
Figure 1 Neurovascular unit. (a, b) Normal vascular hierarchy (top to bottom). Cerebral arteries (a, top; b, i) branch into pial arteries running onto the surface of the brain. Penetrating intracerebral arteries are separated from the brain by the Virchow–Robin spaces. Intracerebral arteries (a, middle; b, ii) branch into numerous smaller arteries and arterioles, which gradually lose the glia-limitans astrocytic membrane (green) of the Virchow–Robin spaces, giving rise to precapillary arterioles and brain capillaries (a, bottom; b, iii). (b) The smooth muscle cell layer (ii, khaki) normally occupies about 90% of the arterial vessel wall. At the capillary level, a tightly 'zipped' brain endothelial layer (iii, yellow) forms the blood–brain barrier. The basement membrane (iii, fuschia) separates the endothelium from other cells of the neurovascular unit, including pericytes (khaki) and astrocytes (green). Astrocytic microdomains (green) ensheathe brain capillary endothelium. Occasional microglia (dark orange) are found, usually in contact with pericytes. Perivascular neurons and synaptic contacts (light orange) are in close proximity to astrocytes (green). (c) Alzheimer's disease (AD) pathology. Large cerebral arteries often display atherosclerotic plaques (a bulge inside the lumen) and may develop thrombotic disorder (i). Pial and intracerebral arteries develop amyloid lesions (ii, blue) and have a reduced smooth muscle cell layer (ii, khaki), characteristics of the cerebral amyloid angiopathy. At the capillary level (iii), there is degeneration of endothelium (yellow), thickening of the basement membrane (fuschia), amyloid lesions (blue), and activation of microglia (dark orange) and astrocytes (green). Local perivascular neurons and synaptic connections (light orange) are severely disturbed. Reproduced from Zlokovic BV (2005) Neurovascular mechanisms of Alzheimer's neurodegeneration. *Trends in Neuroscience*s 28: 202–208, with permission.

of BBB characteristics and play an important role in maintaining vascular integrity and maturation of the BBB. Perivascular pericytes release a large number of growth factors and angiogenic molecules which regulate vascular remodeling, angiogenesis, and blood flow locally within the brain microcirculation, at the capillary level.

Monocytes and Microglia

Perivascular monocytes (which originate in blood and traverse the BBB) and resident microglia play critical roles in innate and adaptive immune responses of the CNS. In certain areas of the CNS, such as in the subventricular zone (SVZ) or dentate gyrus in the hippocampus, pericytes and monocytes are often found together with a small pool of vascular and neuronal progenitor cells which participate in ongoing plasticity responses of the CNS.

Astrocytes

Astrocytes are positioned between neurons and capillary BECs and communicate with these cells through their numerous 'foot processes' (Figure 1(b), panels (ii) and (iii)). Astrocytes play a major role in inflammatory CNS response and regulation of brain water and electrolyte metabolism. Astrocytes, along with vascular smooth muscle cells in small arteries, may contribute to neurovascular coupling, which serves to synchronize neuronal activity and metabolic demands to local cerebral blood flow regulation. Astrocytes contribute

to brain communication pathways by regulating synaptic transmission and neuronal firing thresholds. Autocrine regulations and paracrine cross-talk between endothelial cells, pericytes, perivascular monocytes, microglia, astrocytes, and neurons are critical for normal neuronal functions.

Passive Transport of Molecules in Brain Fluids

Normal cytoarchitecture of brain capillary units allows for rapid diffusion of nutrients and oxygen within brain ISF in the direction from blood to neurons and neurovascular cells, and allows rapid diffusion of neurotransmitters and metabolic waste products away from synapses and neurons back to the microcirculation. The distances for diffusion of molecules between the adjacent human brain capillaries are between 20 and 40 μm.

In addition to passive diffusion, brain ISF–cerebrospinal fluid (CSF) 'bulk flow' mediates transport of molecules into the CSF at a slow rate and irrespective of the size of molecules. The CSF acts normally as a sink for potentially toxic molecules and metabolic waste products. Toxic molecules and metabolic waste products are removed from the CSF by active transport or facilitated diffusion across the choroid plexus epithelium, or by vacuolar transport across the epithelial arachnoid granulations, back into circulation. In contrast, clearance across the BBB mediates rapid removal of several neurotoxins, into the blood, via their respective specialized transport systems.

Brain Capillary Unit in Disorders of the Aging Nervous System

Normal aging is associated with reductions in brain capillary networks and changes in brain microcirculation which result in diminished brain capillary blood flow. These changes, which lead to reductions in the resting CBF, occur in different CNS regions in AD, Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS), and other CNS disorders. Moderate reductions in brain capillary density and severe vessel regression may lead to moderate reductions in resting CBF (oligemia) or to severe reductions in CBF (ischemia), respectively, which in turn may cause reversible or irreversible damage of the neurovascular capillary unit.

Modest reductions in CBF are associated with diminished protein synthesis; normal protein synthesis is important for normal learning and memory. More severe reductions in CBF lead to shifts in intracellular pH and water, imbalance in electrolytes, and accumulation of glutamate in brain ISF at levels which may initiate excitotoxic damage. Finally, severe reductions in CBF, similar to those found in ischemic stroke, may lead to ischemic neuronal death mediated by the intrinsic mitochondria-initiated apoptotic pathway, by the extrinsic death-receptor-initiated apoptotic pathway, by aponecrosis, or by necrosis. In several neurodegenerative disorders, changes in the brain capillary unit, degeneration of the brain capillaries, and/or reductions in the resting CBF may be the first sign of disease process prior to neuronal changes and neurodegeneration. A few examples are discussed in the following sections.

Parkinson's Disease

In normal brain, melanin-containing neurons of the zona compacta have a very close spatial relationship with the blood supply. The neuronal vascular contact is so intimate that the capillary appears to have an almost intracellular position. In brains of PD patients, the normal contact between nigral neuron and capillary is lost, and capillaries do not have their normal shape. In early stages of disease, the most striking feature in PD is the changed relationship between capillaries and nigral cells.

Familial Amyotrophic Lateral Sclerosis

Recent work suggests that brain capillaries in familial models of ALS – for example, in superoxide dismutase 1 (SOD1) mutant mice – are affected early in the course of the disease, even during a presymptomatic stage. Reduction in vascular endothelial growth factor (VEGF) level by only 25% impairs spinal cord perfusion and results in motor neuron degeneration, reminiscent of ALS. Moreover, treatment with VEGF extends survival and improves functional outcome in SOD1 mice, whereas antiangiogenic therapy with VEGF2 receptor (VEGF2R) antagonist aggravates the course of disease by accelerating clinical expression of symptoms and by enhancing mortality.

Alzheimer's Disease

Figure 1(c) (panel (iii)) shows altered cytoarchitecture of the capillary unit in AD. Reduced microvascular density, an increased number of fragmented vessels with fewer intact branches, atrophic string vessels, increased irregularity of capillary surfaces, marked changes of vessel diameter (both enlarged and reduced), capillary basement membrane thickening, and collagen accumulation in the basement membrane have been described in AD. Diminished nutrient/oxygen transport from blood to brain cells and impaired elimination of toxic metabolic waste products caused by dysfunction in the transport clearance systems at the BBB, deregulated CBF, increased interstitial diffusional distances, and interrupted ISF–CSF bulk flow upset normal neuronal functioning.

In AD, the brain endothelial wall often looks degenerated. According to recent findings this may reflect unsuccessful aberrant angiogenesis, which is often aborted at an early stage of brain capillary tube formation. Lack of mesenchyme homeobox gene 2 (*MEOX2*) in AD BECs mediates aberrant angiogenesis in AD and abnormal responses to VEGF and other angiogenic factors, resulting in premature vessel regression. Alzheimer's neurotoxin amyloid beta (Aβ) peptide and amyloid deposits accumulate on the outer side of the basement membrane, promoting a local neuroinflammatory vascular response, including activation of brain endothelium, perivascular microglia, pericytes, and astrocytes. Activated cells of the neurovascular unit secrete proinflammatory cytokines and vasoactive substances (e.g., endothelin), further suppressing the CBF and amplifying cellular stress, which may contribute to cognitive defects. Thus, altered physiology of the capillary unit, compromised brain microcirculation, and vascular neuroinflammatory response are of major importance for the pathogenesis of AD.

Blood–Brain Barrier in Disorders of the Nervous System

The involvement of the BBB in several chronic disorders of the CNS has been well documented.

Multiple Sclerosis

The BBB mechanisms critically regulate immune responses of the CNS in conditions such as multiple sclerosis (MS) and in experimental models of MS such as experimental allergic encephalitis (EAE). It has been shown that transport of different subsets of cytotoxic T lymphocytes from blood to brain is critical for lymphocyte infiltration of the CNS, which in turn results in neuronal killing. It is believed that T helper (Th17) lymphocytes, which secrete interleukin-17, play an important role in neuronal killing. But, whether Th17 lymphocytes are activated from pre-Th17 subsets of T cells in peripheral organs and are transported across the BBB, or whether Th1, Th0, and/or other pre-Th17 lymphocytes initially penetrate the BBB followed by maturation into Th17 cells in the CNS locally, is a matter of debate. The BBB involvement in either case is important. It is obvious that the BBB molecular mechanisms which are involved in transport of different subsets of T cells into the CNS represent potentially important therapeutic targets.

Autoimmune Disease Syndrome Dementia

The BBB-regulated cellular trafficking is critical for development of CNS pathology in different neuroinflammatory conditions, including meningitis, encepalitis, and autoimmune disease syndrome (AIDS) dementia caused by human immunodeficiency virus type-1 (HIV-1). For example, HIV-1 infiltrates the CNS largely via infected monocytes and macrophages. HIV-1 infiltration is mediated by its envelope glycoprotein, gp120, which activates protein kinase C isoforms in brain endothelial cells to alter BBB permeability and allow for monocyte migration. Involvement of MMPs during HIV-1 infiltration, and in other disorders of the CNS such as MS, cerebral ischemia, migraine, and brain tumors, has been well established. Thus, transport of peripheral monocytes carrying the HIV virus across the BBB into the CNS precedes development of AIDS dementia. Better understanding of the BBB molecular mechanisms in this case is not only important for the pathogenesis of the disease, but also may represent an important therapeutic target.

Parkinson's Disease

Transport of putative neurotoxins into and out of the CNS across the BBB is considered to be a potential mechanism by which toxins reach their neuronal targets in PD. It is believed that the absorption or metabolism of putative PD toxins is influenced by genetic factors. The importance of the BBB transport in PD has been suggested by *MDR1* gene polymorphisms, which regulate the expression of the P-gly detoxification efflux system at the BBB. Studies in the Chinese population indicate that polymorphisms in the *MDR1* gene can reduce the risk for PD. Involvement of P-gly at the BBB has also been suggested by a positron emission tomography (PET) study demonstrating an increased retention of verapamil (a P-gly substrate) in the midbrain of PD patients. Thus, low levels of P-gly activity at the BBB may favor retention of putative PD toxins in the midbrain of individuals at risk for PD.

It is well known that paraquat, a widely used insecticide, can produce parkinsonism in rodents. The effect of paraquat can be blocked by competitive inhibition of the BBB large neutral amino acid transporter. This further supports the concept that entry of putative toxins into certain brain regions across the BBB could be important for the pathogenesis of PD. It is interesting to note that guinea-pigs exhibit a selective transport of dopamine across the BBB in the caudate putamen, whereas hippocampus and cortex are impermeable to dopamine, suggesting again regional differences in BBB transport. In rats made hemiparkinsonian by unilateral injections of 6-hydroxydopamine into the substantia nigra, treatment with levodopa increases endothelial proliferation and is associated with increased transport of levodopa. The endothelial proliferation and changes

in levodopa transport are limited to the basal ganglia, subventricular zone (SVZ) region, and hippocampal dentate gyrus, and are not found elsewhere in the CNS. Changes in regional capillary endothelial cells have been correlated with the development of dyskinesia, a serious side effect of levodopa therapy in PD patients. This finding suggests that disease treatments may alter BBB properties, which in turn can influence the course of the disease.

Alzheimer's Disease

Elevated levels of Aβ play a primary role in the pathogenesis of AD, and may precede intraneuronal changes and formation of neurofibrillary tangles and tau pathology in models of AD and in AD patients. Work in experimental models of AD has shown that transport exchanges across the BBB critically influence homeostasis of Aβ in the CNS, which is central to formation of neurotoxic oligomeric Aβ species and vasculotoxic forms of Aβ. Despite the fact that Aβ is produced by almost all cells in peripheral tissues and in the CNS, its physiological role remains a puzzle. Aβ normally circulates in plasma, CSF, and brain ISF as soluble Aβ_{40} > Aβ_{42}, and is bound in plasma mainly to its putative chaperone molecules, including soluble lipoprotein receptor-related protein 1 (sLRP1), which prevents reentry of Aβ into the brain. Major influx and efflux of Aβ receptors at the BBB is discussed in greater detail in the following sections.

Transvascular Transport of Aβ

Receptor for advanced glycation end products (RAGE) is a major influx transporter for Aβ across the BBB. RAGE binds soluble Aβ and mediates its pathophysiologic cellular responses. In contrast to normal BBB, which expresses relatively low levels of RAGE, accumulation of RAGE ligands in the aging brain (e.g., AGE proteins, Aβ) increases RAGE expression. Thus, in AD and in transgenic models of β-amyloidosis, RAGE expression increases in affected cerebral vessels, microglia, and even neurons. RAGE/Aβ interaction at the BBB is implicated in development of the disease process in AD through transcytosis of circulating Aβ across the BBB, inflammatory and procoagulant responses in endothelium, brain endothelial nuclear factor-kappa B (NF-κB)-dependent apoptosis, and suppression of CBF.

RAGE/Aβ interaction stimulates microglia activation and response, and produces oxidative damage to those neurons which express RAGE, thus contributing to neuronal killing directly and indirectly via microglia. RAGE inhibitors which block pathophysiolgical responses of RAGE/Aβ interaction in affected vasculature can inhibit cytokine and chemokine production, oxidant stress, and Aβ BBB transport. RAGE inhibitors are currently being tested in AD patients. Besides AD, RAGE plays a role in diabetic CNS vasculopathy and in acute ischemic brain injury after stroke.

