turned over. Egg laying could raise the stimulus threshold of feeding behavior to levels unlikely to be encountered during the act. However, escape responses superseded all other behaviors. Details in these and other invertebrate model systems differed in ways pertinent to the animals' particular behavioral ecologies.

Invertebrate model systems invited analysis of underlying causality by the accessibility of their nervous systems to circuit analysis. Now Tinbergen's hypothesis could be visited at the neural level to answer how the singleness of behavioral expression actually emerged. Are hierarchies organized on the basis of direct synaptic inhibition among neural networks for different behaviors, or in some other, indirect, fashion?

Initially, it seemed that the simple model would hold. The earliest studies of behavioral choice in *Pleurobranchaea* revealed that food avoidance conditioning was accompanied by synaptic inhibition of feeding command neurons in response to food stimulation. Further, it was demonstrated that active feeding expression caused suppression of reflex withdrawal due to corollary output from the feeding motor network. That corollary output acted to reduce touch stimulus-induced excitation of withdrawal motor neurons, presumably through inhibition of a presynaptic withdrawal interneuron. Similar observations were made in the sea-butterfly *Clione*, a voracious molluskan planktonic predator. Driving identified neurons, the pleural withdrawal cells, caused whole body withdrawal of the animal and inhibition of the swim neurons, which would cause the animal to crumple and drop in the water column – an avoidance behavior. In turn, the pleural withdrawal cells received inhibition when the feeding motor network was activated. In leech, suppression of swimming by activation of shortening was accompanied by inhibition of 'gating,' or commandlike neurons, the 204 cells. The dominance of one behavior over another in these models was in each case explainable by hypothetical inhibitory connections from one motor center to another.

Thus, initial observations in these diverse systems at first seemed very compatible with the concept of simple corollary inhibition of subordinate neural networks by a dominant one, from which the behavioral hierarchy emerged. However, in the absence of more-detailed information about exact neural circuitries, other configurations were not ruled out.

Further investigations in invertebrate model systems markedly refined understanding of the control principles underlying behavioral switching and choice. These involved the neural bases of decisions for alternative expression of escape, feeding, and turning in *Pleurobranchaea*, for ingestive versus egestive motor output in the sea-hare *Aplysia*, and for swimming, shortening, and crawling in the leech *Hirudo*.

Plasticity in Behavioral Hierarchy: Reconfiguration of a Feeding Motor Network

Tinbergen and his contemporaries recognized that behavioral hierarchies were more flexible than those of most human governing and military bodies, from whom the concept of hierarchy was borrowed. Rather, behavioral priorities could change with internal state, such as reproductive condition, to emphasize different goals. Plasticity in feeding behavior, closely regulated as it is by interactions of sensation, appetite, and experience, is one critical aspect that has been studied at the neural level in invertebrate model systems.

Feeding expression, a central aspect of *Pleurobranchaea*'s repertory, is regulated by motivational state (hunger), learning experience, and escape. Sensory thresholds for inducing feeding in animals either satiated or conditioned against a food stimulus with

electrical shock in a food avoidance task rise markedly. In satiated or food avoidance-trained animals, the feeding response is actively suppressed, and they actively avoid food. In analyses of the role of the feeding command neurons, the paracerebral neurons (PCNs), normally excited by food stimuli in hungry animals, showed prolonged inhibition by food stimuli in satiated and trained animals (Figure 2(a)). When the neuronal source of this inhibition was identified, it was intrinsic to the feeding motor network itself, not external in origin.

The origin of the inhibition of the command neurons was in presynaptic neurons that were themselves part of the feeding motor network. An abbreviated structure for the feeding motor network of *Pleurobranchaea* is represented in Figure 2(b). The PCNs are part of the motor network they drive, and during the cyclic biting and swallowing of feeding, their activity is rhythmically entrained to the protraction phase of the cycle of buccal mass movements. Entrainment is accomplished by excitatory feedback from the feeding oscillator during protraction, while inhibitory inputs during the retraction phase punctuate their activity. The inhibitory inputs to PCNs come from small populations of identified interneurons, the interneuron 1 (I1) group, and the interneuron 2 (I2) neurons that potently excite both the I1s and many other retraction neurons in the motor network. Thus, in the hungry, actively feeding animal, the I1s and I2s fire rhythmically during the feeding cycle. However, in satiated and food avoidance-conditioned animals, the I2s fire tonically, driving the I1s to tonically inhibit the PCNs. Through potent outputs to the retraction neurons of the feeding oscillator, tonic I2 activity also essentially locks up the network in the retraction phase of the feeding cycle (Figure 2(c)). In this instance, inhibition of feeding behavior by motivational state and learning is caused by excitation, not inhibition, of elements intrinsic to the underlying network. The mechanism of behavioral choice here is not so much inhibition of the command neurons as a reconfiguration of the feeding network to an alternate state.

The source of the excitatory input to the I2s, as yet unknown, could come from other retraction interneurons of the feeding motor network driven

Figure 2 Suppression of feeding by satiation and food avoidance conditioning in *Pleurobranchaea*. Inhibition of feeding command neurons is mediated by inhibitory neurons intrinsic to the feeding CPG. (a) Records from paracerebral neuron (PCN) feeding command neurons during food stimulation (horizontal bars) in a naive hungry animal (top) and in an animal conditioned to avoid food by paired food–shock (bottom). Arrows indicate rhythmic bites. Calibration: 25 mV vertical, 2 s horizontal. Similar inhibitory activity in PCNs is seen in satiated animals. Modifications induced by experience. *Journal of Neurophysiology* 49: 1557–1572, used with permission from the American Physiological Society.

by satiation and effects of memory, and/or from collateral activity of the turn avoidance network. Avoidance turns are the alternative behavior released when feeding to appetitive stimuli is suppressed.

Suppression of a Subordinate by a Dominant Behavior: Network Reconfiguration

For inhibition of feeding by escape swimming, the mechanism of feeding inhibition is instructively different. Again, actual inhibition of feeding is excited in intrinsic inhibitory neurons of the feeding network. The dominance of escape swimming over feeding arises from actions of corollary outputs of the swim CPG (Figure 3). Inhibition of feeding is specifically exerted by the swim CPG output interneuron A-ci1 and probably yet unidentified cells. A-ci1 is driven by the pattern-generating subset of swim interneurons, A1, A10, and A3, to cause a global inhibition of the swim motor network. A-ci1 causes tonic excitation of the I1 group of the feeding CPG. Excitation of the I1s by A-ci1 interrupts the normal cyclic A1 activity during feeding and tonically inhibits the PCN feeding command neurons. However, as also shown in Figure 3(b), the I1s also provide feedback inhibition to their presynaptic I2 neurons. Activity in the I2 neurons completes a positive feedback loop in

Figure 3 Suppression of feeding by swimming through corollary outputs of the swim network, swim central pattern generator (CPG) output interneurons (A-ci1), that excite inhibitory neurons, I1, in the feeding CPG that directly inhibits both the paracerebral neuron (PCN) feeding command neurons and the I2 major interneurons. (a) Intracellular records showing that driving A-ci1 excites I1 to inhibit PCNs and I2s. A-ci1s are swim network outputs. (b) Synaptic interactions within and among swimming and feeding networks. (c) Idealized activity in the feeding network and A-ci1 during interruption of ongoing feeding activity by an escape swimming. A1, A3, and A10, swim interneurons; As1–4, multifunctional serotonergic neurons; 5-HT, 5-hydroxytryptamine (serotonin). Prot., protraction; Ret., retraction. Calibration: vertical, 40 mV of all top records, 4 mV for bottom records, except for the I1 record in (b), 8 mV; horizontal 3 s. (a) Reproduced from Jing J and Gillette R (2000) Escape swim network interneurons have diverse roles in behavioral switching and putative arousal in Pleurobranchaea. *Journal of Neurophysiology* 83: 1346–1355, used with permission from the American Physiological Society.

the retraction neuron population that is necessary to normal feeding motor output. Thus, during escape swimming there is a global inhibition of the feeding oscillator network, effectively shutting down both populations of protractor and retractor neurons that compose the feeding motor oscillator and its outputs.

In the cases of suppression of feeding by either satiation/learning or escape, inhibition of the behavior is not mediated by direct synaptic inhibition from one CPG to the other. Instead, the feeding network as a whole is reconfigured through targeting strategically placed interneurons (which are not themselves command neurons but have broad effects within the network). Instead of broadly distributed inhibition from extrinsic inputs, the inputs are excitatory. The targeted neurons, activated tonically, work to change the active network configuration.

Moreover, the different modes of feeding suppression exerted from the two sources have adaptive significance. In suppression of feeding by satiation/learning, the network is locked up in one mode of its normal motor output, retraction. Increasing the appetitive sensory stimulus and providing additional excitation to the network can bring it over threshold to express a coordinated feeding attack. In contrast, the suppression caused by escape is much more complete and must ensure that the escape behavior will not be compromised by inappropriate expression of feeding.

Suppression of Turning by Swimming: Recruitment of Essential Elements

A third type of example of inhibition of one behavior by another involves quite a different mechanism: recruitment of neural elements essential to one behavior by a second, dominant behavior. This is seen in the behavioral choice between escape swimming and turning behavior in *Pleurobranchaea*. Here, elements providing the intrinsic network excitation of the pattern generator for one behavior (turning) are effectively assimilated by the pattern generator for the other (swimming). The avoidance turn swivels the animal's body through a wide angle and is followed by rapid locomotion. It is commonly triggered by noxious stimuli such as recognition of a larger, cannibal conspecific. Escape swimming can interrupt the avoidance turn to effect a faster getaway and is commonly triggered at a higher stimulus threshold.

It appears to work as follows, as outlined in Figures 4(a)–4(c): the swim network and the turn network share the four multifunctional serotonergic neurons, As1–4. At lesser intensities of noxious stimulus, As1–4 are recruited into an emergent turn CPG along with the bilaterally paired A4 turn command neurons to mediate an avoidance turn. As the turn CPG is active, the As1–4 fire tonically at a moderate frequency (3–7 Hz; Figure 4(b)), driving intense, tonic, and unilateral A4 activity that itself powers the turn. At higher stimulus intensities, the firing rates of the As1–4 more than double to activate the CPG of the escape swim. The ensuing cyclic inhibition–excitation of As1–4 interrupts and suppresses both tonic A4 activity and the avoidance turn. Thus, when the As1–4 neurons are co-opted into the swim oscillator, the A4 cells are entrained into weak cyclic activity phase locked to the swim cycle and prevented from the tonic unilateral discharge necessary to avoidance turns (Figures 4(b) and 4(c)).

The switch between the escape swim and the avoidance turn in *Pleurobranchaea* is an example of behavioral choice mediated by switching among metastable states of a neural network. Feeding networks in particular may display multiple states, among which transitions are driven by different combinations of both internal and external stimuli (Figure 4(d)). A similar mechanism mediates switching between locomotion and escape swimming in the related sea slug *Tritonia*.

Reversing Motor Output: Reconfiguring the Network

Another example of network reconfiguration underlies switches from ingestion to egestion in mollusks, where the feeding circuitry is reconfigured for opposite behavioral action. A circuit mechanism is being elucidated in the feeding circuitry of *Aplysia*, where it has been shown that the change in coordination of the feeding network from biting and swallowing to rejection is comparable to neuronal models of gait change in vertebrate locomotion.

In *Aplysia* feeding, during retraction the radula closes to grasp food material and draw it into the buccal cavity. During egestion, radula closure is shifted to happen in protraction, to move material out of the buccal cavity. Command neurons of the feeding oscillator in *Aplysia* are named cerebrobuccal interneuron 2s (CBI-2s), likely homologs of the feeding command neurons found in other gastropods. During ingestion another cerebrobuccal neuron is activated, the CBI-3. The CBI-3s are electrically coupled to CBI-2s and fire during the same protraction phase of CPG activity. They make simple synaptic connections within the CPG that reverse the phase of activity of the radula closure motor neurons, from retraction to protraction, and thereby cause egestion. A partial circuit model for switching between ingestion and egestion is shown in Figure 5. While all the circuit details of the switch are not yet known, the simple reconfiguration of the CPG to produce behaviorally opposite actions is an elegant example of multifunction and economy in neural circuit design.

Figure 4 Suppression of the avoidance turn by escape swimming in *Pleurobranchaea* by recruitment of essential turn neurons into the swim central pattern generator. (a) A schematic of the turn network, configured for avoidance. (b) Intense bursting activity of the serotonergic multifunctional (As1–4) neurons provides excitation-sustaining activity of the escape swim network (top), while slower tonic activity supports the avoidance turn activity mediated by the turn command (A4) neurons (bottom). pLBWN, posterior lateral body wall nerve; R and L refer to right and left sides. (c) A simplified schematic representing the relationship between the escape swim and turn networks, which share the As1–4s. Excitatory connections are indicated by open triangles and inhibition by blackened circles. Lines with both symbols mean that both excitation and inhibition are produced by that pathway. (d) A diagram of the multiple states and their transitions found in a molluskan feeding network in *Pleurobranchaea californica* resulting from different combinations of sensory stimuli and internal state. Behavioral Switching With Large Differences in Timescale: Network Reconfiguration

For the leech the application of voltage-sensitive dyes to imaging simultaneous activity in multiple neurons powerfully complements standard microelectrode methods for identifying and characterizing CPG elements. Swimming is produced by alternating dorsal and ventral contractions of longitudinal muscles in a traveling wave that goes from anterior to posterior. Dorsoventral muscles are tonically contracted to flatten the body. During crawling, circular muscles contract to elongate the body, alternating with simultaneous contraction of dorsal and ventral longitudinal muscles to cause a segmental contraction that is propagated posteriorly. Switching between swimming and crawling can happen rapidly. By elicitation of fictive swimming and crawling in the same preparation, neurons can be identified that participate in both rhythmic behaviors. The results indicate that some neurons are multifunctional whereas others appear to be dedicated. The overlapping of the swim and crawl networks is very large, up to 93%.

All species of leech can crawl although not all swim, and it is thus likely that the swim CPG evolved from the more primitive one for crawling. Small but significant modifications may have accrued to allow the CPG to become multifunctional, capable of operating in more than a single state of coordination and in very different timescales. The results of these studies have led to the conclusion that behavioral decisions in this system are mediated by a combinatorial code of multiplexed interneurons.

Figure 5 Switching between ingestion and egestion in *Aplysia*. During egestion (a), excitation of radula closure motor neurons during protraction is driven by strong outputs from neuron B20, while interneurons B4/5 inhibit the motor neurons during retraction. In ingestion (b), coactivation of cerebrobuccal interneuron (CBI)-3 with the command neuron CBI-2 during protraction inhibits B20 and B4/5, allowing other inputs from the central pattern generator (CPG) to invert the phase of radula motor neuron excitation to retraction, which would transport material into the buccal cavity. Feedback connections from the CPG to command neurons are not shown. (c) Idealized phases of activity of the motor network during ingestion and egestion. Prot., protraction; Rad. clos., radula closure; Ret., retraction; P- and R-groups fire during protraction and retraction, respectively; RI and PI are interneurons of the CPG, the Z neurons are hypothetical. (a, b) From Jing J and Weiss KR (2001) Neural mechanisms of motor program switching in Aplysia. *Journal of Neuroscience* 21: 7349–7362.

Invertebrate motor networks provide other instructive examples of how organization of behavioral hierarchy is shaped at the neural level by the transitions between CPG configurations and resulting outputs. This is exemplified in Figure 4(d), which diagrams the distinct states that one such motor network can assume and the transitions it can undergo. The result is reminiscent of the allosteric regulation of complex holoenzymes or ion channels. Distinct inputs direct the network from a 'resting' state into metastable, or partially stable, configurations which can transit to almost any of the others if the input configuration changes, or collapse back to rest. Such plastic configurations represent in principle how multifunctional feeding CPGs can generate both ingestion and egestion, how the locomoting mammal can switch among a variety of gaits, and how the leech can swim, crawl, or shorten using common neuron sets.

No Central Role for Command Neurons in Decision?

In those instances in which a subordinate behavior is suppressed by a dominant one and the neural mechanism is partly understood, the source of command neuron inhibition was found to be intrinsic to the CPG. Suppression of feeding in these instances, was due not so much to command neuron inhibition as to a general reconfiguration of the feeding network to nonfeeding states that incorporated silencing of the PCNs. Here, then, decision is mediated by transition of the feeding network between metastable configurations.

Indeed, two different identified command neurons were tested in the feeding network of the pond snail *Lymnaea* for their roles in actually initiating feeding. It was found that neither was activated faster than a major interneuron of the CPG core. Their actions were to influence motor neuron burst duration in one case and to set the frequency of the feeding rhythm in the other. Neither have single or a small number of neurons been found in the leech that mediate behavioral switching. Thus, combinatorial codes of activity in the different CPG elements appear to underlie the transitions from which emerge hierarchies of behavior.

A simple speculation based on the collective data is that command neurons have roles in stabilizing specific network configurations and in providing a sharp internal CPG switching function that allows vigorous behaviors like swimming or feeding to be turned on and off sharply. Thus, command neurons may not themselves integrate sensory input so much as they integrate the excitation state of their network.

Conclusion

Much remains to be learned of the circuit bases of behavioral hierarchies. However, studies of simple systems have gained several important initial insights. One is that behavioral priorities may be achieved through a dominant CPG acting to suppress competing CPGs and to promote synergistic actions. This can be effected via corollary discharge outputs that reconfigure a subordinate CPG into an inactive or synergistic configuration or through appropriation of essential elements of the subordinate CPG into its own structure or by reconfiguration of a CPG to produce an alternate output.

A second insight regards the nature of certain command neurons, whose functions do not fulfill some previously expected roles. Acting as positive feedback elements in CPGs, they do not act directly to initiate CPG activity but likely accelerate it and may stabilize certain configurations. They are not the sites where a behavioral decision is made, although the decision is strongly manifested in their activity. They are not directly excited by sensory inputs that initiate behavior, nor are they directly inhibited by inputs from dominant CPGs. Rather, when it happens, their inhibition is exerted by inhibitory neurons of their own CPG, which is restructured for a new configuration of activity. Thus, if one wished to alter expression of hierarchical relationships in behavior by some external intervention at the level of the neural circuit, the command neurons are probably not such strategic targets as the CPG neurons that may play roles normally in switching CPG configuration.

Presently it is appreciated, from a few instances in which circuit mechanisms of behavioral choice have been elucidated, that the organization of behavioral hierarchies and choice is based on the observations that CPGs may exhibit plural metastable states of coordination. Those states can be melded or parsed into other networks newly organized into activity by circumstance, where the expression of any one network may be largely dependent on the dynamic configuration of sensory and other inputs from other networks.

The contributions of Nikolaas Tinbergen's field and laboratory studies to the modern understanding of neural bases of behavior continue to strongly influence modern neuroethology. They testify to the power of behavioral observations in predicting the general nature of the underlying neural circuitry and in providing testable hypotheses to drive investigation of detail. Thanks to this, increasing knowledge of the fine details of interactions among neural circuits that organize the expression of behavioral hierarchies is providing a base to understand the neural substrates of cost–benefit decision and social behavior in simple systems, thereby providing valuable models to approach these subjects in more complex animals.

Bell's Palsy

J J Halperin, Overlook Hospital – Atlantic Health, Summit, NJ, USA

Introduction

Each cranial nerve has its own idiosyncratic propensity to damage, dictated at least in part by its anatomy. The fine filamentous nature of the trochlear (4th) nerve makes it susceptible in minor head injury. The long intracranial course of the abducens (6th) puts it at risk with any increase in intracranial pressure. The facial nerve (7th) has a particularly lengthy and complex course, crossing the subarachnoid space, winding through a long, narrow bony canal, exiting to cross through the parotid gland; it should not be surprising that it can be affected in a variety of circumstances. That the detailed pathophysiology of facial nerve palsy remains unclear – over 185 years after its initial description – is remarkable. However the facial nerve's peculiar anatomy must contribute to its particular susceptibility to damage.

In recent years the number of disorders clearly associated with the facial nerve has increased to include sarcoidosis, Lyme disease, HIV, and herpes (zoster and simplex) infections, yet pathophysiologic insights remain frustratingly limited. The therapeutic approach similarly has expanded, but each approach remains controversial. The following overview will attempt to summarize what is known, and elucidate these controversies.

Background

Sir Charles Bell (1774–1842), a gifted Scottish-born surgeon, anatomist, and illustrator, described the course of the facial nerve, and the peculiar 'blight' that befalls it, in 1821. Interestingly, this arguably was one of his lesser accomplishments. The first Professor of Anatomy and Surgery of the College of Surgeons in London, and the first Professor of Physiology at King's College, University of London, among his noteworthy neurologic accomplishments was introducing the concept that motor and sensory functions were segregated in the spinal roots! Also responsible for describing 'Bell's phenomenon,' he is, however, best memorialized in the eponym for a 'palsy' (perhaps a somewhat dubious honor). Over the years, many have described the clinical concomitants of Bell's palsy. Proposed therapeutic interventions have ranged from surgical decompression of all or part of the nerve, to psychological counseling, to numerous points in between.

The facial nerve's anatomy is complex (schematically shown in Figure 1) both functionally and anatomically. Originating in a nucleus in the pontine tegmentum, the motor fibers take a looping dorsal, then ventral, course around the 6th nerve nucleus, joining fibers connecting to the nucleus solitarius and lacrimal and superior salivary parasympathetic nuclei as they travel. Fibers exit the brain stem and travel adjacent to the 8th nerve in the cerebellopontine angle, cross the subarachnoid space, enter the internal auditory meatus, and then traverse the longest, most complex intraosseous course of any nerve in the body. Throughout its course, components come and go. At the level of the geniculate ganglion, parasympathetic fibers (which exit the brain stem in the anatomically distinct nervus intermedius) form the greater petrosal nerve and project to the pterygopalatine ganglion, from which postganglionic fibers pass to the lacrimal gland and to the blood vessels of the Circle of Willis. Damage to this branch results in disorders of lacrimation – either increases or decreases. Clinical interpretation of these changes is often confounded in facial nerve palsy by the equally important contribution of mechanical exposure of the eye, which in and of itself can lead either to increased tearing from irritation or to exposure-related drying.

Other parasympathetic fibers continue with the main trunk of the facial nerve, to emerge slightly more peripherally and contribute to the chorda tympani, through which fibers project to the submandibular ganglion, with postganglionic projections to the salivary nuclei. Neurons of the geniculate ganglion convey sensory input from the nasopharynx, tympanic membrane, and the ear canal. Although these fibers travel with the facial nerve, they ultimately project to the primary sensory nucleus of V and the nucleus of the spinal tract of the trigeminal nerve.

Distal to the geniculate ganglion and the greater petrosal nerve, a small motor branch exits to innervate the stapedius muscle. Damage to this results in hyperacusis. Shortly thereafter, the chorda tympani joins the nerve. This bundle, which, as mentioned, carries efferent preganglionic parasympathetic fibers destined to control salivary glands, also contains fibers of the lingual nerve, conveying taste sensation from the anterior two-thirds of the tongue. Cell bodies of these neurons also reside in the geniculate ganglion; fibers project centrally via the nervus intermedius to the nucleus solitarius. The fibers that remain distal

Figure 1 Schematic diagram of facial nerve.

to the chorda tympani are primarily motor, projecting to the muscles of facial expression (forehead, periorbital, and perioral muscles) and a small group of sensory fibers destined for the skin of the anterior wall of the external auditory canal.

The nerve's long course puts it at risk in multiple locations. Meningeal processes (microbial or neoplastic meningitis) can affect it in the subarachnoid space; skull base tumors can compress it within the long bony canal; inflammatory or neoplastic disease can involve it as it traverses the parotid gland (e.g., in sarcoid). As a fairly long peripheral nerve, it is at risk in peripheral neuropathies, ranging from diffuse demyelinating processes such as Guillain–Barré syndrome, to a mononeuropathy multiplex, as occurs in Lyme disease.

Clinical

Facial weakness can result not only from damage to the facial nerve, but also from damage to descending cortical projections. The clinical observation is that damage to the central descending motor pathways tends to affect movements of the mouth and cheek far more than eye closure and forehead wrinkling. This differentiation, which is generally obvious in the postacute setting, may be less apparent immediately following an acute central event (e.g., lacunar stroke), particularly if it involves deep hemispheral white matter; in such individuals some eye closure and forehead weakness may be evident acutely, improving over the first few postevent days.

The disparity in involvement between the upper and lower face is usually attributed to cortical input to the forehead being bilateral, with that to the lower face being more lateralized. An alternative hypothesis suggested more recently is that the upper face actually receives little cortical motor input from either hemisphere; this would explain clinical observations equally well.

Lesions of the facial nerve can occur anywhere along its course. Damage in the pons is often accompanied by abducens weakness, due to the close proximity of the motor fibers of 7th to the 6th nerve nucleus. As with all brain stem processes, the high density of eloquent structures tends to lead to multiple other associated findings, leading to little uncertainty as to the location of the lesion.

Damage to the nerve outside the brain stem can lead to a number of symptom combinations, depending on the location of the lesion along the nerve's long course, and also on whether damage is to all fascicles of the nerve at that level, or just some. In theory, a proximal lesion would affect all functions, resulting in abnormal lacrimation, hyperacusis, abnormal taste and salivation, weakness, and a small area of hypesthesia on the external ear. As lesions occur more and more peripherally, fewer and fewer of these elements would be evident. Curiously, when this has been studied, in at least some cohorts of patients with facial palsy, no such systematic segregation of syndromes is evident, suggesting that lesions are selective at a fascicular level within the nerve, as well as along its longitudinal course.

The other common clinical concomitant of facial nerve palsy is significant retroauricular pain ipsilateral to the palsy. This often precedes facial weakness by 1 or even 2 days, and can be quite severe. Occurring in the region of the stylomastoid foramen, where the nerve exits the skull, this is often attributed to the nerve swelling in its narrow canal. Given the small sensory component of the nerve, it could also be neuropathic referred pain, from damage to this small group of periauricular afferents. This pain typically resolves in the first few days; corticosteroids may speed this.

The weakness typically occurs fairly rapidly, evolving over about 24 h, usually maximal within 48 h, rarely progressing over as much as a week. Weakness involves all parts of the affected side of the face – forehead wrinkles are lost and the affected side of the forehead cannot be elevated. Eye closure becomes weak, often with sagging of the lower lid. The resulting exposure of the cornea can be one of the most dangerous complications of this disorder. The corner of the mouth cannot be lifted in a smile; lips cannot be sealed or the cheek puffed on the affected side. Drooling out of the affected corner of the mouth is often the patient's first hint of a significant problem. Many patients will notice hyperacusis – although they rarely volunteer this information. Similarly, they often note a change in taste

perception – in some this may be due to decreased salivation but more often it is a true dysgeusia. Proving this requires testing taste on the two sides of the anterior tongue, without allowing the patient to retract the tongue back into the mouth between tests, since diffusion of the test substance will immediately invalidate the test. Patients often describe numbness on the affected side of the face, but objective testing rarely confirms this. Most likely this represents misperception of proprioceptive input with attempted motion of the paralyzed facial muscles.

Epidemiology

The terms 'facial palsy' and 'Bell's palsy' are not synonymous – the latter term is usually restricted to patients with idiopathic acute deficits of the facial nerve.This definition is selected to exclude slowly evolving facial nerve lesions such as those due to posterior fossa or skull base tumors, as well as brain stem strokes, skull base fractures, meningitis-associated multiple cranial neuropathies, Ramsay Hunt syndrome, etc. However, this definition now becomes problematic, since there are quite suggestive data that in many instances Bell's palsy is caused by herpes simplex virus. Since these cases are no longer idiopathic, must they be removed from those considered to be Bell's palsy? What about patients with facial nerve palsies associated with diabetes or with Lyme disease? Clearly, at some point this more than semantic issue will require resolution; for now, cases associated with herpes simplex, Lyme disease, and diabetes are generally included as Bell's palsy.

The reported incidence of Bell's palsy varies somewhat, but is generally felt to be about 20–25 cases per 100 000 population per year, affecting about 1 in 60–70 individuals in their lifetime. The disorder is quite infrequent under the age of 10 years, increases by decade from ages 10 to 39 years, is fairly constant at about 35 cases per 100 000 from ages 40 to 69 years, then increases to over 50 per 100 000 (10 times the childhood incidence) in those over 70 years. There is no significant male: female or side-to-side difference. Involvement is bilateral occasionally; in about 6% of cases it can be recurrent (the recurrence occurring on either the previously affected or unaffected side). The paralysis is complete in a significant proportion of patients, estimates ranging from 45% to 70% in different series. (The former number, from a population-based study in Rochester, MN, probably reflects a number as free of selection bias as possible.) No seasonal or geographic clustering has been evident.

Bell's palsy probably occurs with increased frequency in diabetics. Hypertension has also been considered a risk factor. Although it does appear to increase the likelihood of incomplete recovery, whether the incidence is increased among hypertensives is unclear. Pregnancy has been reported as a risk factor, but results have been conflicting; the most systematic studies have failed to support this association. Incidence is increased in patients with sarcoidosis, in whom involvement can be meningeal, within the parotid, or at points in between. Similarly, incidence is increased in HIV and Lyme infection. When bilateral facial palsy occurs it may be indicative of the Guillain–Barré syndrome, sarcoidosis, or Lyme disease.

Recovery is complete in the vast majority (80–85%) of patients with Bell's palsy. The degree of improvement is commonly graded with the House and Brackmann Grading Scale (Table 1). More extensive lesions tend to predispose to incomplete recovery – presence of pain in addition to the retroauricular pain, complete facial paralysis, tearing changes, and sensory changes are all associated with incomplete recovery. Incomplete recovery is somewhat more common among those over 55 years of age. In the most extensive study of this, complete recovery occurred in 90% of those under 55 years and 79% of those 55 years and older. Although several comorbidities are linked to Bell's palsy, only hypertension is associated with a somewhat worse prognosis.

Interestingly, when all of these factors were considered in a multivariate analysis, only complete paralysis, non-ear pain, and hypertension were found to predict a somewhat worse prognosis. Other factors, such as age, and other neurologic changes apparently merely reflected the impact of these three factors. Among patients with none of these risk factors, complete recovery occurred in 96%. With an overall spontaneous recovery rate of about 85%, and 96% among low-risk patients, it is not difficult to understand why it has been so difficult to determine efficacy of different treatment strategies, and why their use has been controversial.

Pathophysiology

Understanding the mechanism underlying this mononeuropathy has been challenging. A few autopsy cases, published many years ago, were felt to demonstrate inflammatory changes in the affected nerve. Subsequent review raised the possibility that the observed changes were merely what one would expect to see as part of Wallerian degeneration in a nerve damaged more proximally. Surgical series reported swollen-appearing nerves – since it is relatively uncommon to explore normal facial nerves, subsequent authors, including Sunderland, have suggested that this was merely the nerve's normal appearance.

Table 1 House and Brackmann facial nerve grading system

Grade	*Description*	*Characteristics*
I	Normal	Normal facial function in all areas
II	Mild dysfunction	Gross: slight weakness on close inspection; slight synkinesis At rest: normal symmetry and tone Motion Forehead: moderate to good function Eye: complete closure with minimal effort Mouth: slight asymmetry
III	Moderate dysfunction	Gross: obvious but not disfiguring difference between two sides; noticeable but not severe synkinesis, contracture, and/or hemifacial spasm At rest: normal symmetry and tone Motion Forehead: slight to moderate movement Eye: complete closure with effort Mouth: slightly weak with maximum effort
IV	Moderately severe	Gross: obvious weakness and/or disfiguring asymmetry At rest: normal symmetry and tone Motion Forehead: none Eye: incomplete closure Mouth: asymmetric with maximum effort
V	Severe	Gross: only barely perceptible motion At rest: asymmetry Motion Forehead: none Eye: incomplete closure Mouth: slight movement
VI	Total paralysis	No movement

From House JW and Brackmann DE (1985) Facial nerve grading system. *Otolaryngology – Head and Neck Surgery* 93: 146–147.

Neurophysiologic observations have not been as informative as one might wish. The standard method used, electroneurography, consists of stimulating the facial nerve at the stylomastoid foramen, recording the compound muscle action potential on the face in a way designed to span several muscles (a method that can lead to unpredictable summation of the compound muscle action potentials of different muscles), and comparing the amplitude ratio of the affected side to the unaffected side. In many series, only patients with no elicitable response are sent to a neurologist or electromyographer. More sophisticated neurophysiologic studies suggest nerve demyelination in milder cases, with significant axonal damage when the paralysis is severe.

Anatomic studies have suggested that the meatal foramen is the narrowest point along the facial nerve's bony canal; intraoperative neurophysiology has suggested that this is the likely site of damage. This has led to the hypothesis that the nerve swells as a result of an inciting event and becomes entrapped at the meatal foramen. Swelling at this confined point could either produce focal demyelination and conduction block, block axoplasmic transport (resulting in nerve damage), or lead to intranerve pressures exceeding perfusion pressure (resulting in ischemic damage). The highly redundant vascular supply of the facial nerve generally makes widespread ischemia seem unlikely, but such focal ischemia is somewhat more plausible.

Recent work has implicated several specific infections in the etiology of facial nerve palsy. Lyme disease, infection with the tick-borne spirochete *Borrelia burgdorferi*, clearly is associated with facial nerve lesions, which may be bilateral in as many as 25% of such cases. The pathophysiology is unclear. This does not appear to be due to a meningeal process, even though Lyme disease can cause meningitis. Neurophysiologic studies suggest that this is due to a mononeuritis multiplex, although the precise mechanism underlying this is unclear.

One of the most interesting sets of findings in the past decade has focused on the possible association between facial nerve palsy and herpes simplex-1 infection. In one of the best known studies, endoneurial fluid was obtained – at least 15 days after onset of the lesion – at the time of 7th nerve decompression in 14 patients with unrecovering Bell's palsy. Eleven of the 14 were polymerase chain reaction (PCR) positive for HSV-1. Twelve of 13 tested patients had peripheral blood serologic evidence of past HSV-1 infection. Seropositivity and PCR positivity were significantly

more common than among controls. This has led to a number of therapeutic trials of antiviral therapy in Bell's palsy. Apparent response to this has led to a general recommendation for antiviral treatment in Bell's palsy.

The herpes hypothesis is an intriguing one, although gaps remain in our understanding. Methodologically, PCR detection of viral DNA does not necessarily indicate the virus is either viable or pathophysiologically relevant. Herpes in particular is so ubiquitous that the implications of finding it in anybody can only be understood if comparable samples are obtained from normal controls. The presence of virus so many days after the onset of symptoms is curious. In other herpes reactivation syndromes, the number of obtainable virions – weeks after the onset – tends to be small. Herpes viruses generally reside in sensory neurons. Although the facial nerve is primarily motor, it does contain sensory neurons (residing in the geniculate ganglion). It is conceivable that reactivation from the sensory neurons could result in sufficient swelling to damage motor fibers. If this were the case, though, one might expect more marked loss of sensation as part of Bell's palsy.

Diagnostic Approach

In addition to clinical assessment, electromyography (EMG) can be informative. When the lesion is incomplete, blink reflexes can demonstrate slowing indicative of demyelination. Since the lesion is typically intracranial, the nerve portion peripheral to the stylomastoid foramen may remain excitable for several days following onset, regardless of the severity of the damage to the nerve. Inexcitability after day 5 suggests a profound axonal lesion. Needle EMG can be useful in differentiating between a truly complete lesion and one sparing a few motor units, the latter having a significantly better prognosis. Observation of widespread changes of acute denervation obviously reflects a more severe lesion with a worse prognosis. On the other hand, evidence of reinnervation may be apparent on needle EMG exam long before it is clinically evident.

EMG can also be useful to demonstrate synkinesias – regenerating nerves can be misdirected, resulting in eye closure with attempted mouth movements, eye tearing with attempted facial movements ('crocodile tears'), or other peculiar combinations.

Cerebrospinal fluid (CSF) examination is useful primarily in assessing for inflammatory or neoplastic processes in the subarachnoid space. Magnetic resonance imaging (MRI) and computed tomography (CT) imaging can be helpful in addressing structural lesions of the brain stem, skull base, or nerve.

Treatment

The prognosis is generally excellent: 85% of all patients will do well with no treatment whatever. This, coupled with methodological concerns with many of the treatment trials, has led to a rather conservative approach to treatment on the part of many physicians, particularly for nonhypertensive patients with incomplete paralysis and no diffuse pain, for whom rapid and complete recovery is almost assured.

Several aspects of care are mandatory. Eye damage is one of the greatest threats to patients. They should be instructed to patch the eye, particularly when sleeping or when in a dusty environment. Lubricating drops (methylcellulose) during the day, and ointment at night, can be helpful. Weakness of the facial muscles leads to a tendency for food to 'pocket' in the cheek. Brushing the teeth after each meal can limit the risk of dental caries. Patients with complete paralysis can develop contracturing of the denervated muscles, leading to additional facial distortion and potentially limiting recovery when reinnervation occurs. Gentle massage of the paralyzed muscles for at least 10–15 min daily is said to lessen the impact of this.

For patients in whom no recovery occurs, several surgical options have been tried. Transplanting the hypoglossal nerve to facial muscles can lead to some facial muscle control on the paralyzed side (at the cost of lingual hemiatrophy and paralysis). A weight in the affected eyelid can facilitate eyelid closure and eye protection. Occasionally the eyelid must be partially sewn shut to protect the cornea.

The three areas of greatest therapeutic focus have been corticosteroids, antivirals such as acyclovir, and decompressive surgery. Unfortunately, the literature on all three approaches has been highly variable in scientific design, sample size adequacy, and interpretation. Results for each have varied from negative to compelling. The literature was recently explored in depth by a task force of the American Academy of Neurology, resulting in a practice parameter. In their meta-analysis of the available, interpretable literature regarding corticosteroids, the panel concluded that corticosteroids were useful, improving outcomes by 16%. Usual regimens consisted of 1 mg kg^{-1} per day (maximum dose 80 mg) divided into two doses per day for 4 or 5 days, then tapering over 5 to 10 days. Treated patients did not recover more quickly, but a greater percentage recovered fully. Some studies have suggested the acute retroauricular pain improves more rapidly with steroids. Patients faired best if treated in the first week. Although it is often stated that the earlier the treatment, the better the response, beyond the observation that treatment is only useful in the first week there are no compelling data that the

timing of treatment within this window affects the likelihood of recovery – a somewhat surprising observation given that the major nerve damage is thought to occur in the first 48 h. Notably, a Cochrane analysis questioned the validity of the conclusion that steroids are effective, because of methodological problems with several of the largest included studies.

Even fewer studies are available concerning use of acyclovir. Here, too, a meta-analysis led to the conclusion that treating all patients with acyclovir improved the proportion of patients recovering by 22%. Given the small number of studies available, and their sometimes conflicting conclusions, this was felt to be less compelling, but was recommended as appropriate treatment. Again, the fact that this treatment is usually given – and appears to be effective – at a time that maximal nerve damage has already occurred is theoretically puzzling.

Finally, with regard to decompressive surgery, the task force found no scientifically compelling study. While earlier studies were negative, one more recent study of patients in whom recovery was thought to be extremely unlikely by clinical and EMG criteria, who underwent a far more extensive decompression extending to the meatal foramen, provided encouraging results, with 91% of patients improving significantly (but with no controls).

Overall, the likelihood of recovery is great, apparently enhanced with early treatment with corticosteroids and/or acyclovir-like antivirals. In the appropriate setting, potentially contributing disorders such as Lyme disease, HIV, or sarcoidosis need to be considered, and treated appropriately if found Surgical treatment remains unproved, but is occasionally attempted in situations in which the likelihood of recovery seems very limited. In general, prevention of secondary complications, such as exposure keratitis, dental decay, and muscle contractures, is the most important aspect of treatment.

Bergmann Glial Cells

A Verkhratsky, The University of Manchester, Manchester, UK
A Reichenbach, University of Leipzig, Leipzig, Germany

© 2009 Elsevier Ltd. All rights reserved.

The cerebellum of all vertebrates contains specialized radial astrocytes, which send long, vertically oriented processes toward the pia. These glial processes were discovered by Karl Bergmann in 1857 as cerebellar radial fibers. In 1871, Camillo Golgi recognized these structures as cells and found their somata/cell bodies, from where the radial fibers originated. Both Golgi and Ramon-y-Cajal referred to these cells as epithelial cells, and for many years they were generally known as Golgi epithelial cells. In recent times, the common name for these cerebellar radial astrocytes is Bergmann glial cells.