Lipoprotein receptor-related protein 1 (LRP1) is a major efflux transporter for Aβ across the BBB. LRP1 is a member of the low-density lipoprotein (LDL) receptor family and acts as a multifunctional scavenger and signaling receptor. LRP1 is expressed in brain capillary endothelium and is localized to the abluminal side at the BBB. Its reduced expression is observed during normal aging in rodents, in nonhuman primates, and in AD patients associated with positive staining of cerebral vessels for Aβ_{40} and Aβ_{42}. Receptor-associated protein (RAP) null mice with severe functional deficiency in LRP1 at the BBB develop accumulations of Aβ when crossed with amyloid beta peptide precursor protein (APP)-overexpressing mice. On the other hand, overexpression of an LRP1 cluster-IV minigene on neurons promotes Aβ retention in the CNS *in vivo*, suggesting that LRP1 on neurons mediates retention of Aβ in brain. In contrast, LRP1 (or another lipoprotein receptor on astrocytes) mediates degradation of amyloid deposits. Therefore, astrocytes and brain vessels act in concert to export Aβ from the CNS, which ultimately requires LRP1 activity at the BBB.

Work in transgenic mice producing low levels of poorly cleared high beta-sheet vasculotropic Dutch/Iowa Aβ mutants suggests that defective LRP1-mediated vascular clearance of Aβ across the BBB leads to accelerated Aβ brain capillary deposition and formation of amyloid lesions. In contrast, mice overexpressing RAGE in the vascular system have enhanced Aβ accumulation and amyloid deposition when crossed with APP-overexpressing mice. The clearance systems for brain Aβ at the BBB have limited capacity and are impaired in AD and animal models of AD, whereas RAGE expression increases. Thus, it is possible that dense Aβ plaques in APP-overexpressing mice and in AD patients originate on blood vessels which later degenerate and/or disappear in the course of the disease. Findings in models of experimental cerebral amyloid angiopathy (CAA) and human CAA indicate that basement membrane and/or extracellular matrix components are critical for the formation of Aβ fibrils and/or seeding of vascular amyloid deposits.

It is of note that mice which lack P-gly at the BBB (knockouts for *mdr1a* and *mdr1b* genes) have reduced clearance of Aβ from the CNS and lower levels of LRP1 in brain capillaries. Crossing *mdr1a*/*mdr1b* null mice with APP-overexpressing mice accelerates accumulation of Aβ and amyloid deposition, raising a possibility that *mdr1a* and *mdr1b* genes may

influence Aβ clearance either directly through P-gly and/or indirectly through LRP1 at the BBB. The role of BBB mechanisms in maintaining Aβ CNS homeostasis is shown in Figure 2.

Small and Large Cerebral Arteries in AD

Aβ is a potent vasoconstrictor in the cerebral circulation. Early changes in APP-expressing mice are associated with impaired endothelium-dependent regulation of neocortical microcirculation and reduction in functional hyperemia. A mismatch between CBF, metabolism, and brain activity is shown in sporadic AD by magnetic resonance imaging (MRI) and PET. Abnormal responses of pial arteries to brain activation, also known as neurovascular uncoupling, have been demonstrated in AD models and AD patients.

Figure 2 Regulation of brain amyloid beta (Aβ) concentration at the blood–brain barrier (BBB): (1) Rate of production from the amyloid beta peptide precursor protein in brain and periphery; (2) rate of entry into the brain from circulation via the receptor for advanced glycation end products (RAGE); (3) rate of rapid clearance of soluble Aβ from brain to blood across the BBB via lipoprotein receptor-related protein (LRP); (4) binding to proteins such as soluble lipoprotein receptor-related protein 1, apolipoproteins E and J (ApoE, ApoJ), and α_2-macroglobulin (α2M), which can influence Aβ accumulation in brain and/or promote Aβ efflux across the BBB (e.g., soluble LRP in plasma; P-gly, P-glycoprotein); (5) rate of Aβ degradation by a variety of proteases (e.g., enkephalinase, insulinase, plasmin, tissue plasminogen activator, matrix metalloproteinases); (6) rate of slow removal via the interstitial fluid (ISF) and cerebrospinal fluid (CSF) bulk flow into the bloodstream, which appears to be responsible for 10–15% of Aβ clearance from normal brain; (7) rate of oligomerization and aggregation in the central nervous system; (8) transport via other receptors (e.g., megalin). Reproduced from Zlokovic BV (2005) Neurovascular mechanisms of Alzheimer's neurodegeneration. *Trends in Neurosciences* 28: 202–208, with permission.

Pial and intracerebral arteries in AD are affected by CAA. The layer of vascular smooth muscle cells (VSMCs) is often reduced, resulting in the rupture of the vessel walls and intracerebral bleeding. Pathogenic levels of vasculotropic mutant forms of Aβ (e.g., Dutch, Iowa, Arctic, Flemish, Italian) accelerate degeneration of VSMCs, which may contribute to cerebrovascular pathology and hemorrhagic stroke, as seen in familial forms of AD.

Recent studies have pointed out that, in AD, an overexpression of two transcription factors that control VSMC cell differentiation – namely, serum response factor (SRF) and myocardin (MYOCD) – leads to a hypercontractile arterial phenotype and inability of VSMCs to effectively clear Aβ, predisposing to its accumulation in vessel walls and to development of CAA.

Large cerebral arteries in AD do not develop CAA. However, they are regularly affected by atherosclerosis, which reduces resting CBF and brain perfusion and may precipitate a chronic ischemic condition. The Rotterdam Scan Study (a population-based study of nondemented elderly) demonstrated that silent brain infarcts detected on MRI are associated with dementia in elderly people. The longitudinal Nun Study also showed that demented AD individuals with amyloid and tau pathology have numerous brain microinfarctions. The link between increased Aβ production and ischemia has been well documented in these studies.

Neurovascular Model(s) of Neurodegeneration

Accumulating evidence suggests that neurovascular mechanisms and disruption of the neurovascular unit may precede, accelerate, and/or contribute to a disease process leading to neurodegeneration in several disorders in the aging brain. Transport of brain neurotoxins from the circulation across the BBB in AD and PD, inefficient efflux from the CNS of toxic proteinaceous accumulates (e.g., Aβ) or excitotoxins (e.g., glutamate) in AD and stroke, transport of cytotoxic lymphocytes across the BBB (in MS) and of monocytes carrying HIV-1 (in AIDS dementia), and the role of VEGF in ALS are all examples illustrating disease pathways by which the brain capillary unit

controls development of pathology in the aging brain. Activation of endothelium, astrocytes, microglia, monocytes, and pericytes is common to these diseases. Moreover, aberrant angiogenesis and vessel regression at a capillary level may augment brain hypoperfusion already imposed by senescent cerebral vasculature. A chronic neurovascular 'vicious circle' leads to irreversible BBB failure, alterations in the chemical composition of brain ISF, and inflammatory responses which disrupt synaptic and neuronal functions, all leading to chronic neuronal injury and loss.

Bone Morphogenetic Protein (BMP) Signaling in the Neuroectoderm

C M Mizutani and E Bier, University of California, at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The nervous system is a highly heterogeneous tissue comprising a great diversity of cell types that interconnect in complex patterns to control a myriad of conscious and unconscious behaviors. Not surprisingly, creating such an intricate system requires a series of many cellular interactions during development. Because various organisms have a wide range of different life strategies and needs, there is also a great diversity in the function and development of nervous systems across species. Notwithstanding the inherent complexity and diversity of nervous system function and development, there are remarkable parallels between the formation and function of the nervous system in organisms ranging from fruit flies and nematodes to vertebrates. In several cases, homologous gene sets play critical roles in processes such as neural induction, neurite pathfinding, synaptogenesis, action potential propagation, transmitter secretion and reception, and behavior. This high degree of conservation of basic cellular and molecular functions suggests that the common ancestor of current living metazoans had a well-formed nervous system with many of the core properties shared by diverse present-day organisms.

One of the best characterized examples of conserved pathway function in neural development is the role of bone morphogenetic protein (BMP) signaling during neural induction. During this early phase of embryonic development, BMP signaling actively represses neural cell fates in epidermal regions of the embryo. In neuroectodermal regions, BMP signaling is blocked by various BMP antagonists, which permits the default program of neural development to prevail. Because many of the pathway components required for neural induction are similarly deployed in vertebrates and invertebrates, it seems highly likely that this similarity reflects the conservation of an ancestral mechanism for specifying neural versus epidermal cell fates. BMPs also play important roles in the subsequent patterning of the nervous system along the dorsal–ventral (DV) axis. It is less clear, however, whether this latter phase of neural patterning is accomplished by homologous or convergent mechanisms. In this article, we briefly review the evidence for a conserved function of BMP signaling during neural induction and then focus on how BMPs are believed to act during neural patterning in different organisms. We propose that a unifying theme may underlie the apparent diversity of these patterning mechanisms, wherein BMPs act by a common mechanism to repress the expression of neural genes in a dose-dependent fashion. We also consider how conserved and diverse elements of neural patterning may have evolved.

Evolutionary Conservation of BMP Inhibition during Neural Induction

Nearly a century ago, Hans Spemann and Hilde Mangold showed that ventral transplantation of the dorsal lip of an amphibian embryo into a recipient embryo led to the production of a secondary neural axis. Using distinguishable host and donor embryos they demonstrated further that the dorsal lip, or Spemann organizer as it is now often called, was the source of secreted neural-inducing signals which could redirect the development of surrounding cells fated otherwise to give rise to epidermis. Since these seminal experiments, there has been great interest in isolating and understanding the function of neuralizing factors. Several neural inducers have been identified from *Xenopus* in recent years, including Noggin, Chordin (Chd), and proteins in the DAN family, which are expressed in dorsal mesodermal cells making up the Spemann organizer during late blastula and early gastrula stages. These structurally diverse neural inducers function via a common double negative mechanism by antagonizing the function of BMP signaling (**Figure 1(a)**). They bind to BMPs (BMP2/BMP4) with high affinity, preventing them from activating BMP receptors. In the nonneural ectoderm, where BMP4 is expressed at high levels, BMP signaling functions to promote epidermal fates and to repress the expression of neural genes. Similarly, in *Drosophila*, the Chd homolog known as Short Gastrulation (Sog) is expressed in the lateral neuroectoderm and blocks BMP signaling in the dorsal ectoderm. It is likely that the DV axes in vertebrate and invertebrate embryos were inverted during evolution, such that the epidermis forms ventrally in vertebrates but dorsally in invertebrates. In flies, as in vertebrates, BMP signaling represses the expression of neural genes and activates the expression of nonneural genes. It is noteworthy that in *Drosophila* significantly less BMP signaling is required to repress the expression of neural genes than to activate expression of epidermal genes. One of the genes activated by

Figure 1 BMPs suppress neuronal fates in the ectoderm of vertebrates and arthropods: (a) BMP signaling in the nonneural ectoderm represses the expression of all neural genes and activates the expression of epidermal genes, including the BMP4/Dpp genes, thereby creating a positive feedback loop, referred to as autoactivation; (b) an example of the conserved nature of BMP inhibition and neural induction in *Xenopus* embryos. In (a), neural-inducing factors, such as the extracellular BMP antagonists Sog/Chd, are supplied to the neural ectoderm, where they bind to BMPs and prevent them from triggering BMP autoactivation, thereby preventing the invasive spread of BMP signaling into the neuroectoderm. This double-negative mechanism allows cells in the neuroectoderm to follow the default neural development pathway. In (b), the injection of *sog* mRNA from *Drosophila* into ventral blastomeres of early *Xenopus* embryos leads to the formation of secondary neural axes (top embryo; compare to wild-type embryo on bottom) similar to those observed in the original embryo-grafting experiments of Hilde Mangold and Hans Spemann. BMP, bone morphogenetic protein; Dpp, Decapentaplegic (the ortholog of vertebrate BMP4/2); Sog, Short gastrulation (the ortholog of vertebrate Chordin (Chd)). Adapted from Biehs B, François V, and Bier E (1996) The *Drosophila short gastrulation* gene prevents Dpp signaling from autoactivating and suppressing neurogenesis in the neuroectoderm. *Genes & Development* 10: 2922–2934; and Schmidt J, François V, Bier E, and Kimelman D (1995) The *Drosophila short gastrulation* gene induces an ectopic axis in *Xenopus*: Evidence for conserved mechanisms of dorsal-ventral patterning. *Development* 121: 4319–4328.

BMP signaling in *Drosophila* and vertebrates is the Dpp/BMP4 gene itself, which results in a positive feedback loop, referred to as autoactivation. If unopposed by BMP antagonists, BMP autoactivation can result in the invasive spread of BMP signaling into the neuroectoderm. This ectopic expression of BMP ligands leads to the repression of neural gene expression and to the activation of epidermal genes.

Conservation of the Chd/BMP signaling system extends to the functional level, as revealed in cross-species experiments. For example, injection of *Drosophila sog* mRNA into the ventral blastomeres of *Xenopus* embryos generates duplicated neural axes (Figure 1(b)) similar to those induced by injection of vertebrate Chd or by transplantation of Spemann organizer tissue. Similarly, vertebrate BMPs and BMP antagonists have the same activities in *Drosophila* as they do in vertebrate embryos. Other extracellular components of the BMP pathway identified in *Drosophila* have also been shown to play similar roles in early vertebrate embryos (Figure 2). For instance, embryos lacking Tolloid (Tld) and Twisted gastrulation (Tsg) activity have defects in BMP signaling. Tld is a metalloprotease that can cleave and inactivate Sog, whereas Tsg forms a trimeric complex with Sog/Chd and BMPs and modifies the BMP inhibitory function of Sog by binding to it and by generating alternative Tld cleavage products. Similarly, in vertebrates, the *Xenopus* counterpart of Tld, Xolloid (Xld), cleaves Chd in positions corresponding to two of the four sites in Sog that are cut by Tld, thereby reducing Chd activity. In addition, *Xenopus* and zebra fish homologs of Tsg also can form a ternary complex with Chd and BMPs to modulate BMP signaling.