Morphology

The somata of Bergmann glial cells are localized in the Purkinje cell layer (Figure 1). Each Bergmann glial cell has three to six stem processes, which protrude through the molecular layer toward the pial surface. These processes contain many mitochondria and bundles of intermediate filaments, constituted by vimentin and glial fibrillary acidic protein (GFAP). They can be labeled by antibodies directed against these proteins, which reveals that they are organized in palisades, parallel to the long axis of each folium. On average, every Bergmann glial cell in rodent cerebellum has a volume of approximately 3600 μm^3, and altogether these cells occupy approximately 15–18% of the volume of the molecular layer. There are approximately eight Bergman glial cells per every Purkinje neuron; the processes of the former develop intimate relations with the dendritic arborization of the latter.

The stem processes of Bergmann glial cells end at the pia mater, with so-called endfeet, which together form a complete covering of the cerebellar surface. The subpial endfoot membranes are endowed with orthogonal arrays of membrane particles, probably representing locally enriched membrane proteins such as the water pore channel, aquaporin-4, and related channel and transporter proteins devoted to an active exchange of ions and water between the neuropile and the subarachnoidal space. On their way from soma to the pia, the stem processes extend numerous side branches, which form close contacts with synapses present on the dendrites of Purkinje neurons; on average, every Bergmann glial cell covers 2000–6000 such synapses. Morphologically, these gliosynaptic contacts are quite peculiar because they are organized in the form of morphofunctional microdomains (Figures 2 and 3). The microdomains are constructed by protrusions sent from the stem process at rather regular intervals. Each microdomain is made of a thin stalk and a complex 'head' structure, which in turn forms a lamellar perisynaptic sheath for approximately five synapses. The stalk is extremely thin (~0.3 μm) and long (up to 7 μm); the head is a complex structure with an extremely large surface area (~300 μm^2) formed by a relatively small (~16 μm^3) volume. The surfaces of the appendages may form the major part of Bergmann glial plasmalemma (overall, the surface-to-volume ratio for Bergmann glial cell varies between 13 and 17 μm^{-1}, whereas the same ratio for appendage may reach 25 μm^{-1}). The synaptic–glial interactions, therefore, are very much confined to these single microdomains; and these microdomains can be independently excited. Each microdomain also contains on average two mitochondria, which may provide a local energy supply and also serve as a barrier preventing Ca^{2+} diffusion. The coverage of synapses by glial membranes is quite specific because glial membrane tongues almost completely seal the synaptic clefts while leaving a considerable part of extrasynaptic structures uncovered.

Physiology

Membrane Conductance

The resting membrane potential of mature Bergmann glial cells is between −80 and −90 mV, and the resting input resistance is quite low (40–100 mΩ). Potassium channels are responsible for the major part of membrane permeability of Bergmann glial cells. The expression of these channels is developmentally regulated. In the early postnatal (< postnatal day 7 (P7)) period, Bergmann glial cells demonstrate a mixture of inward- and outward-rectifying potassium currents, which can be blocked by cesium, barium, and 4-aminopyrindine. Mature Bergmann glial cells (> P20) display a large passive K^+ conductance manifested by voltage- and time-independent K^+ currents, insensitive to Cs^+, Ba^+, or 4-AP. In addition, these cells have a complement of inward- and outward-rectifying K^+ channels but their density is quite low. There were some reports that Bergmann glial cells express mRNA for the voltage-gated Na^+ channel $Na_v1.6$, but functional channels were never detected electrophysiologically.

Gap Junctions

Similar to other astrocytes, Bergmann glial cells are coupled by gap junctions. The main gap junction

protein expressed by Bergmann glial cells is connexin-43x. The gap junction coupling (as was judged by both electrophysiological recordings and dye coupling; Figure 4) between Bergmann glial cells begins to appear at approximately P7 and is fully developed by P20. The gap junctions are preferentially localized in the distal processes of Bergmann glial cells. Dye spread between Bergmann glial cells in cerebellar slices revealed a peculiar organization of the glial syncytium: dye-coupled cells were always arranged in rows perpendicular to parallel fibers (Figure 4). This is very similar to the two-dimensional orientation of Purkinje neurons and, therefore, both neuronal and glial elements from cellular stacks, which may also have functional impact. There are also indications for the existence of gap junction coupling between Bergmann glial cells and adjacent Purkinje neurons.

Neurotransmitter Receptors

Glutamate receptors The main type of ionotropic glutamate receptors expressed by Bergmann glial cells is of the α-amino-3-hydroxy-5-methyl-4-isoxazole

Figure 2 Bergmann glial microdomains. (a) Reconstruction of an appendage based on electron microscopic data. (1) Fluorescence light micrograph of a dye-injected Bergmann glial cell is shown; the red square (20 × 20 mm) corresponds to the portion that was reconstructed from consecutive ultrathin sections. (2) One of the lateral appendages, arising directly from fiber with all the other side branches omitted for clarity. (3) The same appendage as shown in 2, but with one of the appendages marked by blue. This labeled structure is shown in isolation and at higher magnification in (b). (b) Fine structure of appendages and relation to synapses. (Left) A small lateral appendage, arising from the reconstructed part of the glial fiber (blue in a3), is shown as a slightly turned, isolated three-dimensional reconstruction. Electron micrographs of four sections contributing to the reconstruction (designated 1–4) are shown on the right; glial compartments appear black after conversion of the injected dye. The location of these sections in the reconstruction is indicated by the labeled arrows. (1) Region directly contacting synapses. (2) Glial compartments without direct synaptic contacts. (3) Bulging glial structure containing a mitochondrion. (4) The stalk of the appendage. (c) Another example of a synapse contacted by glial compartments, appearing as black structures (white arrows); in this case, the postsynaptic element can be traced back along the spine (black arrows) to the Purkinje cell dendrite (reddish overlay; the presynaptic terminal is labeled by a green overlay). Adapted from Grosche J, Matyash V, Moller T, Verkhratsky A, Reichenbach A, and Kettenmann H (1999) Microdomains for neuron–glia interaction: Parallel fiber signaling to Bergmann glial cells. *Nature Neuroscience* 2: 139–143.

propionic acid (AMPA) subtype. Bergmann glial cells do not possess the glutamate receptor (GluR)2 subunit, making their AMPA receptors Ca^{2+} permeable. Indeed, activation of AMPA receptors by exogenous kainate triggers substantial Ca^{2+} rises in glial cells (Figure 5). There are indications that Bergmann glial cells may express mRNA for the NR2B subunit of *N*-methyl-D-aspartate (NMDA) receptors; application of endogenous NMDA was reported to trigger $[Ca^{2+}]_i$ elevation and small inward currents. These responses, however, were often blocked by tetrodotoxin, and thus most likely resulted from stimulation of neurons.

Bergmann glial cells express metabotropic glutamate receptors of the mGluR5 type; stimulation of these receptors triggers an inositol 1,4,5-triphosphate ($InsP_3$)-mediated release of Ca^{2+} from the endoplasmic reticulum (ER) intracellular Ca^{2+} stores. This mGluR5-dependent Ca^{2+} mobilization assumes the leading role in the generation of glial Ca^{2+} signals following

Figure 3 Glial microdomains form a substrate for glial–synaptic interactions. (a) Three-dimensional reconstruction of a group of neighboring cerebellar synapses (yellow; synaptic clefts: orange) together with the surrounding leaflets provided by the labeled Bergmann glial cell (blue-green). Arrowheads point to neuronal surfaces not covered by glial sheaths from the labeled cell. (b) Schematic representation of a Bergmann glial microdomain. The basic components of the microdomain, the stalk and the 'head,' are shown together with their relationships to the neighboring neuronal elements. Stimulation of several closely positioned parallel fibers may activate a single microdomain, inducing both membrane currents and local Ca^{2+} signals. Adapted from Grosche J, Kettenmann H, and Reichenbach A (2002) Bergmann glial cells form distinct morphological structures to interact with cerebellar neurons. *Journal of Neuroscience Research* 68: 138–149.

stimulation with glutamate. The contribution of the AMPAR-mediated Ca^{2+} influx is much smaller because of rapid desensitization of these receptors in the presence of glutamate.

Nonetheless, the AMPA receptor-mediated Ca^{2+} entry is functionally important because adrenoviral-assisted genetic introduction of the GluR2 subunit into Bergmann glial cells extinguished the Ca^{2+} permeability of these receptors and resulted in a withdrawal of glial processes from the synapses formed on Purkinje neurons. This, in turn, affected synaptic transmission by slowing the glutamate uptake, and it promoted the reinnervation of Purkinje neurons by several climbing fibers.

GABA receptors $GABA_A$ ionotropic receptors are prominently expressed in young Bergmann glial cells; application of γ-aminobutyric acid (GABA) triggers large Cl^- currents in cells from P5 to P12 animals. Immunohistochemical techniques revealed a prominent expression of α_2, α_3, and γ subunits in these cells. The $GABA_A$ receptors are predominantly located in the distal processes of the Bergmann glial cells. The expression of $GABA_A$ receptors is downregulated during postnatal development; by P20, the amplitudes of GABA-induced currents are very much diminished and only α_2 and γ_1 subunits remain detectable immunohistochemically. The $GABA_A$ receptors in mature Bergmann glial cells are primarily concentrated in the parts of glial membrane ensheathing inhibitory GABAergic synapses formed on Purkinje neurons. In addition to $GABA_A$ receptors, immunoreactivity for $GABA_{B1}$ receptors was detected in Bergmann glial cells; there are also some indications for the possible expression of $GABA_C$Rs. The functional significance of these receptor types remains to be explored.

Figure 4 Gap junction coupling of Bergmann glial cells. (a) Dye coupling. Bergmann glial cell was dialyzed via the patch pipette with a solution containing Lucifer yellow. Fluorescence images were recorded a *t* times indicated times after the whole cell configuration was established using confocal microscopy. Images were three-dimensional reconstructed and illustrate the spread of dye to adjacent, coupled cells. The number of coupled cells are as follows: 1, $n = 4$; 2, $n = 8$; 3, $n = 24$; 4, $n = 26$; 5, $n = 26$. (a6) The image shown in a5 is rotated to the parasagittal orientation. The upper 25 pm of the 120 pm thick cerebellar slice is displayed. (b) Schematic image showing orientation of the coupled Bergmann glia cells. In the parasagittal sections used, the array of coupled cells extends parallel to the slice surface and perpendicular to the parallel fibers. BG, Bergmann glia cells; PC, Purkinje cell. Adapted from Muller T, Moller T, Neuhaus J, and Kettenmann H (1996) Electrical coupling among Bergmann glial cells and its modulation by glutamate receptor activation. *Glia* 17: 274–284.

Purinoreceptors Bergmann glial cells respond to extracellular application of ATP by robust cytosolic Ca^{2+} rises, which are initiated in the processes and then spread toward the soma (Figure 6). These ATP-induced Ca^{2+} responses are mediated by P2Y metabotropic purinoreceptors and subsequent $InsP_3$-induced Ca^{2+} release from the ER Ca^{2+} stores. This conclusion is based on the following observations: (1) ATP-induced Ca^{2+} signals are preserved in Ca^{2+}-free extracellular solutions; (2) applications of ATP do not trigger any measurable membrane currents; and (3) ATP-induced Ca^{2+} signaling is inhibited either by the ER calcium pump blocker, thapsigargin, or by intracellular administration of the competitive $InsP_3$ receptors antagonist, heparin. Incidentally, the P2Y purinoreceptors in Bergmann glial cells can be activated by extracellular administration of NAADP.

Adrenoreceptors Application of endogenous adrenomimetics (epinephrine and norepinephrine) induces cytosolic Ca^{2+} elevations in Bergmann glial cells. These Ca^{2+} responses are of purely metabotropic (G-protein/phospholipase C (PLC)/$InsP_3$-mediated) nature; they are unaffected by Ca^{2+} removal from extracellular milieu and blocked by thapsigargin or intracellularly administered heparin. The monoamine-induced Ca^{2+} signaling is mediated through α_1 adrenoreceptors; the Ca^{2+} responses can be mimicked by the specific α_1 adrenoreceptor agonist, phenylephrine, but not by β-adrenomimetic isoproterenol or α_2-adrenomimetic clonidine. Moreover, the monoamine-evoked Ca^{2+} signals can be almost completely blocked by the α_1 adrenoreceptor antagonist prazozin; however, they are fully resistant to the action of the α_2 adrenoreceptor antagonist yohimbine or the β adrenoreceptor antagonist propranolol.

Histamine receptors Bergmann glial cells express functional H_1 histamine receptors. Stimulation of these receptors triggers $InsP_3$-induced Ca^{2+} release from the ER. Histamine-induced Ca^{2+} signaling is

Figure 5 Stimulation of ionotropic glutamate receptors (GluRs) in Bergmann glial cell in cerebellar slices triggers Ca^{2+} influx. (a) Pseudocolor image of a fura-2-loaded Bergmann glial cell (a scheme of the experiment is shown on the right) in control conditions and upon extracellular application of 100 μM kainate. Note preferential increase in $[Ca^{2+}]_i$ in cell processes. (b, c) $[Ca^{2+}]_i$ and membrane current traces recorded from the same cell. Both removal of extracellular Ca^{2+} (b) and blockade of ionotropic GluRs by 6-cyano-7 nitroquinoxaline-2,3-dione (CNQX; 10 μM; c) inhibited kainate-induced currents and $[Ca^{2+}]_i$ elevation, suggesting a key role for Ca^{2+} influx. F340/380, fluorescence ratio at 340/380 nm. Adapted from Verkhratsky A, Orkand RK, and Kettenmann H (1998) Glial calcium: Homeostasis and signaling function. *Physiological Reviews* 78: 99–141.

very substantially inhibited by the selective H_1 antagonist chlorpheniramine.

Endothelin receptors All three forms of endothelin, ET-1 to ET-3, when applied extracellularly trigger Ca^{2+} signals in Bergmann glial cells. The receptors responsible are selectively sensitive to the ET_B receptor agonist BQ3020 and are blocked by the ER_B receptor antagonist BQ-788; the expression of ET_B receptors was further confirmed by single-cell polymerase chain reaction. Intracellularly, the stimulation of ET_B receptors results in activation of the PLC/$InsP_3$/Ca^{2+} release cascade.

Bergmann glial cells *in situ* express a defined set of neurotransmitter receptors Studies on Bergmann glial cells *in situ* (i.e., in cerebellar slices) revealed that they are always endowed with a strictly defined pattern of functional neurotransmitter receptors: all cells were sensitive to glutamate, ATP, GABA, monoamines, histamine, and endothelin. By contrast, many other neuroactive substances known to activate cultured astrocytes (e.g., bradykinin, oxytocin, substance P, adenosine, vasopressin, or PAF) did not affect the cells. Most interestingly, the sensitivity of Bergmann glial cells to neurotransmitters is very similar to that of its closest neighbor, the Purkinje neuron: in general, the modalities of receptors expressed by these two cell types are identical. Furthermore, neurotransmitter receptors expressed by the neuron and by the glial cell specifically match the neurotransmitters released in their vicinity (Figure 7), thus allowing them to sense the very same incoming information.

Neurotransmitter Transporters

Glutamate transporters Membranes of Bergmann glial cells, surrounding the excitatory glutamatergic synapses formed on the dendrites of Purkinje neurons, contain the glutamate transporter GLAST (glutamate aspartate transporter) and GLT-1 (the former being the

Figure 6 ATP-induced Ca^{2+} signaling in Bergmann glial cells results exclusively from inositol 1,4,5-trisphosphate ($InsP_3$)-mediated Ca^{2+} release from ER Ca^{2+} stores. (a) ATP-induced $[Ca^{2+}]_i$ transients were measured from 'bulk-loaded' Bergmann glial cells stained by incubating cerebellar slices in fura-2 acetoxymethyl ester (AM)-containing solutions. Addition of ATP triggered an increase in $[Ca^{2+}]_i$ that persisted in Ca^{2+}-free extracellular solution. (b) In a similar experiment, incubation of slice with 500 nM thapsigargin completely and irreversibly blocked ATP-induced Ca^{2+} signaling. (c) Intracellular administration of heparin via intracellular dialysis with a patch pipette inhibited $[Ca^{2+}]_i$ increase induced by ATP. Control $[Ca^{2+}]_i$ transient was recorded from fura-2 AM-loaded cells before commencing intracellular dialysis. (d) Illustration of spatial distribution of $[Ca^{2+}]_i$ at the time of maximum ATP response. Note the higher levels of $[Ca^{2+}]_i$ in Bergmann glial cell processes compared with the cell body. Adapted from Kirischuk S, Moller T, Voitenko N, Kettenmann H, and Verkhratsky A (1995) ATP-induced cytoplasmic calcium mobilization in Bergmann glial cells. *Journal of Neuroscience* 15: 7861–7871; and Verkhratsky A, Orkand RK, and Kettenmann H (1998) Glial calcium: Homeostasis and signaling function. *Physiological Reviews* 78: 99–141.

dominant type), whereas the extrasynaptic regions of the neuronal (i.e., Purkinje cell) spines are rich in neuronal excitatory amino acid transporters of the EAAT4 type. The glial and neuronal transporters play distinct roles in controlling the glutamate concentration within and around the synaptic cleft. The affinity of GLAST to glutamate is approximately 10 times lower than that of excitatory amino acid transporter 4 (EAAT4); therefore, GLAST is primarily responsible for rapid uptake of glutamate following its exocytosis. This uptake determines the time course of synaptic events and prevents an escape of high glutamate concentrations from the cleft. Inhibition of GLAST significantly increases the early spillover of glutamate, as judged, for example, by the activation of NMDA receptors on GABAergic terminals, with a subsequent increase in the strength of inhibitory input to Purkinje neurons. In this way, glutamate uptake by Bergmann glial cells can regulate the synaptic inhibition of Purkinje neurons. Furthermore, inhibition of glial glutamate transporters also affects background synaptic transmission to Purkinje neurons by increasing the frequency of spontaneous miniature excitatory postsynaptic currents (EPSCs). The EAAT4, in contrast, buffers low glutamate concentrations and prevents the delayed spillover of the neurotransmitter to neighboring synapses. According to various estimates, approximately 80% of glutamate released during physiological neurotransmission is accumulated by Bergmann glial cells and only 20% is removed by the neuronal postsynaptic compartment.

To translocate glutamate against the concentration gradient, both neuronal and glial transporters utilize transmembrane gradients of Na^+ and K^+. Uptake of a single glutamate molecule requires influx of three Na^+ ions and efflux of one K^+ ion; in addition, glutamate brings one more H^+ ion into the cell (the net cation influx underlies the electrogenic role of transporters). Therefore, the maintenance of transmembrane ion gradients is essential for an effective performance of glutamate transporters. Exposure of Bergman glial cells to glutamate triggers substantial increases in the cytoplasmic Na^+ concentration, which may impair further glutamate uptake. This

Figure 7 Bergmann glial cell and its neighbor Purkinje neuron bear a similar set of neurotransmitter receptors. NT, terminals from tuberomammillary nucleus of the posterior hypothalamus that carry histamine innervation of the cerebellar cortex; LC, terminals from locus coeruleus that utilize noradrenalin and ATP as neurotransmitters; CF and PF, climbing and parallel fibers, respectively, major neurotransmitter glutamate; BA and ST, basket and stellate cells that deliver GABA to the Purkinje neuron layer. Adapted from Verkhratsky A, Orkand RK, and Kettenmann H (1998) Glial calcium: Homeostasis and signaling function. *Physiological Reviews* 78: 99–141.

$[Na^+]_i$ increase can be counteracted by a sodium–calcium exchanger, expressed in the membrane of Bergmann glial cells; sharp cytosolic Na^+ rises turn the sodium–calcium exchanger into the reverse mode (when Na^+ is expelled in exchange for Ca^{2+}). This process may rapidly lower $[Na^+]_i$ and thus sustain the operation of the glutamate transporter. Under pathological conditions that are accompanied by cell depolarization and accumulation of glutamate and Na^+ ions in the glia, the glutamate transporter may also reverse and start to extrude glutamate from the Bergman glial cells, thus exacerbating the glutamate-dependent excitotoxic neuronal death. In addition, Bergmann glial cells express functional cysteine/glutamate transporters, which also may provide a pathway for glutamate extrusion during periods of ischemia.

GABA transporters Bergman glial cells are endowed with a specific GABA uptake system, represented by high-affinity GABA/Na^+/Cl^- transporters of the GAT-1 type. The uptake of one GABA molecule is coupled to the inward transport of two Na^+ ions and one Cl^- ion. This transporter is present in the Bergmann glial cell somata and is also concentrated in the processes enwrapping GABAergic synapses formed on Purkinje neurons. In these compartments, glial GABA uptake can be relevant for the neurotransmitter removal during normal synaptic activity. Under experimental conditions, when the Bergmann glial cells were internally perfused with solutions containing 10 mM GABA and 12.5 mM Na^+, cell membrane depolarization to −40 mV resulted in the reversal of the GABA transporter. Whether such a reversed GABA transport may be relevant *in vivo* (even under pathological conditions) remains unclear.

Glycine transporters Bergmann glial cells possess functional GlyT1 transporters that belong to the Na^+/Cl^--dependent transporter family. These transporters can work in both forward (GABA uptake) and reverse (GABA extrusion) modes, and under certain conditions they can execute glycine efflux. However, this requires a depolarization of the Bergmann glial cell to +20 mV, which is very unlikely to occur under physiological conditions.

Taurine transporters Bergmann glial cells express a Na^+/Cl^--dependent taurine transporting system, which is able to function in both forward (taurine uptake) and reverse (taurine release) modes. The reversal of the transporter requires cell depolarization (up to −50 mV) together with an increase in the intracellular Na^+ concentration above 40 mM; these conditions most likely may occur only during severe ischemia. Functionally, the taurine transporter (working in the forward mode) could be involved in taurine redistribution following a hypo-osmotic shock.

Responses of Bergmann Glial Cells to Neuronal Activity

Electrical responses Stimulation of synaptic inputs to Purkinje neurons, formed by parallel and climbing fibers, induces complex membrane current responses in Bergmann glial cells. These current responses are mediated by activation of both ionotropic AMPA-type glutamate receptors and Na^+-dependent glutamate transporters. The glial AMPA receptor-mediated responses show short-term and long-term plasticity. The former is manifested by prominent paired-pulse facilitation, whereas the latter appears as long-term depression of synaptically induced glial responses following low-frequency repetitive stimulation of parallel fibers. These plasticity patterns may allow Bergman glial cells to distinguish between synaptic inputs displaying different activities. In addition, Bergmann glial cells can also be activated by ectopic glutamate release from climbing fibers. This ectopic release predominantly activates glial AMPA receptors, and it may be important for rapid communication between nerve afferents and Bergmann glial cells.

Interestingly, direct electrical stimulation of Bergmann glial cells was reported to affect the 'background' synaptic activity between parallel fibers and Purkinje neurons. Fifty consecutive depolarizations of Bergmann glial cells (0.5 s duration, delivered at 1 Hz) substantially reduced the frequency of spontaneous postsynaptic currents recorded from the neuron.

Cytoplasmic calcium responses In parallel with membrane currents, electrical stimulation of parallel fibers triggers cytosolic calcium responses in the Bergmann glia. These Ca^{2+} responses are precisely localized, being limited to small compartments within glial cell processes (Figure 8). The size of these Ca^{2+} response sites is similar to that of morphologically distinct microdomains, which enwrap a cluster of synapses formed by parallel fibers. This striking compartmentalization of synaptically induced glial Ca^{2+} responses may be important for spatial discrimination of the incoming signals. The Ca^{2+} responses elicited in Bergmann glial cells following nerve activity result from activation of several pathways, including activation of glutamate receptors and α_1 adrenoreceptors – with subsequent Ca^{2+} release from the ER stores – as well as the NO signaling cascade, which activates plasmalemmal Ca^{2+} influx. The local Ca^{2+} signals in the Bergmann glial processes also occur spontaneously, without stimulation of synaptic inputs; most likely, this is the glial correlate of spontaneous EPSCs in nerve cells.

Development and Morphogenesis of Cerebellar Structures

During ontogenesis, Bergmann glial cells arise by transformation (i.e., loss of the ventricular cell process) from fetal radial glial cells, as well as by proliferation of immature Bergmann glial cells within the primitive molecular layer up to the second postnatal week in rat. From the beginning of their existence, Bergmann glial cells are intimately involved in cerebellar morphogenesis. First, in the early postnatal period (P4–P15) Bergmann glial cells act as a guidance system for young postmitotic granule cells, which migrate from the proliferative zone located on the surface of the cerebellar cortex (external granule cell layer) to the inner granule cell layer positioned below the Purkinje cell bodies. This migratory process involves several defined morphological stages described in detail by Ramon-y-Cajal and Pasko Rakic. First, the newborn granule neuron contacts the fiber of a Bergmann glial cell located within the deep part of the external granule layer. After establishing such a contact, the granule neuron turns first into a bipolar cell and then extends a third process that becomes the leading one, guiding the bipolar neuron along the Bergmann glial cell fiber. When this leading process elongates sufficiently, the soma (including the nucleus) of the granule neuron translocates through it, such that finally the entire neuron attains its destination.

Starting from the third postnatal week, Bergman glial cells become closely associated with Purkinje neurons. This association appears to be reciprocal because without contact with Purkinje cells, the Bergmann glia cannot develop its mature phenotype, whereas the development of Purkinje cell dendrites occurs in close alignment with Bergmann glial cell processes. These developmental neuronal–glial interactions essentially involve the Notch signaling system. Membranes of Purkinje cell dendrites express specific Delta/Notch-like EGF-related receptors (DNER), whereas the processes of Bergmann glial cells express Notch. Binding of DNER to Bergmann glial processes determines the morphological differentiation of the latter, and the inhibition of this type

Figure 8 Stimulation of parallel fibers triggers local calcium signals in Bergmann glial cells. (a) Experimental protocol. Parallel fibers (PF) were stimulated via a pipette connected to a stimulator (STIM) while calcium-dependent fluorescence responses were recorded in a Bergmann glial cell (BG). PCL, Purkinje cell layer. (b) Confocal fluorescence intensity image of a patch-clamped Bergmann glial cell dialyzed with the calcium indicator, Oregon green 488 BAPTA-1 (center right). Three processes were distinguished (indicated as 1–3). Calcium signals in response to PF stimulation were measured independently for each process (left). Time of PF stimulation is indicated by arrows. The responding process (1) was then further subdivided into five regions of interest, in which calcium signals were measured separately (right). Time of PF stimulation is indicated by an arrow and a dotted line. The center left image was obtained from a sequence of serial sections and shows the cell in depth (turned by 90° compared to the right image). The lines indicate the focal plane used for $[Ca^{2+}]_i$ recordings. The process is thus within the volume from which recordings were obtained. Adapted from Grosche J, Matyash V, Moller T, Verkhratsky A, Reichenbach A, and Kettenmann H (1999) Microdomains for neuron–glia interaction: Parallel fiber signaling to Bergmann glial cells. *Nature Neuroscience* 2: 139–143.

of local signaling prevents normal morphogenesis of the glial cells. The intermediate filaments in the glial cell processes may also play a crucial role in these glial–neuronal interactions; in vimentin-deficient mice, many of the Purkinje neurons were found to display a paucity of spiny branchlets, a reduced number of synaptic inputs, and degenerative alterations in their cytoplasm.

Conclusions

Bergmann glial cells are specialized radial astrocytes that constitute an important cellular element of cerebellar architecture. These cells control the development of cerebellar circuits by guiding the granule cells from the external to the internal granule cell layer, and they assist in the morphogenesis of Purkinje neurons. Mature Bergmann glial cells form complex 'microdomain' structures that ensheath the synaptic contacts formed on the dendrites of Purkinje cells. Functionally, Bergmann glial cells are endowed with a well-defined set of neurotransmitter receptors, which allow them to sense the activity of synapses formed on the Purkinje neurons. Neuronal activity stimulates the receptors localized in the Bergmann glial cell membrane, resulting in an activation of both transmembrane currents and intracellular Ca^{2+} responses. The latter are highly localized within the

microdomains, thus enabling spatial discrimination of the incoming signals. Bergmann glial cells also possess numerous transporter systems that participate in the clearance of neurotransmitters released during synaptic activity. Thus, Bergmann glial cells can be regarded as active elements of information processing in the cerebellum.

Bilingualism

K Hakuta, Stanford University, Stanford, CA, USA

© 2009 Published by Elsevier Ltd.

Introduction

Bilingualism (multilingualism) refers to the coexistence of more than one language system within an individual, as contrasted to monolingualism. The question of how the two languages interact at the cognitive and behavioral levels has been of long-standing interest to psycholinguists as well as to neurologists, clinicians, and educators. There has been great anticipation that developments in cognitive neuroscience could shed further light on important fundamental questions in the understanding of bilingualism.

Bilingualism as an individual condition is nested within a distribution of broader societal circumstances that cause language contact. There are many different manifestations of this variability. Bilingualism may be the result of growing up in a bilingual community, such as a bilingual neighborhood of an immigrant community in New York. However, that is different from bilingualism that results from growing up in an officially bilingual country such as Canada, where its two official languages are separated by geographical regions. Bilingualism that is accompanied by literacy in both languages is different from bilingualism in which schooling is available in one language (the one that also carries social prestige) but not the other. Although the interest of the cognitive neuroscientist in bilingualism may be in understanding the neural bases of the distribution of the two linguistic systems in the bilingual, the reality is that research subjects and clinical patients invariably come from a sampling from the social distribution. It is thus necessary to begin an understanding of bilingualism from its social bases.

Societal Characteristics

Social scientists have studied the properties, distribution, and stability of bilingualism in many societies and settings over time. The following sections discuss some key characteristics that may influence the bilingualism of individuals growing up within them.

Social Status

Whether the two languages of the bilingual hold equal or different status within the community will have consequences on the stability of the bilingualism over time, across generations. In English-speaking areas of Canada, for example, bilingualism is commonly attained by English speakers choosing to learn French in order to gain access to the privileges of bilingualism. These communities gain a second language without compromising the first language. At the same time, there are immigrant communities in Canada for whom English is a second language, schooling is available in English, and there is no societal value associated with the home languages of these individuals. For most of these bilinguals, the native language will have a limited range of use (often the homes, neighborhoods, and religious institutions) and it is not likely to survive in future generations. The differential status of the languages will produce bilingualism with different levels of strength and stability, even though these individuals are considered bilingual. Fully developed bilingualism in the absence of social status is mostly a transitional phenomenon.

Compartmentalization

Bilingualism often exists in circumstances in which the functions of the two languages are differently distributed across social and cognitive domains, and therefore the bilingualism is compartmentalized. Schooling is a major domain in which the language of immigrant communities is not represented. In such circumstances, the language repertoire of bilinguals is asymmetrical. Academic words are not developed in the language used only outside of schooling and academic contexts. Measurements of bilingualism using academically oriented tasks, such as a standardized test or a verbal IQ test, may yield results that are questionable in validity for the language that is not used in school.

Literacy

Literacy is a significant proxy for cultural capital and socioeconomic status of an immigrant group. Whether bilinguals have education (and thus literacy) available in both languages is telling of the relative status of the two languages in their society. The size of the mental lexicon is one area of language in which growth continues through the life span, and reading is a key means through which vocabulary growth occurs. Thus, the literacy history of the bilingual individual is important not just as a proxy to socioeconomic status but also in understanding the linguistic environment of the bilingual individual. Bilinguals who come from immigrant backgrounds can differ significantly in the extent to which they may have attained literacy in their home language

prior to immigration. Limited literacy may be due to lack of access to schools in their country of origin or, in extreme cases, a home culture such as the Hmong of Southeast Asia, which does not have a developed system of literacy.

Immigrant Generation

The phenomenon of language shift refers to immigrant communities as they move in successive generations from primary dominance in their heritage language to bilingualism and then to dominance or monolingualism in the new language. This shift is rapid in most immigrant environments, and it has been well documented in the United States. With the exception of the monolinguals who are linguistically assimilated as well as some of the first-generation immigrants who remain isolated, most of the others would be considered bilingual, even though their proficiencies would vary considerably. The first generation is characterized by considerable variation in second language proficiency, which is usually predicted by their age of immigration and educational opportunities. Second-generation bilinguals usually have the highest degree of proficiency in the two languages, especially those who are recruited to serve as translators for their parents. The third generation will contain significant variation in the heritage language proficiency, with a considerable proportion of individuals having passive or limited ability in the language, often limited to the domain of their home. Because immigrant groups tend to come in successive cohorts over a period of time, any given sampling from a seemingly homogeneous group (such as an ethnic category 'Hispanic') will still contain considerable variation with respect to immigrant generation and certainly variation in language proficiency.

Historical Circumstances Other Than Immigration

In many areas of the world, bilingualism occurs for reasons other than immigration through which languages come into contact. Bilingualism also occurs through an interest in learning a language that can provide access to communication and global resources, a status that English holds today. Bilingualism can also occur through conquest or colonization – as contrasted with voluntary immigration – in which an occupying force imposes its language on the community. Such is the case with indigenous languages in the Americas or the Aboriginal languages in Australia. These are all circumstances of bilingualism that require special analysis and attention with respect to the bilingual individuals contained therein.

Individual Considerations

The bilingual literature often classifies bilingual individuals independently from their societal conditions. This does not allow for an appreciation of the fact that the sampling for bilinguals of a given characteristic at the individual level may be different depending on the societal condition from which the sample is being drawn. A bilingual who is literate in both languages is relatively easy to find in some contexts and quite difficult to find in others, and so studies conducted with bilinguals in these two different settings may have very different sample characteristics because they are sampled from different sectors of their society. The following sections discuss considerations of bilinguals at the individual level that have been prominent in the literature but are best framed by the societal conditions in which they occur.

Age of Acquisition

The chronological age at which an individual is exposed to a second language has important consequences for the level of bilingualism attained. Some individuals, known as simultaneous bilinguals, are bilingual from birth and grow up in families in which the two languages are used interchangeably. In cases of simultaneous bilingualism, one might ask the question of whether either of the languages was more dominant (in most circumstances, that would be the mother's language), although this information may be difficult to obtain objectively.

In the case of sequential bilinguals, the individual may begin learning the second language at different ages. Typically, the literature distinguishes between early bilingualism (before age 5 years), late childhood bilingualism (between ages 5 and 15 years), and adult bilingualism. However, there is considerable variability in the actual cutoff points used. Very few studies distinguish between bilingualism in the various stages of adulthood, although this may become an important distinction as bilinguals become increasingly studied in the aged population.

Age of exposure to the second language is necessarily correlated with the degree of development of the first language. Early bilinguals are considered to be learning a second language prior to the full grammatical development of the first, and therefore the two developing systems will interact more actively. Late bilinguals have an established grammar in their first language, but their literacy skills are still in the process of development, and thus schooling becomes an important mediating factor. Adult bilinguals vary considerably in their level of formal

schooling and therefore may exhibit considerable variability in their circumstances of bilingualism based on sociodemographic characteristics. All of these conditions will lead to differing levels of proficiency in the two languages.

The most commonly asked question related to the age of the learner is whether there is a biologically conditioned critical period for second-language acquisition, parallel to the critical period hypothesis for native language acquisition. The central part of the hypothesis is that there is a period of readiness during which limited input is sufficient for complete development and a corollary that no amount of input outside the period is sufficient for normal development. There appears to be an unquestionable decline in second language attainment as a function of the age of exposure to the second language, particularly in the area of phonology. However, there is no convincing evidence for a qualitative difference in the outcome of second-language acquisition that occurs within and outside of the critical period. Since most of the research conducted thus far has used varying psycholinguistic and sociological measures of language proficiency, there is great anticipation that evidence from brain localization and activity can shed light on this most interesting problem.

Language Proficiency

Bilinguals can be differentiated with respect to levels of proficiency in their languages. Grammatical proficiency can involve attainment of native-like control in the linguistic arenas of phonology, morphology, syntax, semantics, or pragmatics. Grammatical proficiency usually involves a scale in which native-like control is an absolute threshold – for example, the control of English regular and irregular past tense marking on verbs. The most commonly examined areas of grammatical proficiency are in phonology, morphology, and syntax. Caution is necessary in using native-like control as a standard when there is considerable social and dialectal variation in the standard. South Asians, for example, are often exposed to a variety of English that is known as 'World Englishes,' which has many linguistic and social characteristics that are quite different from standard English. Also, many immigrant students in the United States are exposed to nonstandard varieties of English in schools, such as African American Vernacular English or Black English.

Another arena of proficiency is in the aspects of language involving literacy. Measures of literacy typically show variability even within a native monolingual population, and many measures are constructed in order to produce a normal distribution of performance. Performance on measures of literacy in the two languages of the bilingual can produce vast discrepancies resulting from formal educational experiences.

Balanced bilinguals are individuals considered equivalent in their proficiencies in the two languages. Many researchers consider this to be an idealized state that is not attained by most bilinguals, and bilinguals need to be identified with respect to their language dominance. It should not be assumed that the native language is dominant in sequential bilinguals, especially among first- and second-generation immigrants who are schooled in their second language. An additional complication arises from the fact that dominance may depend on the domain of language that is sampled.

Semilingualism refers to a state in which proficiency in both languages is considered incomplete. Because the grammatical aspects of language are considered to be part of the innate competence of individuals, those with incomplete proficiency in these aspects in both languages are generally considered to be linguistically impaired, assuming that dialectal differences can be ruled out. In the domain of literacy, it is generally accepted that literacy attained in one language predicts literacy attained in the other language, provided that learning opportunities are provided. Thus, failure to attain age-appropriate levels of literacy in either language is a well-noted phenomenon and worthy of serious investigation.

Active versus Passive Bilingualism

Bilinguals can vary considerably in the extent to which they use their two languages, independent of proficiency. This may be an important consideration, to the extent that responses on psycholinguistic and neurolinguistic tasks of subjects depend on the effects of practice or the recency of use of the language. For example, an adult immigrant who moves to a region where there is no sizeable speech community of speakers of the native language may have a high level of proficiency but very few opportunities for use. Also, an individual who is married to someone of the same linguistic background is more likely to maintain use of the language than someone who marries outside his or her linguistic group. The study of bilingualism that does not consider the level of active use of the two languages and simply examines levels of proficiency may miss an important source of variation on performance on linguistic tasks. Sociolinguists who have studied bilingual speech communities have identified individuals who

may rarely speak the language, or who may have lost some of the language, but are nevertheless considered to be members of that speech community and self-identify as such.

Linguistic Considerations

The similarities and differences between the languages of bilinguals introduce an important set of considerations. Linguists have noted varying amounts of interference across languages that can be characterized with respect to their differences, noting, for example, the difficulty of Japanese learners of English in mastering the /*r*/ and /*l*/ sound distinction or the plural marking on nouns. Languages can vary along the lines of historical relationships, as well as at varying levels of their structural features. For example, Japanese, Turkish, and Tamil are considered similar in grammatical characteristics despite their distance with respect to historical relationships. Yet, historical relationships can be extremely important in areas such as the lexicon because linguistic borrowing due to language contact is a relatively common occurrence.

The study of second-language acquisition has also been guided by the question of linguistic transfer from the first to the second language. Second language acquisition is considered to be more efficient if the two languages are grammatically similar rather than if they are different. Although there is debate as to the comprehensive nature of language transfer, it is undisputable that linguistic similarity will determine to a large extent the rapidity of the learning process: English-speaking adults who are learning Italian, German, Spanish, or French will progress at least twice as rapidly as if they are learning Russian, Bulgarian, Arabic, or Korean under comparable conditions, and with comparable levels of aptitude in learning a second language. On the other hand, linguistic theories that emphasize the common underlying principles of human language, such as the Chomsky-inspired approaches to universal grammar, make special note of the similarities that can also be found among second-language learners despite differences in their native language.

Psycholinguistic Perspectives

The major question dominating psychological studies of bilingualism has been how the two languages are represented – the two poles being independence and interdependence. These questions have been asked in the context of the domains of language comprehension and language production, with considerably more experimental research in the area of comprehension. A related question is how organization might vary as a function of language dominance or degree of proficiency in the two languages.