Opposing Graded BMP and Hh Signals Pattern the Vertebrate Neuroectoderm

A wealth of embryological and genetic evidence in vertebrates indicates that, following their role in neural induction, BMPs play an important role as morphogens in organizing gene expression along the dorsal–ventral axis of the developing nervous system (note that morphogens are molecules distributed in a graded fashion that function in a dose-dependent fashion to activate or repress gene expression). Once the dorsal-most ectodermal region of the vertebrate embryo is specified as neuroectoderm (often referred to as the neural plate), these cells undergo a concerted set of bilaterally symmetric apical constrictions, causing them to fold inside the embryo by the process of invagination (also referred to more specifically as neurulation). BMP-expressing epidermal cells bordering the neural plate are thereby brought into juxtaposition to form a single coherent dorsal epidermal mass (Figure 3(a)). The invaginated neural plate forms a longitudinal cylinder, which then closes on itself and separates from the overlying epidermis to form the neural tube. The dorsal-most cells of the neural tube lie immediately below the BMP-expressing epidermis and are subsequently induced to express BMPs. This

Figure 2 Extracellular regulation of BMP signaling. Diagram of BMP signaling pathway from *Drosophila,* highlighting elements that are conserved in vertebrates. BMP homodimers (e.g., Dpp-Dpp) or heterodimers (e.g., Dpp-Scw) induce the dimerization and then tetramerization of type I and type II BMP receptors. Following receptor dimerization, the type I receptor chain (e.g., Sax or Tkv receptors) phosphorylates the type II chain (e.g., the Put receptor), leading to phosphorylation of the cytoplasmic signal transducer SMAD (or MAD/Medea in *Drosophila*). Phosphorylated MAD (pMAD) then enters the nucleus, where it acts as a transcriptional cofactor to either activate gene expression (e.g., epidermal genes, including *dpp* and *zen*) or repress it (e.g., neural genes, including those of the *Achaete-Scute* complex or *msh*). Extracellular modulators of BMP signaling include Sog/Chd, which binds to Scw and inhibits peak BMP signaling mediated by the Dpp-Scw heterodimer. Tolloid is a metalloprotease that cleaves and inactivates Sog. Dpp is required as a cofactor of Tld in this cleavage reaction, both *in vitro* and *in vivo*. Tsg binds to Sog and Dpp and has been proposed to act in one of two possible ways. First, by forming a trimeric complex with Sog and Dpp-Scw heterodimers, as well as Dpp-Dpp homodimers, it broadens the BMP inhibitory range of Sog. The trimeric complex may also act as a carrier that protects BMPs from receptor-mediated endocytosis and thereby helps concentrate BMP heterodimers along the dorsal midline. The second role of Tsg is to alter the cleavage of Sog by Tld such that alternative, more broadly active forms of Sog (called Supersog) are formed. These truncated forms of Sog can bind directly to either Dpp-Dpp homodimers or Dpp-Scw heterodimers and inhibit their activity. *AS-C*, *achaete-scute* gene complex; BMP, bone morphogenetic protein; Dpp, Decapentaplegic (the ortholog of vertebrate BMP4/2); Gbb, Glass bottom boat; *msh*, *muscle specific homeobox;* Sax, Saxophone; Scw, Screw; Sog, Short gastrulation (the ortholog of vertebrate Chordin (Chd)); Tkv, Thick veins; Tld, Tolloid (the ortholog of vertebrate Xolloid (Xld)); Tsg, Twisted gastrulation; *zen*, *zerknüllt.*

dorsally restricted BMP expression is thought to lead to the formation of a BMP activity gradient, which is high dorsally and low ventrally. High levels of BMP signaling in the dorsal regions of the neural tube result in the expression of genes such as Msx1/2 and Pax7 in cells giving rise to migratory neural crest cells and sensory cells, whereas lower BMP levels result in the expression of lateral markers such as Gsh, Pax6, and Dbx1/2 in cells generating various interneurons (Figure 4(a)). It is not known whether BMPs act directly or indirectly to activate dorsal markers. In current models, BMPs are typically portrayed as having a direct positive role inducing gene expression, in part because a BMP-responsive enhancer region of the Msx1 gene has been shown to have binding sites for SMADs that are required for the activation of this cis-regulatory element. However, it is not clear that this element is responsible for Msx1 expression in dorsal cells of the neural tube because Msx1 is also expressed in ventral cells of the embryo during this same period.

In addition to the gradient of dorsally produced BMPs, the neural tube also receives ventral inductive cues provided by the Sonic Hedgehog (SHh) morphogen. As a consequence of the prior invagination of the mesoderm, cells derived from the Spemann organizer form a stiff longitudinal structure known as the notochord, which underlies the neural tube. These notochord cells secrete SHh and induce the neighboring ventral neural tube cells (called the floorplate) to acquire notochord-like properties, such as expression of the transcription factor HNF3β and SHh itself, which maintains its expression by a positive feedback mechanism (Figure 4(a)). Notochord cells also continue to express BMP inhibitors such as Noggin and Chd. SHh produced in the notochord and floorplate of the neural tube is distributed in a concentration gradient reciprocal to that of the BMP gradient (i.e., SHh is high ventrally and low dorsally). High levels of SHh result in the expression of ventral genes, such as Nkx2.2 and Nkx6.1, in cells that ultimately give rise to motor neurons, whereas lower levels of SHh lead to the expression of lateral markers.

In addition to organizing gene expression in the dorsal and ventral regions of the neural tube, BMPs and SHh also antagonize one another. For example, co-expression of BMP antagonists with limiting amounts of SHh greatly increases the ventralizing activity of SHh. Reciprocally, when BMPs are provided at levels

Figure 3 Early neural development in vertebrate and fly embryos, cross-sectional views of embryos: (a) neurulation in vertebrates; (b) delamination of neuroblasts in *Drosophila*. In (a), (1) is a cross section of the dorsal region of the embryo indicating the neuroectoderm (blue), or neural plate, which later invaginates along the dorsal midline. The adjacent more ventrally located nonneural ectodermal cells (orange) express high levels of BMPs and repress the expression of neural genes. Mesodermal cells (red) have already entered the interior of the embryo by this stage, by the process of involution, which begins dorsally at the blastopore and then expands ventrally. In (2) and (3), as invagination of the neural plate proceeds, its two ventral borders are brought into contact and the adjacent epithelial cells fuse into a single coherent domain as the neural ectoderm detaches to form the neural tube. In (4), The invagination of the neural plate leads to a reversal of dorsal-ventral (DV) polarity of the nervous system with respect to the primary embryonic DV axis because cells located originally at the dorsal midline of the embryo (white triangle) assume the most ventral position in the internalized neural tube. The ventral-most cells of the vertebrate neural tube, which are referred to as the floorplate, come into direct contact with a specialized mesodermal derivative known as the notochord, a rigid rodlike structure that provides support to the tadpole. Cells from the Spemann organizer give rise to the notochord. Flanking the neural tube laterally are the somites, a mesodermal tissue that gives rise to the adult bony skeleton and to muscle. In (b), (1) is a cross-section view of the early *Drosophila* embryo indicating the three germ layers along the DV axis. In (2) and (3), invagination of the mesoderm brings the left and right halves of the neural ectoderm into contact to form the ventral midline of the embryo and nervous system. In (4), neural precursor cells (neuroblasts) individually delaminate from the ectodermal epithelium and reside between the overlying epithelium and the more internal mesoderm. An important comparative point is that, due to the double inversion of the DV axis in vertebrates relative to flies, the final orientation ends up being the same. For example, the ventral midlines of vertebrates and flies are both formed by cells that were originally furthest from the source of BMPs in the nonneural ectoderm. BMP, bone morphogenetic protein; d.m.l., dorsal midline; NT, neural tube; v.f., ventral front; v.m.l., ventral midline. (See also **Figure 4**.) typical of the dorsal or lateral regions of the neural tube, they can override the induction of ventral markers by SHh.

Graded BMP-Mediated Repression of Neural Genes in *Drosophila*

Following their respective resident roles in consolidating cell fate choices within the epidermal and neural regions of the fly embryo during neural induction, Dpp and Sog play nonautonomous roles in the further subdivision of these two regions. Cells in the dorsal region of the embryo express uniform levels of *dpp* RNA and are initially equivalent because they are defined by the absence of the maternally derived Dorsal (Dl) morphogen. (Dl is a transcription factor related to mammalian nuclear factor (NF)-κB that sets up the initial DV polarity of the embryo. High levels of Dl ventrally specify the mesoderm, graded low levels of Dl define the neuroectoderm, and the absence of Dl in dorsal cells permits expression of *dpp*; see **Figure 4(b)**.) Polarity in the dorsal region is created by Sog diffusing dorsally from the lateral neuroectoderm, where it is cleaved and inactivated by the Tld protease, which is co-expressed with Dpp in dorsal cells. The adjacent ventral source of Sog and dorsal Tld sink result in the formation of a Sog protein gradient in the dorsal region, which is high

Figure 4 BMPs pattern the vertebrate and *Drosophila* neuroectoderm, cross-sectional diagrams: (a) the vertebrate neural tube, indicating the opposing gradients of BMPs and Sonic Hedgehog (SHh); (b) a blastoderm-stage *Drosophila* embryo, indicating the opposing Dpp and DI morphogen gradients. In (a), high levels of BMPs dorsally result in the expression of the neural identity gene Msx1, and lower levels specify cells expressing lateral genes such as Gsh. High levels of SHh ventrally lead to the expression of the ventral neural identity gene Nkx2.2, whereas lower levels result in the expression of more lateral markers. The expression patterns of some other transcription factors along the dorsal-ventral (DV) axis are also indicated, including Pax7, Dbx1 (and, but not shown, Dbx2, which extends more ventrally than Dbx1), Pax6 (which also plays a conserved role in eye formation), and Nkx6.1. In (b), threshold-dependent repression mediated by the Dpp gradient helps pattern the *ind* and *msh* domains of expression, whereas concentration-dependent activation by the DI gradient helps defining the *vnd/ind* border. An important mechanism contributing to the sharp, mutually exclusive neural domains is the ventral dominant cross-inhibition among the neural identity genes, wherein Vnd represses the expression of *ind* and *msh* and Ind inhibits expression of *msh*. Adapted from Mizutani CM, Meyer N, Roelink H, and Bier E (2006) Threshold-dependent BMP-mediated repression: A model for a conserved mechanism that patterns the neuroectoderm. *PLoS Biology* 4: e313 (online).

ventrally and low dorsally (Figure 5(a)). It has been proposed that this Sog gradient creates an inverse BMP activity gradient with peak levels in dorsal-most cells and lower levels in more ventral cells, which can be visualized by the *in situ* activation of the signal transducer phospho-MAD (pMAD). Sog may also carry Dpp dorsally and concentrate it along the dorsal midline. This BMP gradient results in the nested activation of a series of genes, including the transcription factors *zen*, *pannier*, and *ush*. The primary consequence of the graded activation of Dpp target genes is the subdivision of the dorsal region into two parts: a dorsal-most extra-embryonic domain (amnioserosa) and a more ventral epidermal domain. Note, however, that even the lower relative levels of BMP signaling present in the epidermal portion of the dorsal region are sufficient to repress the expression of all neural genes in those cells.

There is also evidence for a reciprocal influence of the dorsal ectoderm on patterning the lateral neuroectoderm mediated by Dpp diffusing ventrally (although diffusion of small amounts of Dpp ventrally remains to be demonstrated directly). Because Sog and a transcriptional repressor of BMP signaling known as Brinker (Brk) are expressed in the neuroectoderm, the levels of BMP signaling in neuroectodermal cells would be expected to be much lower than those in the dorsal region, where Dpp is expressed and only low levels of graded Sog are present. As a consequence of Dpp being present in limiting amounts within the neuroectoderm, its ability to repress neural gene expression becomes dosage dependent. This dosage-sensitive repression has been most conclusively studied with regard to the expression of the neural identity genes *vnd*, *ind*, and *msh*, which are required to specify the fates of the three primary rows of neuroblasts in the embryonic central nervous system (CNS) (Figures 4(b) and 5(b)). *vnd*, the homolog of vertebrate *Nkx*2.2, is expressed in the ventral-most row of the neuroblasts; *ind*, the homolog of *Gsh*, is expressed in the middle row of neuroblasts; and *msh*, the homolog of Msx1/2, is expressed in the dorsal row of neuroblasts. The fact that orthologous sets of neural identity genes are expressed in the same relative ventral-to-dorsal order with regard to BMP-expressing cells in vertebrates and flies suggests that this configuration reflects an ancestral state that has been conserved during evolution (Figure 4). (Note that, despite the fact that the primary DV axes are inverted in vertebrates and *Drosophila* embryos, the final relative order of neural identity genes ends up being the same as a consequence of the neural DV pattern being reversed with respect to the remainder of the embryo following invagination of the neural plate. Such a secondary reversal does not take place in *Drosophila*, in which neuroblasts delaminate isotopically from the epidermis to form a subepithelial layer, as indicated in Figure 3(b).)

An important regulatory feature of neural identity genes in *Drosophila* is that they cross-inhibit one another in a ventral-dominant fashion in which Vnd represses expression of both *ind* and *msh*, and Ind inhibits the expression of *msh* (Figure 4(b)). As Dpp diffuses ventrally, it represses expression of the intermediate neural identity gene *ind* more effectively than *msh*. This results in *ind*, but not *msh*, being repressed by BMP signaling in dorsal cells of the neuroectoderm, which are closest to the Dpp source. BMP-mediated repression of *ind* expression, in turn, relieves ventral-dominant repression of *msh* by Ind, resulting in *msh* expression in the dorsal-most domain of the neuroectoderm. Thus, as a consequence of the cross-inhibitory interactions among neural identity genes, sharp boundaries of neural gene expression domains are established in response to graded Dpp signaling along the neuroectoderm. Similar cross-regulation of neural identity genes has also been

Figure 5 BMP-mediated patterning of the fly neuroectoderm: (a) reciprocal BMP gradient created by diffusion of Sog into dorsal regions and its cleavage by Tld protease in the dorsal-most cells; (b) ventral diffusion of Dpp from the dorsal ectoderm into the lateral neuroectoderm. In (a), double staining of Sog RNA and Sog protein reveals that Sog protein can be detected further dorsally forming a gradient, beyond its domain of expression within the lateral neuroectoderm ((1) and (2) show a lateral view and (3) shows a transversal view of the embryo). In (b) the ventral diffusion of Dpp forms a concentration gradient to pattern the expression domains of neural identity genes *msh* (red), *ind* (green), and *vnd* (blue) mRNA. BMP, bone morphogenetic protein; Dpp, Decapentaplegic; Sog, Short gastrulation; Tld, Tolloid. observed in vertebrates, athough it remains to be determined whether they follow a ventral-dominant pattern as has been shown in *Drosophila*.

In ventral regions, it appears that the primary system involved in patterning the neuroectoderm is the opposing ventral-to-dorsal Dl gradient, which is provided maternally as previously described. Moderate levels of Dl in ventral cells activate *vnd*, whereas lower levels activate *ind*. Because Vnd represses the expression of *ind* and *msh*, the graded action of Dl results in *vnd* being expressed exclusively in ventral-most cells of the neuroectoderm and *ind* expression in the adjacent intermediate domain where the levels of Dl are too low to activate *vnd*. Although Dpp signaling can also repress the expression of *vnd* and can regulate the dorsal borders of all three neural identity genes, the border between the *vnd* and *ind* domains is established primarily by graded activation of these genes by Dl, whereas the border between *ind* and *msh* is determined primarily by the threshold-dependent repression of these genes by Dpp signaling emanating from dorsal epidermal cells.