A key emerging generalization appears to be that the bilingual's two languages are usually interdependent, with evidence for a shared storage system. This evidence is strongest in the area of word identification, in which considerable experimental work in lexical access suggests that both languages are activated simultaneously during word recognition. For example, investigations of cognates are revealing because these words appear in both languages. Experiments have found that bilinguals recognize cognates as being words faster than noncognate words, presumably because both lexicons are being accessed simultaneously. Studies of semantic priming in word recognition also support the notion of linguistic interdependence. In these tasks, subjects are asked to make lexical decisions of words that are immediately preceded by a semantically related or unrelated word. In mixed language presentations, there is semantic facilitation even if the priming word is in a language different from that of the test word, again suggesting that both languages are simultaneously active.

Studies of episodic memory, particularly for word lists presented in either language, suggest that bilinguals organize information principally along semantic dimensions, although they are able to remember the language of presentation especially depending on the condition of the task. Studies of semantic memory in which incongruence between the stimulus and the word is explored (such as the Stroop Test, in which subjects are asked to name the color of the ink of words signifying congruent or incongruent colors – for example, the word 'red' printed in red or green ink) show significant cross-language interference, also suggesting a principal effect of cross-language interdependence.

A key area of exploration is the conditions of the task and context that might modulate these basic findings. Computational modeling of bilingual cognition is still in the early stages, with some promising attempts to model linguistic interdependence, independence, and interference. Such models may prove to be useful for bridging theoretical models of representation with the task and context demands of bilingualism.

Differences between bilinguals and monolinguals are an area of some interest, especially by those concerned about the possible positive or negative effects of bilingualism on cognition. Developmental research suggests that bilingualism in children may result in accelerated development in the executive function areas of attention and inhibition but not

necessarily in the area of general cognition. However, there is evidence that bilinguals are slower than monolinguals in tasks such as lexical decision making, presumably because of a larger combined lexicon.

Brain Localization

Evidence of language localization in the left hemisphere, particularly Broca's and Wernicke's areas, for specific functions is supported by the accumulated aphasia literature. Some deviations have been noted, particularly a greater degree of right hemisphere involvement in the less dominant language.

Much research on bilingual aphasia has focused on recovery patterns, such as whether recovery is parallel or whether it is differential and selective. Tabulations of cases of recovery patterns indicate that approximately four in ten cases show parallel recovery, with the remainder being approximately evenly split between stronger recovery in the first language and stronger recovery in the second language. Thus, all possibilities seem to occur in roughly equal proportions. These patterns must all be interpreted with strong caveats about the varying quality of the linguistic assessment of the recovery as well as the descriptions of the bilingual history and proficiency of the subjects. Cases of nonparallel recovery are noted as indicating differentiated organization, although alternative interpretations are possible, such as a 'switch' mechanism between the languages.

Research using bilateral stimulus presentation, such as dichotic listening, that explores the question of hemispheric dominance suggests that language may be represented more bilaterally (i.e., more evidence of right hemisphere engagement) in bilinguals than in monolinguals, with the case being more so for the second language than the first language. This evidence is not conclusive.

Research using the neuroimaging techniques of positron emission tomography and functional magnetic resonance imaging with bilinguals is showing promise in advancing the question of the independence and interdependence of the two languages. Specifically, these studies examine whether there are different or overlapping areas of activation when processing the respective languages of the bilingual.

In language production studies, bilinguals are typically asked to repeat words, generate words, or, in some cases, provide narrative during the scan. The results show that there are overlapping and focused areas of activation for bilinguals with high proficiency in both languages, regardless of whether they are early or adult bilinguals, supporting the interdependence view of bilingualism. However, among adult bilinguals with low proficiency in the second language, the pattern of activation is less focused and exhibits some degree of right hemispheric engagement. The studies strongly point to the importance of language proficiency as an explanatory condition for localization as well as an important control and subject selection criterion.

Studies of language comprehension are better able to control tasks for semantic and syntactic levels of processing. These studies, although fewer in number, suggest that semantic processing (judging whether sentences are meaningful) in the two languages shows a similar pattern of results as those found in the production studies. However, in the area of syntactic processing (judging the grammatical content of sentences), the adult bilinguals showed more extended areas of activation in their second language, even for those with high proficiency. Although these results are quite preliminary, they point to the promise of neuroimaging methods in untangling what is possibly a three-way interaction between language proficiency, age of acquisition, and specific language function (semantics vs. syntax) in bilingual representation.

Conclusion

The neuroscience of bilingualism shows great promise in addressing important issues in the mental representation of bilingualism that have been identified in the psycholinguistics and cognitive science. In turn, the study of bilingualism challenges all fields to be more specific in identifying and incorporating the diversity of the subject population. Language proficiency and age of bilingualism are both key variables in the cognitive and neuroscience literature, and both of these are determined in large part by social and cultural conditions. At a minimum, these background variables must be carefully documented and examined as part of the subject screening and data reporting in order to draw appropriate conclusions from research in the neurological paradigm.

Binocular Rivalry

Binocular rivalry is a form of multistable perception in which visual awareness fluctuates irregularly between different stimuli imaged to corresponding retinal regions of the two eyes. Under ordinary viewing conditions, rivalry is not patently experienced. Instead, people with normal binocular vision usually experience a single stable visual world even though objects throughout most of the visual field produce two retinal images, one in each eye. Evidently the brain manages to blend, or fuse, the two images and to do so in a manner that precisely specifies the three-dimensional relationships among those objects. The processes responsible for such binocular single vision and stereopsis, however, are disrupted when dissimilar monocular stimuli are imaged on corresponding retinal locations. Under these conditions, the eyes transmit contradictory information to the brain, specifying the presence of two different objects situated at the same spatial location at the same time. Faced with this physical impossibility, the brain lapses into an unstable state characterized by alternating periods of perceptual dominance which continue as long as the eyes view discordant stimuli; this is the phenomenon termed binocular rivalry.

During binocular rivalry, conscious visual experience is intermittently dissociated from physical stimulation; a normally visible, complex visual stimulus viewed by one eye may be erased, or suppressed, from visual awareness for several seconds at a time. For this reason, rivalry provides an effective means for identifying neural events accompanying conscious visual awareness. The study of rivalry may also shed light on neural mechanisms underlying perceptual selection and on the resolution of ambiguous sensory information.

History of Binocular Rivalry

The first published account of binocular rivalry was by Giambattista della Porta in 1593. Porta placed one book in front of one eye and another book in front of the other eye. Despite the potential conflict presented by this dichoptic viewing condition, Porta was able to read from one book at a time with no visible disturbance from the book being viewed by the other eye. To change from one book to another, Porta described willfully moving the "visual virtue" from one eye to the other. Several centuries later, more detailed descriptions of rivalry were published in French by Étienne François Dutour, who distinguished between contour rivalry and color rivalry. The first clear description of rivalry in English was provided in 1838 by Charles Wheatstone, who also invented the mirror stereoscope and discovered the geometric basis of stereopsis. Just before the turn of the twentieth century, B B Breese published an influential monograph detailing the stimulus conditions triggering rivalry and influencing the alternations of perception over time. In the 1950s and 1960s, binocular rivalry was used extensively by new look psychologists to show personality and social influences on perception. For example, they showed that, during rivalry between two complex stimuli such as pictures, the one that was meaningful for a person tended to predominate. Psychophysical interest in rivalry was revived in the 1960s, when W J M Levelt published a monograph on it. He offered a formal model of the dynamics of rivalry built around the unifying concept of stimulus strength. Over the next few decades, psychophysical studies of binocular rivalry revealed much about the spatial and temporal characteristics of the phenomenon, together with the relation of rivalry to stereopsis and to other aspects of visual perception. Possible neural concomitants of rivalry have been sought by physiological studies in which responses of single visual neurons are correlated with perceptual reports obtained from alert, behaving animals exposed to rival stimuli. Very recently, brain-imaging studies have provided tantalizing glimpses into possible brain areas involved in producing binocular rivalry in humans.

What Instigates Binocular Rivalry

Binocular rivalry is instigated by presenting dissimilar monocular stimuli to the two eyes, usually via a stereoscope. Binocular rivalry occurs between any stimuli that differ sufficiently in their spatial configurations (contour rivalry) or in their colors (color rivalry). When the images presented to the eyes differ only in their luminances, a form of rivalry called binocular luster may be experienced. When images differ only in their rates of flicker, however, no rivalry is experienced. Rivalry may be triggered by viewing simple stimuli such as lines of differing in orientation (Figure 1(a)) or by viewing complex stimuli such as pictures of a face and of a house (Figure 1(b)). It is not essential that rival stimuli be presented absolutely simultaneously; rivalry can also be observed when the two dissimilar views are presented in rapid alternation.

Figure 1 Examples of dissimilar stimuli which, when imaged separately to the two eyes, provoke binocular rivalry: (a) orthogonally oriented gratings; (b) face and house (the face image is Sir Charles Wheatstone, inventor of the stereoscope and author of the first systematic study of binocular rivalry); (c) pair of rival stimuli in which complete dominance of one entire figure (circular bull's eye) or the other (horizontal contours) requires simultaneous dominance of both eyes within different regions of the visual field; (d) superimposed, orthogonally oriented gratings differing color, a figure that yields monocular, or pattern, rivalry without segregation of the two gratings to different eyes. (c) Adapted from Diaz-Caneja E (1928) Sur l'alternance binoculaire [On binocular alternation]. *Annales d'Oculistique* 165: 721–731.

When a figure is presented to one eye and a blank field to the other, the figure is usually seen continuously. Occasionally, however, the blank field, or even the dark field of a closed eye, can become visible, with the figure temporarily suppressed from vision. It is important to distinguish this form of interocular suppression from Troxler's effect, the spontaneous fading of a binocular stimulus owing to retinal adaptation.

When a figure is presented to one eye and a blank field to the other, introducing a different stimulus onto to the blank field usually results in that stimulus being seen immediately. This abrupt disappearance of the initially dominant figure is referred to as flash suppression, and this procedure provides an effective means for controlling the timing of transitions in perceptual state.

With conventional rivalry, a given eye is exposed to a given figure during the entire rival viewing period. There are, however, other modes of rival stimulation that can produce alternations in perceptual dominance. One technique, illustrated in **Figure 1(c)**, involves splitting each stimulus into two or more parts and presenting some parts to one eye and the other parts to the other eye. Under this condition, observers occasionally experience exclusive dominance of the original stimulus; this outcome – called interocular grouping – would be impossible if one entire eye were completely dominant at any given moment. Another technique involves rapidly and repetitively swapping the two dissimilar figures between the eyes. Here, too, observers sometimes experience periods of exclusive dominance of a given stimulus for periods of time that transcend multiple eye swaps. A third technique is simply to superimpose the two stimuli to the same eye. The relative clarity of the two stimuli fluctuates in the same way as in binocular rivalry, and occasionally one disappears entirely (see **Figure 1(d)**), a phenomenon called monocular rivalry by Breese but now also known as pattern alternation. Whether all of these instances of perceptual rivalry arise from the same neural mechanisms remains a point of contention.

How to Measure Binocular Rivalry

Binocular rivalry is most commonly measured by having an observer track fluctuations in perceptual dominance by pressing one of two buttons to denote exclusive dominance of one or the other stimulus. With this tracking procedure, one can estimate the rate of alternation in perception, the average duration of dominance periods of a given stimulus, and the total duration of dominance of a given stimulus.

Instead of tracking alternations in rivalry using buttons, the observer can be required to respond to monocular probe targets briefly superimposed on a rival stimulus. Probes are more difficult to detect when that rival stimulus is suppressed than when the same rival stimulus is dominant. Thus, probe sensitivity can serve as an index of the perceptual state of a stimulus during rivalry. Moreover, a change in a rival stimulus itself can constitute the probe; an otherwise conspicuous change in a suppressed stimulus can go unnoticed for several seconds, provided that change is made without abrupt alteration in luminance or contrast. For example, an observer may fail to detect a transition from incoherent, random motion to coherent, structured motion when that transition occurs while the motion is suppressed during rivalry.

It is also possible to infer perceptual states of dominance and suppression during rivalry using any one of several alternative physiological measures. These include optokinetic nystagmus (OKN), visual evoked potentials (VER) recorded from the scalp, magnetoencephalography (MEG) which measures magnet fields produced by the brain's electrical activity, and blood-oxygen level dependent (BOLD) signals measured using functional magnetic resonance imaging (fMRI). With all these indirect measures, the amplitude (VER, BOLD, and MEG) and the velocity (OKN) of the evoked signals vary depending on the currently dominant stimulus.

What One Experiences during Binocular Rivalry

When rival targets are first presented, one may experience both simultaneously as if the two were superimposed in visual space. Called false, or abnormal fusion, this perceptual experience lasts only a fraction of a second before one stimulus becomes exclusively visible. Thereafter, alternations begin, interspersed by periods during which bits and pieces of both stimuli are visible simultaneously (mixed dominance). Transitions between perceptual states appear as waves of dominance arising locally and spreading rapidly over space, as if one stimulus were sweeping the other from conscious awareness. Ordinarily, these waves of dominance occur unpredictably, but it is possible to ignite a transition wave locally and then measure the direction and speed of its spread over the visual field.

The incidence of periods of exclusive dominance of a given stimulus during rivalry decreases with stimulus size and light level and increases with retinal eccentricity. Dominance is not strictly confined to the boundaries of a rival stimulus but, instead, extends beyond those boundaries to form a halo of dominance surrounding the stimulus. Neighboring

regions of dominance are not independent, as evidenced by complete monocular dominance of a relatively large target occurring significantly more often than would be expected based on chance alone. Likewise, multiple rival stimuli at different regions of the visual field can engage in synchronized alternations, such that all stimuli of a given configuration (e.g., all green disks) are dominant simultaneously. Moreover, monocular stimulation falling outside the region of rivalry can enhance the predominance of a rival stimulus, acting as if it reinforced the strength of the stimulus itself.

During rivalry, perception alternates unpredictably over time: the successive durations of dominance and suppression are sequentially independent random variables. Moreover, there are large individual differences in alternation rate, and there is some evidence that rivalry rate is related to other cyclic behaviors such as the nasal cycle. Rivalry alternations also vary within the visual field of the same individual, and alternations are generally slower in older individuals. An observer cannot willfully switch from suppression to dominance instantaneously, except perhaps by blinking or suddenly moving the eyes. Nor can most observers hold one rival stimulus dominant indefinitely. Still, the predominance of a stimulus during rivalry is not completely uncontrollable. Manipulations of stimulus variables such as luminance, contrast, contour density, and velocity can produce pronounced variations in stimulus predominance, defined as the total percentage of time that a stimulus is visible during an extended viewing period. This increased predominance is produced largely by decreases in the average duration of suppression periods of a given stimulus – stronger stimuli tend to stay suppressed for shorter periods of time but do not necessarily stay dominant for longer periods of time. The predominance of a given stimulus can also be promoted by repetitively turning off both rival stimuli for several seconds and then turning them back on for several seconds – the rival stimulus dominant at stimulus offset tends to be the dominant stimulus when rivalry is again initiated.

To a limited extent, the dynamics of rivalry are susceptible to top-down influences. At the onset of rivalry, for example, the initially dominant stimulus tends to be the one toward which attention was directed immediately before the onset of rivalry. During rivalry, moreover, the successive durations of dominance of a given stimulus can be significantly prolonged by sustained attention directed to that stimulus. In the nineteenth century, Hermann von Helmholtz described being able to hold one of two rival gratings in dominance by mentally counting the number of light and dark bars making up the grating. Helmholtz attributed this control to attentional volition, but his long-time adversary Ewald Hering skeptically attributed the feat to eye movements and not to attention. Contemporary work, however, has vindicated Helmholtz's claim by showing that attention can indeed modulate rivalry alternations, albeit only modestly. This effect of attention on predominance may explain why a meaningful or an emotionally salient stimulus predominates during rivalry. Mood, too, purportedly affects binocular rivalry, with rate of alternation being significantly slower in people diagnosed with bipolar disorder. Laughter is said to alter rivalry by increasing the incidence of mixed dominance wherein portions of both rival stimuli are visible simultaneously.

Relevance of Binocular Rivalry to Visual Neuroscience

Binocular rivalry remains a topic of enduring interest for multiple reasons. First, the phenomenon itself is inherently fascinating: during rivalry a complex, suprathreshold stimulus disappears from visual awareness for seconds at a time, even though that stimulus remains imaged on the retina – perceptually speaking, a suppressed stimulus seems temporarily nonexistent. Because of this profound intermittent dissociation between physical stimulation and perceptual experience, rivalry affords a paradigmatic case for the study of conscious visual awareness. One expects to find correlated fluctuations in neural activity associated with the intermittent disappearance of a stimulus; as described in the next section titled 'Neural bases of binocular rivalry,' the search for those neural correlates has intensified, using both single-cell recording from monkeys and brain imaging in humans.

Second, and in a related vein, rivalry provides an effective technique for identifying aspects of visual processing that transpire outside of awareness. To what extent does a suppressed stimulus remain visually effective? An answer to this question can shed light on the locus of rivalry relative to other visual processes. To illustrate, exposure to a picture of an object ordinarily makes it easier to name that object when it is subsequently encountered, a phenomenon called visual priming. However, priming is disrupted if an ordinarily effective picture is presented to an eye during suppression and, therefore, outside of visual awareness. Evidently the neural events promoting visual priming arise later in the visual hierarchy than those producing suppression. On the other hand, visual adaptation to translational motion can occur even when the inducing motion itself is suppressed from awareness for a substantial portion of the adaptation phase owing to binocular rivalry. In the case of motion, neural events underlying adaptation

transpire even when the evoking stimulus falls outside of awareness. In general, rivalry can be used to implement what vision scientist Bela Julesz dubbed psychoanatomy: pinpointing the relative loci of neural processes involved in different visual phenomena.

Third, perception during rivalry sometimes assumes a mosaic appearance, meaning that bits and pieces of the competing rival stimuli are perceptually dominant within different regions of the visual field. Usually, however, dominance over portions of the visual field becomes coordinated, yielding global dominance of spatially separated object features. Thus, rivalry offers an effective means for studying the determinants of global perceptual organization. Here, too, there should exist neural signatures of this phase-locked perceptual grouping among neurons representing spatially distributed features.

Fourth, binocular rivalry is widely considered to be one member of a class of visual phenomena that all involve perceptual ambiguity and multistability. According to this approach, the input to vision is inherently underspecified and, hence, ambiguous; this thus forces the visual system to deploy nonsensory information to select among alternative perceptual interpretations. Viewed in this way, multistable phenomena, rivalry included, can be fruitfully used to pinpoint brain areas involved in attention and selection. Furthermore, some people believe that all these forms of perceptual rivalry are driven by a common neuronal oscillator whose intrinsic rate varies among individuals.

Fifth, binocular rivalry can be construed as the default outcome when binocular fusion fails, making rivalry an acid test for assessing the brain's tolerance for monocular mismatches. Rivalry, in other words, reveals the limits for binocular fusion. At the same time, binocular rivalry may shed light on an important process underlying binocular single vision. It is true that left and right foveae rarely receive dissimilar stimulation for any length of time – the oculomotor system attempts to correct this situation by altering vergence angle until matching features are imaged on the two foveae. There are, however, locations on the two retinae where dissimilar monocular images strike corresponding retinal areas, an inevitable consequence of the geometry of binocular vision. Yet one ordinarily does not experience rivalry or diplopia under these conditions. Binocular single vision thus may be accomplished by two processes: binocular fusion and binocular suppression. The potent inhibitory process revealed during rivalry may contribute to normal binocular single vision.

Sixth, rivalry may have implications for understanding the medical condition called strabismic suppression – suppression of vision in one of two eyes of an individual with misaligned eyes – a condition that can lead to the permanent degradation of visual function in that eye. The stimulus conditions eliciting rivalry suppression and strabismic suppression are comparable; corresponding areas of the two eyes receive discrepant inputs. Moreover, there is some evidence suggesting that the two forms of suppression are comparable psychophysically. Inspired by this possible link, several laboratories have used visually evoked potentials to examine the development of rivalry and binocular interactions in very young infants, the motive being to relate those findings to the onset of strabismic suppression.

Neural Bases of Binocular Rivalry

Neural concomitants of binocular rivalry have been investigated in humans using brain imaging and in alert, behaving monkeys using single-cell recording techniques. Both techniques have identified neural events correlated with rivalry dominance and suppression within multiple brain areas within the visual hierarchy.

In monkeys trained to indicate fluctuations in stimulus dominance during rivalry, single-cell recordings reveal modulations in firing rates of neurons within visual areas ranging from V1 to the inferior temporal cortex (Figure 2). In the one study that examined neural responses within the lateral geniculate nucleus (LGN) of alert, behaving monkeys, no changes in firing rate were observed during rival stimulation. In V1, only a minority of neurons show responses that track the perceptual state reported by the monkey, and there is no tendency for such neurons to be dominated by one eye or the other. In contrast, within the inferotemporal (IT) visual area nearly all neurons exhibit fluctuations in spiking activity that closely tracks the monkey's perceptual state. Several neurophysiological studies have described the existence of transient increases in neural synchrony within primary visual cortex in response to the presence of a stimulus that was dominant in rivalry; during suppression phases, neural synchrony was abolished. These fluctuations in neural synchrony are not accompanied, however, by modulations in the firing rate of neurons responsive to the evoking stimulus.

Brain imaging using fMRI in humans reveals that neurally triggered BOLD signals are attenuated in amplitude when the evoking stimulus is suppressed during rivalry (Figure 3). These attenuated BOLD signals have been observed in the lateral geniculate nucleus; in the primary visual cortex; and in areas within the temporal, parietal, and frontal lobes. Within V1, modulations in BOLD signal spread

Figure 2 Neural correlates of binocular rivalry in the monkey visual system: (a) cell activity (action potentials/s) over time in a V4 visual neuron recorded while a trained monkey tracked fluctuations in perception of two rival stimuli, one being the recorded neuron's preferred stimulus; (b) percentage of neurons in different visual areas of the macaque monkey brain whose activity is modulated in synchrony with the animal's perceptual reports of dominance and suppression during rivalry. In (a), the two-tone, shaded timeline below each trace indicates dominance and suppression states of the preferred stimulus as reported by the monkey. IT, inferotemporal visual area; MST, medial superior temporal visual area; MT, middle temporal visual area; STS, superior temporal sulcus; V1, V2, V4, visual cortices. Adapted from Leopold DA and Logothetis NK (1999) Multistable phenomena: Changing views in perception. *Trends in Cognitive Sciences* 3: 254–264 (figure 2), with permission.

over time in a wavelike fashion within the retinotopic map, closely following the spatiotemporal transitions in perceptual state between one rival stimulus and the other. Within inferior parietal and prefrontal areas, transient increases in the BOLD signal are tightly correlated with switches in perceptual state. In contrast, BOLD responses from the amygdala, a lynchpin structure in the network of brain areas underlying processing of affective information, are minimally affected during rivalry. Specifically, BOLD responses in the amygdala are evoked by faces portraying emotional expressions, even when those faces are suppressed during rivalry and produce minimal activity within the putative fusiform face area.

At present, there are discrepancies between the conclusions implied by single-cell recording studies in monkeys and the conclusions being drawn from fMRI studies of humans – the fMRI results imply more pronounced effects of rivalry on neural responses within early visual areas than the single-cell results. It remains to be learned whether these discrepancies are attributable to fundamental differences in technique or to differences between human and monkey visual systems.

Neural Models of Binocular Rivalry

Over the years several neural models of binocular rivalry have been published. Although their details

Figure 3 Neural correlates of binocular rivalry in the human visual system. Each panel shows modulations in event-related, functional magnetic resonance imaging (fMRI) BOLD signals measured from voxels dominated by left-eye stimulation (red) and by right-eye stimulation (blue). The traces in (a) and (b) were measured from voxels in the lateral geniculate nucleus (LGN) and those in (c) and (d) from voxels in primary visual cortex (V1). (a) and (c) show BOLD signal modulations accompanying transitions in perceptual dominance from left-eye/red dominant to right-eye/blue dominant; (b) and (d) show modulations accompanying transitions from right-eye/blue to left-eye red. Solid lines show responses predicted by convolving the reported perceptual alternations with a canonical hemodynamic model of the BOLD response. Reproduced from Haynes J, Deichmann R, and Rees G (2005) Eye-specific effects of binocular rivalry in the human lateral geniculate nucleus. *Nature* 438(7067): 496–499, with permission from Nature Publishing Group.

differ, nearly all these models combine reciprocal inhibition with neural adaptation to produce changes in activity patterns within neural elements representing the alternative rival stimuli (Figure 4). The most recent computational models have added to these elements the strength of excitatory drive to determine which population of neurons is active and which is suppressed. Alternations in the activity over time come about through spike-frequency adaptation, which progressively weakens the strength of excitatory neural signals produced by the dominant stimulus and, as a consequence, the strength of inhibitory influence on the neurons representing the suppressed stimulus. Some computational models implement rivalry within a relatively large ensemble of Hodgkin–Huxley type neurons, whereas others embody interactions within a simpler neural network. Rivalry models can be formulated either in terms of spike rates or conduction dynamics, which can be quite helpful when evaluating the actual physiological plausibility of best-fit parameter values. Contemporary models are formulated in terms grounded in biophysics, implying network susceptibility to levels of specific neurotransmitters (e.g., dopamine and serotonin); these models, unlike their predecessors, imply that rivalry dynamics should be affected in specific ways by experimental manipulations of the levels of those neurochemicals (e.g., through the administration of selective serotonin reuptake inhibitors). Moreover, recent models offer physiologically plausible accounts of individual differences in rivalry dynamics. Finally, these recent models, unlike earlier ones, can account for the wavelike transitions from the dominance of one stimulus to the other and for the effect of spatial configuration of rival targets on rivalry dynamics.

Eye versus Object Rivalry

During binocular rivalry, perceptual experience tells us that one object or the other is currently dominant (or that bits and pieces of both rival objects are jointly visible in the case of piecemeal rivalry). At the same time, we have no idea which eye is viewing the dominant stimulus unless we close an eye to discern the answer. Moreover, as previously mentioned, under

Figure 4 Generic model of binocular rivalry. Arrays of neurons responsive to dissimilar stimuli receive excitatory input (open circles) when their preferred stimuli are present. When those stimuli are imaged on corresponding areas of the two eyes, the neurons exert reciprocal inhibition on one another (interneurons i shown with filled circles). Owing to imbalance in the initial state of activation of the two arrays of neurons, one group of neurons squelches the other's activity promoting dominance of one stimulus over the other. With time, the imbalance in activation between the two groups of neurons diminishes through neural adaptation (dotted lines and filled squares), culminating in a switch in the relative activity levels and, consequently, in the perceptual status of the evoking stimuli. le, left eye; re, right eye.

some conditions people can experience slow alternations in dominance even when the two eyes' views are rapidly and repetitively exchanged during an extended viewing period. Perceptual appearance, in other words, implies that competition for dominance during rivalry transpires between alternative object representations, not between the two eyes. According to this view, the neural concomitants of rivalry competition should be found within high-level visual areas where object properties are seemingly represented. Significantly, neurons within these high-level visual areas retain no information about which of the two eyes is viewing a given object. Yet, at the same time, there is strong indirect evidence implying that binocular rivalry is quite sensitive to eye-of-origin information. Thus, for example, conspicuous changes in a rival stimulus can go completely unnoticed for several seconds when those changes are made during suppression phases of rivalry. This nonselective loss of visual awareness implies that suppression is not tailored to a given stimulus interpretation. In addition, exchanging the dominant and suppressed rival stimuli between the eyes immediately and reliably reverses the stimulus that one experiences, indicating that a given region of the eye – not a given stimulus – dominates at any given time. These and other findings imply that binocular rivalry, in fact, emerges from local competition between corresponding regions of the two eyes.

How is this conundrum to be resolved? Perhaps these seemingly incompatible modes of rivalry – eye versus object rivalry – arise from distributed neural processes, subserved by feed-forward and feedback interactions among multiple neural stages within the visual hierarchy. Indeed, this view may also resolve some of the puzzling inconsistencies among physiological results obtained using different methodologies. The next section considers this distributed view in more detail.

Binocular Rivalry as a Distributed Process

Rather than arising from a single omnibus process, binocular rivalry is more usefully considered as an aggregate of distributed processes, each with its own distinct stimulus determinants and neural concomitants and all organized in a recurrent network. According to this view, a full account of rivalry must specify the stimulus conditions that trigger rivalry in the first place and, once rivalry is triggered, what determines initial selection of one of the two alternative competing views. So, for example, is rivalry triggered only by physical differences between the left and right eyes' images, or can rivalry occur when physically similar images nonetheless give rise to alternative perceptual interpretations because, for example, of differing contexts? Once rivalry is initiated, what governs the dynamics of rivalry? In considering these questions, it is crucial to distinguish between the determinants of perceptual dominance (governing the tendency of a given figure to dominate during rivalry) and the determinants of suppression (controlling the average length of time that a given stimulus remains outside of visual awareness). The determinants of dominance and of suppression are not necessarily the same, although both influence fluctuations in perception over time. It now appears that dominance phases of rivalry are functionally equivalent to ordinary monocular viewing, which means that dominance phases during rivalry are subject to the same influences (e.g., context, prior experience, and emotional connotation) that shape vision under nonrivalry conditions. Whether suppression is influenced by those same factors remains to be determined, and an answer to that question will place important constraints on the nature and locus of neural events underlying suppression. Finally, results from psychophysical, neurophysiological, and brain imaging studies point to the following conclusions: (1) the neural events underlying suppression of a stimulus, inaugurated within early stages of visual processing, are not equivalent to the neural events associated with the physical removal of that visual stimulus, even though those two conditions of stimulation are perceptually equivalent; and (2) the neural events underlying dominance are equivalent to those associated with ordinary, monocular viewing.

Type of Skeletal Systems

The combination of muscles (force production mechanisms) and skeletons enable animals to move in a variety of ways. There are basically three types of skeletons: endoskeletons, the rigid internal skeleton of vertebrates; exoskeletons, the rigid external skeleton of arthropods; and hydrostatic skeletons, which are the focus of this article.

Hydrostatic skeletons do not posses rigid elements but rely on pressure to create stiffness. This can be done based on two types of structures. The first involves a fluid-filled cavity (FFC) which is surrounded by muscles and connective tissue. The second structure is composed mainly of muscles without any internal cavity, termed a muscular hydrostat (MH). In some of the literature, the term hydrostatic skeletons is used exclusively to denote the FFC skeletons, whereas in other publications (as here) this term refers to both types: FCCs and MHs.

FFC skeletons can be found in annelids (segmented worms, e.g., earthworms), echiurans, nematodes (roundworms), nemertean (ribbon worms), echinoderms (starfish and sea urchins), and mollusks (e.g., the foot of bivalves and gastropods). The extent and volume of the FFC is variable. Some animals have this internal cavity divided among body segments (annelids, such as earthworms and leeches), whereas in others it is continuous (echiurans and nematodes).

MH skeletons, on the other hand, are neither segmented nor have a fluid-filled extracellular space but are composed of a tightly packed three-dimensional array of muscle fibers. Examples of MH are the vertebrate tongue, the elephant trunk, the arms, the tentacles and fins of cephalopods, the foot of snails, and the feeding apparatus of some mollusks (e.g., *Aplysia*). MH skeletons have the greatest potential for localized, complex, and diverse movements – much greater than in other types of skeletons.

Hydrostatic skeletons are abundant and diverse, ranging in size from minute worms with a scale of few millimeters and grams to the giant squids reaching 20 m in overall length and giant octopuses attaining an arm span of 6 m and weighing over 40 kg. The hydrostatic skeleton of some animals, such as worms, encompasses their entire body, whereas in others it is used only for a specific organ, as in the elephant trunk. A hydrostatic skeleton may be used in combination with a rigid skeletal support (e.g., the vertebrate tongue). In this article we describe the biomechanics and movement control of hydrostatic skeletons, giving examples of the diversity and unique adaptations.

Basic Structure of Hydrostatic Skeletons

Fluid-Filled Cavity Skeletons

Animals with FFC hydrostatic skeletons usually comprise both circular and longitudinal muscle fibers, and their shapes are typically cylindrical. Diagonal elements (either as muscle fibers, connective tissue, or both) are usually an essential component that prevents kinking. We describe the structure of FFC skeletons here using three examples: the earthworm and the leech (both annelids) and *Ascaris* (a nematode).

Annelids have a segmented body in which each segment is separated by septa. Their FFC is a true coelom; that is, the cavity is completely lined with mesoderm-derived tissue. In the Hirudinean (such as the leech), the coelom is dramatically reduced and septa have been lost, making them more of a MH than a FCC skeleton (Figure 1). This is in contrast to our second annelid example, the earthworm, which has a clearly segmented structure and noticeable fluid-filled compartments (Figure 2).

An earthworm has approximately 150 segments, each with circular (circumferential) muscles responsible for radial contraction and longitudinal muscles that shorten the segment. This shortening causes radial expansion based on a mechanism described later in the article. Waves of alternating activation of the longitudinal and circular muscles produce a peristaltic wave, moving from tail to head, which is used for locomotion and burrowing.

In segmented structures, the larger the number of segments, the greater is the potential for localized control of forces and shape changes. The number and dimensions of the segments are also important in determining the leverage system – the amplification of forces or velocities.

In nematodes (the round worms, such as *Ascaris*) there are no circular muscles but, instead, fibrous cuticle that prevents shortening of the animal (Figure 3). They have longitudinal muscles, located at the body wall and arranged in four groups that can be contracted differentially to produce local shortening and bending. The whole interior of the animal, inside the fibrous cuticle, acts as a hydrostatic skeleton. They have a FFC in the form of a pseudocoelom (i.e., the body cavity is not completely lined with mesoderm), in

Figure 1 A cross section of a leech (*Hirudo*). The reduction of the coelom results in a body structure that is effectively aceolomate. Note the four different muscle groups: circular, oblique, dorsoventral, and longitudinal. Reproduced from Brusca RC and Brusca GJ (1990) *Invertebrates*. Sunderland, MA: Sinauer, with permission from Sinauer Associates, Inc.

Figure 2 A cross section of an earthworm. The fluid-filled compartments (coelom) are separated by septa (not shown). Each segment contains longitudinal and circular muscles. Reproduced from Wallace RA, Sanders GP, and Ferl RJ (1990) *Biology, the Science of Life*, 3rd edn. New York: HarperCollins.

contrast to the annelids. Their muscle composition allows undulatory motion but not peristalsis, due to the lack of circular muscles.

Muscular Hydrostat Skeletons

MHs are mainly composed of tightly packed muscle fibers that are organized in one or more of three major directions: parallel to the long axis of the organ, perpendicular to the long axis, and wrapped helically or obliquely around the long axis. The different MHs show a large variability in the availability, arrangement, and positioning of the different muscle groups. In some cases, connective tissue is the major structural element in one or more of these directions.

The muscle fibers that are parallel to the long axis are termed longitudinal. Their location varies among different species, ranging from locations mainly near the inner core of the organ and up to the periphery of the organ. The perpendicular fibers may show a transverse pattern made of horizontal and vertical fibers in the core of the organ, as in the mammalian tongue, squid arm and tentacle, and octopus arm (Figure 4). A different arrangement is found in the

Figure 3 Stylized cross section of a nematode such as *Ascaris*. All body-wall muscles are obliquely striated longitudinal muscles arranged in four groups. The muscle cells are connected to the ventral or dorsal nerve cords by muscle arms – an extension of the muscle cells and not by neurons. Reproduced from Brusca RC and Brusca GJ (1990) *Invertebrates*. Sunderland, MA: Sinauer, with permission from Sinauer Associates, Inc.

elephant trunk and the tentacles of the chambered nautilus; there the muscles are attached to connective tissue in the center and radiate toward the periphery. Another type of perpendicular organization, that of circular muscles is found in most lizard tongues, in some mammalian tongues, and in the squid tentacles.

The third group of muscle fibers is wrapped helically around the long axis and arranged in opposite directions. This is done based on the combination of muscle fibers and connective tissue to complete the helix (in the octopus arm or the monitor tongue) or using only muscles (as in the squid tentacle).

Biomechanics of Hydrostatic Skeletons and Comparison to Rigid Skeletons

The rigid skeleton (either internal or external) serves some important functions in the generation of movement and the maintenance of posture. The skeleton provides the stiffness needed to resist external and internal forces and supports other organs. Muscles can only exert a pulling force and are unable to push themselves back into their original positions. The rigid skeleton enables the return of muscles to their working regime and the reversibility of shape changes via muscle antagonism, an arrangement of two or more muscles connected to opposing sides of a joint. The relative location of the anchoring points between muscles and bones allow for the amplification of force versus displacement and speed using leverages. In hydrostatic skeletons, these functions are carried out with no rigid elements but, instead, by muscles, connective tissue, and the incompressibility of fluid.

Constant Volume and Muscle Antagonism

The biomechanics of FFC skeletons is based on pressurizing the structure using muscle contraction and resistance of other muscles or connective tissue. Because fluids are incompressible, if the rate of flow out of the cavity is small the enclosed FFC is practically constant in volume. Any change in one dimension will change the pressure in the entire volume and will be compensated for by a change in at least one other dimension. For example, contraction of circular muscles decreases the width of the structure and, as a result of the constant volume constraint, increases its length. This in turn lengthens the longitudinal muscles, which can be later contracted to shorten and widen the structure. Thus, different muscle groups of different fiber orientations act antagonistically.

In MH skeletons, the fluid that maintains a constant volume is contained within the densely packed muscle cells and not in a distinct extracellular cavity. Nevertheless, the biomechanic principle is similar to those of FFC skeletons. Any change in one dimension will cause a compensatory change in at least one other dimension. As in FFC skeletons, the contraction of longitudinal muscles shortens and widens the structure. Contraction of the circular or transverse muscles reduces the diameter and elongates the organ.

Figure 4 The musculature and connective tissue of an octopus arm as an example of a muscular hydrostat. Reprinted from Trueman ER and Clarke MR (eds.) *The Mollusca (11): Form and Function,* New York: Academic Press, Kier WM, The arrangement and function of molluscan muscle, pp. 211–252, Copyright 1988, with permission from Elsevier.

Leverages

The relation between the length and diameter of elongated MH and FFC structures enables the amplification of force or speed, resulting in a leverage system. Here we approximate these structures by a constant-volume cylinder. When the structure is long (the ratio of length to width is large), a small one-unit change in diameter creates a large change in length (Figure 5, from C to D), thus amplifying the displacement and speed. In the other extreme, when the structure is short (has a small length to width ratio), the same one-unit change in diameter results in a much smaller increase in length (Figure 5, from A to B), amplifying the force. Because the length to width ratio itself changes with length, such a system has a variable leverage, depending on the length to width ratio the movement is carried in. This is used in the squid tentacle and some lizards' tongues to protrude the organ very rapidly when these animals catch prey.

Bending

Bending in hydrostatic skeletons is the outcome of differential activation of longitudinal muscles in two sides of the organ and some resistance to compression. The location of the longitudinal fibers at the outer regions of the structure, as found in the elephant trunk, the mammalian tongue, and the octopus arm, creates larger moments. In contrast, tongues that are used for protrusion have their major longitudinal bundles in the center of the organ.

Helical Fibers

Some MH skeletons have helical fibers, and their arrangement and orientation have important implications. Naturally they function in torsional movements in which the organ is twisted along its long axis. But their contribution is not restricted to creating torsion or resisting torsional forces. Depending on their angle relative to the long axis, the contraction of the helical fibers can either elongate the structure (when the angle is less than $54^\circ 44'$) by functioning as circular muscles that decrease diameter or shorten the structure (when the angle is more than $54^\circ 44'$) by functioning as longitudinal muscles.

Stiffness

Generating stiffness is very important in providing structural stability against internal and external forces and in shaping the organ. Stiffness in MHs is achieved by co-contraction of the different muscle groups. When the longitudinal muscles exert the same force as the transverse (or circular) fibers, pressure builds up to stiffen the structure. In MHs such as the octopus arm, this activation scheme not only increases its ability to withstand internal and external forces but also straightens the activated region of the organ. Helical fibers, if present, can also contribute to stiffening of the structure by simultaneous activation of the right-handed and left-handed fibers. This does not result in torsion movement but in increased pressure and in a tendency of the structure to achieve and maintain a stable shape.

Figure 5 The relationship between diameter and length in a fixed volume cylinder is not linear. A unit decrease in diameter when the cylinder is short and wide (from A to B) results in a small increase in length of about 0.6 units. A unit length change applied on a longer and thinner cylinder (from C to D) increases length by more than 10 units. Reproduced from Kier WM and Smith KK (1985) Tongues, tentacles and trunks: The biomechanics of movement in muscular-hydrostats. *Zoological Journal of the Linnaean Society* 83: 307–324, with permission from Blackwell Publishing Ltd.

This biomechanical organizational principle may be seen as a way to simplify control; irrespective of the current shape of the organ, equal and concurrent activations of all muscle groups shape the organ to a standard shape with a degree of stiffness that is dependent on the level of activation. This standard shape is the shape in which all muscle forces are balanced, and its actual dimensions depend on the relative number of muscle fibers in each orientation and their contractile properties.

A similar mechanism can be found in FFC skeletons. Here, too, body stiffness is the result of co-contraction of antagonistic muscles. Moreover, in the leech, contracting the oblique muscles contributes to the stiffness, as well as to the achievement of an intermediate body length, similar to the effect of the helical muscles of MHs.

Interestingly, controlling stiffness by co-contraction of muscles is a known phenomenon for rigid skeleton structures. There, activating of the antagonist muscles around a joint has a stabilizing effect. But this is confined, of course, to stiffness control around a given joint. MHs and some FFCs, on the other hand, have the ability to create a dynamic skeleton by producing stiffened sections at various parts along the structure and by controlling the amount of stiffness of these sections. This is something that is impossible to achieve in rigid skeletons, in which the rigid elements are given and do not change their mechanical characteristics or location along the organ at will.

Localization of Movement

How fine is the ability to perform local movements? This depends on the organization of the biomechanical system, as well as the control system. In segmented structures such as the earthworm, the single segment is the smallest functional unit of movement generation. Naturally a larger number of segments results in a finer ability to perform localized and complex movements. Unsegmented FFCs are limited by the same factor – their one internal FFC transmits forces via its pressure to all the muscles and connective tissue surrounding it. MHs, on the other hand, have the potential for a fine-tuned local control. Their actual ability depends on the size of muscles, the spatial resolution of muscle activation, the capability of controlling muscles independently, and the sensory systems relaying information about their movements. The great degree of localization can be appreciated by considering the arm of *Octopus vulgaris*. It has 3.8×10^5 motor neurons per arm, with muscle cell dimensions of $\sim 0.01 \times 1$ mm, motor unit size of $\sim$3300 muscle cells (occupying a volume of $\sim 0.2\ \text{mm}^3$, which is $\sim$10 ppm of the entire arm) and localized mechanoreceptors. This complexity of anatomy and physiology, combined with a sophisticated motor control system, is the infrastructure for the amazing motor abilities of the octopus.

Mechanical Degrees of Freedom

Related to the issue of localization of movement and an important factor in describing the biomechanics and the motor control system is the number of degrees of freedom (DOFs) of the actuators. The number of mechanical DOFs for rigid skeletons depends on the number and type of their joints. MHs are continuous and flexible structures, and it is difficult to estimate their (obviously huge) number of DOFs or even to use this term to describe such systems. Anyhow, the potential repertoire of movements for an elephant trunk, an

octopus arm, or a tentacle of a squid is vast. Borrowing terminology from robotics, these can be considered as hyperredundant manipulators, meaning that they have many more DOFs than the minimal number needed to perform tasks in space. Planning and executing movement in hyperredundant manipulators is a real challenge in human-made machines. Studying how this is done in animals with MH skeletons may provide important insights for roboticists in the quest to advance technology and allow the production of truly flexible robots. (Later in this article, we describe some of the solutions to motion planning and control problems the octopus uses to deal with the complexity of controlling its arm.)

Variation on a Theme

Following are some examples of different behaviors and typical movements performed by flexible structures with hydrostatic skeletons with their specific adaptations.

Peristalsis and Burrowing

Peristalsis is a common mode of locomotion of many soft-bodied animals (e.g., earthworms, sea cucumbers, caterpillars, and snails). Alternating waves of muscle contraction and relaxation move along the body, anchoring the body to the substratum only in widened regions (Figure 6). In contrast to rigid skeleton animals, in this mode of locomotion there is no change in joint angles between rigid links but, instead, changes in the dimensions of body regions. A region may shorten while increasing in diameter or elongate and contract radially. The changes of body dimensions, especially in FFC skeletons, imply the flow of fluids, increasing the importance of viscous damping forces and decreasing the role of natural frequencies in shaping motion when compared to rigid articulated skeletons.

Figure 6 Peristaltic movement of an earthworm through (or over) the soil is achieved by alternating waves of muscle contraction and relaxation that move along the body. Reproduced from Purves WK, Orians GH, and Helle HC (1994) *Life: The Science of Biology*, 4th edn. Sunderland, MA: Sinauer, with permission from Sinauer Associates.

Peristaltic movements are also used in burrowing. *Urechis caupo* (of the phylum Echiura, unsegmented worms related to the annelids) is a worm specialized for burrowing that lives in U-shaped burrows in marine mud flats. It has longitudinal and circular muscles surrounding a large FFC. It uses peristaltic contractions to pump water through the tube and retrograde contractile waves to move around in its tube and to enlarge its tube by burrowing through the substratum. This body plan can be compared to the segmented body of the earthworm, another burrowing animal; segmentation isolates the effects of muscle contraction, enabling much more localized control of shape and movement and conservation of energy.

Burrowing is also a common behavior of many vertebrates, and unique among them are the caecilians. These are limbless amphibians, found throughout most of the humid tropics, that maintain their body shape during locomotion using hydrostatic pressure. They have obliquely oriented body wall muscles and a vertebral column that moves independently of the skin. This unique morphology enables the generation of a powerful forward force, approximately twice the force found in burrowing snakes of similar size. The snakes rely solely on longitudinal muscles and vertebral column for forward force production, in contrast to the caecilians, which apply force to a crossed-helical array of tendons that surrounds their body cavity, using it as a hydrostatic skeleton. Caecilians are the first vertebrates known to use the entire body as a hydrostatic system for locomotion.

Specialized and Generalized Muscular Hydrostats

Some of the elongated MH structures are generalized and some specialized. This distinction comes from considering the type of movements done by the flexible organ and its structure. The squid tentacle is a remarkable example of specialization. It is a tool specifically constructed for the rapid elongation characterizing the protrusion movement used to catch its prey (70–100% elongation in 20–40 ms, velocities of up to 2 m s^{-1}, and accelerations of up to 250 m s^{-2}). The tentacle is composed of a muscular stalk and a terminal club equipped with arrays of suckers used to grasp the prey. Various adaptations have been described. The transverse and circular muscles fibers are much more numerous than the longitudinal muscle fibers (they occupy more than

60% of the cross-sectional area, compared to 45% in the squid arm). They exhibit a cross-striated pattern typical of fast-contracting muscle cells and differ from other muscles of both squid and cephalopods in general. The tentacle muscle fibers achieve maximal velocity of shortening of 15.5 $L_0\,s^{-1}$(where L_0 is the length at which active isometric muscle force is maximal; it is usually a bit more than the relaxed muscle length), compared to 1.5 $L_0\,s^{-1}$ in arm muscle fibers. The sarcomere structure is especially built for rapid contraction, with almost 10 times shorter thick filaments. A mechanical lever that amplifies speed is also used with a length to width ratio of 20:1 in the resting squid tentacle. When both transverse and circular muscle fibers contract, the result is a rapid increase in length. Approximately 70% elongation of the tentacle is achieved with only a 23% decrease in diameter. The biomechanical adaptations for this fast-protruding mechanism result in a structure that is prone to buckling. This is compensated for by extrinsic support of two of the eight arms in the initial rapid extension phase during prey capture.

The squid protrusion movements and the adaptations allowing this fast movement were studied by various means: using high-speed filming to describe the movement kinematics, studying the muscle ultrastructure and physiology, and using mathematical modeling. The modeling showed that the unusually short myosin filaments of squid extensor muscles are necessary to create the rapid elongation behavior.

In tongues adapted for protrusion, as found in some lizards, in snakes, and in mammalian anteaters, most of the longitudinal muscles are located centrally. In contrast, MHs that are designed for manipulation, such as the elephant trunk, octopus arms, and intro-oral tongues, have smaller length to width ratios; their cross sections show similar amounts of transverse and longitudinal fibers; and their longitudinal muscles are located at the periphery of the organs, providing better leverage for bending.

The tongues of advanced snakes have an interesting subdivision of the arrangement of muscles. At the proximal portion of the tongue, the longitudinal muscles are arranged in two large bundles surrounded by four sheets of transverse muscles – an organization that facilitates protrusion. At the distal parts of the tongue, the longitudinal muscles are arranged in bundles at the periphery with the transverse at the middle – enabling bending.

Some MHs, such as the tongue of the frog *Hemisus*, are composed of muscles fibers oriented in only two directions: longitudinally and vertically. The third dimension has connective tissue but no muscles. The width of the tongue remains constant due to a transversely aligned connective tissue capsule that surrounds the dorsoventral muscle fibers. When the vertical fibers contract, the tongue protrudes with a linear increase in length compared to the geometric increase in the squid tentacle. This difference might partially explain why squid tentacles have higher acceleration ($250\,m\,s^{-2}$) than the tongues of *Hemisus* ($3.5\,m\,s^{-2}$).

Motor Control of Hydrostatic Skeletons

Next we give examples from some of the more advanced studies done on the motor control of hydrostatic skeletons in different animals. Among them are the octopus arm, the tongues of frogs, and the whole body of the leech. Many important systems are not described here due to lack of space (e.g., the control of the human tongue, the feeding mechanism in *Aplysia*, and the tongue protractions of salamanders and chameleons).

The Octopus Arm

The octopus is a solitary animal and an active predator. It uses its eight arms for various motor tasks such as locomotion (swimming and walking), object manipulation (building shelters and pulling or pushing objects), and catching and grasping prey. It can exert great force (as when opening a clamp) and shows immense dexterity (opening jar lids). Octopus movements provide an extreme example for the potential complexity of motor control because the arm can move in any direction from any point along the arm, operating well in constrained and nonpredictable environments.

The motor control of the octopus is divided between the brain and the arms. The brain is composed of 15×10^7 nerve cells, whereas the nervous system of the arms contains 4.75×10^7 neurons in each arm, of which $\sim 3.8 \times 10^5$ are motor neurons, $\sim 2.3 \times 10^6$ are sensory receptors, and 32 000 axons connect the arm and the brain. The majority of the arm nervous system ($\sim 4.5 \times 10^7$ neurons) consists of interneurons. The size of the arm nervous system, the dominance of interneurons within it, and the small number of fibers running between it and the brain suggest a high level of autonomy in the neuromuscular systems of the arms. Indeed, this is supported by the complex local motor reflexes evoked by pain, tactile, or chemical stimuli to the arm. The division of motor control between this autonomous system and the brain suggests a hierarchical organization for the motor control system.

The reaching movement of the octopus is its stereotypical way of extending an arm toward a target by propagating a bend along the arm (**Figure 7(a)**). First, a bend is created somewhere along the arm. Then the base of the arm is directed toward or slightly

Figure 7 The reaching movement of the octopus: (a) a freely behaving octopus reaching toward a target using two of its arms; (b) a similar movement electrically evoked in an arm whose neural connections to the brain were severed; (c) sequence of images from a simulation of arm extension using a dynamic model of the octopus arm. The input to the model was a simple signal of muscle activation propagating from the base of the arm to its tip. Red represents areas of the arm in which all muscles are fully activated; blue represents areas that are not activated. Reproduced from Yekutieli Y, Sagiv-Zoahr R, Aharonov, R, et al. (2005) Dynamic model of the octopus arm, I: Biomechanics of the octopus reaching movement. *Journal of Neurophysiology* 94: 1443–1458, used with permission from The American Physiological Society.

above the target and the arm is straightened until it reaches the target (or misses). When the arm of an octopus touches a target, usually with the suckers, it wraps around the target and brings it back to the mouth (Figure 8).

Kinematic studies of the reaching movement showed that the bend follows a slightly curved planar path. Its velocity has a bell-shaped profile invariant to the direction and the duration of motion. Electromyography (EMG) studies of this movement revealed a characteristic muscle activation wave that moves along the arm and precedes the bend. Moreover, the amplitude of the EMG signal measured at the beginning of the movement was best correlated with the maximal velocity of subsequent bend propagation, meaning that it is possible to predict the kinematics of this movement based on the initial EMG signal. In a denervated arm preparation (whose nervous system was disconnected from the brain), electrical stimuli to the axial nerve cord of the arm or mechanical stimuli to the skin can evoke extension movements similar to natural reaching movements (Figure 7(b)). In the same preparation, the initial posture of the arm determined the direction of the path of the evoked movements.

The control of this movement is characterized by two important principles. The first is the reduction in complexity by the coupling among different DOFs. This is based on the observation that the reaching movement kinematics is dictated by three parameters: two angles in space to control the direction of the base of the arm and a third parameter to control the propagation of the bend along the arm. The second principle is hierarchical organization demonstrated by the division of labor between the central nervous system (presumably controlling the orientation of the base and sending commands to the arm neural network) and the periphery – the neuromuscular system of the arm that executes the movement in an autonomous way.

Figure 8 A quasi-articulated structure is formed during the fetching movement of the octopus. Red arrow marks the location of the food; green, yellow, and blue arrows mark the distal, medial, and proximal bends, respectively. Reprinted from *Current Biology,* 16, Sumbre G, Fiorito G, Flash T, and Hochner B. Octopuses use a human-like strategy to control precise point-to-point arm movements, pp. 767–772, Copyright 2006, with permission from Elsevier.

A forward dynamic model of the octopus arm was used to study the relation between biomechanics and control. The simulations supported the stiffening wave hypothesis, which states that a simple wave of muscle contraction, propagating distally from the base of the arm, can push forward a bend in the arm and straighten it, creating an extension movement (Figure 7(c)). It was shown that water drag forces have a major role in shaping octopus arm movements and that the extension movement is not only a way to simplify control but also an efficient way to move the arm in water. Symmetrical and simultaneous activation of all muscles of the modeled arm was shown to straighten the arm and bring it to the same standard shape irrespective of its initial configuration. Last, dynamic modeling showed that it is possible to control arm stiffness independently of arm kinematics during an extension movement. This stiffness may serve to resist external perturbing forces while performing desired movements. Whether this strategy is actually used by the octopus is not known.

Bringing food to the mouth is achieved by a fetching movement (Figure 8), in which three bends acting like joints are formed along the arm. The arm functions then quite similarly to an articulated structure, with the part of the arm holding the food and bringing it accurately to the mouth. This stereotypic movement also shows a reduction in complexity by coupling DOFs to form a small number of control parameters – the angles of the three joints. Measuring the EMG signals during this movement showed that prior to the formation of the medial joint, two waves of muscle contraction propagate toward the middle, one from the base of the arm and the other from the area holding the food. This observation provides evidence for a mechanism allowing the establishment of the position of the medial joint.

Octopuses use several modes of locomotion. Their fastest mode (also common in squids) is jet propulsion, in which the muscles on the mantle wall contract and squeeze water through their narrow funnel. Benthic species also crawl on the surface, using all or most of their arms. Recently, it was reported that some octopus species use bipedal walking, combining locomotion with the ability to remain disguised. Analyzing these movements revealed an alternating pattern of bend propagation moving along the two walking arms. Each arm in its turn is brought ahead by rotating its base forward. Pushing the octopus forward is achieved by a rotation of the base backward while the part of the arm that touches the surface propagates distally in a form of a bend.

Using muscles to create joints is not unique to elongated MHs such as the octopus and squid arms or the elephant trunk. A novel form of flexible joint mechanism was recently described for the buccal

mass of the octopus, the cuttlefish, and the squid. Their beaks are capable of complex movements using a unique muscular-hydrostatic mechanism to control the location of the pivot between the upper and lower beaks and to generate the force required for beak movements. All this is performed with no articulation of the beaks – that is, they do not have any contact in the form of a skeletal joint.

Tongue Protrusion in Frogs

Tongue protrusion in frogs is done by three main mechanisms, of which only one is based purely on hydrostatic skeleton biomechanics. We briefly describe here these mechanisms and show the relation between the hydrostatic mechanism used to protrude a tongue and other mechanisms from which it probably has evolved.

The first mechanism, and probably the most primitive one, is mechanical pulling. The tongue shortens and the genioglossus muscle (one of the major tongue muscles) contracts, pulling the tongue pad forward over the mandibular symphysis. The tongue is protruded only modestly and unless a prey item is very close, the frog has to lunge forward to catch the prey.

The second mechanism, and the most common one (in terms of the number of species using it), is inertial elongation. Angular momentum generated by the opening of the mouth is transferred to the tongue and elongates it. It requires a tight coordination of tongue and jaw movements that flips the tongue over the mandibles, extending it up to 180 % of its rest length in a very fast, ballistic movement (2.5–4 $m\,s^{-1}$ with accelerations of more than 310 $m\,s^{-2}$). The amount of elongation and precision of movement allow the animal to remain relatively stationary during feeding time. However, frogs using this mechanism are unable to correct the tongue direction during movement.

The third mechanism is hydrostatic elongation, in which the genioglossus muscle has parallel fibers (genioglossus longitudinalis) as in other frogs and also unique vertical fibers (genioglossus dorsoventralis). When the vertical fibers contract, tongue thickness decreases and, due to the constant volume, the length increases. As in inertial elongation, the tongue rotates forward over the mandibular symphysis, but it can also be aimed laterally and in elevation relative to the head. Tongue protrusion in some hydrostatic elongators (e.g., *Hemisus*) is too slow for the inertia to play a role in the movement, whereas others (e.g., *Dyscophus*) protract their tongues fast enough so that inertia may play a significant role in addition to hydrostatic elongation. There appears to be an accuracy versus speed trade-off in hydrostatic elongators.

The force production of protractor muscles in the different frog species cannot explain the differences among these three mechanisms because it differs by only 20–30%. Several other biomechanical and anatomical differences were described.

Mechanical pullers have the largest number of collagen fibers parallel to the long axis, resisting elongation. Inertial elongators have fewer fibers and hydrostatic elongators have the fewest. In *Hemisus*, a hydrostatic elongator, most of the collagen fibers are oriented perpendicularly to the long axis of the tongue.

Other differences exist with regard to the motor control of movement. Inertial elongators use fast, ballistic, movements with feed-forward control to coordinate jaw and tongue movements. They need a precise coordination of tongue and jaw to achieve accurate and successful movements. In contrast, mechanical pullers and hydrostatic elongators have slower movements and use both feed-forward and feedback control of tongue movements. They do not rely on the precise coordination of tongue and jaw. In mechanical pullers, the tip of the tongue is only a few millimeters out of the lower jaw, and in hydrostatic elongators, the tongue movements do not depend on inertia for elongators and thus are controlled independently of the jaw.

These differences are manifested anatomically. Mechanical pullers and hydrostatic elongators lack hypoglossal afferents (carrying proprioceptive information about the tongue) that modulate the phase of activity in the jaw muscles. This is in contrast to inertial elongators, in which it appears that these fibers have evolved convergently at least four times independently.

There is also a difference in the size of the motor units. In inertial elongators (*Bufo marinus* and *Rana pipiens*), approximately 250 motor neurons innervate the genioglossus muscle, compared to approximately 950 motor neurons for the same muscle in a hydrostatic elongator (*H. marmoratum*). This may serve for a more localized and diverse tongue movement and for sequential recruitment to support the tongue against gravity in slow and gradual protraction.

Leech Motor Control

Many aspects of the control of movement in the medicinal leech were investigated in great detail, including the control of its hydrostatic skeleton. The leech is a member of the annelids whose coelom is dramatically reduced and septa have been lost, making them more of a segmented MH than a FCC skeleton.

The leech has four types of muscles used for overt movements: longitudinal, circular, oblique, and dorsoventral (**Figure 1**). The four muscle activations produce

different movements: the contraction of the longitudinal muscles produces shortening, circular muscle contractions produce a reduction in cross section and elongation; contraction of the oblique muscles cause stiffening at an intermediate body length, and dorsoventral muscle contractions cause a flattening of the body and contribute to elongation. The innervation pattern of the muscles allows fine control of shape and movement. The motor neurons are either excitatory (using acetylcholine (ACh) as the neuromuscular transmitter) or inhibitory (using γ-aminobutyric acid (GABA)). Each motor neuron connects to a subset of muscle fibers of a single type in a specific region of one segment only (e.g., the longitudinal muscle fibers on the right dorsoventral side). The leech has stretch receptors embedded in the dorsal, lateral, and ventral body walls of each segment.

Figure 9 shows four distinguishable behaviors that leeches perform by combinations of lengthening, shortening, and bending using a characteristic temporal and spatial pattern of muscle contraction. As

Figure 9 Example of four leech behaviors: (a) local bending as a response to light touch on different body sides; (b) swimming using undulatory movements of the whole body (swimming direction is to the left); (c) rapid shortening of the whole body as a response to touch; (d) crawling by the coordination of body elongation and shortening with sucker attaching and detaching (crawling direction is to the right). Reprinted from Kristan WB Jr., Calabrese RL, and Frissen O (2005) Neuronal control of leech behavior. *Progress in Neurobiology* 76, pp. 279–327, with permission from Elsevier.

described for other hydrostatic skeletons, the internal pressure functions as the mechanism for the transfer of forces between the different muscle groups, rendering them antagonist muscles.

Some of the behaviors described are rhythmic and produced by central pattern generators (CPGs) and can be reproduced in the isolated nervous system. These include swimming (Figure 9(b)), crawling (Figure 9(d)), and feeding. Other movements such as local bending (Figure 9(a)) and shortening (Figure 9(c)) are elicited in response to a well-defined stimulus in a reflexive way.

Local bending in response to light touch is produced by the contraction of longitudinal muscles on the side of the touch and relaxation of the other side. The response is mainly based on a feed-forward mechanism of a simple network that maps sensory locations on to motor space. This mapping resembles the computations described for other systems, such as eye movements in mammals, arm movement in primates, escape responses in crickets and cockroaches, and flight orientation in insects.

As in other hydrostatic skeletons, shortening is caused by the simultaneous contraction of all longitudinal muscles. This can be either localized to a small number of segments or span the whole body.

Swimming in the leech is an undulatory movement of a flattened body shape. The flattening is achieved by tonic contracting the dorsoventral muscles, forming a paddlelike structure that is better for propelling the body in water. Then, alternating contraction and relaxation of dorsal and ventral longitudinal muscles produce rhythmic bending of the body. An isolated nerve cord preparation is capable of producing rhythmic bursting in the motor neurons. The cycle period is longer than in the actual swimming, and the intersegmental phase lags are reduced. This indicates the role of sensory information and feedback loops. Stretch receptors in the leech body wall are the mediators of the sensory information.

The crawling of the leech involves a more complex movement than the peristaltic locomotion of the earthworm. The leech uses front and back suckers to attach to the surface, and their activity must be coordinated with the extension and contraction of the body. Elongation of each segment is produced by the contraction of the circular muscles and contraction of all longitudinal muscles within that segment. Measuring the activity of the motor neurons of a single segment during crawling reveals an alternation of bursting of the circular and longitudinal motor neurons. The same pattern of activity has been reproduced in semi-intact and isolated nervous preparations. As in swimming, this fictive motion had longer cycle periods than the intact animals.

The Role of Modeling

Modeling is an essential component of our understanding of the hydrostatic skeletons' dynamics and control. Combined with other experimental techniques, it is a powerful tool. The complexity of biomechanics and control of hydrostatic skeletons, especially of MHs, require detailed and quantitative models of these systems. Such models were used to test ideas and predict aspects of the design of the system (sarcomere of the squid); confirm assumptions about the biomechanics (stiffening wave hypothesis of the reaching movement in the octopus); show the relative significance of the biomechanical design (the forward model of frog tongue protrusion); illuminate the relative importance of the different forces (the drag forces in the reaching movement of the octopus); and allow us to investigate the interaction of dynamics, sensory information, and neuronal control (leech bending and crawling).

Modeling should be based on accurate and reliable measurements of the different properties of the system: architectural, anatomical, and physiological (e.g., tissue properties; muscle fiber orientation, composition, and forces; EMG; and neuronal signals). It must be based on kinematic and dynamic movement data (e.g., positions, velocities, and forces). This calls for the development of new tools for data acquisition and description, as well as ways to incorporate and integrate multiple-level data with modeling techniques.

Bipolar Disorder

M P DelBello, C M Adler, M A Cerullo, D E Fleck, and S M Strakowski, University of Cincinnati College of Medicine, Cincinnati, OH, USA

© 2009 Elsevier Ltd. All rights reserved.

Epidemiology and Clinical Characteristics

Bipolar Disorders

Bipolar disorder is a common psychiatric disorder that is typically characterized by recurrent episodes of mania, hypomania (a milder version of a mania that is shorter in duration and does not cause the same degree of impairment), depression, and mixed (co-occurring mania and depression) states. Bipolar I disorder is defined by having at least one manic or mixed episode. A manic episode is a distinct period of abnormally and persistently elevated, expansive or irritable mood that lasts at least 1 week (or any duration if hospitalization is necessary), during which at least three (four if the mood is only irritable) of the following symptoms persist: grandiosity, decreased need for sleep, pressured speech, flight of ideas or racing thoughts, distractibility, increased goal-directed activity or psychomotor agitation, and excessive involvement in pleasurable activity that has a potential for painful consequences. Subtypes of bipolar disorder other than bipolar I disorder are well established and have reasonable empirical data. Specifically, bipolar II disorder is characterized by periods of hypomania (manic symptoms that last for 4 days and do not cause marked impairment in social or occupational functioning) and depression with no history of a full manic episode. Cyclothymic disorder is diagnosed by a period of hypomanic and depressive symptoms (which do not meet the criteria for a major depressive) that continues for at least 2 years (1 year in children and adolescents) with no period of 2 or more months without manic or depressive symptoms. The diagnosis also requires that no major depressive, manic, or mixed episode occurs during the first 2 years of the disorder. Finally, the diagnosis of bipolar disorder not otherwise specified includes disorders with bipolar features that do not meet criteria for any specific bipolar disorder (e.g., individuals who experience manic and depressive symptoms that rapidly alternate over days but do not meet minimal duration criteria for a manic, hypomanic, or depressive episode or individuals with recurrent hypomanic episodes). Children and adolescents with bipolar disorder most commonly present with bipolar disorder not otherwise specified because youth with bipolar exhibit rapidly fluctuating mood symptoms that do not meet minimal duration criteria for a manic or hypomanic episode.

Epidemiology and Prevalence

The prevalence of bipolar I disorder is 1% or 2% in adults. Studies suggest that the prevalence of bipolar spectrum illnesses (bipolar II disorder, cyclothymia, and bipolar disorder not otherwise specified) may be as high as 5–10% in community samples of adults. The onset of bipolar disorders most commonly occurs during late adolescence or early adulthood. Bipolar I disorder and cyclothymia are equally common in men and women. In contrast, bipolar II disorder is more common in women. Bipolar disorder is the sixth leading cause of medical disability worldwide. Patients with bipolar disorder have a higher risk of suicide than patients with any other psychiatric or medical illness. Rates of suicidal ideation and attempts range between 35% and 50%, and the rate of completed suicide is approximately 20%.

Outcome

Although most individuals with bipolar disorder recover from their initial manic episode, the early course of bipolar disorder is characterized by persistent functional impairment. Moreover, following an initial manic episode 80–90% of bipolar patients will have a recurrent mood episode. Disruptions in psychosocial functioning often persist during euthymic periods (i.e., relatively symptom-free periods) and typically include deficits in areas of role function, interpersonal relations, sexual activity, and recreational enjoyment.

Vulnerability to poor outcome in bipolar disorder has been associated with several clinical variables, including the number of prior affective episodes, the presence of psychotic features (especially mood-incongruent psychosis), substance abuse, poor adherence to medications, male gender, and lower social class. Neurocognitive deficits that predate illness onset and are stable across illness course (i.e., trait or core deficits) have not been well established. However, a progression of abnormalities in cognitive domains, such as impairments in attention, memory, and executive function, may be related to the poor functional outcome.

During the past decade, research efforts to identify neurobiological markers of vulnerability to poor functional outcome have increased. Neurobiological markers may be more representative of underlying genetics than observable clinical syndrome. Advances in identifying neurocognitive, neuroanatomical, neurophysiological, and neurochemical measures that act as

markers of poor functional outcome will likely dictate improvements in diagnostic and prognostic accuracy. These types of neuroscientific characteristics will be more resistant to biases inherent to clinician-rated symptomatic, syndromic, and functional outcomes.

Neuropsychological Characteristics

Neurocognitive impairment in patients with bipolar disorder may or may not be evident in a clinical setting. However, during manic episodes, patients generally experience clinically significant cognitive dysfunction in one or more domains. This dysfunction may persist, albeit usually in an attenuated form, during periods of euthymia. However, bipolar disorder is generally not considered to involve global processing deficits, as is common in patients with schizophrenia. Unlike the relatively stable negative syndrome that characterizes the end state in schizophrenia, cognition, mood, and neurovegetative factors continually fluctuate throughout the course of bipolar disorder. In keeping with evidence that cognitive and emotional systems operate in dependent, and sometimes antagonistic, fashion in the healthy human brain, cognitive performance changes across mood states during the normal course of bipolar disorder.

Neurocognitive studies have indicated relative processing deficits in a number of specific domains during mood episodes. The most common deficits reported include decrements in sustained attention, verbal memory impairment (especially on recall and other retrieval-based measures), and deficient executive functioning. In each case, there is evidence for decreased performance during acute mood episodes with at least some normalization during euthymia. The most severe euthymic deficits are typically associated with a chronic course of illness, as indexed by an increased number of mood episodes and hospitalizations or longer mood episodes, which may be suggestive of a neurodegenerative process. There is evidence to suggest that during euthymia, accuracy measures on attention, memory, and executive tests normalize, whereas response latencies remain increased, indicating that reaction time slowing occurs independent of improvements in mood symptoms and performance accuracy (evidence also indicates that psychomotor slowing cannot be fully accounted for by the influence of medications). In general, current data do not support the view that bipolar disorder is characterized by a specific neuropsychological profile but instead suggest that cognitive deficits become more severe and diffuse during acute mood episodes, periods of psychosis, with chronic illness, and in elderly patients.

The view that bipolar disorder is related to right cerebral hemisphere dysfunction to a greater extent than the left has been largely disproved. The prevailing view is that cognitive impairment in bipolar disorder is consistent with fronto-subcortical dysfunction, particularly of the anterior limbic brain network modulating human mood and cognition. Abnormalities in typical brain/behavior relationships have been reliably identified in bipolar disorder. In adults, these abnormalities include, but are not limited to, decreased prefrontal cortical volumes related to disinhibition and poor planning, decreased striatal volumes (e.g., caudate nucleus, putamen, and globus pallidus) underlying psychomotor dysfunction, and increased amygdala volumes related to problems regulating mood and emotion. These cortical areas monitor both internal and external sensory information in order to modulate emotional and social behavior and, ultimately, maintain emotional homeostasis. Indeed, lesion studies indicate that emotional and cognitive problems often result from damage to the frontal lobes as well as to temporal limbic structures.

Beyond structural changes in brain regions involved in cognition, a number of studies have noted functional alterations in dynamic neural networks during active cognitive task engagement in bipolar patients despite a normal structural magnetic resonance imaging (MRI) (based on an individual neuroradiological interpretation). These results suggest that bipolar disorder likely does not cause brain damage *per se*, at least in the majority of cases. Instead, cognitive impairment may result from functional or chemical alterations that demonstrate a degree of plasticity relative to mood symptoms or episodes. For instance, increasing symptoms may act as a trigger for the cognitive system to recruit additional resources from functional cortical regions to compensate for decreased attentional capacity. The degree of symptom interference within the cognitive system may mediate performance across mood states, but more stable neurophysiological changes might be revealed during euthymia by processing inefficiency measures such as psychomotor slowing. Thus, the relationships among global processing deficits (e.g., overall psychomotor slowing, distractibility, and impulsivity) that cut across numerous cognitive domains (e.g., attention, memory, and executive functioning), mood states, and neuroimaging findings warrant further study in individuals with bipolar disorder.

Neuroimaging Findings

Affective experience has been linked to the actions of specific brain regions since at least 1937, when

Figure 1 Model of the ALN highlighting hypothesized interactions between structures. Dotted lines indicate inhibitory interactions.

James Papez theorized the involvement of Broca's '*le grande lobe limbique*' in emotional expression. Recent research has led to the extension of the limbic network to include portions of the prefrontal cortex, anterior cingulate cortex (ACC), thalamus, amygdala, hippocampal complex, and fornix and given rise to proposals that mood and behavior are mediated by neuronal interactions within cortico-striatal-pallido-thalamic or cortico-striato-thalamic circuits. Other investigators have postulated that emotional expression is related to interactions within a larger, anterior limbic network (ALN) that encompasses a group of cytoarchitecturally similar brain regions that appear to modulate emotional and cognitive responses through a series of feedback loops between prefrontal, medial temporal, and subcortical structures (Figure 1). The ALN subsumes the extended limbic network and includes input from structures such as the cerebellum not classically associated with affective expression.

Neurostructural Findings

Several lines of evidence suggest that the affective and cognitive symptoms of bipolar disorder are related to disruption of the ALN. Prefrontal cortical volume, for instance, is decreased in bipolar patients compared with healthy controls. Decrements in volume appear to be most prominent in ventral portions of the prefrontal cortex and portions of the ACC identified with emotional regulation and include areas of glial and neuronal cell loss. Studies using voxel-based morphometry (VBM), a structural analysis technique that allows volumetric comparisons within regions and without *a priori* defined structural boundaries, similarly localize decreased prefrontal volume to the dorsolateral prefrontal cortex (DLPFC), ventrolateral prefrontal cortex (VLPFC), orbitofrontal cortex, and ACC. Region-of-interest (ROI) studies in children and adolescents largely fail to replicate these findings, but VBM studies in younger bipolar patients also observe decreased DLPFC and orbitofrontal volume. VBM studies of first-episode bipolar patients, including adolescents, and of patients early in their illness course suggest that structural changes in the VLPFC appear only over time. This interpretation is supported by other studies demonstrating age- and episode-related changes in prefrontal volume.

Portions of the temporal lobe, including anterior temporal cortex and superior temporal gyrus, also appear to be smaller in bipolar patients. Medial temporal findings, however, have been mixed. Amygdala volume has been widely reported to be increased in adult patients with bipolar disorder, whereas volumetric differences have for the most part not been observed in the hippocampus. In contrast, bipolar children and adolescents demonstrate decreased hippocampal and amygdala volume. These discrepant findings may be due to fundamental differences between early and later-onset bipolar disorder, or they may represent evidence of age- or episode-related changes in medial temporal structures.

In general, thalamic volumes have not been found to be affected in either adult or adolescent bipolar patients. However, a minority of studies report thalamic enlargement. Conversely, increased striatal volumes have been widely observed in patients with bipolar disorder, with only a minority of investigators failing to replicate these findings. Similarly, although findings in children and adolescents are also mixed, several studies report observations of increased putamen volumes. Although the cerebellum has been linked only recently with affect regulation, a small number of studies have consistently observed decrements in the cerebellar vermal size of bipolar patients.

Studies using diffusion tensor imaging, a magnetic resonance technique that utilizes measurement of water diffusion to study white matter tracts *in vivo*, suggest that abnormalities are also present in white matter tracts connecting subcortical structures to portions of the prefrontal cortex. Specifically, white matter abnormalities in the anterior fronto-occipital fascicules, which include tracts connecting the orbitofrontal cortex to the temporal and occipital lobes,

and in the anterior genu of the posterior internal capsule (corticothalamic fibers) are present in patients with bipolar spectrum disorders. Similarly, evidence of white matter pathology in prefrontal white matter tracts has been noted in first-episode bipolar patients. Furthermore, increased numbers of white matter hyperintensities (WMHs), areas of increased signal intensity on T2 MRI images that may be indicative of white matter neuropathology, are also increased in patients with bipolar disorder. These areas are concentrated in the frontal cortex and may represent early signs of demyelination. Moreover, WMHs are associated with both poor outcome and cognitive deterioration in bipolar patients.

Neurofunctional Findings

Structural abnormalities in portions of the ALN and in the white matter tracts linking subcortical structures with the prefrontal cortex are accompanied by evidence of functional changes encompassing subcortical, medial temporal, and prefrontal regions.

Functional neuroimaging studies observe changes in neuronal activity in portions of the ALN across a wide range of affective and nonaffective cognitive stimuli. In particular, the VLPFC is overactivated in euthymic bipolar patients in response to most cognitive stimuli. One exception is the Stroop, an inhibition task associated with decreased VLPFC activity across both adult and adolescent studies. Activation of the closely networked ACC is both increased and decreased across functionally disparate subsections.

Prefrontal cortex is reciprocally connected to the amygdala and hippocampus, with projections into the amygdala arising from orbital, medial prefrontal, and lateral portions of the prefrontal cortex. The basal ganglia, and in particular the striatum, also play a significant role in both cortical and emotional regulation. Multiple striatal pathways project to orbitofrontal, medial, and lateral prefrontal regions, and these prefrontal areas project to the ventromedial striatum and thalamus to create feedback loops through which the prefrontal cortex influences psychomotor response to emotion. The nucleus accumbens, which forms part of the ventral striatum, is a central structure in these interconnected limbic and striatal networks. The nucleus accumbens projects to the ventral pallidus, hypothalamus, and brain stem, and it receives abundant afferents from the prelimbic cortex, hippocampal formation, thalamus, and amygdala. The nucleus accumbens is particularly closely associated with the amygdala; the extended amygdala and portions of the nucleus accumbens may be part of a common functional anatomic continuum. Through reciprocal connections, increased ALN activity is also associated with inhibition of neuronal activity in the DLPFC in response to affective and nonaffective stimuli, interfering with performance on cognitive tasks mediated through this region. Euthymic bipolar patients viewing affective faces also showed increased activity in striatum, thalamus, and potions of the medial temporal cortex. Increased activation was similarly reported in these regions in response to nonaffective cognitive stimuli, including attention and working memory tasks. Findings in bipolar adolescents are limited but are consistent with those in adult patients. Limitations of most studies examining neurofunctional abnormalities in patients with bipolar disorder include variability in patient mood state and medication exposure.

Neurochemical Findings

Magnetic resonance spectroscopy (MRS) studies are consistent with findings of neurostructural and neurofunctional abnormalities in bipolar patients. Studies using phosphorous MRS (31P-MRS) show evidence of altered phospholipid metabolism in bipolar disorder that may be indicative of metabolic dysfunction. Decreased phosphocreatine (PCr) and phosphomonoester (PME) concentrations in euthymic bipolar patients are consistent with impaired metabolic activity. Increased concentrations of lactate, also observed in portions of the ALN of bipolar patients, suggest that these findings are associated with a shift in neuronal metabolism from oxidative phosphorylation to glycolysis, which may reflect neuronal hyperactivity as well as mitochondrial dysfunction. Intracellular abnormalities in pH are also consistent with the presence of impaired mitochondrial function, leading several investigators to hypothesize that mitochondrial dysfunction is directly involved in the pathophysiology of bipolar disorder. This hypothesis is supported by genetic studies linking bipolar disorder with specific polymorphisms and transcriptional abnormalities of mitochondrial DNA. Impaired metabolic function may in particular interfere with membrane turnover and impact secondary messenger systems related to the phosphatidylinositol cycle. In addition, mitochondrial dysfunction in patients with bipolar disorder may increase their vulnerability to excitotoxic insults. Indeed, proton MRS (1H-MRS) studies indicate that *N*-acetyl-aspartate (NAA), which is an amino acid found in high concentrations within neurons that is widely utilized as a nonspecific marker of neuronal viability and integrity, is decreased in prefrontal cortical regions of patients with bipolar disorder. This finding is consistent with more gross morphological observations of decreased prefrontal volume.

1H-MRS studies also report increased Glx (glutamate, glutamine, and γ-aminobutyric acid (GABA))

levels in prefrontal regions (e.g., the ACC and VLPFC) of bipolar adults and youth, particularly during mood episodes. The elevated Glx resonance also supports the notion of abnormal metabolism in bipolar patients since most (80–90%) of the total cortical glucose oxidation is associated with the energy required for glutamatergic neurotransmission. Although the 1H-MRS Glx resonance includes glutamate, glutamine, and small amounts of GABA, in prefrontal cortical areas Glx is predominantly glutamate. Increased concentrations of glutamate, an excitotoxic neurotransmitter, are associated with cellular death and may in turn be related to findings of decreased NAA during episodes of mania.