Neural Patterning in Other Groups of Organisms

Primary insights into the mechanisms of neural induction have been provided by classical model systems such as flies, frogs, zebra fish, and mice, however, it is important to complement these studies with analyses of organisms from other phylogenetic groups. Such evo-devo studies provide two important types of information. First, cross-genome comparisons have revealed a striking degree of gene loss during the evolution of lineages that include the model systems *Drosophila* and *Caenorhabditis elegans*. Thus, finding a vertebrate gene not present in flies or other insects does not necessarily imply that the gene evolved within the vertebrate lineage following its divergence from invertebrates but, rather, that it may simply have been lost in the insect lineage. Second, one of the most interesting features of evolution is the appearance of novel structures within specific lineages which can only be understood through comparative studies using diverse organisms.

Figure 6 Simplified phylogeny of the bilateralia. Evolutionary tree indicating the relationships of the three major groups of bilateral animals. This tree is based on cladistic analysis of morphological characters and on 18S ribosomal RNA sequence-divergence data. Because of the rapid diversification of animal forms during and preceding the Cambrian radiation, the relationships at the base of the tree are not certain. The current view depicted in this tree is that the bilateralia consist of three major groups: (1) chordates (which include vertebrates and tunicates), hemichordates, and echinoderms; (2) the ecdysozoa, which includes arthropods such as insects and nematode worms such as *C. elegans*, and (3) the lophotrochozoa, which includes mollusks, flatworms, and annelid worms. The great majority of developmental studies have focused on the first two branches of the tree (chordates and ecdysozoa); there has been much less analysis of lophotrochozoan development. Further comparisons of developmental strategies and genetic pathways among these three groups will provide a much improved view of the common ancestor of the bilateralia.

Current phylogenies tentatively group metazoa in one of three major groups: deuterostomes, which include chordates (vertebrates and ascidians), hemichordates, and echinoderms, ecdysozoa (which include arthropods such as *Drosophila* and nematodes such as *C. elegans*), and lophotrochozoa (which include flatworms, annelid worms, mollusks, and other shell-enclosed organisms) (Figure 6). Conspicuously missing among the model organisms, which have been used to define developmental paradigms, are those in the large diverse group of lophotrochozoa. Studies from additional members of the ecdysozoa and chordate lineages would also provide more generality to our current views of development and should shed light on which features are truly conserved versus which independently evolved in different lineages. We briefly summarize some current evo-devo studies in other organisms that bear on the mechanistic origins of neural induction and patterning. It is important to bear in mind, however, that each of these species is also likely to have lost genes that were present in the common ancestor of bilateral animals.

In spider embryos, the DV axis is established in a very different way than in *Drosophila* or vertebrates. A small group of Dpp-expressing mesodermal cells migrates under the epidermis, leaving a linear track of overlying epidermal cells in which BMP signaling persists and which ultimately forms the dorsal midline. The spider *sog* gene is expressed in the ventral ectoderm which gives rise to the nervous system, as in other arthropods. *sog* function is required for ventral cell-fate specification, including the nervous system, because the reduction of *sog* activity by RNA interference (RNAi) results in the spread of high BMP signaling into ventral cells and the subsequent loss of ventral structures. The invasion of BMP signaling into the neuroectoderm of *sog* RNAi spiders and its suppression of neuroectodermal fates parallel the role of BMP signaling in *Drosophila* and vertebrates. Despite the difference in how BMP signaling is established in the spider embryo, the way it is employed supports the view that an ancestral role of neural inducers was to prevent BMP from spreading into the neuroectoderm and suppressing neurogenesis.

Hemichordates, which are thought to be most closely related to echinoderms, include marine worms and other sessile marine organisms that retain only a moderate degree of DV organization as a consequence of their nearly rotationally symmetric body plans. Early during development, BMP4 and Chd/Sog are expressed in opposing domains and define a DV axis in hemichordate embryos consisting of three germ

layers and distinct domains of gene expression, except for the nervous system. Unlike vertebrates and arthropods, the nervous system in hemichordates is not condensed into either dorsal or ventral ganglia but, rather, consists of dispersed neurons which send their axons into one of two major axonal bundles, one running dorsally and the other ventrally. Because neurons form around the entire circumference of these embryos, BMP signaling does not inhibit the formation of neurons in the dorsal region, nor does BMP overexpression inhibit neuron formation elsewhere. In addition, although hemichordates have recognizable counterparts of at least *vnd/Nkx2.2* and *msh/Msx*, the homologs examined so far do not display any obvious restriction in their expression along the DV axis. One possible explanation for these observations is that the neural repressive function of BMPs in vertebrates, arthropods, and spiders arose following the separation of these lineages and that the original function of BMP signaling in bilateral ancestors may have been to establish DV polarity. Alternatively, the neural suppressive function of BMP signaling may have been lost during the course of hemichordate evolution as specialization along the DV axis became greatly simplified and the animals assumed a nearly rotationally symmetric body plan. This latter view accounts for the common pattern of neural identity gene expression in vertebrates and arthropods, as well as its potential common dosage-sensitive regulation by BMP signaling. Future experiments should resolve this question, particularly by examining the expression of neural identity genes in other chordate branches and in various lineages of the lophotrochozoa, the third major branch of the metazoan evolutionary tree. When compared to the other groups, the lophotrochozoa appear to be one of the slowest evolving groups, having lost far fewer genes present in the common bilateral ancestor and typically having ventral nerve cords similar to those in arthropods, although primitive flat worms (platyhelminths) have either diffuse nervous systems or only anterior nerve nets.

In sum, the current knowledge of neural induction in diverse bilateral embryos suggests that the role of BMPs in neural induction reflects the conservation of a mechanism that evolved from a common bilateral ancestor, although it is formally possible that this may have arisen independently in several different lineages. Clearly there are species-specific aspects that have been described, but it is not clear whether this is evidence against a common origin rather than an indication that the mechanism has been lost or highly modified in various lineages. Further analysis of additional groups should resolve these issues.

A second important evolutionary question is whether the role of BMPs in patterning neural identity also originated in a common ancestor. Indeed, because vertebrates and flies share a common set of neural identity genes expressed in the same relative order with regard to a source of BMPs and because BMPs play a prominent role in patterning the dorsal region of the nervous system in both flies and vertebrates, it seems likely that neural patterning by the BMPs was a common feature of the bilateral ancestor. Clearly, other species-specific signaling pathways are also important in DV patterning of the nervous system; for example, primary morphogens involved in ventral neural patterning appear to be different in flies (i.e., Dl) and vertebrates (i.e., Hedgehog (Hh)). Nonetheless, it is tempting to speculate that BMPs once were sufficient to pattern the entire neural DV axis. According to this hypothesis, additional signaling systems were then added to buttress patterning at the low end of the BMP gradient during the divergence of the vertebrate and invertebrate lineages. Consistent with this view are experiments on DV patterning of the mouse spinal cord. When the function of the Hh signaling pathway is completely abolished (i.e., by removing both SHh and the default repressor of the Hh pathway, known as Gli3), much of the ventral pattern is restored relative to what is lost in *SHh*-single mutants. In addition, under conditions of low-level Hh signaling, the gene-expression profile in neural-plate explants can be adjusted to ventral, lateral, or dorsal levels by adding increasing doses of BMPs, indicating again that BMPs alone are able to pattern the full DV span of neural cell fates. Thus, in the early bilateral ancestors, which are believed to have been very small (less than 2-mm long), a single BMP morphogen gradient may have been sufficient to create a pattern along the entire DV axis.

DV Inversion in Vertebrates?

The fact that DV polarity of the nervous system and the circulatory system appears to be reversed in vertebrates relative to invertebrates was noted by the renowned French comparative anatomist Geoffroy St.-Hilaire, who proposed that vertebrates were essentially upside-down invertebrates (**Figure 7(a–c)**). The patterns of gene expression in vertebrates and invertebrates summarized here have led many modern evo-devo enthusiasts to support Geoffroy St.-Hilaire's hypothesis. One possible exception to the axis inversion model, however, is the head region. Comparison of gene-expression markers for eyes such as *Pax6/eyeless* (which are thought to have played an ancestral role in specifying some properties of light-sensitive organs in metazoa), as well as genes expressed in the vertebrate hypothalamus and a potentially homologous neuroendocrine organ in

Figure 7 Possible origins of dorsal–ventral (DV) axis inversion in vertebrates: (a) invertebrate DV axis; (b) vertebrate DV axis; (c) Geoffroy St.-Hilaire model; (d) and (e), alternative models. In the early nineteenth century, Geoffroy St.-Hilaire proposed that the DV axis of vertebrates was inverted with respect to that of invertebrates, based on the opposite positions of the nervous system and heart (dorsal in flies pumping anteriorly vs. ventral in vertebrates pumping posteriorly). Several scenarios have been proposed to account for the apparent axis inversion in light of recently obtained molecular data. In the original Geoffroy St.-Hilaire model (c), the entire DV axis was inverted, followed by a ventral migration of the mouth orifice. Alternatively (d), only the trunk region was rotated by 180° with respect to the head, followed by migration of the mouth opening as well. An attractive feature of this hypothesis is that it also explains why the left and right sides of the vertebrate sensory nervous system map primarily to the opposite side of the brain. Another possibility (e) is that the last common bilateral ancestor had only a condensed anterior nervous system (or brain) and that the condensed central nervous system (CNS) trunk later evolved separately (and with opposite DV polarity). This hypothesis does not account for the similar BMP-mediated mechanisms for establishing the conserved neural patterning along the DV axis.

Drosophila, suggests that the order of DV patterning in the brain might be the same in flies and invertebrates. Thus, the relative DV patterns in the head and trunk appear to be opposite. One explanation for the apparent differences in head and trunk patterning is that the anterior brain may have evolved first from an anterior net of cells and then condensed trunk nervous systems developed later and in opposite DV orientations following the split of vertebrates and arthropods (Figure 7(e)). One argument against this model is the shared DV pattern of neural identity gene expression and the dosage-sensitive regulation of these genes by BMPs, which seems difficult to imagine having evolved twice by chance. Another possible explanation is that the inversion of neural pattern was confined to the trunk and that the body was rotated by 180° with respect to the head, which remained in a fixed DV orientation (Figure 7(d)). This hypothesis could also offer a potential explanation for an otherwise puzzling feature of the vertebrate nervous system – that the primary sensory axonal projections cross from left to right (or decussate, in the jargon). In other words, the right hand maps primarily to the left sensory cortex, as does the right eye to the left visual cortex. There is no evidence for an analogous primary cross-representation in invertebrates. For example, eyes project primarily ipsolaterally in all invertebrates examined. It is also possible that apparent differences between the head and trunk reflect a sampling bias and that further analysis of additional conserved gene sets expressed in the head will support the original Geoffroy St.-Hilaire model for the full-body axis inversion. One interesting testable prediction of the head–trunk rotation model is that genes expressed along the entire anterior–posterior (AP) axis of the nervous system in a restricted DV pattern in arthropods might have opposite split DV expression domains in the head versus trunk regions of vertebrates.

Conclusion

BMPs play a similar all-or-none role in repressing the expression of neural genes in epidermal regions in vertebrates and arthropods and then play a dosage-sensitive role in establishing a conserved pattern of neural identity gene expression during early patterning of the neuroectoderm. An important question to resolve is whether BMPs function in vertebrates as they do in flies, by using threshold-dependent repression of neural identity genes in conjunction with ventral-dominant cross-inhibition among neural identity genes. Analysis of the role on BMPs in patterning the nervous systems of other organisms will provide additional information for reconstructing the elements of neural induction present in the common bilateral ancestor. Such broadened evo-devo studies will also reveal how evolutionary novelties arise in specific lineages to give rise to the rich array of neural development and function in diverse organisms.

Borderline Personality Disorder

H W Koenigsberg and L J Siever, Mount Sinai School of Medicine, New York, NY, USA; and James J Peters VA Medical Center, Bronx, NY, USA

© 2009 Published by Elsevier Ltd.

Introduction

Borderline personality disorder (BPD) is one of a set of ten discrete personality disorders – disorders affecting the characteristic and habitual ways the individual reacts to emotional stimuli, interpersonal situations, and impulses. At one time, the personality disorders were conceptualized as arising primarily from early life experience, whereas the acute, recurring, or chronic psychiatric syndromes, such as schizophrenia, depression, or bipolar disorder, were seen as having strong biological determinants. A body of work examining personality development and temperament, inheritance of personality traits, and the neurochemistry and regional brain activity in personality disorder patients has led to recognition of the role of neurobiological factors in the personality disorders.

BPD is a prevalent disorder, estimated to occur in 1% or 2% of the population. Patients with BPD are characterized by great emotional reactivity, high degrees of impulsivity, recurring self-destructive behaviors, inappropriate levels of anger, intense and unstable relationships with others, and a sense of emptiness and confusion about their own identities. As a result, their moods shift unpredictably, their relationships are stormy and tumultuous, they often alienate others, and they hurt themselves. They repeatedly threaten or attempt suicide. In the diagnostic classification system of the American Psychiatric Association, the diagnosis is made when five of nine observable features are present (Table 1).

The patterns of feeling and behaving which characterize BPD are likely to arise from the interaction between biological tendencies and developmental life experiences. Understanding the neurobiology of BPD provides a window onto one important determinant of the disorder. It may help in identifying factors that predispose to BPD, in clarifying the relationship between BPD and so-called near-neighbor disorders such as bipolar disorder, and in guiding the development of pharmacologic treatments. This article focuses on the neurobiological aspects of BPD.

Two distinct personality traits, impulsive aggression and affective instability, which appear to have strong biological correlates, co-occur in patients with BPD. Each of these traits has been shown to run separately in families of patients with BPD, and when they coincide in a relative, that individual is likely to meet criteria for a diagnosis of BPD. During the past decade, researchers have begun to tease out some key biological correlates of these personality traits.

The Neurobiology of Impulsive Aggression in BPD

Neurotransmitter Dysregulations

Serotonin Early studies of impulsive and violent suicide attempters identified lower levels of the serotonin metabolite, 5-HIAA, in cerebrospinal fluid. Autopsy studies of such subjects found increased density of serotonin (5-HT) receptors in the frontal cortex compared to nonsuicidal subjects who had died by other violent means. This work suggested that reduced serotonin function might be associated with impulsive aggression in personality disordered patients. Taking advantage of the fact that secretion of the hormone prolactin is stimulated by the action of 5-HT at serotonin receptors in the hypothalamus, the functional state of cerebral serotonin systems may be assayed *in vivo* by challenging the subject with a serotonin agonist and measuring the release of prolactin in response. A series of studies using fenfluramine, a serotonin reuptake inhibitor and releasing agent, found a diminished prolactin response following the fenfluramine challenge in personality disorder patients with a history of impulsive aggression compared to those without, and the degree of blunting in prolactin response was correlated with the extent of impulsive aggression reported by the subjects. A blunted prolactin response to fenfluramine was also observed in BPD patients compared to patients with other personality disorders. Similar findings were observed when more specific serotonin agonists were employed, such as buspirone, a partial agonist at the serotonin 5-HT_{1A} receptor; ipsapirone, a more selective 5-HT_{1A} agonist; and *m*-chlorophenylpiperazine (*m*-CPP), a 5-HT_{2A} and 5-HT_{2C} partial agonist.