Manic episodes are also associated with other neurochemical evidence of abnormal neuronal metabolism, including decreased PCr and PME resonances. PCr is a high-energy phosphate formed from adenosine triphosphate (ATP) and creatine that transfers high-energy phosphate from the mitochondria when ATP is consumed. PCr transfers its phosphate to adenosine diphosphate (ADP) to replenish ATP stores, acting to buffer concentrations of the latter, energy storage molecule. 31P-MRS studies demonstrate decreased levels of PCr in bipolar patients during manic episodes, suggesting that bioenergetic impairments worsen with mania. Additionally, 31P-MRS and 1H-MRS studies of PME, choline, and myo-inositol (mI) concentrations in bipolar patients suggest the presence of alterations in membrane turnover and second messenger signal transduction systems which are also indicative of changes in cellular metabolism.

Together, functional and structural imaging findings suggest that the pathophysiology of bipolar disorder is characterized by abnormalities of the ALN. Studies of euthymic bipolar patients demonstrate a pattern of neurofunctional responses indicative of oversensitivity both in portions of the ALN involved in perception and expression of mood and in those involved in regulating and modulating this expression. During mania, there appears to be a loss of compensatory activity in modulatory portions of the ALN that is associated with the behavioral manifestations associated with bipolar disorder.

Heritability and Genetics of Bipolar Disorder

Family, Twin, and Adoption Studies

The heritability of bipolar disorder is determined through family, twin, and adoption studies. In family studies, the relatives of patients with bipolar I disorder are examined to determine if they have bipolar disorder or other mental illness. In the 17 major family studies of bipolar disorder, subjects with one immediate family member (i.e., parent, sibling, or child) with bipolar I disorder have a 2–19% chance of being diagnosed with bipolar I disorder. Thus, bipolar I disorder clearly aggregates in families. However, family studies cannot determine if this aggregation is due to shared genetics or environmental factors. For this, twin and adoption studies are needed. Twin studies compare the prevalence of bipolar disorder in monozygotic (identical) and dizygotic (fraternal) twins who share the same environment, and adoption studies examine the prevalence of bipolar disorder in parents of adopted children with bipolar disorder. In 6 studies of twins raised together, if one monozygotic twin (i.e., identical twin) has bipolar I disorder, there is a 20–75% chance the other twin will have the disorder compared to 0–7% chance of sharing the disorder in dizygotic twins. The two adoption studies of bipolar disorder also support the heritability of this disorder. Adoptive parents of bipolar children have a 2% or 3% rate of bipolar disorder compared to a 5–7% rate in the biological parents.

These three types of studies demonstrated a high level of heritability in bipolar I disorder, which may the highest of any major psychiatric disorder. Finally, family studies have also shown that bipolar I disorder also aggregates with major depressive disorder and bipolar II disorder. Eleven to 19% of subjects with an immediate family member with bipolar I disorder have major depressive disorder. In contrast, there is a low risk (1% or 2%) of bipolar I disorder in subjects with immediate family members with major depressive disorder. Bipolar I disorder is found in equal rates in family members of patients with bipolar I and II disorder. However, bipolar II disorder is more prevalent in relatives of patients with bipolar II disorder (6.1%) compared to relatives of patients with bipolar I disorder (1.8%).

Genetic Studies

A significant limitation of family, adoption, and twin studies is that they cannot identify the exact nature of the heritability found. Determining the specific genetic components involved requires linkage and association studies. Linkage studies search chromosomes for genetic markers of diseases in families with a high prevalence of bipolar disorder by looking at the association between marker genes and disease expression. These studies allow the identification of specific regions of the chromosome that are associated with disease expression. In bipolar I disorder, several chromosomal regions have been found that are associated with disease susceptibility. The following chromosomal regions have the most evidence

for their involvement in bipolar disorder: 2p, 4p, 4q, 6q, 8q, 11p, 12q, 13q, 16p, 16q, 18p, 18q, 21q, 22q, and Xq.

Association studies examine whether particular gene variants are associated with disease susceptibility. Instead of looking at families with a high prevalence of a disease, association studies examine individuals with the disease and comparison subjects without the disease and search for the presence or absence of candidate alleles. Candidate genes are generally selected based on animal models or knowledge of the disease pathology. In bipolar I disorder, association studies have found evidence of the involvement of multiple alleles, including *COMT*, *DAT*, *HTR4*, *DRD4*, *DRD2*, *HTR2A*, *5-HTT*, *G72/G30*, *DISC1*, *NCAM1*, *P2RX7*, *MAOA*, *GABRA3*, *GRIN2A*, *CHMP1.5*, *ADCY9*, and *BDNF*. Many of these genes are involved with the neurotransmitters dopamine (DRD5, DAT, DRD4, DRD2, and MAOA), serotonin (HTR4, HTR2A, 5-HTT, and MAOA), GABA (*GABRA3*), and glutamate (*GRIN2A*). Other genes are involved in neural growth (*BDNF* and *NCAM1*), structural proteins (*DISC1*), and neuronal signaling pathways (*P2RX7*, *CHMP1.5*, and *ADCY9*). There are also some genes whose functions are not clear (*G72/G30*). Among these multiple genes, the *G72/G30* gene complex, located on chromosome 13q, is the only finding that has been fully replicated. However, the specific causal mechanisms by which this gene complex or any of the other suspected genes leads to the pathology of bipolar disorder is unknown. One of the difficulties with genetic studies in bipolar disorder is that disease expression likely requires the interactions of multiple candidate genes, not any single gene. Therefore, future research is needed to examine the specific effects of the interactions among multiple genes. In addition, endophenotypes may prove useful for future heritability studies. Endophenotypes may include alterations in neurocognitive tests, brain structure, neurophysiology, or neurochemical marker. Since many of these traits can be quantified, they will allow greater statistical power in linkage studies.

Treatment

Several pharmacological agents are available to treat the acute mood (i.e., manic and depressive) episodes of bipolar disorder and to prevent further episodes (i.e., maintenance treatment). Mood-stabilizing medications commonly used to treat bipolar disorder include lithium; antiepileptic agents such as valproic acid, carbamazepine, and lamotrigine; and atypical (second-generation) antipsychotics such as olanzapine, 2-clozapine quetiapine, risperidone, aripiprazole, and ziprasidone. Although these medications are effective, large clinical trials suggest that only approximately half of any bipolar patient group will exhibit an acute antimanic treatment response to any given medication. Similarly, the acute antidepressant effect of these agents appears to be less than the antimanic response. Combining medications improves response rates by approximately 15–20%; however, this strategy results in more adverse events. Furthermore, maintenance studies report high rates of affective episode recurrences even with good medication adherence.

Although a number of clinical predictors of drug response (e.g., specific symptoms) have been hypothesized, these predictors are unreliable in individual patients. Therefore, the early treatment course of bipolar disorder often consists of repeated ineffective medication trials. Moreover, the mechanisms by which pharmacological agents exert their effects in bipolar patients remain largely unknown. Neurobiological predictors of treatment response may be more useful than clinical predictors. Neuroimaging studies may identify neurobiological predictors of treatment effects and neurobiological changes associated with treatment response. For example, lithium, which inhibits inositol monophosphatase, has been shown *in vivo* to reduce mI levels in the frontal lobe of patients with bipolar disorder. However, the mI reduction occurs at a time when the clinical state is unchanged, suggesting that the effects of lithium are more downstream in cellular processes. Other studies have demonstrated that elevated mI levels, prior to lithium administration, are associated with lithium response. Functional magnetic resonance imaging (fMRI) and MRS studies examining the neurofunctional and neurochemical effects of other medications for bipolar disorder are needed to improve the clinical management and decrease the morbidity and mortality of bipolar disorder.

Conclusion

Bipolar disorder is a common psychiatric disorder characterized by affective instability and cognitive deficits, particularly during mood episodes. Abnormalities within the ALN and related brain regions appear to be involved in the neurophysiology of bipolar disorder. Moreover, studies indicate a high level of heritability in bipolar disorder, although the involvement of specific genes has not been definitively established. Several effective pharmacological treatment options exist for patients with bipolar disorder. Future studies combining neurocognitive, neuroimaging, and genetic techniques may be useful to identify endophenotypes of bipolar disorder and ultimately to develop rationale treatment strategies and improve the outcomes of individuals with bipolar disorder.

Bird Brain: Evolution

E D Jarvis, Duke University Medical Center, Durham, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

The classical century-old view of bird brain evolution was based on a theory of linear and progressive evolution, where the vertebrate cerebrum was argued to have evolved in lower to higher anatomical stages, with birds at an intermediate stage. As such, the avian cerebrum was thought to consist mostly of basal ganglia territories, and these were thought to control mostly primitive behaviors. This view, although slowly challenged, was not formally changed until 2004 and 2005, when a forum of neuroscientists that reevaluated brain terminologies and homologies for birds and other vertebrates published a new nomenclature that reflects a modern understanding of bird brain evolution. This view proposes that the avian cerebrum was inherited as a package with pallial (or cortical-like), striatal, and pallidal regions from its recent reptilian and distant stem amniote ancestors. The avian pallial domain is organized differently from the mammalian pallium or cortex in that the avian is nuclear and the mammalian is layered. However, the pallia of both groups perform similar functions and have some similar connectivity. The avian striatal and pallidal domains are organized more similar to those of mammals and, likewise, perform similar functions in both groups. This article reviews these classical and modern views for bird brain evolution in the context of vertebrate brain evolution.

The Classical View

The classical view of telencephalic evolution had its origin in the late nineteenth and early twentieth century following the impact of Darwin's theory of evolution. Inspired by Darwin's theory, Ludwig Edinger formulated an evolution-based model of brain organization from 1885 to 1908. Edinger and others combined Darwin's concept of 'evolution' with the nineteenth-century version of Aristotle's 'scala naturae,' resulting in the view that evolution was unilinear and progressive, from fish to amphibians, reptiles, birds and mammals, primates, and, finally, humans, ascending from 'lower' to 'higher' intelligence in a chronological series. They believed that the brains of extant vertebrates retained the ancestral structures and, therefore, that the origin of specific human brain subdivisions could be traced back in time by examining the brains of extant nonhuman vertebrates. Although the spinal cord, hindbrain, midbrain, thalamus, and cerebellum appeared to be well conserved across vertebrates, Edinger noted that the internal organization of the telencephala or cerebrum exhibited the most pronounced differences across vertebrates. In mammals, the outer part of the telencephalon had prominently layered gray matter (Figure 1(b), green), whereas the inner part had nuclear gray matter (Figure 1(b), purple). The inner part was located ventral to the lateral ventricle. In nonmammals, the outer and inner parts of the telencephala had mostly nuclear gray matter, and most of it was located ventral to the lateral ventricle in birds and reptiles (Figure 1(b), purple).

On the basis of these considerations, Edinger proposed that telencephalic evolution occurred in progressive stages of increasing complexity and size, culminating with the human cerebrum. He argued that the stages proceeded in a ventral-to-dorsal direction, with each new vertebrate group acquiring a more advanced cerebral subdivision. He argued that first there was the old brain, the paleoencephalon (also called the basal ganglia or subpallium), which controlled instinctive behaviors, followed by the addition of a new brain, the neoencephalon (also called the pallium or mantle at the top), which controlled learned and intelligent behaviors. The telencephalic subdivisions within each vertebrate group were further named by him, Ariëns-Kappers, and others with the prefixes 'paleo' (oldest), 'archi' (archaic), and 'neo' (new) to designate the presumed relative order of evolutionary appearance of each subdivision. To these prefixes the root word 'striatum' was added for the presumed paleoencephalic subdivisions and 'pallium' (meaning mantle) or 'cortex' (meaning bark) for the presumed neoencephalic subdivisions. The term striatum was used because a large part of the basal ganglia (i.e., paleoencephalon) in mammals, which is now commonly call caudate putamen, contains fiber bundles coursing through it, giving it a striated appearance.

The classical view that became dominant in the context of bird brain was that the bird subpallium consisted of 'paleostriatum' (old striatum) inherited originally from fish, said to be the antecedent of the human globus pallidus, and devoted to olfactory information processing. Above the paleostriatum, birds were said to have inherited an 'archistriatum' (archaic striatum) originally from amphibians, said to be the antecedent of the human amygdala. Above and adjacent to the archistriatum, birds were said to have inherited a 'neostriatum' (new striatum) from their closest relative, reptiles, said to be the antecedent of the human caudate and putamen. Reptiles were

Figure 1 Avian and mammalian brain relationships. (a) Side view of a songbird (zebra finch) and human brain to represent avian and mammalian species. In this view, the songbird cerebrum covers the thalamus; the human cerebrum covers the thalamus and midbrain. Left inset next to the human brain is the zebra finch brain to scale with that of the human. Human brain image is from John W. Sundsten of the Digital Anatomist Project (http://www9.biostr.washington.edu/da.html) and used with permission. (b) Classic view of avian and mammalian brain relationships. Although past authors had differing opinions regarding which brain regions are pallium versus subpallium, the images are color-coded to the meaning of the names given. (c) Modern view of avian and mammalian brain relationships according to the conclusions of the Avian Brain Nomenclature Consortium. White solid lines are lamina, cell-sparse zones separating brain subdivisions. Large white areas in the human cerebrum are axon pathways called white matter. Dashed lines divide regions that differ by cell density or cell size; dashed white lines separate primary sensory neuron populations from adjacent regions. Classic view: Ac, accumbens; B, nucleus basalis; Cd, caudate nucleus; CDL, dorsal lateral corticoid area; E, ectostriatum; GP, globus pallidus (i, internal segment; e, external segment); HA, hyperstriatum accessorium; HD, hyperstriatum dorsale; HV, hyperstriatum ventrale; IHA, interstitial hyperstriatum accessorium; L2, field L2; LPO, lobus parolfactorius; OB, olfactory bulb; Pt, putamen. Modern view where different: B, basorostralis; E, entopallium; HA, hyperpallium apicale; Hp, hippocampus; IHA, interstitial hyperpallium apicale; MV, mesopallium ventrale. (b, c) Adapted from Jarvis ED, Gunturkun O, Bruce L, et al. (2005) Avian brains and a new understanding of vertebrate brain evolution. *Nature Reviews Neuroscience* 6: 151–159, with permission.

additionally thought to have elaborated the paleostriatum into an older part (the primitivum) and a newer part (the augmentatum), which was passed onto birds. Birds were then thought to have evolved a large additional basal ganglia subdivision, the 'hyperstriatum' (hypertrophied striatum), considered unique to birds.

The bird pallium was said to consist of a 'paleocortex' inherited from fish pallium and believed to be the antecedent of the human olfactory cortex. Birds were said to have inherited an 'archicortex,' also thought to be olfactory and primitive, from amphibians and believed to be the antecedent of the human hippocampus. Birds were thought not to have evolved any further pallial regions. In contrast, mammals were thought to have evolved from the paleocortex and/or archicortex, a 'neocortex.' The archicortex and/or paleocortex with their two or three cell layers were assumed to be primitive; the neocortex with its six layers was assumed to be more recently evolved and a substrate for more sophisticated behavior. This classical view was codified in the major comparative neuroanatomy text by Ariëns-Kappers, Huber, and Crosby in 1936 and became pervasive throughout neuroscience. This view is now known to be incorrect.

The Modern View

In 2004 and 2005, an international consortium of specialists in avian, mammalian, reptilian, and fish neurobiology – the Avian Brain Nomenclature Consortium – published several reports on a new nomenclature that represents the current understanding of avian telencephalic organization and homologies with mammals (Figure 1(c)). The consortium concluded that the avian telencephalon is organized into three main, developmentally distinct domains that are homologous in fish, amphibians, reptiles, birds, and mammals: pallial, striatal, and pallidal domains (Figure 1(c)). For birds, they renamed these domains and their respective subdivisions with homology-based terms or roots that allow reference to named regions in mammals. In doing so, they eliminated all phylogeny-based prefixes (paleo-, archi-, and neo-) that erroneously implied the relative age of each subdivision.

The avian paleostriatum was simply renamed striatum after its mammalian homolog (Figure 1(c)). The paleostriatum primitivum and adjacent ventral region was renamed pallidum also after its mammalian homolog. Similar to the mammalian pallidum, the avian pallidum has a sparse distribution of cells, giving the region its pale appearance and its name. The dorsal part of the avian pallidum was determined to be homologous to the mammalian globus pallidus and renamed as such, whereas the ventral part was determined to be homologous to the mammalian ventral pallidum. The dorsal pallidum, however, differs between mammals and birds. In mammals, it consists of two segments with distinct connectivity, the internal and external globus pallidus, whereas in birds neurons with both phenotypes are intermingled (Figure 1(c)).

The avian pallium was determined to be organized not into three striatal subdivisions (hyperstriatum, neostriatum, and archistriatum) but, rather, into four pallial subdivisions renamed as hyperpallium (hypertrophied pallium; upper part of old hyperstriatum), mesopallium (middle pallium; lower part of old hyperstriatum), nidopallium (nest pallium; old neostriatum), and arcopallium (arched pallium; most of old archistriatum) (Figure 1(c)). Several neuronal populations adjacent to the arcopallium and the posterior part of what had been regarded as archistriatum were considered homologous to pallial and subpallial parts of the mammalian amygdala, and they were renamed as the avian amygdaloid complex. Other regions that were widely recognized to be homologous among vertebrates – the hippocampus, olfactory (piriform) cortex, and olfactory bulb – did not require name changes.

Some Anatomical and Molecular Parallels

Some key similarities between avian and mammalian subpallium include a high enrichment of dopaminergic axon terminals in the striatum that originate from the substantia nigra pars compacta and ventral tegmental area neurons of the midbrain. Both avian and mammalian striatum contain two major classes of spiny neuron types, those with the neuropeptide substance P (SP) and those with the neuropeptide enkephalin (ENK), which project to two different neuron populations in the pallidum. In both birds and mammals, the SP neurons seem to be involved in promoting planned movement, whereas the ENK neurons seem to be involved in inhibiting unwanted movements. Both the avian and the mammalian striatum participate not only in instinctive behavior and movement but also in motor learning. Developmental studies indicate that the avian and mammalian subpallium consists of two separate histogenetic zones that express different sets of transcription factors: (1) a dorsal zone that corresponds to the lateral ganglionic eminence and that selectively expresses the transcription factors Dlx1 and Dlx2 but not Nkx2.1 and (2) a ventral zone that corresponds to the medial ganglionic eminence and selectively expresses all three transcription factors. The lateral ganglionic eminence gives rise to the striatum and the medial ganglionic eminence

gives rise to the pallidum. Similar striatal and pallidal territories have been found in reptiles.

Some similarities between avian and mammalian pallium (i.e., mammalian cortex) include direct projections of sensory visual, auditory, and somatosensory input from the thalamus. The corresponding avian brain regions subserve the same type of sensory information processing as is performed by the mammalian cortex. Likewise, the avian hyperpallium and arcopallium give rise to major descending projections to premotor and motor neurons of the brain stem and spinal cord, as do mammalian corticobulbar and corticospinal pathways. These avian brain regions subserve critical roles in motor control and sensorimotor learning, similar to the mammalian cortex. The pallial relationships between these avian and mammalian brain regions are also supported by molecular embryology studies. During development, the avian hyperpallium, mesopallium, and nidopallium and the mammalian pallium selectively express the pallium-specific transcription factors Emx1, Pax6, and Tbr1. In adult birds and mammals, comparative expression profiles of the neurotrophic factor brain-derived neurotrophic factor and the glutamate receptor mGluR2 indicate that the avian arcopallium express these pallial-specific mRNAs at high levels, as does the mammalian cortex.

A Modern View of Telencephalic Evolution

The organization of the true basal ganglia of birds relative to mammals and other vertebrates (i.e., distinct nuclear striatal and pallidal domains) is quite conserved. In contrast, the organization of their pallial domains differs to a greater degree. The nuclear type of organization of the pallium found in birds is also present in reptiles. The avian hyperpallium possesses a unique organization so far found only in birds; it consists of semilayered subdivisions, and it might have evolved more recently than the mammalian six-layered cortex since birds evolved well after mammals (by ~50–100 million years) (Figure 2). The region below the ventricle, called the dorsal ventricular ridge (DVR), contains mesopallium, nidopallium, and arcopallium, and it is a nuclear pallial organization that is unique to birds and reptiles. The six-layered cortex is a pallial organization unique to mammals. Because all major groups of living mammals (monotremes, marsupials, and placentals) have a six-layered cortex, it was presumably inherited from their common therapsid ancestor more than 200 million years ago (Figure 2). Furthermore, mammals may not have arisen from reptiles but, rather, from therapsids, because reptile and mammal lineages apparently had their last common ancestor in stem amniotes. Because all nonmammalian therapsids are extinct (Figure 2), it is difficult to trace from stem amniotes to mammals the evolutionary history of mammalian telencephalic organization – layered, nuclear, or otherwise. Thus, the reptilian nuclear pallial organization cannot be assumed to represent the ancestral condition for mammals, as it is for birds.

In general, the evidence suggests that pallial, striatal, and pallidal domains exist in most or all vertebrates. Thus, it has been hypothesized that the telencephalon of early fishes possessed all three domains, which were then inherited as a package by later vertebrates, including birds, and independently

Figure 2 Simplified modern view of vertebrate evolution. The diagram begins with the fish group that contains the most recent ancestor to land vertebrates. This view differs from the classic view in that instead of giving rise to reptiles, ancestral amphibians are thought to have given rise to stem amniotes. Stem amniotes then split into at least two major groups: the sauropsids, which gave rise to all modern reptiles as we know them today, and the therapsids, which, through a series of now-extinct intermediate forms, evolved into mammals. Many sauropsids (reptiles) are currently living. Solid horizontal lines indicate temporal fossil evidence. Dashed lines indicate proposed ancestral links from other types of data. MYA, millions of years ago. Based on Carroll RL (1987) Fossils and relationships. In: *Vertebrate Paleontology and Evolution*, pp. 1–13. Chichester, UK: Wiley.

modified in them. The conserved organization of striatal and pallidal domains indicates that there might be constraints on how the basal ganglia can be organized. The diverse organizations of the pallial domains suggest that there are fewer constraints on how the pallium can be organized.

Detailed Views That Need Further Testing

When the modern view of bird brain evolution was developing, it was accompanied by several new hypotheses about one-to-one homologies between specific avian and mammalian pallial subdivisions. These hypotheses are under active investigation and make up a large area of research on bird brain evolution. They are classified into two main categories: nuclear-to-layered hypotheses and nuclear-to-claustrum/amygdala nuclei hypotheses.

Nuclear-to-Layered Hypotheses

First proposed by Karten, these hypotheses (Figure 3(a)) state that the similarities in connectivity between the avian hyperpallium, nidopallium and arcopallium of birds, and the six-layered cortex of mammals stem from a common origin of these structures – that is, they are homologous. Karten proposed that the common ancestor of birds, reptiles, and mammals possessed a nuclear pallium that was transformed into a laminar pallium early in the mammalian lineage, maintaining connectivity of the ancestral nuclear network. In this regard, he argued that the avian pallium is divided into three sets of serially connected types of neurons – thalamorecipient neurons (field L2, entopallium, and basorostralis), pallio-pallial neurons (nidopallium), and extratelencephalic projection neurons (arcopallium) – with cell types and interconnectivity similar to those of mammalian cortical layers IV, II and III, and V and VI, respectively (Figure 3(a)). Similar arguments were made by others for the avian upper hyperpallium (also known as the Wulst), which also has serially connected neuron types that resemble those found in the mammalian cortex. In this view, avian L2 neurons are homologous to layer IV neurons of mammalian primary auditory cortex, basorostralis neurons to layer IV of primary somatosensory cortex, entopallium neurons to layer IV of extrastriate visual cortex, and the interstitial hyperpallium apicale neurons to layer IV of striate visual cortex. Supporting this hypothesis, gene expression studies have shown that avian thalamorecipient nuclear fields (L2, entopallium, basorostralis, and interstitial hyperpallium) and the mammalian thalamorecipient layer IV of cortex selectively express some of the same genes. Avian extratelencephalic projection neurons (in the arcopallium but not in the hyperpallium) and mammalian extratelencephalic projection neurons (layer V neurons of cortex) both selectively express some of the same genes. Thus, although the avian pallium is not organized cytoarchitectonically into layers, its nuclear subdivisions bear marked similarities in connectivity and molecular profiles to different layers of the mammalian cortex.

Nuclear-to-Claustrum/Amygdala Hypotheses

These hypotheses differ from the nuclear-to-layered hypotheses with regard to mammalian homologies with the avian DVR (mesopallium, nidopallium, and arcopallium; Figure 3(b)). In an early formulation of the nuclear-to-claustrum/amygdala hypotheses, Bruce and Neary proposed that the avian DVR represents an elaboration of parts of the mammalian amygdala. Subsequently, Striedter proposed that the avian DVR represents an elaboration of the mammalian amygdala and claustrum, and that the connectivity that the DVR shares with the neocortex evolved independently. Support for this view is based on findings that both the avian DVR and mammalian claustrum/amygdala are nuclear in organization, that both the avian DVR and part of the mammalian amygdala have similar connections, and that both have conserved developmental expression patterns of regulatory genes that play key roles in brain regionalization and morphogenesis. Puelles and colleagues proposed that the common topographic expression patterns of the transcription factors Emx1 and Pax6 in the avian mesopallium and in the mammalian dorsal claustrum and basolateral amygdala indicate that these structures commonly arose from the lateral pallium (Figure 3(b)). They argued that the absence of Emx1 but the presence of other pallial genes in the avian nidopallium and in the mammalian ventral claustrum and lateral anterior amygdala indicate that these structures commonly arose from the ventral pallium. They further argued that the avian arcopallium and mammalian amygdala consist of subpallial parts derived from striatal and pallidal cell groups and, by this association, that the avian arcopallium is homologous to the mammalian amygdala, as originally proposed by Edinger.

Both categories of hypotheses have their limitations. For the nuclear-to-layer hypotheses, developmental studies have not been conducted to test whether the three types of serially connected neurons in birds arise from cell types similar to those that give rise to the cortical layers in mammals. Furthermore, not all gene expression patterns support one-to-one molecular relationships between avian pallial subdivisions and mammalian cortical layers. Neither do all findings support the nuclear-to-claustrum/amygdala nuclei hypotheses. More investigation is required. This is an active area of research and debate, but the

new avian terminology is compatible with adoption of any one-to-one homology hypothesis should future evidence be more convincing.

Avian Cognition and Brain Function

Based on the modern view, the adult avian pallium, as in mammals, comprises approximately 75% of the telencephalic volume. This realization of a relatively large and well-developed avian pallium that processes information in a similar manner to mammalian sensory and motor cortices may help explain some of the cognitive abilities of birds. As summarized by the Avian Brain Nomenclature Consortium, pigeons can memorize up to 725 different visual patterns, learn to categorically discriminate objects as 'human-made' versus 'natural,' discriminate cubistic and impressionistic styles of painting, communicate using visual symbols, rank patterns using transitive inferential logic, and occasionally 'lie.' New Caledonian crows make tools out of leaves or novel human-made material, use them appropriately to retrieve food, and are believed to pass this knowledge on to other crows through social learning. Magpies develop an understanding

of object constancy at an earlier relative age in their life span than any other organism tested and can use this skill to the same extent as humans. Scrub-jays show episodic memory, recall for events that take place at a specific time or place, once thought to be unique to humans. This same species modifies its food-storing strategy according to the possibility of future stealing by other birds and therefore displays a behavior that would qualify as theory of mind. Owls have a highly sophisticated capacity for sound localization, used for nocturnal hunting, that rivals that of humans and that is developed through learning. Parrots, hummingbirds, and oscine songbirds possess the rare skill of vocal learning. This trait is a critical substrate in humans for spoken language, and with the exceptions of cetaceans and possibly bats and elephants, it is not found in any other mammal. Parrots, in addition, can learn human words and use them to communicate reciprocally with humans. African gray parrots in particular can use human words in numerical and relational concepts – abilities once thought unique to humans. These vocal behaviors are controlled by vocal learning pathways through both pallial and subpallial regions.

In general, these cognitive functions are carried out by the telencephalon, including the six-layered cortex in mammals but by nuclear pallial areas in birds. That is, the mammalian six-layered cortical architecture is not the only neuroarchitectural solution for the generation of complex cognitive behaviors. Pallial-cortical folding is also not required. Birds apparently cannot use cortical folding because of the nuclear organization of their telencephalon; among mammals, such folding is related more to absolute brain size than to behavioral complexity. Rather, the presence of specific brain subdivisions and connections is a more important factor for the generation of behavioral complexity. This suggests that there is an avian method to perform complex behaviors and a mammalian method.

Conclusion

The avian telencephalon is thought to have been inherited from its common ancestors with reptiles and mammals as a package containing pallidal, striatal, and pallial domains. It conserved the pallidal and striatal domains but modified the pallial domains. The pallial domain still performs similar functions as the pallial regions of mammals, such as the six-layered cortex and amygdala. To determine more specific homologies between avian and mammalian pallia, additional investigations are necessary, and such investigations should help determine the basic functions of specific cell types in the vertebrate brain.

Bird Song Systems: Evolution

E D Jarvis, Duke University Medical Center, Durham, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Bird song systems refer to specific neural systems found in those species of birds that produce learned vocalizations, usually learned songs. This vocal learning trait is rare, as it is found to date in only three distantly related groups of birds (parrots, hummingbirds, and songbirds) and at least four distantly related groups of mammals (cetaceans, bats, elephants, and humans). Vocal learning is a critical behavioral substrate for spoken human language. Brain pathways for vocal learning have been studied in the three vocal learning bird groups, where each appears to have seven similar but not identical cerebral vocal nuclei distributed into two vocal pathways: a posterior vocal pathway, which in songbirds is used for producing learned song, and an anterior vocal pathway, which in songbirds is used for learning song. These vocal pathways are not found in vocal nonlearning birds but are similar to brain pathways used for other types of sensorimotor learning in mammals. An auditory pathway that includes the cerebrum is present in all birds and is used to perceive the vocalizations and possibly for auditory learning. This article presents the organization and function of these pathways in vocal learning birds and discusses hypotheses about their evolution.

Vocal Learning Behavior

The unique aspect of bird song systems is that they are involved in vocal learning. Vocal learning is the ability to acquire vocalizations through imitation rather than instinct. It is distinct from auditory learning, which is the ability to make associations with sounds heard. Auditory learning occurs when a dog learns to associate the words 'sit' (English), *sientese* (Spanish), or *osuwari* (Japanese) with the act of sitting. The dog understands the word but cannot imitate the sound of the word. Vocal learners, such as humans, parrots, and some songbirds, are able to imitate noninnate sounds such as sit, *sientese*, or *osuwari*. Most vocal learners, however, imitate sounds of their own species that have been passed on through cultural transmission. Vocal learning depends on auditory learning, but auditory learning does not depend on vocal learning. Vocal learners must hear the sounds they will later imitate. They use auditory feedback to correct their vocal output by comparing the output with auditory memories of the sounds they are trying to imitate.

Given the above definitions, most, if not all, vertebrates are capable of auditory learning, but few are capable of vocal learning. The latter has been found experimentally to date only in the three distantly related groups of birds (parrots, hummingbirds, and songbirds, Figure 1(a)), and the four distantly related groups of mammals (cetaceans, bats, elephants, and humans). There is some suggestion that sea lions are also vocal learners. Each of the vocal learning avian (Figure 1(a)) and mammalian groups has close vocal nonlearning relatives. Thus, it has been argued that vocal learning has evolved independently of a common ancestor in the three vocal learning bird groups and presumably in the vocal learning mammalian groups. The question that thus arises is whether there is something special about the brains of animals that can imitate sounds.

Vocal Learning Song Systems

Only vocal learners – such as songbirds, parrots, hummingbirds, and humans – have brain regions in their cerebrums that control the acoustic structure and syntax of their vocalizations. In birds, these regions make up what are called song systems because they control learned song. Remarkably, in all three vocal learning bird groups, their song systems consist of seven comparable vocal brain nuclei: four posteriorly located nuclei and three anteriorly located nuclei (Figure 1(b); abbreviations in Table 1). These vocal nuclei have been given different names in each bird group because of the possibility that each group evolved its vocal nuclei independent of a common ancestor with such nuclei.

The connectivity of the vocal nuclei has been studied best in songbirds (Figure 2(a)), but sufficient information exists about parrots and some about hummingbirds to make comparisons (Figure 1(b)). In all three vocal learning bird groups, the posterior nuclei form a posterior vocal pathway that projects from a nidopallial vocal nucleus (songbird HVC, parrot NLC, hummingbird VLN) to an arcopallial vocal nucleus (songbird RA, parrot AAC dorsal part, hummingbird VA), to the midbrain premotor (DM) and medulla vocal motor (nXIIts) neurons (Figures 1(b) and 2(a), black arrows). The nXIIts projects to the muscles of the syrinx, the avian vocal organ.

Figure 1 Phylogenetic relationship of birds and comparison of song pathways in vocal learners. (a) Family tree of living avian orders. The tree was derived from DNA–DNA hybridization analysis by Sibley CG and Ahlquist JE (1990) *Phylogeny and classification of birds: A study in molecular evolution*. New Haven, CT: Yale University Press. The Latin name of each order is given, along with examples of common species. Passeriformes are divided into two suborders: suboscine and oscine songbirds. MYA, millions of years ago. Red and green circles show the minimal ancestral nodes where vocal learning could have either evolved independently or been lost independently. Independent losses would have required at least one common vocal learning ancestor prior to parrots. The tree is not meant to present the final dogma of avian evolution, as there are differences of opinion among scientists. (b) Proposed comparable vocal and auditory brain areas among vocal learning birds. Yellow regions and black arrows indicate proposed posterior vocal pathways; red regions and white arrows indicate proposed anterior vocal pathways; dashed lines show connections between the two vocal pathways; blue indicates auditory regions. For simplification, not all connections are shown. Basal ganglia, thalamic, and midbrain regions have broken-line boundaries to indicate that they are deeper in the brain relative to the anatomical structures above them. Scale bar = ~7 mm. Abbreviations are in **Table 1**. Adapted from Jarvis ED, Ribeiro S, da Silva ML, et al. (2000) Behaviourally driven gene expression reveals song nuclei in hummingbird brain. *Nature* 406: 628–632.

The connectivity of the other two cerebral posterior vocal nuclei in hummingbirds is not known, nor has it been well studied in parrots. In songbirds, one of these nuclei (NIf) projects to HVC, and the other (Av) receives a projection from HVC. The posterior vocal pathway is responsible for production of learned song and calls (determined only in songbirds and parrots); songbird HVC is thought to generate syntax and RA the acoustic structure of syllables. Vocal nonlearning birds have DM or nXIIts, but without projections from the arcopallium, for production of innate songs and calls. The posterior vocal pathway is also called the vocal motor pathway because of its role in song production.

The anterior nuclei (connectivity examined only in songbirds and parrots) are part of an anterior vocal pathway loop, in which a pallial vocal nucleus (songbird MAN, parrot NAOc) projects to a striatal vocal nucleus (songbird Area X, parrot MMSt), the striatal vocal nucleus projects to a nucleus of the dorsal thalamus (songbird DLM, parrot DMM), and the dorsal thalamus projects back to the pallial vocal nucleus (songbird MAN, parrot NAOc; **Figures 1(b)** and **2(a)**, white arrows). The parrot pallial MO nucleus also projects to the striatal vocal nucleus (MMSt). Connectivity of the songbird MO-like analog has not yet been determined. The anterior vocal pathway is responsible for learning song (determined mostly in songbirds); lateral MAN (LMAN) is thought to generate variability and Area X to generate stereotypy. Functions of the other nuclei of the anterior vocal pathways are not yet well studied. The anterior

Table 1 Abbreviations

AAC: central nucleus of the anterior arcopallium
AACd: central nucleus of the anterior arcopallium, dorsal part
AACv: central nucleus of the anterior arcopallium, ventral part
ACM: caudal medial arcopallium
Ai: intermediate arcopallium
Area X: area X of the striatum
Av: avalanche
B: basorostralis
CM: caudal mesopallium
CMM: caudal medial mesopallium
CSt: caudal striatum
DLM: medial nucleus of dorsolateral thalamus
DM: dorsal medial nucleus of the midbrain
DMM: magnocellular nucleus of the dorsomedial thalamus
E: entopallium

L2: field L2
L3: field L3
LLD: lateral lemniscus, dorsal nucleus
LLI: lateral lemniscus, intermediate nucleus
LLV: lateral lemniscus, ventral nucleus
LMAN: lateral part of MAN
MAN: magnocellular nucleus of anterior nidopallium
MLd: mesencephalic lateral dorsal nucleus
MMAN: medial part of MAN
MMSt: magnocellular nucleus of the anterior striatum
MO: oval nucleus of the mesopallium
MOc: oval nucleus of the mesopallium complex
NAOc: oval nucleus of the anterior nidopallium complex
NCM: caudal medial nidopallium
NDC: caudal dorsal nidopallium
NIDL: intermediate dorsal lateral nidopallium
NIf: interfacial nucleus of the nidopallium
NLC: central nucleus of the lateral nidopallium
nXIIts: tracheosyringeal subdivision of the hypoglossal nucleus
Ov: nucleus ovoidalis
PAm: nucleus parambigualis
RA: robust nucleus of the arcopallium
RAm: nucleus retroambigualis
SO: superior olive
St: striatum
Uva: nucleus uvaeformis
VA: vocal nucleus of the arcopallium
VAM: vocal nucleus of the anterior mesopallium
VAN: vocal nucleus of the anterior nidopallium
VAS: vocal nucleus of the anterior striatum
VA/VL: ventral anterior/ventral lateral nuclei of the mammalian thalamus.
VLN: vocal nucleus of the lateral nidopallium
VMM: vocal nucleus of the medial mesopallium
VMN: vocal nucleus of the medial nidopallium

vocal pathway is sometimes called the vocal learning pathway but is most often called the anterior forebrain pathway (AFP) because of its anterior location.

One major difference among vocal learning birds is in the connections between the posterior and anterior vocal pathways. In songbirds, the posterior vocal pathway sends input to the anterior vocal pathway via HVC to Area X; the anterior pathway sends output to the posterior pathway via LMAN to RA and medial MAN (MMAN) to HVC (Figures 1(b) and 3(a)). In contrast, in parrots, the posterior pathway sends input into the anterior pathway via ventral AAC (AACv, parallel of songbird RA) to NAOc (parallel of songbird MAN) and MO; the anterior pathway sends output to the posterior pathway via NAOc to NLC (parallel of songbird HVC) and AAC (Figures 1(b) and 3(b)). An important distinction in this regard is that the parrot posterior pathway vocal nuclei do not appear to send projections to the striatal nucleus of the anterior pathway. Another major difference is the relative location of the posterior vocal nuclei; in songbirds, they are embedded in the auditory regions; in hummingbirds, they are situated more laterally but still adjacent to the auditory regions; in parrots, they are situated far laterally and physically separate from the auditory regions (Figure 1(b)). At a minimum, the axons connecting the vocal and auditory systems would have to take different routes in the different vocal learners.

Cerebral Auditory Pathway

Vocal learning and vocal nonlearning birds have very similar auditory pathways. These similarities include projections from ear hair cells to cochlear ganglia neurons, to auditory pontine nuclei (CN, LL), to midbrain (MLd) and thalamic (Ov) nuclei, and to primary (L2) and secondary (L2, L3, NCM, and CM) pallial areas. A descending auditory feedback pathway from the dorsal nidopallium (vocal learners: songbird HVC shelf; parrot NIDL; vocal nonlearner; pigeon Nd) to the intermediate arcopallium (vocal learners: songbird RA cup, parrot ACM; vocal nonlearner: pigeon AIVM) to shell regions around thalamic (Ov) and midbrain (MLd) auditory nuclei (Figure 2(b)). An auditory region exists in the striatum (CSt) of all birds examined, but because of lack of detailed study of the connectivity of CSt in different species, it is not yet possible to make reliable comparisons for the striatal auditory region.