These neuroendocrine studies assess the function of serotonin systems in the brain in the region of the hypothalamus. Although this provides a window into serotonergic activity in the brain, the hypothalamus is not directly involved in behavior. Functional neuroimaging studies have made it possible to measure serotonin system activity in regions of the brain that are more directly involved in the control of behavior.

Table 1 *DSM-IV* criteria for borderline personality disorder

A pervasive pattern of instability of interpersonal relationships, self-image, and affects and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following:

1. Frantic efforts to avoid real or imagined abandonment. Note: do not include suicidal or self-mutilating behavior covered in criterion 5.
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation.
3. Identity disturbance: markedly and persistently unstable self-image or sense of self.
4. Impulsivity in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, and binge eating). Note: do not include suicidal or self-mutilating behavior covered in criterion 5.
5. Recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior.
6. Affective instability due to marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days).
7. Chronic feelings of emptiness.
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, and recurrent physical fights).
9. Transient stress-related paranoid ideation or severe dissociative symptoms.

From the American Psychiatric Association (1994) *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn. Washington, DC: American Psychiatric Association.

Other neurotransmitter systems Animal studies have suggested a link between aggression and levels of vasopressin in the central nervous system. A study of personality disorder patients found a positive correlation between levels of arginine vasopressin in the cerebrospinal fluid and a lifetime history of aggression.

Norepinepherine modulates arousal level and vigilance to dangerous or threat conditions. It appears to be associated with irritability and anger and may be associated with outwardly directed aggression, but there is little evidence associating norepinepherine with impulsive aggression *per se* in BPD.

The Neuroanatomy of Impulsive Aggression

Positron emission tomography (PET) studies, which use radioisotopes to image regional brain metabolic activity, have demonstrated reduced activity in prefrontal regions that inhibit behavior. A PET study, which compared regional brain metabolic activity at baseline and after fenfluramine infusions, showed that patients with a history of aggression or impulsivity had smaller increases in activity after fenfluramine than did healthy control subjects in the orbital prefrontal and adjacent ventromedial prefrontal cortex and the cingulate cortex. A similar study using *m*-CPP as the serotonergic agonist found that patients with high levels of impulsive aggression did not show *m*-CPP activation in the left anteriomedial frontal cortex or the anterior cingulate cortex but showed greater activation in the posterior cingulate cortex compared to healthy controls (Figure 1). The rate of serotonin synthesis in brain regions may be imaged by obtaining a PET scan after administration of radiolabeled α-[^{11}C]methyl-L-tryptophan (α-MTrp). α-MTrp is an analog of the serotonin precursor L-tryptophan. It is not incorporated into the protein but is trapped in the neuron as serotonin synthesis occurs. Its irreversible trapping provides an index of serotonin synthesis. Male and female BPD patients show decreased α-MTrp trapping in the anterior cingulate gyrus and in the superior temporal gyrus compared to healthy controls. In addition, both male and female borderline patients showed a negative correlation between their scores on a laboratory measure of impulsivity and α-MTrp trapping in the medial frontal gyrus, anterior cingulate gyrus, temporal cortex, and striatum. A PET study utilizing the serotonin transporter radiotracer, [^{11}C]McN5652, demonstrated decreased transporter availability in the anterior cingulate cortex in personality disorder patients with impulsive aggression, most of whom met criteria for BPD. Taken together, these studies provide convincing evidence that in impulsive aggressive BPD patients there is a decreased responsiveness of serotoninergic neurons located in regions of the cerebral cortex that provide inhibitory control of behavior.

Genetic Contributions

Although family studies, including studies comparing concordance rates of BPD among monozygotic and dizygotic twins, suggest that genetic factors play a role in borderline personality disorder, identifying the genetic polymorphisms specific to personality disorders is a difficult undertaking because personality disorders may arise only when several genes are affected simultaneously, or there may be several different genetic pathways leading to the same personality disturbance. In addition, treating the personality disorders as phenotypes may yield phenotypes that are too heterogeneous to be associated with specific gene polymorphisms. Despite these limitations, there is

Figure 1 Horizontal slices of the brain showing regions with reduced (blue) and increased (red) metabolic activity after the administration of *m*-CPP in BPD patients compared to healthy controls. *Z* represents Talairach *z* coordinate of slice. Note the decreases in activity in the orbital frontal cortex in the patients compared to controls. Adapted from New AS, Hazlett EA, Buchsbaum MS, et al. (2002) Blunted prefrontal cortical ^{18}fluorodeoxyglucose positron emission tomography response to meta-chlorophenylpiperazine in impulsive aggression. *Archives of General Psychiatry* 59: 621–629.

suggestive evidence of associations between certain specific genes and borderline personality disorder.

Because of the role of the serotonin system in impulsive aggression, efforts to find genetic correlates of impulsive aggression have centered on candidate genes known to code for proteins involved at various stages of serotonin neurotransmission. Mice in which the gene that codes for the 5HT1B receptor has been deleted are particularly aggressive. In humans, the G allele of the 5HT1B gene has been found to be associated with a history of suicidality in a sample of Caucasian subjects with personality disorders. In another study, one particular allele of the 5-HT2A receptor gene was associated with self-mutilation in a group of personality disorder subjects and with suicide in a subgroup of males within that sample. Polymorphisms of a gene that codes for tryptophan hydroxylase, the enzyme controlling the rate-limiting step in serotonin synthesis, have also been examined for associations with aggression, but different studies have found conflicting results. Further work needs to be done to identify the genetic correlates of BPD. One promising strategy is the identification of intermediate phenotypes associated with BPD – phenotypes that may be more closely related to biological attributes of BPD than more global phenotypes such as a diagnosis of BPD or even the impulsive aggressive or affective instability phenotypes.

The Neurobiology of Affective Instability in BPD

Affective instability, the vulnerability to intense and rapid shifts in affect in response to psychosocial cues, is a defining feature of BPD and is associated with the intense anger, identity disturbance, and suicidality of borderline patients.

Neurotransmitter Dysregulations

Cholinergic systems A diverse body of evidence has implicated cholinergic systems in mood regulation. When administered to patients with depression, arecholine, an agonist at cholinergic receptors, induces increased levels of depression, anger, and hostility. The administration of physostigmine, an agent which increases cholinergic activity by inhibiting the cholinesterase enzyme, has been shown to induce depression in depressed and manic bipolar patients. Sensitivity to physostimine in healthy males, as indexed by their behavioral and cardiovascular response, correlated with the subjects' reported levels of affective lability, irritability, feelings of stress, and low life contentment. In BPD patients, infusions of physostimine induced a depressed mood, whereas it did not do so in healthy controls. Procaine, a cholinergic agonist which activates limbic structures including the amygdala, has been shown to produce a high level of dysphoria in BPD subjects. Finally, REM latency, which is under cholinergic control, is shortened and more variable in BPD patients than in healthy controls. These observations suggest that a heightened sensitivity to cholinergic activity may be associated with affective instability in BPD.

Other neurotransmitter systems The noradrenergic system modulates arousal level and vigilance to the environment. Increased noradrenergic activity could explain the heightened reactivity to environmental

stimuli seen in borderline patients. Dextroamphetamine, a releaser and reuptake inhibitor of norepinepherine as well as of dopamine, induced a level of dysphoria in a group of healthy subjects which correlated with the degree of affective lability present. A more specific assay of the functional activity of noradrenergic systems can be assessed by administering clonidine, an α_2 agonist, to subjects and measuring the level of growth hormone (GH) secretion induced, since growth hormone release is mediated by postsynaptic α_2 receptors. In patients with BPD as well as in healthy controls, but not in depressed patients, clonidine-induced GH levels correlated with subjects' ratings of irritability.

Gamma-aminobutyric acid (GABA) acts as an inhibitory neurotransmitter in the central nervous system. The amygdala, which plays a key role in the evaluation and expression of emotion, is rich in GABA receptors. These observations raise the possibility that low levels of GABA activity may be associated with affective instability. This hypothesis receives additional support from the observation that three mood stabilizers – lithium, valproate, and carbamezepine, which can reduce affective instability in BPD patients – appear to increase GABAminergic activity. However, few studies of the GABAminergic system in BPD have been carried out, so the involvement of GABA dysregulation in BPD remains conjectural.

The Neuroanatomy of Affective Instability

The amygdala plays a central role in assessing the emotional salience of stimuli and in mediating the emotional response to those stimuli. Its connections to the hippocampus enable explicit memories to trigger emotional reactions as well. These two structures may be implicated in the affective instability in BPD. Several structural imaging studies of BPD have identified decreased amygdalar and hippocampal volumes. In addition, one study found a decrease in anterior and posterior cingulate gyrus gray matter in BPD – a finding of particular interest because of the role of the cingulate in regulating emotion and impulsive action. Two studies employing functional magnetic resonance imaging to measure regional brain activity found greater activation in the amygdala and fusiform cortices in BPD patients with affective instability than in healthy controls as they viewed pictures that elicited negative emotions. These studies suggest that amygdalar dysregulation may be associated with the affective instability of BPD. It is also possible that structural or functional disturbances of brain regions upstream of the amygdala may be contributory. For example, dysfunctions of the orbital frontal cortex, a region which has inhibitory control over the amygdala, may play a role in affective instability. A pilot study of the voluntary suppression of emotional reactions to negative pictures suggested that BPD patients were less able than healthy control subjects to activate the rostral and pregenual cingulate cortex – regions involved in the regulation of emotion.

Summary

There is increasing evidence that two distinct traits which co-occur in BPD, impulsive aggression and affective instability, are associated with particular neurobiological dysregulations. Decreased serotonin activity in the orbital frontal cortex has been found in BPD patients with high impulsive aggression. Increased levels of arginine vasopressin or norepinepherine may also be implicated in impulsive aggression in BPD. Affective instability, although less well understood, may involve disturbances in cholinergic neurotransmission as well as decreased amygdalar and hippocampal volumes. Dysregulation in norepinepherine or GABA mechanisms may play a role in affective instability in BPD. The finding of decreased serotonin activity provides a neurobiologic rationale for the use of selective serotonin uptake inhibitors to reduce impulsive aggression in BPD, a treatment shown to be clinically effective. A promising next step in research on the neurobiology of BPD would be the identification of clinically valid biological intermediate phenotypes of BPD. Such intermediate phenotypes may help in identifying genetic correlates of BPD. In addition, functional imaging of BPD patients as they process affective stimuli should help us to better understand the mechanisms of affective instability in BPD. As the neurobiological correlates of BPD are better understood, we will be better able to formulate developmental models of the disorder which integrate biological and environmental factors.

Botulinum and Tetanus Toxins

T Lang, University of Bonn, Bonn, Germany
R Jahn, Max-Planck-Institute for Biophysical Chemistry, Göttingen, Germany

© 2009 Published by Elsevier Ltd.

Introduction

Bacteria of the genus *Clostridium* produce so-called clostridial neurotoxins (CNTs) that represent nature's most toxic proteins. They include seven botulinum neurotoxins (BoNTs; indicated with letters from A to G) and tetanus toxin (TeNT). CNTs are composed of three functional protein domains, which reflect the multistep mechanism by which they block neurotransmitter release. The three domains include a binding and a translocation domain, which are linked by a disulfide bond to an enzymatic domain with zinc-endopeptidase activity. Once released into the bloodstream, the binding domain binds with high specificity and affinity to presynaptic membranes of neuromuscular junctions. Neurospecific binding is followed by receptor-mediated endocytosis into acidifying vesicular compartments, and acidification triggers the translocation domain to expose the enzymatic domain into the reductive milieu of the cytosol in the nerve terminal. The disulfide bond is cleaved, leading to activation of the catalytic domain. In the cytosol of the nerve terminal, block of neurotransmitter release is achieved by cleavage, and thereby interfering with the function, of so-called SNARE proteins that represent the core of the synaptic vesicle fusion engine. Whereas botulinum toxins directly block the invaded nerve terminal causing muscle paralysis (botulism), the intracellular pathway of TeNT is different: after endocytosis, TeNT-containing vesicles are retrogradely transported to the dendrites of the motor neuron. Here, the toxin is released, crosses the synaptic cleft, and enters the nerve terminals of inhibitory interneurons. As a result, motor neurons are hyperexcited, resulting in muscle cramps (tetanus). Since approval by the US Food and Drug Administration in 1989, botulinum neurotoxin A has been proven to be an effective drug for treating muscle hyperactivity and spasticity disorders. It is also widely used in cosmetics to eliminate wrinkles.

Clostridial Neurotoxins

The genus *Clostridium* comprises a group of diverse gram-positive, anaerobic eubacteria that can form endospores resistant to heat and chemicals. Some strains are extremely prolific in producing neurotoxins. They include *Clostridium tetani*, which produces TeNT (causing tetanus), and certain strains of *Clostridium botulinum*, *Clostridium barati*, and *Clostridium butyricum*, which produce the seven known BoNTs, termed BoNT/A, BoNT/B, BoNT/C1, BoNT/D, BoNT/E, BoNT/F, and BoNT/G (causing botulism). Apart from neurotoxins, some *Clostridae* produce toxins causing severe infections such as gas gangrene. Animals that are killed by the toxins serve as anaerobic fermenters for the strictly anaerobic bacteria, a fact that is thought to constitute the main evolutionary advantage of the toxins for the bacteria. When the nutrients of the cadavers are consumed, *Clostridia* sporulate and the spores are dispersed into the environment. In the case of *C. tetani*, spores germinate in deep wounds or skin ruptures that are sealed from air exposure, followed by toxin production in the bacterial cytosol. The toxin is released into the bloodstream by autolysis of the bacteria and then reaches the presynaptic terminals of motor neurons. In contrast, botulism is caused only rarely by wound infection with spores (wound botulism). Instead, the major route of poisoning is consumption of food contaminated with spores of BoNT-producing bacteria. After ingestion, BoNTs evade proteolysis and denaturation in the digestive tract. This is due to the fact that unlike TeNT, BoNTs are secreted in complex with other proteins (some with hemagglutinating activity) that presumably protect the toxin during the passage of the stomach. In the intestine, the slightly alkaline pH causes dissociation of the toxin complexes and the free BoNTs enter the blood vessels through transcytosis. Finally, similar to TeNT, they bind to nerve terminals of motor neurons.

CNTs Domain Composition

All eight CNTs are homologous proteins with similar domain structure that are probably derived from a common ancestor. CNTs are composed of three functionally distinct domains, each of which performs a particular task during intoxication. Toxins are synthesized as single-chain polypeptides of approximately 150 kDa. The polypeptides are posttranslationally cleaved by a single proteolytic cut to yield dichain molecules (Figure 1) composed of a 50 kDa light chain (LC) and a 100 kDa heavy chain (HC) linked by a disulfide bond. The LC carries the catalytic activity that leads to block of neurotransmitter release, and the HC is required for binding, internalization, and transfer of the LC into the neuronal cytosol. This 'division of labor' between a catalytically active polypeptide and a separate domain that mediates internalization is shared with other bacterial toxins, such as diphtheria toxin, cholera toxin, and anthrax toxin,

Figure 1 CNT domain composition. CNTs are composed of three major functional domains which mediate neurospecific binding to presynaptic membranes of motor neurons (cyan), membrane translocation from endocytic compartments into the cytosol of the nerve ending (dark purple), and proteolysis of proteins driving synaptic vesicle fusion (pink). The proteolytic domain is located on the 50 kDa light chain that is C-terminally attached via a disulfide bond to the 100 kDa heavy chain. The domain has a zinc-endopeptidase activity that is activated upon cleavage of the disulfide bond in the cytosol of the nerve terminal. The heavy chain contains the domains for neurospecific binding and for translocation from acidifying endocytic compartments into the cytosol of the nerve ending (in the case of TeTx, endocytic compartments migrate to the neuron dendrites where the toxins transsynaptically intoxicate interneurons). The binding domain can be further subdivided in two domains, each providing a separate binding site.

Figure 2 Mechanism of CNT intoxication. The CNT binding domain (cyan) interacts with corresponding receptors at the surface of presynaptic neurons at neuromuscular junctions. Binding is followed by endocytosis involving clathrin-coated vesicles. BoNT-containing vesicles remain in the nerve terminal, whereas vesicles with TeNT are retrogradely transported to the dendrites where they enter transsynaptically inhibitory interneurons. In any case, the endocytosed vesicular structures acidify, triggering membrane insertion of the H_NC domain (dark purple) accompanied by translocation of the light chain (LC; pink) across the membrane. The reductive milieu of the neuronal cytosol reduces the disulfide bond connecting the light and the heavy chain, activating the cleavage activity of the LC. The active toxin can diffuse to its targets (SNARE proteins) localized at the plasma or synaptic vesicle membrane. Proteolysis of SNAREs inhibits synaptic vesicle fusion. The LCs of different CNTs cleave the three different SNAREs involved in neuronal exocytosis at different positions within the SNARE motif.

each of which causes cell damage or cell death by a different enzymatic mechanism.

The HC is composed of two functionally different domains of approximately equal size. The C-terminal domain (H_CC) contains two subdomains and mediates highly selective binding to synaptic plasma membranes. Binding is followed by endocytotic uptake of the toxin, resulting in internalization. Upon acidification of the endocytotic organelle, the N-terminal domain of HC (H_NC) mediates translocation of the catalytic domain into the synaptic cytoplasm. The N-terminally localized LC possesses a catalytic center with a zinc-dependent endopeptidase activity. The zinc ion is coordinated by means of side chain interactions of a conserved zinc-binding HExxH motif that is characteristic for zinc proteases. The dichain molecule shows no enzymatic activity. For activation, the disulfide bond connecting the LC with the HC needs to be reduced, which occurs in the reductive milieu of the presynaptic cytoplasm.

Mechanisms of Intoxication

The mechanisms of synapse invasion and of intoxication are very similar for all CNTs, although the intracellular routes differ between TeNT and the botulinal toxins. For the BoNTs, the steps include: (1) neurospecific binding to the surface of presynaptic motor neurons, (2) internalization into acidifying endocytic compartments, (3) translocation from these compartments into neuronal cytosol, and (4) proteolytic activity in the nerve terminal that causes block of neurotransmitter release (Figure 2). For TeNT, additional steps are involved between steps 2 and 3. Despite the overall similarities in the intoxication mechanism, there are differences between the individual CNTs with respect to surface receptors and the intracellular proteolytic targets of the LCs.

Binding

TeNT and BoNTs bind to the surface of peripheral nerve terminals by means of their respective H_CC domains. Binding occurs at femtomolar concentrations and with very high specificity. Both

polysialogangliosides and specific neuronal surface proteins serve as receptors for toxin binding, but there are differences between the individual toxins. In the H_CC domain of TeNT, two different polysialoganglioside binding sites have been identified. By contrast, BoNT/A and BoNT/B have only a single high-affinity polysialoganglioside binding site that, in addition, differs from those present in TeNT. Furthermore, it is becoming clear that the proteins involved as toxin coreceptors are different. TeNT binds to the GPI-anchored surface protein Thy-1, but due to the high-affinity interaction with gangliosides, efficient invasion does not depend on the coreceptor. In contrast, luminal domains of synaptic vesicles have been invoked as coreceptors for BoNTs, including synaptotagmins I and II for BoNT/B and-G and SV2 for BoNT/A. Hence, a combined receptor model has been proposed for BoNTs which involves a low- and a high-affinity binding site provided by gangliosides and synaptic vesicle proteins, respectively. As part of the synaptic vesicle membrane, the surface exposure of both synaptotagmin and SV2 is increased during synaptic activity, in line with the observation that BoNTs preferentially bind to the surface of active neurons.

Internalization

Once bound to the surface of peripheral nerve terminals, CNTs are internalized by clathrin-mediated endocytosis into acidifying vesicular compartments. For this process, the H_CC domains appear to be sufficient. For some CNTs, it has been shown that high-frequency stimulation of neurotransmitter release increases toxin internalization, indicating that CNTs exploit the endocytotic pathway of synaptic vesicles. This notion is supported by the fact that both synaptotagmins and SV2s serving as coreceptors for BoNTs are synaptic vesicle proteins. However, the exact nature of the toxin-carrying endocytotic compartments and their relation to early and recycling endosomes and to recycling synaptic vesicles is unclear. Furthermore, the reasons for the different intracellular pathways taken by BoNTs and TeNT have remained elusive. BoNTs largely remain within the nerve terminal they invade, a feature that has been exploited in their clinical use as safe drugs for blocking muscle excitation in a highly localized fashion. In contrast, TeNT-containing vesicles are transported retrogradely along the axon toward the dendrites of the motor neurons. Here, the toxin is released by postsynaptic exocytosis (transcytosis) and subsequently endocytosed by the nerve terminals of glycinergic interneurons that are then inhibited. What is the reason for this difference? It is possible that TeNT and BoNTs are internalized by different organelles or differentially sorted after endocytosis. Alternatively, the toxins may share a common entry pathway but TeNT then generates a signal that triggers vesicle binding to microtubule-dependent motors involved in retrograde transport, thus separating it from BoNT-containing vesicles that would remain inside the presynaptic terminal.

Translocation

As mentioned previously, the exact nature of CNT uptake compartments is unknown, but there is general consensus that these compartments acidify by the activity of the vacuolar proton pump after internalization. Like other bacterial toxins that translocate enzymatically active domains into the cytoplasm, CNTs undergo a major pH-dependent structural rearrangement that predominantly involves the H_NC domain (translocation domain). As a result, the toxin is converted from a water-soluble conformation into a conformation in which hydrophobic segments are exposed on the surface. It is assumed that in this conformation the toxin can permeate the lipid bilayer of the endocytic compartment. Evidence for a mechanism involving the formation of hydrophilic pores has been provided by studies showing that the H_NC domains of TeNT and BoNTs form ion channels in artificial and biological membranes at low pH. These channels probably operate as protein-translocating channels that transfer the catalytic domain across the vesicle membrane into the cytosol of the nerve terminal. Alternatively, the channel-induced permeability changes could lead to osmotic lysis of the CNT-containing organelles, thereby releasing the toxin into the cytosol of the nerve terminal. In any case, the released toxin is not active unless the catalytic domain refolds in the neutral environment of the cytosol, and the interchain disulfide bond is completely reduced.

Proteolysis

The LCs of CNTs are proteolytic enzymes that are solely responsible for the toxin action in inhibiting neurotransmitter release. Unlike other neurotoxins that function as channel or receptor blockers, the enzymatic nature of CNTs allows for elimination of many targets by a single CNT molecule. It is thus conceivable that a single CNT molecule suffices to inactivate a nerve terminal, which may be one of the reasons why the CNTs are by far the most potent of all known natural toxins.

The molecular mechanism by which the CNTs inactivate neurotransmission is well understood. All CNTs are metalloproteases with an extraordinary substrate specificity. The toxins exclusively cleave

three synaptic membrane proteins termed syntaxin 1, SNAP-25, and synaptobrevin 2 (or VAMP2). These proteins belong to the SNARE superfamily of proteins that function as catalysts of membrane fusion in intracellular vesicle traffic and exocytosis. A characteristic feature of all SNAREs is a conserved stretch of 60–70 amino acids arranged in heptad repeats termed SNARE motif. Syntaxin 1 and synaptobrevin 2 contain a single SNARE motif adjacent to the C-terminal transmembrane domain. In contrast, SNAP-25 lacks a transmembrane domain and contains two SNARE motifs that are separated by a palmitoylated linker. Although many details are unclear, the overall mechanism by which SNAREs mediate membrane fusion is well understood. Prerequisite for fusion is that complementary SNAREs must reside in the membranes destined to fuse. In the synapse, synaptobrevin 2 resides in the membrane of synaptic vesicles, whereas syntaxin 1 and SNAP-25 are in the presynaptic plasma membrane (Figure 3). During exocytosis, the four SNARE motifs provided by the three SNAREs form a tight complex that pulls the opposed membranes together, thus overcoming the energy barrier separating the two membranes and finally leading to membrane fusion.

All CNTs block neurotransmitter release by executing a single proteolytic cut within the SNARE motifs, thereby arresting the process of synaptic vesicle fusion. With the exception of BoNT/C1 (which cleaves syntaxin 1 but also has weak activity for SNAP-25), each of the toxins is specific for only one of the three neuronal SNARE proteins: BoNT/A and -E cleave SNAP-25, whereas TeNT and the remaining BoNTs cleave synaptobrevin 2. Considering the common evolutionary origin of the toxin, this diversity is astounding. Even more fascinating is the fact that even the toxins specific for the same substrate cleave at different positions within the SNARE motif (with the exception of TeNT and BoNT/B, which both cleave synaptobrevin at the same site).

What is the reason for this extraordinary specificity which is highly unusual for proteases? The crystal structures of the catalytic chains of BoNTs -A, -B, and -E have revealed that overall folds and catalytic sites are largely identical, with the differences being confined to surface residues. Thus, the structures of the catalytic sites cannot explain substrate specificity. Deletion mutagenesis studies have revealed that only rather large fragments of the SNAREs are cleaved by the toxins, suggesting that substrate recognition requires extended stretches located N-terminal of the scissile bond. The crystal structure of a toxin–substrate complex (BoNT/A–SNAP-25) has been solved, revealing multiple interactions between the substrate and the toxin distal to the cleavage site (Figure 4), in line with a cooperative recognition mechanism.

Figure 3 SNARE cleavage by CNTs. All CNTs cleave specifically neuronal SNAREs, including syntaxin 1 and SNAP-25 at the presynaptic membrane and synaptobrevin 2 at the synaptic vesicle membrane. All cleavage sites (numbers indicate amino acid positions) are located within the SNARE motifs, the parts of the SNARE proteins that are involved in the formation of SNARE complexes that pull the opposed membranes closely together, leading to fusion. As a result of CNT action, SNARE complexes cannot form properly, blocking synaptic vesicle fusion and thereby neurotransmitter release.

Figure 4 Crystal structure of a CNT–SNARE complex. Crystal structure of BoNT/A-LC (yellow) in complex with the C-terminal SNARE motif of SNAP-25 (green). An array of binding sites distal from the catalytic center wraps the substrate around the light chain and determines specificity (brackets indicate prominent contact points). The catalytic center contains a Zn^{2+} ion (red sphere) and cleaves SNAP-25 (red arrow) close to its C-terminal end.

The requirement of additional binding sites is also consistent with the need for allosteric activation of the toxins' catalytic activity. Hence, the cleavage mechanism involves SNARE binding to the CNTs via the corresponding binding sites on the toxin surface that are distal to the catalytic center, a substrate-induced conformational change activating the catalytic site, the fitting of the SNARE motif into the active site, and finally the cleavage of the substrate. From structural work it is evident that the substrates fit into the active sites only as random coils, which explains why SNAREs are cleavage resistant in SNARE complexes in which they adopt an α-helical conformation. In addition, crystal structures of the holotoxins have revealed that the translocation domains hinder access of the substrate to the cleavage site, in agreement with the observation that chain dissociation mediated by reduction of the interchain disulfide bonds is a prerequisite for activity.

Motor Neuronal Intoxication and Regeneration

The release of neurotransmitter from the nerve terminal is lost a few days after intoxication of a motor neuron by a sublethal dose of BoNTs. Although CNTs efficiently block the function of the neuron, they do not affect any other cell function and they do not cause morphological changes or induce apoptosis. In addition, although the poisoned neuromuscular junction remains structurally intact, some morphological changes at the endplate are observable. Thin neuritic processes emanate from intoxicated nerve endings (terminal sprouting) or from the preterminal node of Ranvier (nodal sprouting), extending and connecting to the muscle fiber. Synaptic activity reappears in the sprouting network and functional neurotransmission recovers. At this point, the parent terminals are still completely blocked. At later times (from a few weeks to several months, depending on the type of BoNTs), the parent terminal recovers and the network of sprouting axon collaterals progressively 'loses' its activity and is retracted.

There are significant differences between the BoNTs with respect to the duration of muscle paralysis. In humans, local injections of BoNT/A, -B, -C, -E, and -F cause neuromuscular paralysis for approximately 4–6, 3, 4 or 5, 1, and 2 months, respectively. Hence, BoNT/A induces a fivefold longer inhibition compared to BoNT/E, although the same SNARE is cleaved. The reasons for these discrepancies are not fully understood. For instance, it has been suggested that the truncated SNAP-25 remaining after BoNT/A cleavage persists in the synapse, thus effectively competing with newly generated intact SNAP-25, whereas the BoNT/E truncated SNAP-25 (which is smaller) may have a shorter half-life. An alternative explanation suggests that differences in the lifetime of the corresponding LCs in the neuronal cytosol may be responsible for the differences in recovery time, with the LC of BoNT/A persisting longer than the LC of BoNT/E. Finally, some observations suggest that the truncated SNAP-25 generated by BoNT/A is replaced more slowly than that generated by BoNT/E, thus increasing the half-life of the nonfunctional SNARE fragment.