The source of auditory input into the vocal pathways of vocal learning birds is unclear. Various routes have been proposed. In songbirds, these include the HVC shelf into HVC, the RA cup into RA, Ov or CM into NIf, and from NIf dendrites in L2. In parrots, these include the NLC shell into NLC, and nucleus basorostralis, L1, and L3 into the comparable NIf-like nucleus LAN. More study is necessary to determine whether any of these regions truly brings auditory input into the vocal pathways.

The cerebral auditory pathway is thought to be responsible for processing complex sounds, including species-specific songs, in a hierarchical manner. Auditory stimuli are relayed from the thalamus (Ov)

Figure 2 Comparison of vocal and auditory pathways of the songbird brain. Only the most prominent and/or most-studied connections are indicated. (a) Vocal pathway. Black arrows show connections of the posterior vocal pathway (or vocal motor pathway); white arrows, connections of the anterior vocal pathway (or pallial-basal ganglia-thalamic-pallial loop); and dashed lines, connections between the two pathways. (b) Auditory pathway. Most of the hindbrain connectivity is extrapolated from nonsongbird species. For clarity, reciprocal connections in the pallial auditory areas are not indicated. Colors denote major cerebral brain subdivisions of birds. Abbreviations are in **Table 1**. Adapted from Jarvis ED, Güntürkün O, Bruce L, et al. (2005) Avian brains and a new understanding of vertebrate brain evolution. *Nature Reviews Neuroscience* 6: 151–159.

to the cerebrum, where L2 first performs a simple processing of the acoustic features of sounds, then L1, L3, and NCM process more-complex aspects of sounds, such as sequencing and discriminations, and finally CM, the highest station, processes the most complex aspects, such as fine discriminations. In this regard, NCM and CM are also thought to be involved in auditory learning for sound associations and discriminations, and have been proposed to be involved in auditory memory formation of songs used for vocal learning. This hypothesis still needs verification.

Evolution of Vocal Learning Pathways

In the simplest of interpretations, there are three alternative explanations of the way similar, although not identical, vocal learning brain pathways could have evolved among birds (**Figure 1(a)**): (1) the vocal systems in the three vocal learning bird groups evolved independently of a common ancestor. If this is true, then the similarities are remarkably coincidental. (2) In the common ancestor of vocal learning birds, there was a vocal learning pathway with seven cerebral nuclei, which were then lost multiple independent times in closely related bird groups. If this were true, then the similarities are not as remarkable, but it would suggest that there is strong selection to extinguish vocal learning. (3) Most, if not all birds have vocal learning to various degrees, and songbirds, parrots, and hummingbirds independently amplified the associated brain pathways for their more highly developed vocal learning behaviors. If this were true, it would mean that many birds have at least primordial brain structures for vocal learning. So far, the evidence for this last hypothesis has been lacking.

One proposed answer is that different factors are dependent on or independent of a common ancestor. A proposed dependent factor is preexisting connectivity and function. The connections of the anterior and posterior vocal pathways resemble nonvocal motor pathways in mammals (**Figure 3(c)**), and the regions around the vocal nuclei form connections similar to those of the vocal nuclei and are active during production of nonvocal motor behavior. A proposed independent factor is that out of the proposed preexisting motor system, the vocal learning systems for song in the three bird groups evolved independently.

Specifically, the songbird and parrot posterior vocal pathways are similar in connectivity to mammalian motor corticospinal and corticobulbar

Figure 3 Comparative and simplified cellular connectivity of anterior and posterior vocal pathways in (a) songbirds and (b) parrots, and (c) motor pathways in mammals. Dashed lines: connections between anterior and posterior pathways; inputs and outputs are labeled relative to anterior pathways. Output from songbird MAN to HVC and RA is not from the same neurons; MMAN neurons project to HVC, and LMAN neurons project to RA. **O**, excitatory neurons; •, inhibitory neurons; +, excitatory glutamate neurotransmitter release; −, inhibitory GABA release; MSp, medium spiny neuron; GPn, globus pallidus-like neuron in songbird Area X and parrot MMSt. Only the direct pathway through the mammalian basal ganglia (St to GPi) is shown as this is the pathway most similar to Area X connectivity (MSp to GPn). X-p, X-projecting neuron of HVC; RA-p, RA-projecting neuron of HVC; PT-5, pyramidal tract neuron of motor cortex layer 5; IT-3, intratelencephalic projecting neuron of layer 3. Abbreviations are in **Table 1**. Adapted from Jarvis ED (2004) Learned birdsong and the neurobiology of human language. *Annals of the New York Academy of Science* 1016: 749–777.

pathways (Figures 3(a)–3(c)). Projection neurons of songbird RA and parrot AACd are similar to pyramidal tract (PT) neurons of lower layer 5 of mammalian motor cortex. The latter send long axonal projections out of the cerebrum through pyramidal tracts to synapse onto brain stem and spinal cord premotor and α-motor neurons that control muscle contraction and relaxation. The RA-projecting neurons of

songbird HVC and projection neurons of parrot NLC are similar to layer 2 and 3 neurons of mammalian motor cortex, which send intrapallial projections to layer 5 (Figures 3(a)–3(c)). Mammalian parallels to songbird NIf and Av are less clear. In mammals, sensory neurons from the thalamus project to layer 4 of cortex; motor feedback from the thalamus projects to layer 5 (in primary motor cortex) or layer 3 (in frontal cortex). NIf is directly adjacent to L2 and, like L2, similar to mammalian layer 4 neurons, it receives thalamic input from UVa, but like the mammalian thalamic input to layer 3, UVa has motor-associated activity, firing during vocalizing.

The songbird and parrot anterior vocal pathways are similar in connectivity to mammalian cortical-basal ganglia-thalamic-cortical loops (Figures 3(a)–3(c)). The projection neurons of songbird MAN and parrot NAO are similar to intratelencephalic (IT) neurons of layer 3 and upper layer 5 of mammalian premotor cortex, which send collateral projections, one to medium spiny neurons of the striatum ventral to it and the other to other cortical regions (Figures 3(a)–3(c)). Unlike mammals, the spiny neurons in both songbird Area X, and presumably parrot MMSt, project to pallidal-like cells within vocal nuclei Area X and MMSt instead of to a separate globus pallidus structure consisting only of pallidal cells. This striatal-pallidal cell intermingling may be a general trait of the anterior avian striatum. The projection of the pallidal-like cells of songbird Area X and parrot MMSt is similar to the motor pallidal projection neurons of the internal globus pallidus (GPi) of mammals, which project to the ventral lateral (VL) and ventral anterior (VA) nuclei of the dorsal thalamus (Figures 3(a)–3(c)). Mammalian VL/VA projects back to layer-3 neurons of the same premotor areas, closing parallel loops, like songbird DLM and parrot DMM projections to LMAN and NAO.

Because connections between the posterior and anterior vocal pathways differ between songbirds and parrots, comparisons between them and mammals will also differ. Input into mammalian cortical-basal ganglia-thalamic-cortical loops is from collaterals of PT–layer-5 neurons of motor cortex, one that projects to the brain stem and spinal cord and the other that projects into the striatum (Figure 3(c)). In the songbird, however, a specific cell type of HVC, called X-projecting neurons, projects to the striatum separately from those neurons (neurons of RA) that project to the medulla. Parrot vocal connectivity is even more different from mammalian connectivity. In parrots, AAC of the arcopallium has two anatomically separate neuron populations, AACd, projecting to the medulla, and AACv, projecting to anterior pallial vocal nuclei NAO and MO. Output of mammalian anterior pathways are the collaterals of IT-layer 3 and IT-upper layer 5 neurons that project to other cortical regions (Figure 3(c)).

In terms of function, recent results suggest that vocal nuclei of vocal learning birds are embedded within at least seven brain areas active during the production of limb and body movements. The same movement-associated brain areas are found in vocal learning birds, such as ring doves. These and related findings have led to a motor theory for the origin of vocal learning whereby in the avian brain, a preexisting motor system in a vocal nonlearner ancestor is proposed to have consisted of seven brain regions distributed across mesopallial, nidopallial, arcopallial, and striatal brain subdivisions and separated into two pathways: an anterior premotor pathway that forms a pallial-basal ganglia-thalamic-pallial loop and a posterior motor pathway that sends descending projections to brain stem and spinal cord premotor and α-motor neurons. Then a mutational event or events might have caused descending projections of avian arcopallium neurons that normally synapse onto nonvocal motor neurons to instead synapse onto nXIIts neurons in vocal learners. Thereafter, cerebral vocal brain regions could have developed out of adjacent motor brain regions using the preexisting connectivity. Such a mutational event would be expected to occur in genes that regulate synaptic connectivity of pallial motor neurons to α-motor neurons. This hypothesis needs to be tested with more experiments before it can be accepted with more confidence. If it is true, then this hypothesis needs to account for how auditory information enters the vocal pathway during evolution of a vocal learning system.

Evolution of the Auditory Pathway

The auditory pathway described in birds has a number of similarities with auditory pathways in reptiles and mammals (Figure 4). Birds, reptiles, and mammals have ear hair cells that synapse onto sensory neurons, which project to cochlea and lemniscal nuclei of the brain stem, which in turn project to midbrain (avian MLd, reptile torus, mammalian inferior colliculus) and thalamic (avian Ov, reptile reunions, mammalian medial geniculate) auditory nuclei. The thalamic nuclei in turn project to primary auditory cell populations in the pallium (avian L2, reptile caudal pallium, mammalian layer 4 of primary auditory cortex). For connectivity in the cerebrum, detailed studies exist only for mammals and birds. It has been proposed that avian L1 and L3 neurons are similar to mammalian layers 2 and 3 of primary auditory cortex, the

Figure 4 Comparative and simplified connectivity among auditory pathways in reptiles, birds, and mammals. The connectivity from CM to CSt in birds needs verification by retrograde tracing. Abbreviations are in **Table 1**. From Jarvis ED (2004) Learned birdsong and the neurobiology of human language. *Annals of the New York Academy of Science* 1016: 749–777.

latter of which receives input, like L2, from layer 4. Avian NCM and CM have been proposed to be similar to layers 2 and 3 in that they form reciprocal intrapallial connections with each other and receive input from L2. Neurons of the songbird RA cup, parrot ACM, and pigeon AIVM of the arcopallium are similar to mammalian layers 5 and 6, which send descending auditory feedback projections to the shell regions of mammalian thalamic and midbrain auditory nuclei. Avian CSt may be similar to an auditory region in mammals that is located caudally in the striatum. The connectivity of this region has not been verified in birds or mammals.

The similarities suggest that the auditory pathways of birds, reptiles, and mammals may be homologous. Further, since this auditory pathway exists in all birds studied, the auditory pathway in vocal learning birds was presumably inherited from their common avian ancestor, which inherited it from their common stem-amniote ancestor with other vertebrates, thought to have lived ~320 million years ago. A cerebral auditory pathway would explain why birds and nonhuman mammals, including dogs, exhibit auditory learning, including learning to understand the meaning of simple human speech, although presumably with less facility than a human has. In this regard, when a vocal learning system evolves, it presumably uses the preexisting auditory pathway to bring auditory information into it.

Evolution of Vocal Learning Behavior

The previous sections discuss neural or genetic-based factors that may have influenced the evolution of bird song systems. This last section discusses the possible epigenetic, or environmental/behavioral factors. A number of hypotheses have been proposed to explain what selects for vocal learning. These include: (1) individual identification, (2) semantic communication, (3) territory defense, (4) mate attraction, and (5) rapid adaptation to sound propagation in different environments. For individual identification, the argument is that among vocal learners, each individual can learn its own song and thus have a unique signature that differentiates it from others of its population. However, individual identification by voice is not a unique characteristic of vocal learners. As no two individuals look identical, neither do any two individuals within an avian or mammalian population sound identical, allowing vocal nonlearners to identify individual conspecifics by voice. It is true

that with vocal learning, individuals can be called by unique names. This, however, has so far been found among humans and maybe bottlenose dolphins but no other vocal learners. Thus, it is unlikely that individual identification was a primary driving force for the selection of vocal learning.

A common notion is that a selective advantage of language is semantic communication. Semantic vocal communication means that animate or inanimate objects have a specific vocalization or series of vocalizations associated with them. It contrasts with affective vocal communication, which means that vocalizations have emotional content associated with them. Despite this common notion, many vocal nonlearners, such as chickens and vervet monkeys, use innate calls to communicate semantic information, such as 'an eagle above,' 'a snake on the ground,' or 'a food source.' Vocal learning birds also use innate calls with such semantic information and only rarely have been found to use learned vocalizations for mainly semantic communication. Examples of the latter include the African Grey parrot's use of human speech words and the black-capped chickadee's use of calls to indicate predator size. Since this is not the common use of learned vocalizations among vocal learners, semantic communication was probably not a major driving force for the selection of vocal learning.

Vocal learners use their learned vocalizations most commonly in affective contexts, to defend territories and/or attract mates. These uses are found among the songbirds, parrots, and hummingbirds. Many vocal nonlearners use their innate calls and crows to defend territories and attract mates; examples include the crowing of male doves and chickens. There is, however, an additional feature of mate attraction that vocal learners use learned vocalizations for: variability. Vocal learners, but not vocal nonlearners, have the ability to produce more-varied frequency modulation (FM) and syntax, during vocal development and/or, in some species, after reaching adulthood. These variations in FM and syntax are preferred by females of the songbird species that have been examined. In addition, canaries have been shown to use their two voices, common among birds, to produce even greater FM variations, thought to stimulate estrogen production in the listening females; these are sometimes called sexy syllables or songs. In fact, in vocal nonlearners, such as ring doves, artificially increased computer-generated FM of innate sounds is more stimulatory for mating than are the innate coos. Therefore, birds with the ability to produce more vocal variety are likely to be selected for this trait. Once the ability to produce variable sounds is selected for, then the ability of vocal learning maybe selected for. In this regard, mate attraction was probably a major driving force in the selection for vocal learning.

For sound transmission, vocal nonlearners produce their vocalizations best in specific habitats, which makes their vocal behaviors less adaptable to changes in the environment. For example, a pigeon's low-frequency vocalizations travel best near the ground, whereas an eastern phoebe's higher-pitched vocalizations travel better higher in the air. In contrast, vocal learners have the ability to change voice characteristics, either during the lifetime of an individual or through several generations, presumably allowing better group communication in different environments.

If mate attraction for varied sounds and a minimal mutational event to cause motor pallial areas to synapse onto α-vocal motor neurons is what it takes to evolve vocal learning, then this still does not explain why it is so rare. One proposed explanation is that predation is a strong selection factor against vocal learning. If more-varied syntax is attractive to mates, it may also be more attractive to predators. As innate vocalizations tend to be more constant, they may be naturally habituated to more easily, potentially becoming part of the background noise. Therefore, in order for a predator not to habituate to the sounds of his prey, he would have to evolve a neural mechanism to overcome the natural habituation at times when he is hungry. If this were the case, then a species would have to overcome predatory pressure or have a relaxed predatory pressure before it could evolve vocal learning. In this regard, some mammalian vocal learners have very few if any major predators (humans, whales, and elephants). Hummingbirds, because of their rapid flight and escape behavior, are also commonly known to be fearless of many animals. Various parrot species and ravens (a corvid songbird) are prey to hawks and large owls, like other birds, but they are said to be highly effective at mobbing behavior to evade such predators. A cautionary note: it is not known how valid the distinction is between vocal learners and nonlearners in terms of predation, as no systematic study has been done on prey and predatory behaviors across vocal learning and vocal nonlearning groups.

Some findings support this association. Okanoya and colleagues have shown that Bengalese finches that have been bred in captivity, without predators, for the past 250 years and without human selection for singing behavior show more-varied syntax than their white-backed munia conspecifics still living in the wild, from which they derive. Zann has shown that zebra finches bred in captivity show more variation in the songs learned among adults of a colony than do their wild-type conspecifics. For both species, females prefer the more varied songs. Given these findings, one

would expect to find more syntax complexity selected for in the wild than currently exists. Perhaps predatory pressure is selecting against it.

In summary, the investigations into the evolution of bird song systems are an active area of study, often leading to insights and to novel hypotheses about evolution of brain systems for complex behaviors, including spoken language. A great amount of knowledge has been obtained, but a great amount more is needed before various hypotheses can be rejected or new ones generated.

Introduction

Birdsong has been compared to human speech because both are examples of animal vocalizations that are at least partially learned. Indeed, some of the neural pathways underlying these vocal behaviors may be similar in songbirds and humans. More generally, birdsong can be compared to any motor behavior that involves sequential control and learning and is an ideal playground for experimental and theoretical explorations of the neural basis for motor learning and control.

The neurons involved in song production and learning are clustered in a small number of discrete nuclei with well-defined boundaries, fairly well-characterized connectivity, and increasingly well-studied neurophysiology. The various species of oscine songbirds display a vast spectrum of complexity in syllable sequencing (syntax), improvisation, and vocal acquisition. For example, song can be as simple as repetitions of a set of syllables arranged in fixed order (e.g., zebra finches), or it can be intricately improvised, with syllable ordering governed by probabilistic transitions between different syllables (e.g., domesticated bengalese finches). Mockingbirds can acquire novel songs and learn novel nonbird sounds throughout life. Yet the basic neural song circuit is similar in all oscines. This diversity of behavior subserved by an underlying similarity of structure makes birdsong an intriguing system for future comparative studies of sophisticated motor sequencing and control.

Models have so far focused on the zebra finch, a songbird with one of the simplest of oscine song repertoires, because most recordings of neural activity have been obtained from these birds. The male zebra finch learns one song motif with fixed syllable order and sings repetitions of that motif throughout its life. Song acquisition takes place in a sensory phase, when the juvenile bird acquires a mental template of the song of a possibly unrelated adult tutor, and an overlapping sensorimotor phase, when the juvenile begins to vocalize and tries to match its vocalizations with its mental template. In the laboratory the sensory and sensorimotor phases can be separated: template acquisition is fast and can be completed and the tutor bird removed from the juvenile's presence before the juvenile has begun to practice its song. Sensorimotor learning is a slow process of self-generated trial and error and can proceed successfully in complete auditory and social isolation after template acquisition. However, auditory feedback of the bird's own vocalizations is crucial during sensorimotor learning because a bird deafened at this stage cannot learn to reproduce its mental template of the tutor song.

This article focuses on the motor and sensorimotor aspects of song production, in particular the formation of neural sequences to drive song, the learning of the motor map, and the reasons song may be encoded the way it is by songbird premotor neurons. The aim is to illustrate how theoretical work has contributed to the understanding of the song system and highlight the resulting predictions for experiment. Auditory neural coding and dynamics and the physics (acoustics and mechanics) of songbird vocal production are beyond the scope of the article.

Basic Functional Anatomy of the Song Pathway

In the oscine vocal premotor circuit, high-level vocal center nucleus (HVC) projects to nucleus robustus archistriatalis (RA). RA drives the motor neurons that innervate the syringeal and respiratory organs for song production (Figure 1). Lesioning any of these nuclei immediately disables song production, while nuclei upstream of HVC are not necessary for singing in adult zebra finches. Therefore, HVC originates the top-level premotor drive for adult zebra finch song. Although the circuitry between the premotor nuclei is feedforward, connectivity within HVC and within RA is extensively recurrent. In addition to the premotor circuit, the song system contains the anterior forebrain pathway (AFP), which connects HVC to RA through an indirect path. Lesion studies reveal that the AFP is crucial for the sensorimotor phase of song learning and long-term song maintenance but not for song production. The AFP is an avian homolog of the mammalian thalamocortical–basal ganglia pathway.

Based on anatomical, neurophysiological, and lesion data, it is believed that HVC generates the spatiotemporal premotor drive for sequential motor activation in the form of sequential neural activity. The HVC activity is 'abstract,' in the sense that it encodes only temporal ordering, not song features (Figures 2(a) and 2(b)). The synapses from HVC to RA and from RA to the motor neurons convert the sequence of HVC activity patterns into the sequence of motor commands that produces song (Figure 2).

Figure 1 The neural pathways underlying song learning and song production. (a) Song learning and production involves a discrete set of nuclei. (b) The same areas, unfolded to better illustrate their connectivity. Lines terminating in arrows designate excitatory or putative excitatory connectivity. Lines terminating in circles designate inhibitory synapses. Blue nuclei are part of the premotor pathway. Green nuclei are part of the anterior forebrain pathway (AFP) and are important for sensorimotor song learning but not song production. HVC, high-level vocal center nucleus; LMAN, lateral magnocellular nucleus of the anterior nidopallium; NIf, interfacial nucleus; RA, nucleus robustus archistriatalis.

According to this perspective, there are two types of learning. First, HVC acquires the capability of generating a long sequence of neural activity patterns (Figures 2(f) and 2(g)). Second, the circuitry downstream from HVC acquires the capability of mapping HVC activity patterns to the correct sound-producing patterns of activity in RA. The HVC–RA synapses show extensive structural plasticity, with synaptic growth followed by massive retraction, precisely during the sensorimotor learning period. Electrophysiological synaptic maturation accompanies such structural remodeling. Therefore, motor map learning from HVC to the vocal outputs is likely to involve plasticity in the HVC–RA synapses. Other possible loci of plasticity for sensorimotor learning, not ruled out by experiments, include the recurrent RA–RA synapses or the RA–motor neuron connections.

Sequence Generation

The high-level premotor area HVC displays clear sequential patterns of neural activation. In the awake singing zebra finch, each recorded RA-projecting HVC neuron (also called an HVCRA neuron) fires at most one brief burst of spikes (lasting ≈6 ms) per second-long song motif (Figure 2(a)). These neurons are otherwise inactive during singing. Different RA-projecting HVC neurons fire their single bursts at different fixed times in the motif. Thus as a population, the HVCRA neurons cover time during song.

In addition to RA-projecting neurons, HVC contains inhibitory interneurons which ramify within HVC and X-projecting neurons which send their outputs to the AFP. Inhibitory interneuron activity is very different from HVCRA activity: these neurons fire tonically throughout song, with high rates and relatively little modulation in firing frequency across song (Figure 2(b)).

In the adult zebra finch, deafening causes no immediate effect on song production, suggesting that auditory feedback is not important for sequence generation. Also, lesion studies indicate that input from the higher interfacial nucleus to HVC is not necessary for singing in zebra finches. What network connectivity and neural dynamics underlie the sequence generation dynamics observed in the top-level premotor area, and how might that connectivity become established as hatchlings mature?

The Synaptic Chain Model

The 'synaptic chain' model is an old idea for how networks of neurons might produce sequential patterns of activity. (The idea was already old when it was critiqued by Lashley in 1951 under the name 'associative chaining' model.) In the model's simplest version, the neurons in a network are divided into groups, and the groups are ordered in a sequence. From each group of neurons, there are excitatory synaptic connections to the neurons in the next group of the sequence. The groups and their synaptic connections are like the links of a chain.

If the first group in the sequence is activated, it sends synaptic drive to the second group, which then becomes active. The second group in turn excites the third group to become active, and so on down the chain. (An alternative mechanism for the propagation of sequential activity in songbird HVC is based on the removal of lateral inhibition between groups of

Figure 2 Summary of data and schematic model. (a)–(e) Activity in the premotor pathway. (f) Flow of activity: HVC drives RA, which drives muscle contraction via motor neurons in a feedforward path. In addition, connectivity within HVC and RA is recurrent. Dashed lines represent weights that are likely to be plastic; solid lines with arrows designate weights assumed to be fixed. HVC, with its recurrent connectivity, produces the high-level sequential drive. Motor neurons, designated by motor neuron pools m1 and m2, sum the activity from RA ((g), middle eight traces) to generate drive for the muscles ((g), bottom two traces). Sequence learning involves plasticity in the recurrent HVC connectivity. In this simple picture, sensorimotor learning is dissociable from sequence learning and involves plasticity in the HVC–RA and perhaps RA–RA connections.

neurons; however, this mechanism does not allow for the self-propagation of sequential activity, instead requiring an external periodic drive (clocked input) to induce transitions between activity states.)

More-complex versions of the synaptic chain model include inhibitory as well as excitatory synapses or different types of synaptic currents with multiple time constants. In still other versions, precisely synchronous spiking of one group is required to activate the next group. These are known as synfire (or 'synchronous firing') chain networks.

The role of intrinsic bursting Two recent models have implemented the synaptic chain idea with excitatory conductance-based neurons to model sequence generation in the zebra finch HVC.

Recordings in the singing zebra finch show that when an RA-projecting HVC neuron is active during song, it fires a high-frequency burst of four to six spikes in a 6–10 ms interval (Figure 2(a)). Previously we discussed the question of the mechanism of sequential activation in HVC. Another basic question concerns the mechanisms that give rise to the bursting behavior. One possibility is that the neurons burst because they are driven by synaptic input that lasts for the duration of the burst. Alternatively, the neurons might burst as a result of the dynamics of their intrinsic conductances.

Li and Greenside have advanced a model that does not use intrinsic bursting. It is consistent with the fact that previous brain slice studies of HVC neurons have not revealed intrinsic bursting. The network model is able to produce sequential neural activity with multispike bursts (Figure 3(a)). However, the realism of this model is compromised by the fact that the peak firing rate within the propagating multispike burst achieved by the model (≈15 ms interspike intervals) is approximately 10 times lower than seen in the actual HVC (≈1.5 ms interspike intervals).

In contrast, Jin et al. have advanced a model in which HVC neurons are intrinsically bursting. The model generates multispike bursts at peak firing rates consistent with those seen in experiments (Figure 3(b)). For comparison, Jin et al. also simulated a synaptic chain model without intrinsic bursting. Unlike Greenside and Li, they were able to achieve higher peak firing

Figure 3 (a,b) Propagation of bursts in synaptic chain models of high-level vocal center nucleus (HVC). (a) Neurons in the model are not intrinsically bursting. Activity propagates due to synaptic chain connectivity, and the burst of spikes in each neuron is due to sustained synaptic drive from the network. Spike frequency during the burst is ≈10 times lower than in nucleus robustus archistriatalis (RA)-projecting HVC (HVCRA) neurons. Adapted from Li M and Greenside H (2006) Stable propagation of a burst through a one-dimensional homogeneous excitatory chain model of songbird nucleus HVC. *Physical Review. E, Statistical, Nonlinear, and Soft Matter Physics* 74(1.1): 011918. (b) HVCRA neurons are assumed to possess an intrinsic mechanism for burst generation. A synaptic chain network can robustly produce stable sequences of multispike neural activation. Adapted from Jin DZ, Ramazanoglu F, and Seung HS (2007) Intrinsic bursting enhances the robustness of a neural network model of sequence generation by avian brain area HVC. *Journal of Computational Neuroscience* 23(3): 283–299. (c,d) Unidirectional synaptic chain versus bidirectional connectivity. (c) In a synaptic chain, connections between different groups of neurons project in a predominantly 'forward' direction. Activity initialized at group 1 (red 'electrode') will drive sequential activity up to the end of the chain, at group 7. Stimulation of the last group of the chain (blue 'electrode') will produce no propagating activity or sequence playback. Activation of a group near the middle of the chain will generate playback of a fragment of the original activity sequence. The resulting vocalization should correspond to normal song, but beginning midsong or midsyllable. (d) Bidirectional synaptic connectivity. Activity initialized at group 1 (red 'electrode') will produce a unidirectional sequence of activity propagating from beginning to end, as in the synaptic chain. Stimulation at the end of the chain (blue 'electrode') will lead to sequence playback in the reverse direction, from group 7 to 1. The resulting vocalization should be the song or a syllable sung in reverse. Stimulation of a central group in the chain will lead to activity propagation in both forward and backward directions. The resulting vocalization should be a superposition of the song (or a syllable) sung forward and in reverse, starting in the middle.

rates more consistent with experimental data, but this required careful fine-tuning of parameters like synaptic strengths. In contrast, the model with intrinsic bursting was quite robust to changes in parameters like synaptic strengths.

Superficially, the Jin et al. model may seem inconsistent with previous experiments *in vitro*, in which somatic current injection did not trigger intrinsic bursting in RA-projecting HVC neurons. However, one can imagine two scenarios in which this inconsistency is resolved. First, somatic current injection might be ineffective for revealing intrinsic bursting that is caused by a dendritic calcium spike. This depends on the strength of coupling between the soma and dendrite and on the voltage threshold for a dendritic spike. Second, the intrinsic properties of RA-projecting HVC neurons appear to be different *in vitro* and in the brain of a singing bird. For example, the peak firing rates observed *in vitro* are never as high as those observed during song. Possibly, HVC neurons *in vitro* lack some neuromodulator secreted during song, and this neuromodulator could be necessary for intrinsic bursting. Given the findings of Jin et al. regarding robustness, it seems important to look again for intrinsic bursting of HVC neurons.

Directionality of excitatory connectivity In the synaptic chain models mentioned earlier, there are excitatory synapses from each group to the next group in the chain. Unidirectionality is a fundamental feature. While the synaptic chain model is intuitively plausible, it is important to subject it to experimental testing and to contrast the model's predictions with those of competing models. For example, one can imagine a bidirectional synaptic chain in which there are excitatory synapses between adjacent groups in the chain, but the synapses go in both directions, 'forward' and 'backward' (**Figures 3(c) and 3(d)**).

In both the unidirectional and bidirectional models, it is assumed that song is initiated by activation of the first group in the chain. This causes the entire chain to be activated sequentially in the forward direction (**Figures 3(c) and 3(d)**, red 'electrode'). Both models can reproduce the sequential activity patterns observed in HVC during singing. However,

the bidirectional model can also produce other kinds of activity patterns that the unidirectional model cannot (Figures 3(c) and 3(d)), which could be used as the basis of experimental tests that distinguish between the two models.

In these tests, activity in the HVC network would be initiated by some means, and the subsequent response to stimulation would be observed. If the last group in the chain is stimulated (Figures 3(c) and 3(d), blue 'electrode'), there would be no subsequent activity in the unidirectional model. In the bidirectional model, the activity would propagate backward along the chain and would result in a sequence of motor commands that is reversed from normal song. Another experiment would be to stimulate an intermediate group in the chain (Figures 3(c) and 3(d), green 'electrode'). According to the bidirectional model, subsequent activity would simultaneously propagate both forward and backward along the chain. (Note that the playback will not continue from the forward to the backward direction, or from the backward to the forward direction, because of the existence of a refractory period for activation. This point is well known in the theory of excitable media.) In the unidirectional model, activity would propagate only forward.

While such experiments may sound straightforward, they are actually technically demanding. So far no topographic organization of RA-projecting HVC neurons has been detected. In other words, the location of a neuron in HVC does not seem to be related to the time at which it is activated during a song motif. If coactive neurons were co-located in HVC, it would be relatively straightforward to activate a hypothetical group in the synaptic chain models by stimulation through a microelectrode. Instead, the neurons of a hypothetical group appear to be scattered throughout HVC. Therefore, a group would be best identified through optical imaging of activity, and best stimulated through optical means also.

So far, no one has attempted to precisely stimulate a group of HVC neurons. However, cruder perturbation experiments have been performed. For example, HVC activity during song has been perturbed by stimulating RA, which leads to retrograde effects on HVC. Stimulation leads to skips in motif sequencing, but the subsequent vocalization is a recognizable fragment of the motif sung in the forward direction, beginning at a different position within the motif. This is more consistent with the unidirectional model than with the bidirectional model. But more-conclusive tests will require precisely controlled stimulation of activity in HVC.

A more direct way of testing the synaptic chain models is to check their predictions concerning the synaptic connectivity of HVC. Since the real HVC is no doubt 'messier' than in these idealized models, the predictions should be phrased probabilistically. Suppose A and B are two RA-projecting HVC neurons that are activated in succession. In the unidirectional model, the probability of a connection from A to B is expected to be higher than that of a connection from B to A or of a connection between two neurons chosen at random. (Alternatively, the predicted asymmetry of coupling between A and B might be reflected in synaptic strength rather than in the presence or absence of connections.) In the bidirectional model, the probability of a connection from A to B is equal to the probability of a connection from B to A.

Testing this kind of prediction could be done by comparing physiological and neuroanatomical measurements. Optical imaging could be used to find two neurons A and B that are activated in succession. Then optical stimulation could be used to see whether and how they are connected to each other. Alternatively, a completely neuroanatomical approach would be to reconstruct the entire connectivity of HVC using serial section electron microscopy, look for a chain within this connectivity, and determine its directionality.

The role of inhibition The synaptic chain models above were based on synaptic excitation, without reference to the role of synaptic inhibition. Inhibition is often included in such models to globally 'dampen' activity in a temporally nonspecific way and can enhance the stability of sequential activity in the excitatory neurons. To implement such a global inhibition effect, each inhibitory interneuron receives excitatory input from a large random set of projection neurons, and each projection neuron in return receives synapses from the interneurons. If the burst times of the projection neuron population were distributed across the entire song motif, then each interneuron would receive roughly continuous drive and would spike continuously.

Consistent with this picture, the temporal firing patterns of inhibitory interneurons in HVC are much less specific than those of the HVCRA neurons: an inhibitory interneuron is typically active throughout most of the motif. This suggests that the connectivity of inhibitory neurons is also much less specific than that of excitatory neurons.

Sequence Learning

Hand in glove with the question of what intrinsic neural properties and network architectures could underlie the stable propagation of activity in HVC is the challenge of understanding how such architectures could emerge from initially less-structured networks.

Intuitively, associative (Hebbian) learning rules such as spike-timing-dependent plasticity (STDP) seem ideally suited to produce the kinds of asymmetric connectivity characteristic of synaptic chains: if neuron A fires before B, the connection from A to B is strengthened, but that from B to A is weakened. If a naïve network is trained with this rule for synaptic plasticity on a set of input patterns presented sequentially, one would expect network weights to encode the temporal correlations in the training patterns and later to autonomously reproduce the same long, stable chains of neural activity when stimulated.

But contrary to intuition, past modeling studies show that associative learning rules are not sufficient to configure networks to autonomously generate long neural sequences. Networks trained in this way usually require finely tuned excitatory and inhibitory connectivity that is continuously renormalized to balance network activity during learning, as well as additional pacemaker inputs to propagate activity from one time step to the next. The situation is even worse if the network does not have access to training inputs that are themselves sequential. In such cases, the best response even with fine-tuning of parameters is the formation of extremely short chains (fewer than five steps) using thousands of neurons.

The reason for this is that associative learning rules do not balance activity equitably across space (neurons) and time; instead, they tend to amplify inequities. For example, a neuron that by chance receives strong synapses from its inputs will fire often. Because of its frequent firing, it will tend to rapidly form strong outgoing synaptic connections as well. As a result, activity tends to accumulate around a few overly active neural hubs, producing epileptic or synchronous burstlike network states rather than long, orderly chains. Empirically, these problems remain unsolved with the imposition of local constraints on the maximum strengths of individual synapses. For these reasons, the question of how plasticity rules that are local in both space and time can impose global constraints on activity balance over all space and all time is nontrivial.

Two independent models provide a conceptual framework for how associative learning rules must be augmented to allow initially unstructured networks to self-organize and generate stable, long sequences of neural activation. Both models use STDP as the primary activity-dependent mechanism for synaptic change. But crucially, in addition to STDP, both models rely strongly on competitively enforced synaptic bounds that are not computed on the level of single synapses but are triggered by neuronwide constraints. Although the rules governing synaptic remodeling are not local to the individual synapses, they are local to single neurons. Remarkably, these local neural bounds nevertheless serve to uniformly and globally distribute activity throughout the network in both space and time.

The qualitative nature of these synaptic bounds, and how they are triggered and enforced, is where the two models diverge. The model of Jin and Jun assumes that the formation of a finite number of strong connections from a neuron triggers axon remodeling and elimination of weak synapses. Fiete et al. propose two separate schemes based on neural resource constraints: one assumes that the production rate of synapse-building resources is limited, so potentiation in one synapse triggers a uniform heterosynaptic weakening of all other synapses at that neuron. The other scheme assumes a cap on the total resources a neuron can devote to synaptic maintenance; therefore all synapses at a given neuron undergo uniform weakening whenever STDP drives their summed synaptic strength to exceed the cap.

Both models make predictions for the rules governing synaptic plasticity within HVC and for the statistics of the resulting connectivity within HVC. The Fiete et al. model produces several sequences of different lengths, with a definite distribution of chain lengths. Determining whether this distribution matches syllable length distributions in birdsong could indicate whether songbird syllables attain their specific lengths largely due to bottom-up (low-level network) properties or top-down (behavioral, evolutionary, or respiratory) constraints.

Sensorimotor Learning of the Motor Map

The main goal-directed aspect of learning in zebra finches takes place during the sensorimotor phase, when the juvenile learns to match, through auditory feedback and template comparison, its own string of vocalizations with its memorized mental copy of the tutor song. Because the goal-directed aspect of song acquisition is so striking and because natural goal-directed learning behaviors that are easy to quantify are rare, several models have focused on this aspect of song learning. Yet the microscopic synaptic plasticity rules that underlie such learning remain experimentally undiscovered and theoretically debated. Predictions from existing theoretical or computational models can serve to greatly narrow, in a principled way, the dauntingly large number of possible plasticity paradigms to investigate in experiment, and they are now specific enough to be tested in detail in slice preparations of the song system. (Experimental testing of the proposed paradigms is contingent on

the identification of a reinforcement or critic signal, which is widely expected to exist but has not yet been found.)

Existing models of goal-directed sensorimotor song learning share the essential schema of the cartoon model (Figure 2) for the roles assigned to the different premotor nuclei: HVC produces a high-level sequence, and sensorimotor learning involves mapping that abstract sequence into the correct vocal motor sequence through plasticity in the HVC–RA synapses. The primary differences between models lie in the roles assigned to the AFP (Figure 4), in the particular rules for how activity triggers plasticity in HVC–RA synapses, and in their levels of biophysical realism and detail. The plausibility of different assumed roles for the AFP can already begin to be evaluated with existing electrophysiological and lesion results.

Early experiments showed that lesioning the terminal lateral magnocellular nucleus of the anterior nidopallium (LMAN) of the AFP, which projects back into the premotor pathway, abolishes the ability of juvenile songbirds to learn song. Moreover, the immediate and lingering effect of the LMAN lesion, besides stoppage of song learning, is to dramatically reduce the large trial-to-trial variability of juvenile song. These results suggested that the role of LMAN in song learning is possibly to drive vocal experimentation through perturbation of the premotor song pathway.

An early, and in several respects prescient, computational model is based in part on these observations. The model applied the specific algorithm of weight perturbation (with momentum) from the reinforcement learning literature to suggest that LMAN directly generates small static weight changes in the HVC–RA connections (Figure 4(a)). According to the model, these LMAN-driven static weight changes last for the duration of one song rendition, after which they are selectively retained, based on correlation with a song evaluation (reinforcement or critic) signal. The reinforcement (critic) signal is a function of the match between the actual and desired (tutor) songs. Because the weight perturbation rule has been proven by others to perform gradient climbing on the scalar reinforcement signal, it will improve song performance and do so independent of most parameter values. Numerical simulation of a small network model of the birdsong network, consisting of rate-based units or neural assemblies with time 'coarse-grained' into syllable-long chunks, has demonstrated how this may happen. Experimental studies have supported several features of the model, including the high-level schema of actor–critic reinforcement learning (Figure 5), the role of perturbations in song learning, and the role of the AFP in driving perturbations.

Figure 4 Proposed roles for lateral magnocellular nucleus of the anterior nidopallium (LMAN) in sensorimotor learning. The dashed line indicates a plastic synapse between high-level vocal center nucleus (HVC) and nucleus robustus archistriatalis (RA) neurons. (a) The hypothesis of Doya and Sejnowski: LMAN must produce different, independent perturbations in each HVC–RA weight originating from different HVC neurons. These perturbations must be static over the duration of one song rendition but vary across renditions. LMAN must also broadcast a separate, spatially uniform reinforcement signal to the premotor pathway. (b) The hypothesis of Troyer and Doupe. LMAN's sole role is to provide a spatially uniform reinforcement signal to the premotor pathway. Learning is associative (Hebbian). (c) The hypothesis of Fiete and colleagues: LMAN must inject different perturbations to different RA neurons. The perturbations are excitatory synaptic inputs to RA and vary in time over one song rendition. (A spatially uniform reinforcement signal is assumed to arrive at RA from elsewhere in the network.)