Pathologies

Clostridia are not pathogenic, but the toxins they produce cause fatal diseases. The first clinical description of CNT poisoning was documented 25 centuries ago and was caused by TeNT. Hippocrates described the symptoms of a paralyzed patient with hypercontracted skeletal muscles causing spastic paralysis, a condition that he termed tetanus (in Greek, *tetanos* means contraction). Severe intoxication with TeNT usually follows wound infection with spores of *C. tetani*. The violent and persistent spasms affect muscles of the head, trunk, and limbs and can lead to body exhaustion. Death may occur due to respiratory failure or heart failure. Spores of *C. tetani* are widespread and tetanus vaccination is compulsory in many areas of the world. However, tetanus still causes death of thousands of humans annually in countries in which regular vaccination programs are not available.

The first well-documented cases of poisoning by botulinum toxins were described in 1817 by Justinus Kerner. He reported the typical symptoms as a result of an increase in fatal food poisoning occurring in Württemberg, Germany, during the Napoleonic wars. The disease was linked to the consumption of blood sausages and termed botulism (Latin for 'sausage-related condition'). The hallmark of botulism is a generalized muscular weakness, first affecting ocular and throat muscles and later extending to all skeleton muscles. In the more severe forms, a generalized flaccid paralysis develops which ultimately causes death by respiratory failure. Currently, because sterile methods of food preservation are standardized, botulism caused by contaminated food is rare. However, occasional outbreaks occur – for instance, when home-preserved, spore-contaminated vegetables and fish are consumed or when food storage is compromised. In addition, spore-contaminated honey is known to precipitate botulism of infants. So-called infant botulism was discovered in 1976. It is caused by spores that find ideal conditions for germination in the intestines of infants. Generally, artificial respiration

keeps patients suffering from botulism alive, and full recovery occurs once neurotransmission is regenerated. Although botulism is rare in humans, fatal outbreaks of botulism are common in animal populations, particularly among birds and fish.

Pharmacocosmetics Utility

The therapeutic utility of BoNTs is based on their ability to locally block involuntary muscle activity for weeks to months with high specificity and potency. Botulinum toxin A was first approved in 1989 by the US Food and Drug Administration for treatment of three disorders (strabismus, hemifacial, and blepharospasm), and since then the number of indications has increased (including numerous focal dystonias, spasticity, tremors, and migraine and tension headaches). A recent application is the immobilization of damaged joints in preoperative and postoperative care (e.g., to reduce widening of facial scars). Here, preferentially BoNT/E is applied, which causes synaptic blockades of relatively brief duration.

For treatment, highly diluted toxin is directly injected into the hyperactive muscle. One of the primary complications of BoNT/A therapy is the development of an immune response, which counteracts the efficacy of the toxin, particularly in long-term treatment regimens. BoNT/B is used as an effective alternative for patients who no longer respond to BoNT/A. Also, side effects have been described that are caused by diffusion of toxin to neighboring muscles leading to transient and sometimes debilitating ptosis. Another 'side effect' that was first observed by ophthalmologists led to widespread application of the toxins in cosmetics. When BoNTs were used to treat blepharospasm, frown lines and facial wrinkles temporarily disappeared – an observation that resulted in increased general use of the toxins in beauty salons. More than 1 million Americans annually use BoNT/A injections for the elimination of wrinkles, thus comprising the largest market for BoNTs. Finally, the cosmetic application of toxins led to the accidental discovery that local BoNT injections decrease the frequency of migraines in some cases, leading to another field of therapeutic application of BoNTs.

Brain Adrenergic Neurons

Introduction

Following initial anatomical descriptions of brain catecholamine neurons, initially based on the Falk–Hillarp fluorescence method and subsequently confirmed with immunocytochemical localization of tyrosine hydroxylase (TH) and dopamine-β-hydroxylase (DβH), it became clear that there was a distinct population of neurons that also contained the enzyme phenylethanolamine-*N*-methyltransferase (PNMT). These PNMT-containing neurons, which have been observed in many mammalian species, contain the other enzymes required for epinephrine (EPI) biosynthesis and have frequently been referred to as adrenergic neurons. In the initial description of brain stem neurons containing PNMT-like immunoreactivity, as well as the other enzymes required for EPI synthesis, these putative adrenergic neurons were shown to exist in three distinct populations in the caudal brain stem. This article focuses on three topics related to these neurons. First, the anatomical location and connections of these neurons are presented, suggesting that these neurons are situated in a manner consistent with their involvement in control of physiological systems. Second, neurochemical aspects of these neurons are considered, leading to the conclusion that it is inappropriate to consider them as 'adrenergic' neurons. Finally, the functional characteristics of these neurons are discussed. Although these PNMT-containing neurons are found in three loose clusters in the medulla, most of the information regarding these neurons is based on one of these cell groups, the C1 cells. Throughout this article, most of the information presented is based on studies in rat, by far the most studied species in this regard, although similar neurons exist in other mammalian species including humans.

Neuroanatomical Organization of Adrenergic Neurons

Location and Architecture of PNMT-Containing Neurons

PNMT-containing neurons are classically grouped according to an alphanumeric nomenclature that defines three groups of neurons – C1, C2, and C3 – spatially segregated within the caudal brain stem. This classification schema follows from a similar convention in which A1–A17 was initially used to define topographically segregated populations of noradrenergic and dopaminergic neurons extending from caudal medulla through the forebrain to the olfactory bulb.

The C1 cell group, in close relation to the noradrenergic A1 cell group, is a component of the lateral tegmental catecholamine cell column in the ventrolateral medulla. As the name implies, the catecholamine neurons that contribute to this column are found within the ventral and lateral portion of the brain stem. The disposition of C1 with respect to the A1 noradrenergic cell group is best appreciated in sagittal sections prepared for dual localization of PNMT and TH (Figure 1). In such preparations, the A1 and C1 cell groups are visible as a continuous column extending from the spinomedullary junction rostrally to the caudal border of the facial motor nucleus. There is little overlap between A1 and C1, with a relatively sharp transition occurring at a coronal plane marking the rostral extent of the dorsal motor nucleus of the vagus nerve and the C1 cell column in rat extending approximately 2 mm longitudinally from that point. The rostral C1 cells form a phenotypically distinct component of the rostroventrolateral medulla (RVLM), a region containing neurons that innervate sympathetic preganglionic neurons in the spinal cord and are involved in cardiovascular regulation. The C1 neurons are distributed throughout RVLM but are present in largest numbers in the rostral portion of the nucleus (Figures 1(b)–1(e)). C1 cells are also found extending caudal to the RVLM. The dendritic arbors of C1 neurons are extensive when viewed in the coronal plane and extend in all directions from the multipolar somata, which approximate 20 μm in widest diameter (Figures 1(c)–1(e)). Horizontal and sagittal sections through the nucleus confirm that the largest radial extent of dendritic fields of individual neurons is in the coronal plane.

The C2 and C3 cell groups are both found in the dorsal aspect of the caudal brain stem (Figures 2 and 3). C2 neurons reside within the nucleus of the solitary tract (NTS), principally at intermediate and rostral levels of this complex cell group (Figure 2(b)). The largest population of C2 neurons is found in the intermediate portion of the NTS that is adjacent to the area postrema (Figures 2(b) and 2(e)). The PNMT immunopositive neurons in this area are approximately 10 μm in widest diameter, densely concentrated in a dorsolateral subdivision of NTS, and give rise to restricted dendritic arbors that are largely confined to the area of cell aggregation. A second group of

Figure 1 The location and morphology of neurons contributing to the C1 cell group are illustrated. (a) The location of C1 in the ventrolateral medulla is shown by the red boxed area in the sagittal diagram, approximately 2.0 mm lateral from the midline. (b) Dual localization of PNMT and TH in the sagittal plane reveals that C1 neurons co-localizing these enzymes (and thus appearing yellow) extend caudally from the facial nucleus (CN VII) for approximately 2 mm. (c, d) Rostrally, these neurons are largely coextensive with the cardiovascular regulatory nucleus of the rostral ventrolateral medulla. The morphology of these neurons in coronal sections through three representative planes through rostral, intermediate, and caudal levels of C1 is shown in (c)–(e). The approximate location of the coronal planes for each of these figures is indicated in (b). (a) Adapted from the Paxinos and Watson rat brain atlas.

PNMT immunopositive neurons is present in the rostral third of the NTS, rostral to the area postrema (Figures 2(b)–2(d)). Although fewer in number compared to the aforementioned neurons, these neurons are larger in size and give rise to more extensive dendritic arbors. The cell bodies of the most rostrally situated neurons are concentrated along the borders of the NTS and their dendrites project differentially into the NTS (Figures 2(b) and 2(c)). Based on location, morphology, and relative staining intensity of PNMT and TH, the caudal and rostral clusters of C2 neurons might represent distinct anatomical and functional subgroups.

C3 neurons are located medially to the more rostrally situated subset of C2 neurons and extend more rostrally (Figure 3(b)). They form a column in relation to the medial longitudinal fasiculus on either side of the midline. The C3 group is similar to that of C2 in that it is composed of two subgroups of neurons that are distinguished by their location and cytoarchitecture. One subset of C3 neurons forms a compact bundle immediately subjacent to the ependymal lining of the fourth ventricle (Figures 3(b)–3(d)). The perikarya of these neurons approximate 10 μm in widest diameter. In the coronal plane, these neurons appear to give rise to a very limited dendritic arbor (Figure 3(b)), but horizontal sections through this cell group reveal an extensive dendritic arbor with a rostrocaudal orientation (Figure 3(c)). The second subgroup of C3 neurons is characterized by larger multipolar perikarya. These neurons are widely dispersed around and below the medial longitudinal fasiculus and give rise

Figure 2 The location and morphology of neurons contributing to the C2 cell group are illustrated. (a) The location of C2 in the caudal and dorsal medulla is shown by the red boxed area in the sagittal diagram, approximately 1.0 mm lateral from the midline. (b) Dual localization of PNMT and TH in the sagittal plane reveals that C2 neurons co-localizing these enzymes (yellow) occupy intermediate and rostral levels of the nucleus of the solitary tract (NTS) and are spatially separate from the A2 noradrenergic cell group (red). The morphology of C2 neurons in coronal section through three representative planes through rostral, intermediate, and caudal levels of NTS is shown in (c)–(e). The approximate location of the coronal planes for each of these figures is indicated in **Figure 3(b)**. (d, e). Note the dense terminal arbor concentrated in the dorsal motor nucleus of the vagus (DMV). (a) Adapted from the Paxinos and Watson rat brain atlas.

to a large dendritic arbor that is most extensive in the coronal plane (**Figure 3(d)**).

Distribution of PNMT-Containing Afferents

Terminal arbors immunopositive for PNMT, although extending through the rostrocaudal extent of the neuraxis, are considerably more restricted than those observed with immunocytochemical localization of TH or DβH. The densest terminal arbors are found within the hypothalamus, medulla, and thoracic spinal cord. Spinal cord afferents are sequestered principally within the column of sympathetic preganglionic neurons. The densest concentrations of PNMT-containing afferents in the medulla are observed in the dorsal motor vagal complex and within the area of C1 neurons. The plexus within the dorsal vagal complex is particularly dense within the motor nucleus of the vagus (**Figures 2(d) and 2(e)**). However, a plexus of moderate density is also present at intermediate and caudal levels of the NTS, whereas the rostral NTS contains only sparse terminals (**Figures 2(c)–2(e)**). The most prominent plexus in the rostral medulla and midbrain is found within the ventrolateral periaqueductal gray matter. Within the hypothalamus, particularly dense terminal arbors are present in the perifornical subdivision of the lateral hypothalamic area, within the parvicellular subdivisions of the paraventricular nucleus, and in the periventricular region surrounding

Figure 3 The location and morphology of neurons contributing to the C3 cell group are illustrated. (a) The location of C3 in the dorsal medulla rostral to the dorsal vagal complex is shown by the red boxed area in the sagittal diagram, approximately 0.1 mm lateral from the midline. (b) Dual localization of PNMT and TH in the sagittal plane reveals that C3 neurons co-localizing these enzymes (yellow) are concentrated in two distinct groups that differ in location and morphology. The A2 neurons appear red because they contain TH but not PNMT. (b, d) Neurons immediately subjacent to the ependymal lining of the fourth ventricle form a compact aggregation above the medial longitudinal fasciulus (mlf). When viewed in horizontal section (plane of section marked by red arrows in b and d), the neurons exhibit an extensive dendritic arbor (c; PNMT stained green). The second group of neurons is larger and dispersed more widely in columns parallel to the midline. These neurons are multipolar and give rise to radiating dendrites that are best viewed in the coronal plane (d). (a) Adapted from the Paxinos and Watson rat brain atlas.

the organum vasculosum of the lamina terminalis. Arbors of moderate density are present in the dorsomedial hypothalamic and arcuate nuclei. It is notable that the diencephalon also contains a plexus of moderate density in the thalamic paraventricular nucleus. The densest concentration of fibers in the limbic forebrain is found within the bed nucleus of the stria terminalis. Sparse terminal arbors are present in the central amygdaloid nucleus, the nucleus accumbens, and the anterior olfactory nuclei.

Circuit Organization of the PNMT-Containing Neuronal Cell Groups

The afferent and efferent connections of the PNMT-containing cell groups are not well-defined because the disposition of these cell groups has made them difficult to analyze with conventional tracers. Chief among the difficulties in this regard is the fact that the neurons are interposed among other heterogeneous noncatecholaminergic cell populations. Thus, demonstration of afferents to areas containing

PNMT-containing neurons cannot be equated with synaptic input to those neurons without ultrastructural analysis. This approach has been used to identify afferents to C1 and C2, but it is clear that there is much to be learned regarding the identity of the afferents that regulate the activity of these brain stem neurons.

Retrograde tracing has proven to be more informative in defining the projection targets of brain stem PNMT-containing neurons. It is well established that C1 neurons are a prominent contributor to reticulospinal projections that exert regulatory influence over sympathetic outflow, and it has also become apparent that C2 and C3 contribute to this projection. Additionally, retrograde tracing has documented ascending projections of all three PNMT-containing cell groups to the hypothalamus. Nevertheless, the contribution of the PNMT-containing cell groups to the catecholamine innervation of these projection targets, which is known to also arise from PNMT-containing cell groups, has been impossible to determine with classical anterograde tracers since they do not discriminate among phenotypically distinct populations of neurons. This technical limitation has been circumvented by the development of a lentivirus expression system in which a synthetic DβH promoter controls the expression of a green fluorescent protein reporter gene. Using this phenotypically restricted expression of a reporter that fills axons, the distribution of C1 efferents has been mapped in detail, demonstrating that these neurons project to many central sites involved in autonomic regulation. Given the spatial separation of the C2 and C3 cell populations from other catecholamine cell groups, it should also be possible to use this method to map the distribution of their efferent projections.