Figure 5 The empiric synapse hypothesis. (a) The empiric synapse hypothesis for goal-directed learning consists of three parts: The actor network, which is responsible for performing the desired task and has plastic synapses, and two of its inputs, one an experimenter, whose role is to drive perturbations in the actor through empiric synaptic inputs, and the other a critic, which provides through a reinforcement signal a scalar assessment of the performance of the actor on the desired task. Actor neurons are hypothesized to correlate experimenter-driven perturbations with the reinforcement signal to derive a signal for synaptic change, in the direction of the gradient of the reinforcement signal. (b) In the song system, the actor network is hypothesized to be the premotor pathway including high-level vocal center nucleus (HVC) and nucleus robustus archistriatalis (RA) and plastic HVC–RA synapses. The experimenter is hypothesized to be the AFP. A critic-generated reinforcement signal (R) is widely assumed to exist in the song system, although its neural identity is unknown. Adapted from Fiete IR, Fee MS, and Seung HS (2007) Model of birdsong learning based on gradient estimation by dynamic perturbation of neural conductances. *Journal of Neurophysiology* 98: 2038–2057.

What are the biophysical assumptions and implications of this model? According to the model, both the song evaluation (reinforcement) signal and the perturbative drive are generated in the AFP, and delivered to the premotor pathway by LMAN. This means that LMAN must carry and convey two independent signals, for perturbation and reinforcement, to the HVC–RA synapses (Figure 4(a)).

The model is based on batch mode weight perturbation, and it assumes that LMAN can somehow directly perturb the weights of the HVC–RA synapses in a way that the perturbations vary from song rendition to rendition but are static over the course of a rendition. Moreover, for the weight perturbation scheme to explore enough of the motor space for song learning, HVC–RA synapses that originate from different HVC neurons must receive different, and independent, perturbations from LMAN. There are a few experimental inconsistencies with these requirements in the birdsong system. First, single- and multiunit activity in LMAN varies rapidly during a song motif, without an unusually large transient at the beginning. It is therefore difficult to imagine how LMAN neurons could provoke an instantaneous perturbation in the HVC–RA weights at the beginning of a song rendition, which is held constant for the rest of the rendition. (It may be possible for weight perturbations to be driven by slow neuromodulatory action of LMAN onto the HVC–RA synapses; within the model, reinforcement would then have to be mediated either by ordinary synaptic transmission from LMAN to RA or through a second neuromodulator released by LMAN neurons into RA.) Second, each RA neuron receives an estimated 1000 inputs from up to 200 HVC neurons but only approximately 20–50 inputs from LMAN. Thus, it is unlikely that synapses from different HVC neurons could receive independent perturbations to fulfill the requirements for weight perturbation.

Finally, Doya and Sejnowski found that learning with purely random inputs from LMAN was too slow, with poor convergence to the tutor song, even though the simulated network was far smaller than the songbird motor pathway and even though a song motif consisted of very few time steps (each time step represented an entire syllable). Therefore, they assumed that LMAN activity itself evolves by reinforcement learning on the same global reinforcement signal, so that its output is composed of a term proportional to the true HVC–RA weight gradient, superimposed on a random component. With this assumption, the AFP must perform at least three functions: (1) generate and carry random perturbation signals whose dimension might be as large as the number of HVCRA neurons, (2) generate and carry a true gradient estimate after correlating its random activity with reinforcement, and (3) function as a critic, generating and carrying the reinforcement signal. With these assumptions, the model indeed learns; however, the AFP is assumed to possess these capabilities *de facto*, without modeling how the necessary computations are performed or how the resulting signals are carried by LMAN and delivered to the premotor pathway, leaving crucial questions unresolved. Whether the AFP actually possesses these capabilities is an experimentally open question.

A model proposed by Troyer and Doupe in 2000 suggests that plasticity in HVC–RA synapses and RA–RA synapses may be largely associational or Hebbian in nature. According to the model, plasticity is gated by a reinforcement signal, which LMAN

delivers to the premotor network (Figure 4(b)). The associational rule also includes a subtraction term for synaptic weakening, bringing it closer to reinforcement learning rules, but the specific form used is not proven in the literature to guarantee improved performance. As a result, there are no general assurances of convergence or stability, even in networks of simplified rate-based neurons. The model requires fine-tuning by hand of several homeostatic mechanisms to maintain stability during learning. The authors demonstrated through numerical simulation in rate-based networks that under particular parameter settings, with a small set of RA assemblies, HVC–RA connections, and a few syllable-long time steps, the network can learn to match a desired output.

A strength of this model is that, unlike others in the literature, it stresses the importance of lateral connections within RA, which, when subject to the same plasticity rules as HVC–RA synapses, form assemblies that are capable of pattern completion even with partially correct inputs, to generate 'good' output syllables. The AFP's only role in the model is to generate and convey a spatially uniform reinforcement signal to RA (Figure 4(b)). However, in the zebra finch, LMAN activity is spatially inhomogeneous (neural activity is not strongly correlated across the nucleus), and connections to RA are not highly divergent, which implies that different RA neurons are likely to receive fairly uncorrelated inputs from LMAN rather than a uniform signal. As formulated, the model cannot explain why, in experiments, LMAN lesions reduce song variability. Experiments fail to reveal qualitative changes in LMAN activity when an adult bird's auditory feedback is altered, which suggests that LMAN may not primarily convey an error or match signal. (If LMAN does generate an error signal, but bases it on learned predictions about auditory feedback, it is possible that prolonged rather than transient exposure to distorted auditory feedback is necessary to produce changes in LMAN activity.)

Subsequent informal proposals, not grounded in numerical simulation or modeling, have espoused more information-rich primary roles for LMAN in song learning. These include suggestions that LMAN may provide detailed instructive or supervisory error signals to RA. Unfortunately, these suggestions lack mechanistic proposals or models of how the AFP might correctly compute and generate these information-rich, time-varying supervisory signals, leaving the bulk of the computational burden of song learning unsolved and at the door of the AFP. In reality it is possible that the AFP supplies such a supervisory signal to RA, but no experimental or computational studies exist yet to suggest that it does.

A recent model of song learning by Fiete and collaborators returns to a reinforcement learning framework and attempts to do two things: (1) propose that, and illustrate how, spiking RA neurons might perform reinforcement learning by using rapidly time-varying LMAN synaptic inputs that perturb RA membrane voltages (rather than using static synaptic perturbations of the plastic HVC–RA weights; Figure 4(c)) and (2) show as a proof-of-principle that although it is widely thought to be slow, reinforcement learning can be fast enough to explain song acquisition in a full-scale model of the birdsong network with spiking, conductance-based neurons, delayed feedback, scalar reinforcement, and purely random independent perturbations.

The model assumes that LMAN perturbs the premotor pathway by injecting independent random currents into different RA neurons (Figure 4(c)) through ordinary glutamatergic synaptic transmission (Figures 5, 6(d), and (e)). This is consistent with recent stimulation and pharmacological inactivation experiments in LMAN, which show that LMAN helps drive song variability through glutamatergic synaptic projections to RA. The model requires at most as many independent LMAN inputs as there are RA neurons. The LMAN inputs are assumed to be time varying throughout song. Reinforcement is assumed to be computed and delivered from elsewhere in the brain, with learning following the high-level, actor–critic schema. Under these conditions, the derivation of the rules for how activity should modify synaptic weights, and the rules themselves, are quite different from weight–perturbation-like algorithms (Figures 6(d)–6(f)): each HVC–RA synapse must somehow deduce an instruction for change based on time-varying fluctuations in the conductance of its postsynaptic RA neuron rather than simply decide whether to retain or discard direct static perturbations of its own weight through correlation with the reinforcement signal. The resulting rule is guaranteed to robustly (without parameter tuning) improve song performance, even in recurrent networks of conductance-based spiking neurons and with delayed reinforcement.

The model is able to produce learning in a biologically realistic network model of the song system, with spiking neurons and an impoverished, delayed reinforcement signal (Figures 6(a) and 6(b)). Learning takes place online, and activity in the network evolves on the millisecond timescale, driven by 5–6 ms bursts in the HVC inputs. Within 2000 iterations, the network output resembles the tutor song, which is a recording of an actual zebra finch song (Figure 6(c)). Fiete et al. have shown that learning time even with random LMAN input should scale well in the full-sized premotor network and may converge in far

Figure 6 Empiric synapses: results and predictions. (d) Possible experimental design for testing the empiric synapse rule in the birdsong pathway involves focused stimulation in HVC, intracellular recording in RA, and fiber bundle stimulation of the lateral magnocellular nucleus of the anterior nidopallium (LMAN)–RA axons, together with control of the reinforcement signal (R). (e) Magnified schematic of a single RA neuron and its inputs. Each RA neuron receives a few empiric synapses from LMAN and several from different HVC neurons; in addition, RA receives a reinforcement signal. Blue (gray): active (quiescent) premotor inputs; green: empiric input; red: reinforcement signal. (f) Protocol for induction of bidirectional synaptic plasticity in active HVC–RA synapses: Simultaneous stimulation of an HVC neuron and the LMAN axon bundle, followed by administration of reinforcement, should lead to potentiation of all stimulated HVC synapses.

fewer iterations than sung by the typical zebra finch (≈100 000 renditions) during song acquisition.

The model's central prediction is a specific paradigm for the induction of bidirectional, heterosynaptic activity-dependent synaptic plasticity in the premotor vocal pathway (Figure 6(f)) that should be possible to test in slice experiments.

The model above is consistent with a large body of experimental data in the song system and provides concrete predictions for synaptic plasticity. However, LMAN's role in the model is to provide purely random exploration. This assumption does not contradict the data but is a limited view of what the AFP, a complex neural pathway, might be capable

of. More-sophisticated strategies for AFP-delivered perturbation may speed up learning. This avenue is wide open for discovery by theory and experiment.

More generally, models of song learning based on the AFP as a source of random or directed perturbations to the premotor system could be used as comparative tools for studying the role of the basal ganglia thalamocortical loop in mammalian sensorimotor learning.

Premotor Codes and Representations

Up to 30 000 neurons are devoted to song production and learning in the zebra finch. Together, these neurons drive only eight to ten muscles that produce song. What are some of the functional requirements and costs that determine why so many neurons are required for song production?

The ultrasparse or unary coding of song by HVCRA neurons (Figures 2(a)) exacts a large energetic and space cost in terms of the number of neurons required to encode a given set of patterns. To produce a sequence of 100 steps (L) with 200 neurons per time, unary coding requires 20 000 neurons. At the other extreme, a combinatorial code with a downstream readout capable of distinguishing between different combinatorial patterns would require far fewer neurons, scaling as log (L) instead of L; intermediate possibilities would require intermediate numbers of neurons. What are some of the properties of a unary code that might offset its capacity costs and explain why it exists in HVC?

A possible explanation for ultrasparse HVC sequences could be mechanistic: recurrent networks cannot store many dense patterns because of increasing interference between patterns. Studies show that sparsely active attractor networks can store more patterns. Nevertheless, in these studies, 'sparse' is far denser than unary, so the reason for ultrasparse coding must lie elsewhere.

Because oscine birdsong is learned, a natural place to investigate the role of unary HVC codes is in learning. There are actually two distinct roles that unary codes could play in song learning.

First, an analytical and numerical study by Fiete et al. shows that unary coding within HVC enables optimally fast learning of the feedforward motor map from abstract sequences in HVC to sequences of muscle activation. If each HVC neuron were to fire twice instead of once, at random times in a song motif of fixed length, the fastest possible speed with which the input–output map can be learned is twice as slow (Figures 7(a)–7(d)). There is an intuitive explanation of the underlying mathematical reason for this effect. Suppose an HVC neuron and its corresponding HVC–RA synapses are active twice, when the tutor song has opposing characteristics (e.g., pitch or amplitude), at those two times. The synapses will be pulled in opposing directions to best match the tutor song (Figure 7(c)) at each time. Because the learning task is realizable, there is some value of synaptic strength that achieves the desired output, and in the end this value will be reached. But the conflicting demands on synapse strength at the two times in the motif make approach to the solution with a hill-climbing rule slower, even if the parameter controlling learning step size is optimized to produce the fastest possible learning without network instability.

Yet answers to why questions, however compelling, risk being just-so stories unless they generate specific testable predictions. The work described above argued that unary codes may exist in HVC because of their utility for fast song learning. However, single-unit HVCRA activity and unary codes have been observed only in adults. Thus, the central prediction – which if false would invalidate the hypothesis – is that activity in HVCRA neurons, even if nonsparse initially (early in the sensory period), should be unary near the onset of sensorimotor learning in juvenile zebra finches instead of emerging gradually after or toward the end of sensorimotor learning.

The analysis leads to an additional prediction. To accommodate a larger song repertoire, HVC could change in two *a priori* equally likely ways: (1) keep HVC volume (number of neurons) fixed but increase the number of bursts per neuron or (2) increase HVC volume but maintain a unary code. Energetics might favor the first possibility. But according to the learning speed analysis, if zebra finches are under pressure to learn their songs quickly, then unary coding should be conserved, even at the cost of a larger HVC. This suggests that coding in HVC across zebra finches and related songbirds with somewhat larger repertoires (measured by number of unique syllables) should remain unary while HVC size scales with repertoire size. Indeed, existing experimental findings corroborate these predictions: HVC size scales with repertoire size after correcting for overall brain size, while RA, LMAN, or other song nuclei do not display similarly consistent relationships.

Second, analysis and simulation by Fiete et al. has shown that if the HVC code is unary and if, during a song rendition, performance is continuously evaluated and a reinforcement signal continuously delivered (albeit delayed), then the time taken to learn a song is independent of the length of the learned song. Because the HVC code is unary in zebra finches, this prediction can be used in experiments (where learning time is monitored for birds trained on tutor songs of

Figure 7 Unary coding in high-level vocal center nucleus (HVC) helps speed the acquisition of the motor map. (a) The activity of three hypothetical HVC neurons. The first two are each active only once in the song motif, but the third is active twice. (b) Hypothetical pitch of the tutor song (black) and the pupil network (gray). (c) Direction in which synapses should change to reduce error between tutor and pupil pitch. Synapses from HVC neuron 3 should be strengthened at the first and weakened at the second activity burst to improve the tutor–pupil match. Such conflicting demands on the synapses of neurons that are active at two or more random times in a motif cause a slowdown in learning speed. (d) Contours of iso-error in the learning surface. Learning a feedforward map in a network with unary coding in the top layer is like learning on an isotropic cost surface and can be fast. Denser coding in the input layer produces correlations and makes the learning surface anisotropic. To keep the error from diverging along the steep directions, the learning rate must be kept low. As a result, best-case learning is slower than in the isotropic case. HVC activity tuned to acoustic features may be helpful for generalizable learning. (e) If HVC neurons fired multiple bursts at selected points when the acoustic features of tutor song are similar, rather than at random times, there would be no interference in the learning update, (f). If HVC neurons acquired such a tuning to features in the tutor song, it could be easy for the bird to quickly reproduce a specific heard sound by activating the requisite sound-tuned HVC neuron. RA, nucleus robustus archistriatalis.

different lengths) as an indirect probe of whether the elusive reinforcement signal in the song pathway is delivered online or in batch mode. If the reinforcement signal is evaluated and delivered only once, at the end of song, then the time taken to learn a tutor song should scale linearly with its length. Similarly, if the HVC code at each time consisted of a random pattern of activations, with half of all neurons active per time

(dense code), learning time should scale with song length (even if reinforcement is delivered online).

Do other songbirds also display unary HVC representations of song? At present, single-unit recordings of RA-projecting HVC neurons are available only from zebra finches. Learning with a pure time code is nongeneralizable: like one piece of magnetic tape, each pattern is used to produce song at only one specific time. An entirely different set of HVC neurons and HVC–RA weights must be used and trained to produce the same sound if it recurs elsewhere in the motif. Therefore, songbirds that rapidly acquire and imitate new songs (albeit after slowly acquiring a first song) may use a different encoding strategy (e.g., tuning codes based on acoustic features) from a time-code (Figures 7(e)–7(g)). In addition, songbirds with vastly larger repertoires, regardless of the speed of song acquisition, may display different HVC codes because of capacity constraints.

Conclusions

Advances in the acquisition of behavioral and anatomical data and neurophysiological recordings from awake, singing birds are rapidly turning the birdsong circuit into an ideal system for unraveling the mechanisms underlying motor control and learning. Theoretical models, by quantitatively validating or eliminating candidate explanations of network function, have helped lay a groundwork for understanding the dynamical and coding principles that lead to such functionality. Theoretical models also provide a functionally motivated set of predictions about neural activity, connectivity, coding, and plasticity that narrow the choices of future experiments and are presently ripe for experimental testing. Future experiments and modeling in songbird species with more-flexible learning behaviors should greatly enhance understanding of generalizable motor learning and control.

Birdsong: Definitions and Functions

In animal communication, a signal is classified as a 'song' generally on the basis of its perceived function. The vocalization that is used in a reproductive context to attract a mate and/or defend a territory can be thought of as the individual's song while vocalizations that function to signal the presence of predators or food, to maintain group cohesion, or to allow parents to communicate with their young are called 'calls.' The definition of birdsong is further complicated because songbirds are a taxonomic unit (i.e., the order Passeriformes, or perching birds). Thus birdsongs, strictly defined, are the species-typical vocalizations that serve the function of mate attraction or territorial defense and that are produced by avian species in this order. These vocalizations are usually quite elaborate and melodious, which is why members of the order Passeriformes were given the name 'songbird.' However, the songbird order is quite large, consisting of nearly 50% of the more than 9000 living species of birds. There is, not surprisingly, substantial variation within this group, so for a particular species, the song produced as defined by its function is not necessarily the most complex vocalization in its repertoire.

Birdsong is of interest to neuroscientists because it is a complex motor behavior that is learned via a developmental process that involves the precise guiding of motor patterns by auditory feedback. The neural circuit for this behavior has been described in some detail, so it provides neuroscientists with an excellent opportunity to attack a number of important questions relating to learning and motor production. Furthermore, song is one of a suite of traits that is needed for successful reproduction, so not surprisingly, the production, and to some extent the learning, of song is profoundly regulated by gonadal sex steroid hormones as well as, in some contexts, by adrenal glucocorticoids. This article summarizes behavioral, comparative, and hormonal aspects of birdsong learning that places neural and neuroendocrine studies of birdsong in a broader perspective.

Birdsong Learning: Behavioral and Comparative Perspectives

Experience and some sort of learning effects on vocal production are widespread among vertebrate species. What makes birdsong learning so unusual compared with vocalizations produced by many other taxa is how profoundly important auditory feedback is in order for songbirds to produce songs that are anything like the stereotypic species-typical vocalizations one hears in the field. Pioneering studies by William Thorpe at Cambridge University and Peter Marler at the University of California Berkeley and Rockefeller University of north temperate zone songbirds such as the chaffinch, the white-crowned sparrow, the song sparrow, and the swamp sparrow clearly established the basic phenomenon. Thorpe and Marler employed an experimental approach in which they raised birds in acoustic isolation from shortly after hatching and documented serious deficits in the later song that was produced when the birds reached sexual maturity. They were able to rescue these behavioral deficits if they provided the nestlings with conspecific vocal experience. They then observed how song develops through a gradual process by which the young bird matches its vocal output with an auditory memory it previously formed for conspecific song based on experiences with conspecifics. Typical of these early studies was the approach taken by Marler in his studies of white-crowned, song, and swamp sparrows, in which he carefully manipulated the types of songs that the birds heard during ontogeny. He was able to establish some basic principles based on this work. These will be summarized here. However, it is important to note at the outset that subsequent work by many investigators has shown that there are important variations on these principles.

The Behavioral Development of Song

The gradual process of song development is itself a type of evidence that song must be learned via auditory feedback. A young male songbird typically begins singing sometime after learned songs have been memorized, but the imitations are not fully formed. Instead, the young male starts with subsong, an amorphous, noisy twittering that changes gradually, first into plastic song, which also is highly variable but contains the first obvious signs of mature song structure, and finally crystallizing into the stable patterns of mature, adult song. Subsong resembles the babbling of human infants and may be important for developing the motor skills of singing and other prerequisites for song learning, such as the ability to guide the voice by the ear. Rehearsal of previously memorized song patterns begins in plastic song. Often more plastic song themes are produced than are needed for mature singing, and many are discarded when song crystallization occurs. At song crystallization, a stereotypic form of the species-typical song is produced.

The Song-Learning Process

Sensitive Periods for Song Learning; The Effects of Isolation and Deafness; Learning Preferences

There is an underlying pattern in the steps typically required in learning to sing. First is the acquisition phase, when a bird hears songs and commits some of them to memory. These are stored for a period that varies markedly from days to months among species until the bird begins to recall songs from memory and starts to produce imitations. There is thus a separation in time of the acquisition or sensory phase and the production or sensorimotor phase, ending with the production of crystallized (i.e., stereotyped), species-typical adult song.

There are often sensitive periods for song acquisition, sometimes restricted to a short period early in life and sometimes extending into adulthood. Even close relatives, such as sparrows and canaries, may differ in this respect. Several species of sparrows have a sensitive period for acquiring songs, beginning at about 20 days of age, soon after young males become independent from their parents, and ending 4 to 6 weeks later. These sensitive periods for learning are another aspect of the process that exhibits significant species variation. Some birds will keep learning throughout their lives whereas others seem to learn only during a specified time in their first year. However, proving such limits definitively can be quite difficult. Also, the boundaries of sensitive periods can vary depending on the strength of song stimulation and the influence of physiological factors, such as hormonal states, that vary with the season. If young are hatched late in the season and singing has already ceased for that year, closure of the sensitive period may be delayed until the following spring. The experimental withholding of stimulation by songs of the birds' own species can also delay closure of the learning. Species that learn song only during a sensitive period early in ontogeny are known as age-limited learners. There are also species that continue to learn new songs throughout their lives, and these are referred to as age-independent learners. Still other species fall between these extreme cases in terms of song development.

Regardless of whether they have had the chance to learn, songbirds can generally produce some aspects of the song that can be recognized as being species typical. When sparrows are raised in isolation, for example, the note structure and tonal quality of their songs are abnormal, but each species still produces some basic features of normal song organization. Studies of deaf birds' songs, which are highly abnormal and variable in structure, have been valuable in explicating the importance of auditory feedback and its timing (Figure 1). A degraded form of singing is observed both if a male becomes deaf before he experiences song and if he is deafened after hearing song but before the development of singing (Figure 1). To transform a memorized song into a produced

Figure 1 Sonagram illustrating the songs of two closely related songbird species, song sparrows and swamp sparrows. The top row illustrates the normal species-typical song produced by adults. The second line illustrates song produced by males that had been deafened after the sensory phase of song learning but before the onset of the sensorimotor phase. The third line illustrates sonagrams of songs produced by males that had been deafened and raised in social isolation. Note that in birds that develop song in the absence of auditory feedback, there is still evidence of species-typical structure. In birds raised in complete auditory isolation, the degree of song degradation is profound. From Marler P and Slabbekoorn H (eds.) (2004) *Nature's Music: The Science of Birdsong.* Amsterdam: Elsevier.

song, the bird must be able to hear its own voice. One can infer that there are auditory memories for song, involved in guiding song production, that must vary in their specifications from species to species.

One aspect of the process of memory formation needed for song learning is that it involves selective or biased learning. In several sparrow species, for example, it has been shown that species-typical vocalizations appear to be privileged in that they are learned preferentially. Another aspect of this memory that has been strongly advocated by Marler and colleagues is that the memory encodes species-typical patterns of vocal behavior even before it hears the song of its own species. This idea of an innate specification of species-typical vocalizations would be one way to explain why, even in sparrows reared in isolation, many species-typical attributes of their vocalizations are apparent in the abnormal songs they produce. According to this view of song learning, the formation of the auditory memory guiding song learning would result from a memorization by selective activation and attrition of innate circuits rather than via a selective instruction process. The relative validity of these two opposing models of auditory memory formation has yet to be resolved.

Species Variation in Song Learning: Evolutionary Considerations

Species variation in song learning can be approached from several different levels. First, there is variation at a high level of taxonomic classification, such as class, order, or family. Second, there is interspecific variation within a family and then intraspecific variation within a species or population. We will consider both levels of variation and discuss possible functions for this variation. Vocal learning of the sort described in songbirds has been described in only two vertebrate classes: mammals and birds. Within these classes there seems to be marked variation as to whether a taxon exhibits any type of learned vocalization based on auditory feedback. For example, in birds there is clear evidence in three of 23 extant orders of birds that vocal learning via auditory feedback matching occurs: the parrot, songbird, and hummingbird orders. Coincidently, these are among the most successful avian orders in terms of number of species. The occurrence of vocal learning in these three orders is associated with the emergence of neural specializations for vocal learning and perception, at least according to studies of immediate early gene expression associated with song production and the hearing of song. Further, more-detailed neuroanatomical studies are needed to clarify the similarities and differences among these different orders, but to a first approximation, there does seem to be a coevolutionary process between the evolution of vocal learning and specialized brain structures. This link between brain variation and behavioral variation is also apparent within the songbird order. The order Passeriformes consists of two suborders. The Tyranni suborder consists of mostly New World species, such as flycatchers, manakins, and cotingas. On the basis of a number of anatomical traits, this group can be viewed as a more primitive songbird compared with the suborder Passeri, which contains a larger number of species and is thought to be more-recently evolved. Passeri contains the traditional species one thinks of as songbirds, such as sparrows, tits, wrens, buntings, tanagers, and warblers. Studies of a very few extant species suggests that Tyrannid species do not learn their vocalizations, and there is evidence that birds in this suborder lack forebrain neural specializations, known as the song system, that are involved in the vocal learning and production so prominent in the Passeri suborder. Thus, one general principle of interest to neuroscientists is that vocal learning coevolves with neural changes. There are some suggestions that members of the Tyranni may exhibit vocal learning. It will be interesting to find out via follow-up studies whether this is the case and whether the occurrence of vocal learning is associated with the emergence of brain specializations associated with vocal learning.

A question that has been addressed by ethologists for many years is why, in terms of adaptive significance, this form of vocal learning has evolved at all. Despite long-standing interest in this question, the answer remains enigmatic. Hypotheses include the fact that variation in song gives males an advantage in mate-choice competition (females often prefer males with more-complex songs) and in male–male interactions (larger learned repertoires are often more effective in repelling conspecific competitors). Another idea, proposed 30 years ago, is that vocal learning promotes the formation of regional dialects that can act as a signal for individuals in the same population who share similar local, coadapted gene complexes. The problem is that nonlearning taxa can exhibit similar processes, and it does not seem necessary to have learning *per se* in order to have complex vocal signals that are effective in intra- and intersexual competition. The fact that many avian orders with vocal learning exhibit a large number of species does suggest that vocal learning will facilitate speciation. However, even in this case, the correlation is not perfect, as in the case of the neotropics, where nonlearning songbirds in the suborder Tyranni can have a higher species density than learning members of the suborder Passeri.

Recently there has been an increase in interest in understanding variation in learning strategies within

taxa that exhibit vocal learning. There are many variations on the theme of vocal learning. Beecher and Brenowitz have pointed out that songbird species vary in when they learn their songs (whether it is the first month or the entire first year or their entire life); in whether they learn a single songtype or an entire repertoire of songs; in whether this repertoire develops by imitating models, by improvising on songs heard from others, or even by inventing songs that apparently bear little in common with model songs; in whether they absolutely require experience with species-typical songs or whether they can learn songs even when isolated from conspecific song; and in whether they are limited to copying conspecific sounds or tend to incorporate many sounds from their environment. All this variation raises questions about mechanism (how does variation in the nervous system control this variation in learning strategies?) as well as function (what are the advantages and disadvantages of this variation?). Issues of mechanism are beyond the scope of this article. Some of the hypotheses relevant to the function of intraspecific variation in song learning overlap with hypotheses put forward for interspecific variation in the occurrence or nonoccurrence of learning. For example, repertoire size, which appears to facilitate the effectiveness of song presentation in some species in both an aggressive and a reproductive context, is enhanced by any learning strategy that enhances the maintenance of variation in song. Another variable that is often evoked is the enhancement of song matching. Song matching means that an individual sings songs that are similar to a neighbor's song. Neighbors with similar songs tend not to fight as much as neighbors with different songs. Data such as these are consistent with the 'dear enemy' hypothesis that new neighbors are much more apt to be expansionist than established neighbors. Hence one will tolerate birds with whom one shares songs because that is a sign that they are from the same local area. How can such matching come about? One way is that songs overproduced during plastic song can be selected based on the population the male settles in when he first reaches sexual maturity. Studies of field sparrows have found that interactions between a male and his neighbors can influence which of the overproduced songs will be selected for crystallization and inclusion in the final repertoire. Songs most similar to the neighbors' songs are retained, and those that are different are rejected. It is as if a process akin to operant conditioning influences which songs are selected for later crystallization among those in auditory memory. The studies that have been completed suggest that there is a rich opportunity to critically evaluate both the functional basis of existing variation in song learning and the question of whether this variation has coevolved with a particular set of neural specializations.

Hormones and Song Learning and Production

Steroid hormones play an important role in regulating the timing of song production as well as phases of the learning process. The link between sex steroid hormone action and song behavior was first made on the basis of field studies correlating seasonal changes in physiology with changes in song behavior. Many male temperate-zone songbirds sing at high rates in the spring compared with other seasons. In these species, seasonal differences in male song are positively correlated with dramatic seasonal increases and decreases in aspects of reproductive physiology such as gonadal size and hormone secretion in the plasma. These correlational studies have implicated testosterone of gonadal origin as being particularly important in promoting high rates of song. However, there is interspecific variability in the degree to which maximal rates of singing are observed outside the breeding period. For example, robins living in northern Europe sing at relatively high rates throughout the year, only pausing in July, although most other songbirds living in the same region do not. Birds that sing outside the breeding season do exhibit seasonal cycles in gonad size and endocrine secretions that are similar to other temperate-zone species. Studies of select species that exhibit territorial song production in the autumn, such as song sparrows in the western United States, mockingbirds, and the European robin, clearly suggest that song behavior in the fall can be elicited by the appropriate stimulus in the absence of gonadal testosterone. It is interesting that in the case of the song sparrow, there is evidence that this autumnal singing involves estrogen acting in the brain even though the gonad is inactive. The source of this neuroactive estrogen in this case does not appear to be from testosterone of gonadal origin that is then locally metabolized. Overall, these data indicate that there is no tight correlation between endocrine activity and song rate in all temperate-zone species.

Seasonal changes in reproductive physiology in these species may relate to changes in other aspects of song, such as repertoire size or stereotypy. For example, seasonal changes in song repertoires have been observed in European starlings and canaries, in which the number of song types and other measures of song complexity may change. In addition, seasonal changes in other measures of song, such as stereotypy, have been described in white-crowned sparrows and song sparrows. A careful consideration of behavioral data from temperate-zone songbirds suggests that although song output is positively correlated with various measures of reproductive physiology,

including hormone concentration in the plasma, there is not necessarily a strong causal relationship between the two, as is the case for sex steroids and certain reproductive behaviors such as lordosis in rats, the bow coo display in male ring doves, or male-typical copulatory behaviors in Japanese quail. Experimental studies of the effects of exogenous hormone administration or castration with hormone replacement on song have been performed on a relatively small number of species, but these studies confirm this view of the relationship between steroids and song behavior. Administering exogenous testosterone can clearly increase song rate. Several different studies of zebra finches have shown that castration greatly reduces but does not eliminate male-typical song whereas in red-winged blackbirds, castration was reported to eliminate adult song production. In the case of song sparrows in the western United States, castrated males were able to maintain fall territories and sang at high rates in response to territorial challenge in a manner that was indistinguishable from intact controls. The hormonal control of song behavior therefore appears to be a clear case of a hormone-enhanced, rather than hormone-dependent, behavior. Species-typical stimulus factors (the presence of a conspecific male and/or female as well as a nest site or a favorable environment) promote song production in males. The presence of gonadal steroids in the plasma can increase the probability and intensity of these behavioral responses to the appropriate stimulus, but this presence is not essential for behavioral activation. One should therefore not be surprised by reports of substantial song production being observed in association with low steroid hormone concentrations in some cases. The stimulus factors releasing song can be so strong in some cases that high gonadal steroid concentrations are not necessary for song production to be observed. The critical hormone acting in the brain to promote song production is not necessarily an androgen. Steroid hormone replacement studies in castrated birds indicate that both androgenic and estrogenic metabolites of testosterone are needed to completely restore high rates of singing. In zebra finches, it has been suggested that estrogenic metabolites selectively promote female-directed song. These data indicate that the two primary metabolites of testosterone may act differently on song behavior.

There is also evidence that sex steroid hormones may also play a role in the song-learning process. Castrated male songbirds are able to form the auditory memories needed for song learning, but they fail to develop the crystallized song characteristic of male birds when they reach sexual maturity in their first year. The birds will stay in a nearly constant state of plastic-song production, but when they receive exogenous testosterone, the song rapidly crystallizes. When juvenile birds are administered testosterone after the sensory phase, when they have formed an auditory memory that will guide sensorimotor

Figure 2 Changes in plasma concentrations in testosterone (top panel) and 17β-estradiol (second panel) during song development in male song sparrows. The bottom panel illustrates the timing of songs that were learned and later produced by the males when they reached sexual maturity. Note that high plasma estradiol concentrations correlate with the high rate of song acquisition prior to day 100, whereas testosterone is high during the onset of song crystallization. The transition from plastic song to crystallized song is illustrated by the inset below the top panel.

learning but before the onset of the sensorimotor-learning period, they will prematurely crystallize their song, albeit in a degraded state. Findings of correlational studies of steroid-hormone changes during development in song sparrows are consistent with the conclusions of these experimental studies (**Figure 2**). Testosterone is relatively low during the sensory phase of song learning and the period afterward, but it rises significantly in close correlation with the transition from the plastic stage of song learning to the stage of crystallized song. These studies of changes in plasma steroid hormones during song development also suggested a possible role for 17β-estradiol in song learning *per se*. It was found that estradiol is high in the plasma during the period of auditory memory formation but that it declines prior to the onset of sensorimotor learning, the time when androgens increase to establish crystallized song (**Figure 2**). Thus estrogens and androgens may play very different but complementary roles, facilitating song learning, in the case of estradiol, but then ending the period of song variability, in the case of androgen. This hypothesized role of estrogen is based on correlational studies and has not been experimentally investigated. The possible cognitive enhancing effects of estrogens on vocal learning remain an intriguing but untested hypothesis.

Song Behavior

The Structure of Song

Birdsong and other acoustical signals can be visualized using a sound spectrograph, which plots the frequency components of the signal as a function of time. Many birdsongs are relatively tonal, with sound energy focused within a narrow frequency band centered between 1 and 5 kHz, and can sound pleasantly musical to our ears. Other birdsongs describe a broader frequency bandwidth with little or no harmonic structure, and they sound noisy and less musical to human listeners. One feature of tonal songs is that they can be easily heard above environmental sounds, such as the sound of the wind, water, and rustling leaves, which typically have spectral energy below 1 kHz. Thus, tonal birdsongs are especially effective long-distance communication signals that help individuals maintain large breeding territories during the nesting season.

The elementary unit of song is the note, which appears as a continuous trace on a sound spectrograph (Figure 1). Birds group one or more notes together to form syllables and in turn order these syllables into a stereotyped sequence referred to as a phrase or a motif. The phrase may be repeated one or more times in rapid succession during a song bout. Some adult songbirds, such as white-crowned sparrows and zebra finches, utter only a single song phrase which they maintain largely unchanged throughout life. Other adult songbirds, such as mockingbirds, can sing tens or even hundreds of different songs, which are referred to as song types. Both the fine temporal structure of individual notes, often involving rapid (millisecond range) modulations in frequency and amplitude, and the overall sequence of notes and syllables constituting the phrase are learned features of the bird's song.

The Function of Song

Oscine songbirds comprise more than half of the 9000 extant avian species, a taxonomic diversity paralleled by rich variation in song structure, the degree to which one or both sexes sing, and the social contexts in which song is used. In most species, song is a reproductive behavior uttered by adult males to communicate identity, to establish territory, and to attract females. As with many mating displays, male birdsong serves as a form of ritualized combat to minimize aggressive encounters with other males and as a sexual aphrodisiac to attract and arouse receptive females. Male and female songbirds are extremely proficient at recognizing the songs of other birds, which is not surprising given the importance of song recognition for reproductive success. For example, males largely ignore the songs of familiar neighbors but still respond aggressively when they hear an unfamiliar conspecific song. Another example of recognition is that males of some species with multiple song types will sing songs that most closely match those of their neighbors. Female songbirds recognize and choose mates based on acoustical features of male song. Indeed, perceptual studies suggest that females actually surpass males in their ability to distinguish conspecific songs from imitations of those songs produced by avian mimics, such as mockingbirds. The male song features that females find attractive are not well understood, but one idea is that they are honest indicators of fitness, as with sexually selected features in other animal species. An intriguing and unusual twist with respect to birdsong is that sexual selection acts on a learned rather than innate trait.

Learning/Sensitive Periods

Young birds learn their songs during a juvenile sensitive period marked by two phases, both of which depend on auditory experience. During the first phase, known as sensory acquisition, the young bird listens to and memorizes the song of a tutor, most often the bird's father or a neighboring conspecific male. However, young songbirds raised by a foster species mimic the songs of their foster rather than of their biological parents. Furthermore, young birds raised in isolation from any song model subsequently fail to develop species-typical songs and instead develop rudimentary 'isolate' songs.

During the second phase of song learning, known as sensorimotor learning, the pupil matches its own song to the memorized tutor model. Song produced during sensorimotor learning is highly variable in note and sequence structure, but such plastic song is gradually refined so that it becomes similar to the tutor model. Song structure loses its variable nature and becomes highly stereotyped or 'crystallized' with the onset of sexual maturity. Although juvenile birds do not need further exposure to the tutor song during sensorimotor learning, they do need to hear their own

Figure 1 Song structure and nomenclature. A sound spectrograph of the song of an adult male white-crowned sparrow (*Zonotricha leucophrys*). Notes (arrows) are the elementary units of song, and they are grouped to form syllables *(brackets),* a defined sequence of which constitutes the song phrase or motif. The spectrograph, wherein hotter colors correspond to louder sounds, was generated using sound analysis software provided by Ofer Tchernichovski and Partha Mitra.

songs: juvenile birds deafened after hearing a tutor but before starting to sing subsequently develop highly aberrant songs. This suggests that the juvenile uses auditory feedback to learn its song, perhaps by evaluating differences between its own song and a 'template' created by hearing the tutor song. Interestingly, isolates still rely on auditory feedback to develop their songs, and isolate songs within a species share basic features, pointing to the existence of an innate song model that can guide rudimentary learning. Thus, song learning involves two forms of learning: auditory imprinting on the tutor song and vocal motor learning guided by auditory feedback.

Song learning exhibits many remarkable features. One is that exposure to the tutor song regulates the sensitive period duration: juveniles raised in isolation from a tutor display an extended sensitive period and will copy song models later in life than will birds with normal access to a tutor. This indicates that the sensitive period is governed in part by auditory experience rather than an innate 'clock.' Another remarkable feature is that long delays can separate sensory acquisition and sensorimotor learning: in swamp and song sparrows, as well as most other temperate zone songbird species, sensorimotor learning usually begins 8–10 months after the close of sensory acquisition. Yet another feature is that accurate memorization often requires only very limited exposure to the tutor: young nightingales accurately reproduce strings of 75–100 syllables after hearing these strings as few as 15–20 times. Finally, in many species, auditory feedback continues to play an important role in song maintenance: adult songs can decrystallize when birds are deafened or exposed to distorted auditory feedback. These behavioral aspects of song learning make the songbird's brain a rewarding place to search for the neural mechanisms that regulate sensitive periods for learning, facilitate prodigious feats of auditory memorization, and enable feedback-dependent vocal learning and maintenance.

Mechanisms of Singing and Song Learning

Peripheral Mechanisms

The avian organ of song is the syrinx, a bipartite structure located at the confluence of the trachea with the two bronchi. Elegant studies of syringeal and respiratory activity in singing birds have lent considerable insight into avian vocal gymnastics. Particularly impressive is the songbird's capacity to produce asymmetrical series of vocal gestures by operating the two halves of the syrinx independently, in some cases simultaneously generating two harmonically unrelated notes. The exact details of how the spectral features of song are controlled by the syrinx are still debated but depend in part on the bird's ability to manipulate the bronchial apertures via fine control of the syringeal muscles. In addition, upper vocal tract filtering, including effects due to dynamic changes in beak gape, regulates vocal pitch while also removing harmonics, yielding highly tonal sounds. The temporal features of song, as with speech, rely on an extremely fine temporal integration of vocal and respiratory activity. In birds, the respiratory system is highly modified to meet the metabolic demands of flight and includes an extensive set of air sacs that act as bellows to constantly perfuse the relatively inflexible lungs with oxygenated air. Songbirds exploit their superior respiratory capacity to produce virtuoso vocal displays that are distinguished by extremely rapid trills (>30 Hz) of often extended duration.

Central Mechanisms for Singing

In a manner analogous to the evolution of the peacock's exuberant tail fan, sexual selection based on learned vocalizations in songbirds has resulted in a tremendous hypertrophy of those brain areas important to singing and song learning. The songbird's brain is distinguished from those of nonlearners by a well-defined neural

circuit essential to singing referred to as the 'song system' (Figure 2). A striking neuroanatomical parallel between human speech and birdsong is that both are under the executive control of the telencephalon, in contrast to the brain stem-mediated vocalizations typical of many other vertebrates, including nonhuman primates. The amenability of the song system to detailed electrophysiological recordings makes the songbird especially attractive for probing neural mechanisms pertinent to human speech, including auditory–vocal interactions and respiratory–vocal integration executed under telencephalic influence.

The song system can be functionally divided into two separate pathways: one is obligatory for singing and the other is essential to audition-dependent vocal plasticity. The song production pathway includes a series of serially organized telencephalic nuclei, including HVC and RA, the latter of which directly innervates the brain stem vocal–respiratory network. The brain stem vocal–respiratory network includes the tracheosyringeal (XIIts) motor neurons that innervate the muscles of the syrinx, as well as the respiratory premotor neurons in the lateral medulla that control the respiratory rhythm and provide synaptic input to the XIIts motor neurons. The idea that RA strongly modulates and coordinates syringeal and respiratory activity during singing is supported by the observation that bilateral RA lesions render the bird mute for singing but not for other unlearned vocalizations. Further direct support for RA's role as a song motor area derives from studies employing chronic recordings in singing zebra finches, which show that single RA neurons display amazingly precise (<1 ms jitter) action potential discharge locked to specific acoustical features of the bird's song.

How are premotor signals transformed between HVC and RA? In contrast to single RA neurons, which fire many times per motif, the HVC neurons that innervate RA (HVC_{RA} neurons) generate an extremely sparse burst of action potentials, firing only one brief (~10 ms) burst of action potentials per motif. Ultimately, a high degree of synaptic convergence between many HVC axons and single RA neurons could transform a temporally sparse and purely time-based code in HVC to a more continuous movement-based code in RA. One functional advantage of sparse temporal activity in HVC_{RA} neurons is that it maximizes learning rates: Error signals that 'correct' the connections of any single HVC_{RA} neuron alter one rather than many time points in the motif.

Despite important insights into the patterns of HVC and RA neuronal activity during singing, and increasingly detailed information about the synaptic architecture of the song system, the song patterning mechanisms remain enigmatic. In many central pattern generators (CPGs), rhythmical activity is an emergent property of a distributed network of neurons, whereas in other CPGs, rhythmical activity arises from highly localized master oscillatory neurons. Whether the song CPG is distributed across many neurons in one or more song nuclei or localized to a smaller population of master oscillatory neurons is unknown.

Figure 2 Neural circuitry for singing and song learning. A sagittal view of the songbird's brain (left) and an equivalent schematic (right) showing neural pathways important to learned vocalizations. HVC, RA, and RA's brain stem targets (nXIIts and nAM/nRAm) form a descending vocal motor pathway (red) essential to song, which is emitted from the bird's syrinx. HVC contains two distinct projection neuron populations – one that innervates RA give and another that innervates the anterior forebrain pathway (AFP; blue). The AFP, which is essential to audition-dependent plasticity in juvenile and adult birds, includes the basal ganglia homolog area X, the thalamic nucleus DLM, and LMAN, which influences vocal quality through its connections to RA. Auditory information to both song pathways derives from HVC, which in turn is believed to receive its auditory input from NIf and field L (the equivalent of mammalian primary auditory cortex; Ov is the avian homolog of the mammalian medial geniculate body). The names of various song nuclei are given as acronyms for simplicity sake. Dashed lines indicate that intervening synapses are not shown.

Neural Circuits for Song Learning

A major attraction of the song system is its potential for shedding light on the cellular and systems mechanisms of learning. One tantalizing clue about neural mechanisms of sensorimotor learning is that a second major part of the song system, known as the anterior forebrain pathway (AFP), must be intact for audition-dependent vocal plasticity in both juvenile and adult birds. The AFP connects HVC to RA via an interposed series of structures, including area X (a possible homolog to the mammalian basal ganglia), a thalamic nucleus (DLM), and an anterior telencephalic nucleus (LMAN), and thus resembles mammalian cortico-basal ganglia pathways in its general organization. Lesions of LMAN made in juvenile birds 'freeze' song development, even though similar lesions made in adults exerted no discernible effect on their crystallized songs. Rather remarkably, adult LMAN lesions block deafening-induced song degradation, indicating an active role for the AFP in song maintenance.

What is the synaptic basis for the AFP's effect on vocal plasticity? Intracellular studies revealed that LMAN and HVC axons provide convergent input onto the same RA premotor neurons, with LMAN axons predominantly activating postsynaptic NMDA receptors and HVC axons activating mostly AMPA receptors. That this synaptic arrangement actually drives vocal plasticity is supported by the finding that electrically stimulating LMAN can induce slight song variability in adult birds and that pharmacologically blocking LMAN input onto RA neurons can temporarily freeze song structure in juvenile birds. These observations show that LMAN is necessary for vocal plasticity and point to synaptic mechanisms for vocal plasticity. An important next step is to understand whether the AFP's role in song learning is to actively instruct the song motor system to generate a 'correct' song or simply to permit vocal plasticity.

In support of the idea that the AFP serves an instructive role, neurons in LMAN (as well as those in HVC, the source of auditory input to the AFP) respond in a highly selective manner to playback of the bird's own song (BOS) and thus appear well suited to detect variations in song performance. Although it is tantalizing to speculate that LMAN activity is influenced by auditory feedback when the bird sings its song, the singing-related activity patterns of LMAN neurons do not immediately change when adult birds are exposed to distorted auditory feedback. This suggests that much or all of the singing-related activity in the AFP is a corollary discharge of song motor activity emanating from HVC. Similar distorted auditory feedback studies are necessary in other parts of the song system, including HVC and its auditory afferent NIf, to better understand whether auditory feedback directly modulates singing-related activity in any part of the song system. One possibility is that the auditory activity that can be detected in the song system may serve functions other than conveying feedback, perhaps those related to song perception – a view supported by the finding that lesions in both HVC and the AFP impair the bird's ability to recognize the songs of other birds. Ultimately, a major goal of future research will be to detect where auditory feedback signals affect neurons during singing and how auditory information about vocal performance is translated into a signal that can correct or reinforce certain vocal patterns.

Another outstanding goal is to ascertain the mechanisms of sensory learning. Namely, where and how is the template stored? At first glance, song system neurons with selective auditory response properties might seem well suited to function as part of a template. However, numerous studies indicate that song system neurons are biased to the BOS, in contrast to a template model wherein neurons show a tutor song bias. Although preliminary, emerging evidence suggests that tutor-selective cells may localize to secondary areas of the auditory telencephalon. Whether and how such auditory information is used to influence song learning remain unknown, but the discovery of areas containing neurons with a strong bias to the tutor song could provide important clues as to where early auditory experience acts on the brain and in the future could help reveal how auditory memories literally are recalled.

Conclusions

The songbird is a master vocal mimic that relies on its keen auditory memory and auditory feedback to learn its courtship songs. The behavioral aspects of sensitive periods for song learning are fairly well understood, but we still understand relatively little about the underlying cellular mechanisms that limit such prodigious vocal learning to juvenile life. Are there molecules that regulate the duration of the sensitive period, and can these be artificially regulated to reopen the sensitive period in adult birds? Elegant studies in singing birds have revealed important features of the peripheral mechanisms that generate song and have also revealed some of the central premotor activity patterns associated with singing. Despite these important advances, our understanding of the dynamical neural processes of song patterning remains largely incomplete. Is there a localized central pattern generator for song, or is song produced by a more distributed network? Also, important steps have been

taken toward unraveling the neural mechanisms of vocal plasticity, but exactly how plasticity mechanisms are engaged in the service of sensorimotor learning is unclear. Finally, we still do not know how early auditory experience of a tutor produces lasting song memories and how auditory feedback interacts with these memories to guide sensorimotor learning. Answering these important questions will require more extensive electrophysiological recordings in freely behaving birds, including longitudinal recordings during juvenile periods of song learning, coupled with detailed intracellular analysis of the song circuitry. Some of the most exciting and technically challenging questions in the field of song learning are still awaiting answers.

Blindsight: Residual Vision

R L Tomsak, Case Western Reserve University School of Medicine and University Hospitals of Cleveland, Cleveland, OH, USA

Published by Elsevier Ltd.

Introduction

The word blindsight is an oxymoron and the phenomenon is a paradox. I treat this subject from the perspective of a clinical neuro-ophthalmologist who has background in experimental psychology and visual neuroscience.

In the least ambiguous sense, blindsight is the discernment of a visual stimulus in the absence of conscious awareness (blindsight type 1 of Weiskrantz). However, it will soon be evident that much of the literature deals with cases in which the subject acknowledges some perception in the blind region of visual field without actually recognizing the stimulus (blindsight type 2 of Weiskrantz). Further subcategorization of blindsight has been done and will be discussed later. All cases of blindsight require some damage to the primary visual cortex (V1) with sparing of parts of visual association cortex and/or associated neural circuitry. Blindsight, in some ways, can be considered a condition in which there is unawareness of awareness, although this term could be applied to certain forms of agnosia, especially anosoagnosia, or the unawareness of a body part. Furthermore, unawareness and denial of cortical visual loss is present in Anton's syndrome. Most types of blindsight, however, are not agnosia but something more primitive, involving damage to, and sparing of, specific neural circuitry dealing with the basics of visual perception.

Background

Long before the term blindsight was coined by Weiskrantz in 1974, the effects of trauma to the visual cortex had been investigated. At the turn of the twentieth century, Inouye systematically studied soldiers who sustained traumatic injury to the visual cortex in war. Thirteen of his cases were totally blind initially (could not distinguish between light and dark), yet all recovered the ability to at least count fingers over weeks to months. Thus, even in adults with wounds resulting in total blindness, recovery of some degree of form vision was the rule rather than the exception.

A few years later, Riddoch studied soldiers wounded in similar circumstances during World War I. He detailed 10 cases and divided them into three groups. The first group (5 cases) could perceive movement in the blind areas of visual field (usually homonymous hemianopsia, complete or incomplete) but at best could perceive only light and no form. The second group (4 cases) ultimately recovered some object vision, but in all movement perception returned first and first became noticeable in the periphery of the abnormal visual field. The last single case (group 3) noted no recovery of either form or movement vision. Riddoch concluded that movement could be considered a special type of visual perception, that the appreciation of movement returned before abilities for object recognition, that improvement of movement perception began in the periphery of visual field, and that the appreciation for light – but not form – returned coincident with the ability to sense movement.

Helen the Monkey

Much of the blindsight literature describes cases of partial blindness – that is, humans or animals with complete or incomplete homonymous hemianopsias, with some form of residual vision in the blind half of the visual field. Rather than starting with the hemianopic situation, I prefer to describe in some detail the best studied case of an adolescent monkey after almost complete surgical removal of the striate cortex (V1).

The monkey was called Helen by Humphrey and co-workers. Following her death 8 years after operation, her brain was studied. Pathologic analysis showed that the striate cortex was removed bilaterally, with the exception of a small island of left calcarine cortex that would correspond to a small portion of the far peripheral right upper visual field. If this visual island was functional, it was nowhere near the part of visual field involved in high acuity form vision.

Helen was carefully studied behaviorally and psychophysically. For the initial 19 months following operation, only light perception vision was apparent. Thereafter, the first visual function to recover was the ability to turn her head or eyes toward a moving object. After training, she could reach out for objects. Ultimately, she could recognize black objects against a light background, best done if the objects were presented in her central visual field. At this time, she appeared to have tunnel vision for stationary objects, but full-field movement perception. Reaching behavior

was always preceded by fixating eye movements, and she did not reach for objects presented eccentrically without looking directly at them first. This was in contrast to normal monkeys who easily reach for eccentric objects without looking directly at them.

Approximately 5 years after operation, she was taken outdoors for walks. Initially, she collided with obstacles, but ambulatory vision improved almost daily. Soon she was recognizing trees and reaching out for branches with apparent judgment of depth. In the laboratory, her ability to recognize small objects (currants or pieces of chocolate) on a white floor became acute, but she grasped these objects with her palm rather than with her fingers. When she picked up objects, she was almost always ambulating, leading Humphrey to speculate that her judgment of distances was facilitated by self-motion and dynamic visual information rather than static visual information. She could move in and around three-dimensional objects placed around the room without difficulty. However, when a black piece of tape was placed on the floor surrounded by three-dimensional obstacles and she was allowed to roam the room, she would return to, and persist in trying to pick up, the same piece of tape even after multiple attempts.

She never learned to differentiate shapes. In other experiments, this was demonstrated by her inability to discriminate between a triangle and a circle surrounding a central black spot. Similarly, she could not discriminate between two circles of same size with only one having the central black spot. However, she could easily and accurately choose between a lone black spot and a circle with a black spot at its center. Other experiments were done with light stimuli of different luminances and color stimuli. All and all, it seemed that Helen's focal, or central, vision had been significantly altered by removal of the striate cortex with preservation to large extent of her peripheral or ambulatory vision.

D.B., G.Y., and Other Hemianopes

A large amount of literature reports experiments done with hemianopic human subjects. A number of criticisms have been directed at this experimental model for blindsight. Perhaps the most obvious is the well-documented observation that scotomatous areas can have various depths of visual insensitivity. However, the consensus of data shows that residual visual functions do exist, allowing subjects to detect and localize stimuli presented in the blind areas. What is missing is the normal ability to recognize these stimuli – an ability sometimes described as visual consciousness.

Weiskrantz and colleagues extensively studied human subject D.B., who developed hemianopsia following removal of a benign lesion in the right occipital lobe at the age of 33 years. A second man, G.Y., also has been extensively studied. G.Y. developed hemianopsia after being struck by a car at the age of 8 years. Research on these two individuals, as well as on others, revealed that given the right setting, subjects could detect stimulus orientation, location, spatial frequency, wavelength, and movement in the blind areas of visual field. Other studies found that emotional content could be recognized, and figure completion performed, when the abnormal field was stimulated. Pupillary reactions could be elicited by isoluminant visual stimuli presented in the blind field. Furthermore, priming experiments showed that a stimulus presented to the abnormal field could alter the response to a stimulus presented soon after to the normal half of vision.

In this regard, Marcel studied two right-sided hemianopes who were semantically primed. A word with ambiguous meaning (e.g., 'bank') was presented in the normal field after the abnormal half of field was primed with a word that would bias the interpretation of the other (e.g., 'money' and 'river'). The priming impressively biased the meaning of the ambiguous word in this study.

The previous discussion is not meant to imply that every one of the subjects reported had all abilities demonstrated. Indeed, most hemianopes do not have blindsight; Weiskrantz found blindsight in only 5 of 25 hemianopes tested for this ability. In this regard, my neurologist colleague, Dr. Monroe Cole, wrote an excellent personal description of the subjective effects of hemianopsia. He has never had blindsight or Riddoch phenomenon but initially was very bothered by visual hallucinations. It is interesting that the blindsight literature routinely does not comment on the presence or absence of hallucinations since these might represent confounding events and are very common in clinical practice, especially in the first few weeks following development of hemianopsia.

Types of Blindsight and Neural Pathways

As noted in the introduction, Weiskrantz described two types of blindsight. Type 1 is the ability to discriminate a visual stimulus without conscious perception of doing so, and type 2 involves an awareness of some sort of visual experience in the blind field in the absence of correct recognition of the stimulus.

Danckert and Rosetti expanded the classification to three types (Figure 1), in part based on the observation that in some people with blindsight, a motor act (e.g., accurately pointing to, or looking at, a stimulus) is the

Figure 1 Schematic representation of the various pathways for visual information from the retina to striate (V1) and extrastriate cortex. The primary geniculostriate pathway is indicated by the dashed line from the temporal hemiretina to the left eye and the widely spaced dotted line from the nasal portion of the right eye. The two secondary pathways indicated are shown originating from the optic tract for clarity, with the retinotectal pathway indicated by the dashed/dotted line and the geniculostriate pathway indicated by the closely spaced dotted line. The pathways are also represented in simple box and arrow form below the schematic. Note that anatomical work in monkeys has shown direct koniocellular projections to area MT. The possibility exists for other such pathways from the interlaminar layers of the LGN to regions of extrastriate cortex other than area MT. Reproduced from Danckert J and Rossetti Y (2005) Blindsight in action: What can the different subtypes of blindsight tell us about the control of visually guided actions? *Neuroscience and Biobehavioral Reviews* 29: 1035–1046, with permission from Elsevier.

best demonstration of their residual vision: (1) action-blindsight is demonstrated by grasping, pointing, or saccades; (2) attention-blindsight is demonstrated by detecting spatial orientation, motion detection, and other tasks of discrimination; and (3) agnopsia (to not know what one sees) is the ability of form or wavelength detection and semantic priming. Implicit in this classification is the concept that different neural pathways (Figure 1) subserve each type of blindsight.

A pathway involving superior colliculus, pulvinar nucleus of the thalamus, and poster parietal cortex mediates action-blindsight. A pathway that travels through superior colliculus and pulvinar but terminates instead in the MT region of extrastriate cortex (V5) also mediates attention-blindsight. Agnopsia purportedly is mediated through the koniocellular regions of the dorsal lateral geniculate, interlaminar nuclei of the thalamus, and more ventral regions of extrastriate cortex.

The possible role of koniocellular pathways in blindsight is discussed in detail by Vakalopoulos. This K cell pathway arises in the lateral geniculate from regions between the magnocellular and parvocellular layers. In primates, the K cells project to cytochrome oxidase-rich blobs in V1, as well as to foveal regions in V2, and also to V4 and inferotemporal cortex.

Diffusion tensor imaging has been performed on hemispherectomized individuals with and without attention-blindsight. Ipsilateral and contralateral projections from superior colliculus to primary visual areas, visual association areas, precentral area/frontal eye fields, and internal capsule of the remaining hemisphere were found only in those with attention-blindsight.

Clinical Implications: Visual Restitution Training

A commercially available product (NovaVision) aims at visual restitution training (VRT) for hemianopes. Binocular visual stimulation is performed on a computer monitor within a transition zone between the intact visual field and the impaired field. Debate exists as to whether described improvements are real or are the result of adaptive strategies such as eccentric fixation or changes in saccadic behavior. Scanning laser ophthalmoscopy was used to control fixation behavior in 17 patients with hemianopic field defects studied after VRT training for 6 months; there was an insignificant reduction in the size of the field defects. However, approximately two-thirds of patients believed that the training helped from a subjective standpoint.

Poggel and colleagues studied a man who had a gunshot injury to the back of the head causing visual field loss. Spontaneous recovery of visual field occurred over a 16-month period and then stabilized. Seven months after stabilization, VRT was begun and visual field examinations were done sequentially for approximately 1 1/2 years. VRT-related improvement was found at the borders of the visual field defects, but it was noted that light stimuli of 2000 ms (per VRT protocol) were more easily perceived than stimuli presented by conventional threshold static perimetry (150 ms). Over time, the subject noted improvement in everyday functions such as riding a bicycle, shaking hands with another person, and avoiding obstacles when walking.

In another study, visual field improvement, as measured by clinical perimetry, was only 0.4° on average, but it was 4.9° by the perimetric methods of the VRT protocol (the normal horizontal dimension of visual field is approximately 170°).

Unfortunately, subjects given VRT have not been investigated systematically for blindsight.

Conclusions

Blindsight is a fascinating phenomenon whose study provides insights into the neurophysiology of normal vision. Factors complicating its study include spontaneous improvement of visual functioning after injury, varying depths of scotomatous areas, and operational issues surrounding definitions and experimental designs. Also, the role of learning is a potentially important factor, as shown especially by Helen the monkey. Currently, the efficacy of VRT is controversial and has not been directly correlated with the capacity for blindsight.

Blood Pressure: Baroreceptors

A F Sved, University of Pittsburgh, Pittsburgh, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

For normal functioning of the cardiovascular system it is essential that arterial blood pressure (ABP) be highly regulated within the normal range. Usually, ABP is tightly regulated, and fluctuations in ABP on a minute-to-minute or hour-to-hour time frame are minimal. As with most homeostatic systems, the key parameter, in this case ABP, is controlled, at least in large part, by a powerful negative feedback reflex. The arterial baroreceptor reflex, the major negative feedback reflex controlling ABP, is composed of afferent nerves sensitive to changes in ABP that convey information to the central nervous system (CNS), outputs of the CNS that can impact ABP, and the central neural pathways connecting these inputs and outputs. This article describes the afferent limb of this reflex, the efferent components, and then the central neural systems connecting the inputs and outputs and providing a complex neural circuitry for the integration of these reflexes with the physiological status of the organism.

Arterial Baroreceptors

The afferent component of the baroreceptor reflex is composed of pressure-sensitive receptors associated with two major blood vessels, the aortic arch and the carotid sinus, and their projections into the CNS. The blood pressures in these two major arteries are arguably the most critical to the organism, because they represent, respectively, whole-body perfusion pressure and perfusion pressure of the brain. The afferents from the aortic arch form the aortic depressor nerve, which joins with the vagus nerve in the neck. The cell bodies of these afferents, as well as other vagal afferent fibers, are present in the nodose ganglion. The baroreceptor afferents from the carotid sinus, along with chemosensitive afferents from this region, form the carotid sinus nerve, which joins with the glossopharyngeal nerve. The cell bodies of these afferents, as well as other glossopharyngeal afferents, are present in the petrosal ganglion. These baroreceptor afferents all project into the CNS and terminate in the dorsal medial medulla in a distinct region of the nucleus tractus solitarius (NTS). A few studies have suggested the presence of arterial baroreceptors in the coronary circulation, but if they exist they do not have the profound influence on cardiovascular regulation that can be readily shown for the aortic and carotid baroreceptors.

Arterial baroreceptors are stretch receptors that are activated (and therefore fire more action potentials) when ABP increases and distends the blood vessel wall (**Figure 1**). As with stretch receptors in other tissues, the response of these afferents adapts to prolonged stretch; in the case of baroreceptors, this adaptation, or resetting, begins to occur within minutes of a sustained change in blood pressure (**Figure 1(b)**). Thus, baroreceptor afferent firing codes acute changes in pressure rather than a specific pressure. It is important to keep in mind that ABP is a pulsatile parameter, and baroreceptor afferent activity follows this pressure wave and provides the brain with a dynamic and pulsating signal.

In addition to being directly sensitive to changes in pressure, various local and circulating factors (e.g., endothelin, prostacyclins) also influence the firing rates of baroreceptor afferent nerves (**Figure 1(c)**). Thus, while changes in ABP clearly influence the baroreceptor signal provided to the brain, this signal cannot be considered as solely reflecting ABP or providing an accurate high-fidelity signal of absolute ABP. Rather, baroreceptor afferent activity might be considered as coding changes in ABP, but in a manner that is influenced by other factors as well. This issue is important when considering the role of the baroreceptor reflex in the long-term regulation of arterial pressure.

In recent years, studies have begun to address the role of specific ion channels involved in barosensitivity of the baroreceptors. Most of this research has focused on the degerin/epithelial Na^+ channel (Deg/ENaC) family of ion channels, and the current data suggest that this family of channels is responsible for the key mechanoelectrical transduction events (**Figure 1(a)**). Deg/ENaC subunits are expressed by barosensitive neurons, and the mechanosensitivity of these neurons is inhibited by the Deg/ENaC blocker, amiloride. Recent data in knockout mice also suggest a role of Deg/ENaC subunits, primarily 1 and 2, in barosensitivity. However, the Deg/ENaC family does not comprise the only channel types at the baroreceptive endings that are involved in baroreceptor activity. Transient receptor potential (TRP) channels have also been suggested to be part of the sensory transduction process, but they are likely involved more as modulators of the primary barosensitive channels. Although TRP channels impart mechanosensitivity in certain other systems, this does not appear to be the case for arterial baroreceptors.

Figure 1 Schematic of a baroreceptor afferent neuron (a), showing the mechanosensitive channels (Deg/ENaC, degerin/epithelial Na^+ channel) on the endings at the blood vessel (ABP, arterial blood pressure), the generation of action potentials at the action potential trigger zone, and the transmission into the nucleus tractus solitarius (NTS). The firing rate of baroreceptor afferent nerves is increased with increasing blood pressure, but this relationship is modified by adaptation to higher or lower pressures (b) or response to chemical agents such as prostaglandin I_2 (PGI_2) or platelets (Pla) (c). (b) Adapted from Munch PA, Andresen MC, and Brown AM (1983) Rapid resetting of aortic baroreceptors *in vitro*. *American Journal of Physiology* 244: H672–H680. (c) Based on Chapleau MW, Cunningham JT, Sullivan MJ, et al. (1995) Structural versus functional modulation of the arterial baroreflex. *Hypertension* 26: 341–347.

Depolarization of baroreceptor endings resulting from stretch, and modified by a variety of other influences, results in the generation of action potentials carried along the axons of these pseudounipolar neurons that ultimately project to the NTS.

Effector Systems of Arterial Baroreceptor Reflexes

The term 'arterial baroreceptor reflex' is used to refer to a variety of physiological responses elicited by

Figure 2 Baroreceptor reflex effector systems. Changes in baroreceptor afferent activity reflexively influence many outputs of the brain relevant to cardiovascular regulation. ACTH, adrenocorticotropic hormone.

changes in baroreceptor afferent activity. While the baroreceptor reflex is often used in specific reference to the reflexive change in ABP and heart rate brought about by changing autonomic outflow to the heart and vasculature, there are a large number of physiological responses resulting from changes in baroreceptor afferent input, and they would each appropriately be termed a baroreceptor reflex. For example, decreases in ABP sensed by arterial baroreceptors elicit an increase in vasopressin (antidiuretic hormone) secretion from the posterior pituitary and an increase in thirst (as reflected by increased fluid ingestion). Thus, baroreceptor reflexes can be viewed as having autonomic, endocrine, and behavioral effectors, all of which interact to promote cardiovascular homeostasis (Figure 2).

At the core of baroreceptor reflexes are the changes in sympathetic outflow, directed at the vasculature and the heart, and in parasympathetic (vagal) outflow, directed at the heart. Changes in baroreceptor afferent activity evoke reflexive changes in autonomic activity to the heart and sympathetic activity to many (but not all) vascular beds. Baroreceptor reflex control of autonomic activity to the heart provides a rapid means of adjusting cardiac output to match ABP. Imposed increases in ABP, detected by arterial baroreceptors, reflexively decrease heart rate (and cardiac output) by increasing parasympathetic activity and decreasing sympathetic activity. Conversely, decreases in ABP elicit the opposite responses (Figure 3). However, these two directions of responses should not be considered simply symmetrical responses. Rather, the decrease in cardiac output elicited by increased ABP is more related to increased parasympathetic activity, whereas the increase in cardiac output elicited by decreased ABP is more related to an increase in sympathetic activity, at least in some species. For example, in rats, the bradycardia caused by acute increases in ABP can be largely blocked by drugs that interfere with the parasympathetic nervous system.

Changes in baroreceptor afferent activity markedly alter sympathetic nerve activity directed toward certain vascular beds, particularly those impacting total peripheral resistance. Thus, whereas baroreceptors readily influence sympathetic activity directed toward renal, mesenteric, splanchnic, and muscle vascular beds, they have limited impact on the cutaneous or cerebral circulations. Increased baroreceptor afferent activity can powerfully inhibit sympathetic vasomotor outflow, whereas decreased baroreceptor afferent activity powerfully excites it.

While these influences of baroreceptor activity on autonomic outflow directed to the heart and blood vessels might be at the core of baroreceptor reflex responses, several other baroreceptor-evoked responses also contribute to cardiovascular homeostasis (Figure 2). Several of these responses are considered here to illustrate specific points.

One of the most powerful regulators of renin secretion from the juxtaglomerular cells of the kidney is the sympathetic innervation of these cells, and this sympathetic innervation is controlled in large part by baroreceptor input. Thus, decreases in ABP result in decreased arterial baroreceptor input to brain and in turn result in increases in sympathetic stimulation of the juxtaglomerular cells and increased renin secretion. The resulting generation of angiotensin II produces a variety of physiological effects, ranging from increased constriction of blood vessels to increased sodium reabsorption by the kidneys and increased fluid intake. Thus, arterial baroreceptors, by influencing renal renin secretion, have a wide influence on systemic physiology.

Arterial baroreceptors also influence secretion of posterior pituitary hormones. Decreased ABP sensed by

Figure 3 Relationship between arterial blood pressure, baroreceptor afferent activity, and cardiovascular autonomic outflow. SNS, sympathetic nervous system; PNS, peripheral nervous system; HR, heart rate; CO, cardiac output.

arterial baroreceptors increases vasopressin secretion from the posterior pituitary, with readily understandable influences on cardiovascular homeostasis: increased fluid retention by the kidneys and increased arterial vasoconstriction. Increases in ABP momentarily inhibit the activity of vasopressin-secreting cells (a response that has been used as a defining characteristic of magnocellular vasopressin neurons), but this effect does not appear to be sustained long enough to have any physiological impact. Arterial hypotension also causes secretion of the other major posterior pituitary hormone, oxytocin. While the physiological significance of hypotension-evoked oxytocin secretion is not clear, recent studies indicate that this hormone promotes renin secretion from the kidney, at least in rats. In contrast to vasopressin-secreting cells, increases in ABP appear to have no effect on oxytocin-secreting cells.

Changes in ABP, sensed by arterial baroreceptors, influence drinking behavior. Decreases in ABP stimulate fluid intake, an effect that appears to be mediated entirely via arterial baroreceptor-evoked renin secretion with the resulting increase in blood levels of angiotensin II acting on the brain to stimulate drinking. In contrast, increases in ABP inhibit drinking behavior and this effect appears to be mediated by baroreceptor-stimulated neuronal pathways in the brain.

In summary, changes in the afferent activity of arterial baroreceptors reflexively elicit a variety of autonomic, endocrine, and behavioral responses included in cardiovascular homeostasis. While many of these responses occur in opposite fashion to increases and decreases in ABP, the mechanisms responsible for these different effects might be quite distinct.

Central Pathways and Processing

Input to the central nervous system from arterial baroreceptors is through the NTS in the dorsomedial medulla. Within the NTS, baroreceptor afferents synapse with second-order sensory neurons, and at this stage the information begins to get integrated and relayed. The baroreceptor afferents are excitatory to the second-order neurons, likely using glutamate as the primary neurotransmitter. Neural transmission at this initial synapse can be blocked by glutamate receptor antagonists, as can baroreceptor reflexes when such drugs are applied to the NTS. The neural pathways subserving baroreceptor reflex control of parasympathetic and sympathetic responses have been well studied and this circuitry is well established (Figure 4). Neurons in the NTS, likely the second-order sensory neurons, innervate parasympathetic cardiac preganglionic neurons, most of which are present in the nucleus ambiguus. The synapse between the second-order sensory neuron and the parasympathetic preganglionic neuron is excitatory and likely to use glutamate as a neurotransmitter. The baroreceptor reflex circuitry linking the NTS with the sympathetic preganglionic neurons in the intermediolateral cell column in the thoracolumbar spinal cord is somewhat more complex and necessarily involves an inhibitory interneuron, because increases in baroreceptor input decrease sympathetic activity. Barosensitive glutamatergic NTS neurons, at least some of which are second-order sensory neurons, innervate neurons in the caudal ventrolateral medulla (CVLM) and excite γ-aminobutyric acid (GABA)ergic

Figure 4 Central nervous system baroreceptor pathway linking baroreceptor afferents to sympathetic and parasympathetic outflow. Plus (+) and minus (–) symbols refer to excitatory synapses and inhibitory synapses, respectively.

neurons in this region. The GABAergic CVLM neurons innervate sympathoexcitatory neurons in the rostral ventrolateral medulla (RVLM) that innervate sympathetic vasomotor preganglionic neurons in the spinal cord. Thus, activation of baroreceptor afferents inhibits sympathetic vasomotor outflow by a pathway involving an excitatory projection from NTS to CVLM, an inhibitory projection from CVLM to RVLM, and an excitatory projection from RVLM to sympathetic preganglionic neurons. Available evidence supports glutamate being the primary neurotransmitter at each of the excitatory synapses in this reflex pathway and GABA being the neurotransmitter at the inhibitory link from CVLM to RVLM. At each of the sites in this pathway, inputs from other brain regions have the capacity to modify baroreceptor reflex responses, and most brain-evoked responses that influence cardiovascular function have some influence on baroreceptor reflex processing.

Central nervous system pathways mediating other baroreceptor-evoked responses are less well characterized. Hypotension-evoked secretion of vasopressin from the posterior pituitary gland involves activation of the magnocellular vasopressin neurons of the paraventricular and supraoptic hypothalamic nuclei, likely by a pathway involving the ventrolateral medulla. Presumably hypotension-evoked excitation of magnocellular oxytocin neurons is via similar pathways, but this has not been extensively studied. The inhibition of vasopressin neurons by acute increases in ABP is mediated by distinctly different pathways from the NTS to hypothalamus (again illustrating the asymmetry between responses evoked by activating vs. unloading of baroreceptors).

As for the central neural pathways involved in baroreceptor-mediated influences on drinking, hypotension-evoked drinking involves activation of the sympathetic innervation of the kidney juxtaglomerular cells, with the resulting generation of angiotensin II. This angiotensin II then acts on neurons in the subfornical organ, a forebrain region lacking a blood–brain barrier, to activate brain circuits involved in drinking. In contrast, increases in ABP inhibit drinking via central neural pathways from the NTS that have not been studied in any detail.

The extensive nature of central baroreceptor reflex circuits is readily demonstrated by studies showing numerous brain regions expressing immediate-early genes such as c-*fos* in response to arterial baroreceptor activation or unloading. All of the regions directly involved in the aforementioned baroreceptor responses express immediate-early genes under conditions in which they would be expected to be activated by baroreceptor manipulations, but many other regions, presumably involved in higher order integration of baroreceptor responses, also express immediate-early genes in these studies.

Role of Arterial Baroreceptors in Cardiovascular Regulation

Arterial baroreceptors provide a dynamic signal to the brain regarding changes in ABP and elicit reflex responses to maintain ABP within a narrow range.

Baroreceptor reflexes are essential for normal cardiovascular homeostasis and stabilize ABP at normal levels on a rapid time frame. Studying the impact of destruction of arterial baroreceptors on cardiovascular regulation has provided useful information on their function. Elimination of baroreceptor signals carried in the aortic depressor nerve and carotid sinus nerve results in a rapid increase in ABP and heart rate, reflecting the marked decrease in baroreceptor afferent signal to brain. Over the course of several days, ABP returns to a normal average level, but the variability around this normal average is markedly increased. A conclusion that can be drawn from such observations is that arterial baroreceptor reflexes are not critical for the maintenance of a normal average level of ABP, but they are essential for stabilizing ABP. These results from baroreceptor-denervated animals have also been used to support the notion that baroreceptor reflexes are not important in the long-term control of blood pressure, but this conclusion has been challenged by more recent studies showing that chronic stimulation of arterial baroreceptor afferents can have a sustained influence on ABP.

Cardiopulmonary Baroreceptors

In addition to the baroreceptors positioned to sense ABP, there are also baroreceptors in the atria, and veins leading to them, referred to as cardiopulmonary baroreceptors. These baroreceptors sense stretch in the atria, which, because of the distensible nature of the atria, and veins leading to them, reflects blood volume. Thus, hypovolemia decreases stretch on these receptors and this leads reflexively to a number of responses aimed at restoring blood volume. Responses initiated by unloading cardiopulmonary baroreceptors include increased vasopressin secretion, increased renin secretion, and increased thirst. Nonhypotensive hypovolemia, as can be caused by moderate hemorrhage or removal of isotonic plasma volume by various experimental procedures, elicits each of these responses. As noted previously, each of these responses is also characteristic of hypotension in the absence of hypovolemia, but the response to unloading of arterial and cardiopulmonary baroreceptors at the same time, as might be produced by hypotensive hemorrhage, is much greater than are responses produced by either stimulus in isolation.

Neurovascular System – Functional Hierarchy

The neurovascular system in the normal brain is organized at different functional levels; the different levels are integrated with each other in order to maintain a tightly controlled chemical composition of the neuronal internal microenvironment. The neurovascular system controls functioning of neuronal circuits through regulation of cerebral blood flow (CBF), in response to brain activation and brain metabolic and clearance demands, and blood–brain barrier (BBB) bidirectional transport of molecules in and out of the central nervous system (CNS). Normal vascular hierarchy in the brain is illustrated in Figure 1. This hierarchical arrangement includes three important functional segments of the neurovascular system: the brain capillary neurovascular unit, the small pial and intracerebral arteries, and the large cerebral arteries. Here, the role of the brain capillary unit in the pathogenesis of chronic neurodegenerative disorders is discussed; how neurovascular dysfunction in small and large cerebral arteries may contribute to neurodegeneration and neuronal injury in Alzheimer's disease (AD) is briefly reviewed.

Brain Capillary Unit in Healthy Brain

Normal human brain has about 100 billion capillaries, which corresponds to about 100 billion neurons. Thus, the ratio of brain capillaries to neurons in normal adult human brain is 1:1. The total length of capillaries in adult human brain is about 400 miles. The surface area available for molecular transport exchanges between blood and brain interstitial fluid (ISF) is about 12 m^2.

Blood–Brain Barrier

Brain capillary endothelial cells (BECs) represent the site of the anatomical BBB; they are normally sealed to the tight junctions, forming a continuous cellular layer that limits free transport of solutes between brain ISF and blood, and vice versa (Figure 1(b), panels ii and iii). The thickness of the cerebral endothelial membrane is 0.3–0.5 μm.

The endothelial monolayer of the BBB expresses numerous substrate-specialized transport systems, some of which are preferentially localized to the luminal, or blood-facing, side, whereas others are expressed mainly at the abluminal, or brain-facing, side. The BBB has a high metabolic rate, reflecting high energy demands for active ATP-dependent transporters, such as the sodium pump, which is localized mainly at the abluminal side of the BBB and regulates sodium and potassium homeostasis in the CNS. The BBB specific transporters for different classes of nutrients (e.g., for glucose, amino acids, vitamins, and nucleosides), and/or the BBB receptors that transport proteins (e.g., leptin receptors, transferrin, and insulin) and lipoproteins (e.g., low-density lipoprotein receptor) and metals (e.g., iron), mediate transcellular influx of their respective circulating substrates across the endothelium in the direction from blood to brain. Other transport systems at the BBB work mainly to reduce the levels of potentially toxic molecules in the CNS; such toxic components are the result of brain activity and metabolism (e.g., excitatory transmitters, amyloid beta, and metabolic waste products). The efflux systems transport toxic molecules and waste metabolic products in the direction from brain ISF to blood, and the transport process is initiated at the abluminal membrane. The multidrug transporter P-glycoprotein (P-gly) is an ATP-dependent efflux pump that has been shown to be required for the BBB to mediate rapid removal of ingested toxic lipophilic metabolites, including many drugs. The P-gly protein is encoded in humans by the *MDR1* gene and in rodents by the *mdr1a* and *mdr1b* genes.

Basement Membrane

The basement membrane separates endothelium from pericytes and astrocytes, two other cell types which regulate function of the neurovascular unit. The basement membrane is composed of different extracellular matrix structural proteins (e.g., collagen, laminin). In addition, embedded into the basement membrane are several important receptors (e.g., integrins), which play a key role in mediating endothelial signaling, cell migration, and brain capillary tube formation during angiogenic responses. Growth factors such as vascular endothelial growth factor (VEGF) are also bound to extracellular matrix proteins and are activated *in situ* by matrix metalloproteinases (MMPs).

Pericytes

Pericytes are situated on the outer side of the basement membrane. They are responsible for the development