Cellular and Molecular Biology of Adrenergic Neurons

Since the time of the initial characterization of the brain stem PNMT-containing neurons, it was clear that they contained the other enzymes required to synthesize EPI (TH, aromatic amino acid decarboxylase, and DβH) and these neurons have often been referred to as adrenergic neurons. However, there is reason to believe that they might not utilize EPI as a neurotransmitter or even synthesize it in appreciable quantities.

The first sign that something might be amiss with the synthesis of EPI in these 'adrenergic neurons' might have been that levels of EPI are not as high as might be expected. For example, in the rat C1 area the levels of norepinephrine are more than an order of magnitude higher than the levels of EPI. This holds for the terminal fields as well, where EPI levels in terminal fields of PNMT-containing neurons are much lower than might be expected based on the density of the PNMT-containing terminals. In the hypothalamus, especially the paraventricular nucleus, there is a substantial input from brain stem PNMT-containing neurons but EPI levels are surprisingly low compared to norepinephrine levels.

Understanding the route and location of EPI synthesis in the hypothalamus is complicated by the existence of PNMT-containing cells that do not contain the other enzymes required for catecholamine synthesis. Nonetheless, EPI in the hypothalamus is dependent on ascending projections from the brain stem; transection of the brain at the level of the colliculi eliminates hypothalamic EPI levels, although it does not appreciably decrease PNMT levels. Furthermore, the catecholamine neurotoxin 6-hydroxydopamine, which does not destroy PNMT-containing catecholamine neurons because they do not express membrane catecholamine transporters, nonetheless eliminates hypothalamic EPI levels. The most straightforward explanation for hypothalamic EPI levels, as initially proposed by Ivan Mefford, is that EPI is synthesized from norepinephrine released in the hypothalamus, which is then N-methylated by the local PNMT-expressing cells with the resulting EPI then being taken up into terminals of classical noradrenergic neurons (Figure 4). This EPI could then be stored and released in a depolarization-induced, calcium-dependent manner, as is the case with sympathetic nerve terminals exposed to high circulating levels of EPI released from the adrenal gland.

In the spinal cord, the situation is somewhat clearer because all of the PNMT activity can be explained by PNMT terminals of PNMT-containing brain stem neurons. In the area of the intermediolateral cell column in the spinal cord, despite an abundant innervation by PNMT-containing nerve terminals, there is essentially no detectable EPI. In contrast, the levels of norepinephrine are at least 1000-fold higher, even though approximately half of the DβH-containing terminals also appear to contain PNMT. (Although some studies have reported low levels of EPI in rat spinal cord, specificity problems with the various assay methods could easily account for this finding.)

If nerve terminals of brain stem PNMT-containing neurons have all the enzymes necessary to synthesize EPI but still do not make EPI, one question that arises is why they do not synthesize EPI. One possibility for why EPI is not synthesized in these cells is that the

Figure 4 Putative mechanism for the presence of EPI in noradrenergic nerve terminals in hypothalamus. The putative mechanism for EPI synthesis and storage in the hypothalamus involves the synthesis of EPI from norepinephrine in the extracellular fluid, with the EPI then taken up and stored in terminals of noradrenergic neurons. Tyr, tyrosine; DA, dopamine; EPI, epinephrine; PNMT, phenylethanolamine-*N*-methyltransferase; NE, norepinephrine; TH, tyrosine hydroxylase; AAAD, aromatic amino acid decarboxylase; Vmat, vesicular monoamine transporter; DβH, dopamine-β-hydroxylase; NET, norepinephrine transporter.

Figure 5 Putative explanation for why EPI synthesis does not occur in PNMT-containing neurons. In this model, PNMT is present in the cytoplasm and norepinephrine, which is synthesized and sequestered in synaptic vesicles, does not again access to PNMT. The gray line represents a step that is not thought to occur. Tyr, tyrosine; DA, dopamine; NE, norepinephrine; EPI, epinephrine; PNMT, phenylethanolamine-*N*-methyltransferase; TH, tyrosine hydroxylase; AAAD, aromatic amino acid decarboxylase; Vmat, vesicular monoamine transporter; DβH, dopamine-β-hydroxylase.

enzymes are compartmentalized in the neuron in such a way that PNMT does not have an opportunity to methylate norepinephrine (Figure 5). In the adrenal medulla, where EPI-synthesizing enzymes are present in great abundance, DβH is an intravesicular enzyme, whereas PNMT is cytoplasmic. This compartmentalization appears to be similar at other sites. This raises the issue of how norepinephrine, which is synthesized from dopamine inside synaptic vesicles, exits the vesicle, is N-methylated by PNMT, and then reenters the vesicle. Although mechanisms exist to transport catecholamines from the cytoplasm into vesicles (i.e., the vesicular monoamine transporter), there is no known transporter that would mediate transport in the opposite direction. This would allow norepinephrine to be made in vesicles but prevent cytoplasmic PNMT from converting it to EPI. This scenario would predict that PNMT-containing nerve terminals would contain norepinephrine, which appears to be the case.

In this scenario, how could the adrenal chromaffin cells synthesize EPI? Surprisingly, viewed in the context of this compartmentalization, it is not clear how EPI could be synthesized even in adrenal chromaffin cells, in which EPI synthesis most certainly does occur. Clearly, there is something about this well-accepted biosynthetic pathway that is yet to be understood. As noted previously, in the hypothalamus, EPI might be synthesized from norepinephrine that is released from vesicles. However, chromaffin cells lack a plasma membrane catecholamine transporter, so the norepinephrine must be generated intracellularly and gain access to the cytoplasm.

A second question that arises as a result of the PNMT-containing neurons not synthesizing EPI is why they have PNMT and the other biosynthetic enzymes. Because there are no data that bear directly on this issue, any suggestion is pure speculation. One possibility is that it is necessary for PNMT to be expressed during development, possibly as a developmental cue. In this regard, it is interesting to note that in rats (and presumably other species) PNMT-containing neurons are vastly overexpressed early in development and then are pruned to adult numbers during early postnatal maturation. Another possibility is that PNMT expression is regulated along with certain other proteins. It is interesting to note that PNMT-expressing catecholamine cells (both adrenal chromaffin cells and central nervous system neurons) lack a plasma membrane catecholamine transporter, suggesting that the presence of one might be a regulatory corequisite of the absence of the other.

As noted previously, the PNMT-containing catecholamine neurons might synthesize and store norepinephrine. Furthermore, this stored norepinephrine might be releasable upon stimulation, as suggested by a decrease in norepinephrine levels in the thoracic intermediolateral cell column in response to high-frequency electrical stimulation of the C1 area. The release of norepinephrine along with the absence of a plasma membrane catecholamine transporter in these neurons suggest that norepinephrine released from these neurons might have a longer duration action and a wider area of influence than with more classical noradrenergic neurons. However, the neurotransmitter phenotype of

these neurons is not limited to a catecholamine. The PNMT-containing catecholamine neurons all express the vesicular glutamate transporter VGLUT-2, suggesting that they are glutamatergic. Furthermore, a variety of neuropeptides, most notably neuropeptide Y, also exist in subpopulations of these PNMT-containing neurons.

Functional Aspects of Adrenergic Neurons

Functions of PNMT-containing neurons are not well elucidated, in part because of a lack of tools to study them. Initial attempts to clarify the actions of these neurons were based on the use of drugs to inhibit PNMT. However, two significant issues hampered such studies. First, all of the early PNMT inhibitors had additional potent effects, most notably blockade of α-adrenergic receptors. Second, although these drugs might block the conversion of norepinephrine to EPI, the neurons could continue to release norepinephrine, and this switch from EPI to norepinephrine may not have major consequences for the receptor. Based on the understanding that these neurons might not synthesize EPI, this approach is even less useful. The PNMT-containing cell groups are not discrete homogeneous populations, interfering with experimental approaches to manipulate these cells. Furthermore, the classical catecholamine neurotoxin 6-hydroxydopamine does not destroy these neurons because they lack a plasma membrane catecholamine transporter.

Three approaches have allowed the study of the functional involvement of these neurons. First, the anatomy of the PNMT-containing neurons has allowed suggestions of their functions. For example, C1 cells projecting to the region of sympathetic preganglionic neurons in the spinal cord are located in a region of the ventrolateral medulla involved in cardiovascular regulation. Thus, the jump to suggesting that these C1 neurons might be involved in cardiovascular regulation is a small one. Functional suggestions based on neuroanatomy received support from the use of expression of early response genes, such as c-fos, as anatomical markers of neurons activated by various stimuli. Consistent with a role of the C1 cells in cardiovascular regulation, these neurons express Fos in response to hypotension. Second, electrophysiological characterization of the response properties of the neurons helps to clarify their function. With the development of juxtacellular labeling to allow phenotypic characterization of the recorded neuron, it became possible to describe the firing properties of these neurons in response to a variety of stimuli. Finally, studies have used an immunotoxin consisting of an antibody to DβH conjugated to saporin to selectively destroy DβH-containing neurons, including those that also contain PNMT; injecting this toxin into the area of the C1 neurons selectively destroys these cells.

Using these three approaches, a functional role of C1 cells is beginning to emerge, but the more sparse C2 and C3 groups remain relatively unstudied. Here, we provide a brief review of the potential functions of C1 neurons.

C1 neurons were first suggested to be important in cardiovascular regulation because of their anatomical overlap with the region of the RVLM critical for the supraspinal drive of sympathetic vasomotor tone, their projections to the region of sympathetic preganglionic neurons, and their sensitivity to cardiovascular perturbations. These general observations have been confirmed and refined during the past 20 years since the critical importance of the RVLM in cardiovascular regulation was widely acknowledged. The rostral group of C1 cells certainly has neuroanatomical connections and response properties consistent with their involvement in cardiovascular reflexes. However, they are intermingled with neurons that also have response properties consistent with a role in cardiovascular regulation. Furthermore, the electrophysiological characteristics and spinal cord pharmacology are consistent with the non-C1 population potentially playing a more dominant role. With the development of anti-DβH saporin toxin, it has been possible to selectively destroy the C1 population in the RVLM and examine the consequences for cardiovascular regulation. Substantial depletions of C1–RVLM neurons produce a decrease in resting mean arterial pressure of approximately 10 mmHg and attenuate sympathoexcitatory cardiovascular reflexes. The response properties of the ascending C1 neurons, projecting primarily to hypothalamic regions, are generally similar to those of the spinally projecting C1 neurons and therefore may play a role in the integration of sympathetic responses with behavioral and neuroendocrine outputs. The activation of C1 cells to a variety of stressful stimuli is consistent with this notion.

Summary

Despite the initial discovery of brain stem PNMT-containing catecholaminergic neurons more than 25 years ago, surprisingly little is known about these neurons. They appear to function within the brain circuits involved in autonomic regulation and integration of autonomic, behavioral, and endocrine responses. The broad appreciation of their anatomical connections is being refined with newly developed techniques but remains consistent with a role of these neurons in autonomic regulation. Finally, the initial

notion that these PNMT-containing neurons are adrenergic neurons is being questioned as more is learned about their neurochemistry.

Brain Asymmetry: Evolution

A W Toga, K L Narr, P M Thompson, and E Luders, University of California at Los Angeles School of Medicine, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

The structural and functional specialization of the two cerebral hemispheres has warranted a tremendous amount of research during the past century. A number of everyday occurrences, whether we are consciously aware of them or not, provide evidence for asymmetrical behavioral traits: the foot preference of the snowboarder, the ear preference of the cell phone user, or the inclination for most people to use their right hands for fine motor activities. Neuroimaging and lesion studies of the brain confirm hemispheric specialization (or lateralization) for specific behavioral functions and show pronounced asymmetries in the structure of some brain regions in the two hemispheres.

Behavioral Traits: Language and Handedness

The most recognized manifestations of functional lateralization are the dominance of the left hemisphere for handedness and language. Approximately 90% of the population is right-handed, with the motor control of the right hand confined to brain regions in the left hemisphere that include the precentral gyrus or primary motor cortices. Observations that language is more severely impaired in response to tumors or strokes in the left hemisphere, as first reported by nineteenth-century anatomists Broca and Wernicke, also confirm that language functions are lateralized to the left hemisphere in most individuals. Specifically, the brain regions supporting language production and some aspects of syntactic processing are localized primarily in anterior left hemisphere regions that include the opercular and triangular sections of the inferior frontal gyrus (Broca's area). Language comprehension, such as understanding spoken words, is processed in the left posterior section of the superior temporal gyrus and around the temporoparietal junction (Wernicke's area). Interestingly, language dominance and handedness are not perfectly correlated. Approximately 97% of right-handers have their speech and language localized in the left hemisphere, whereas 3% demonstrate right hemisphere lateralization or bilateral language representation. These relationships degrade to 70% (right-lateralized) versus 30% (left-lateralized) in left-handed individuals.

Structural Asymmetries

Asymmetric behavioral traits and functional lateralization appear to be accompanied by hemispheric differences in brain structure. Although cursory examination of the human brain fails to expose profound left–right differences, more careful comparisons of the two hemispheres reveal a variety of asymmetric features. Macroscopic asymmetries (e.g., of fissurization) are complemented by microscopic asymmetries (e.g., of dendritic arborization) and by neurochemical asymmetries (e.g., in dopaminergic sensitivity). The first structural hemispheric differences were described in the late 1800s. They were macroscopic and concerned regions surrounding the Sylvian fissure, a deep sulcus on the lateral surface of the brain which separates the temporal lobe from the frontal and parietal lobe. Subsequently, increasingly more features of the brain have been shown as structurally asymmetric. Findings based on simple visual inspections have been confirmed and complemented by observations from manual region-of-interest analyses and from contemporary computational image analysis methods that allow whole-brain measurements. However, the results across laboratories are not always consistent, and the functional significance of structural asymmetries is not always obvious or agreed upon.

Petalias and Related Asymmetries

Among the most prominent observations of brain asymmetry are the right frontal and left occipital protrusions of the surface of one hemisphere relative to the other (Figure 1). These protrusions also induce imprints on the inner skull surface, known as petalias. Several studies have shown that these petalias are more prominent in right-handers. A second feature, sometimes regarded as separate from the frontal and occipital protrusions, is that the right frontal region is often wider than the left, whereas the left occipital region is often wider than the right (Figure 1). Another related prominent geometric distortion of the hemispheres is known as Yakovlevian anticlockwise torque. This prenatally established pattern encompasses the features described previously and includes the frequent extension of the left occipital lobe across the midline (over the right occipital lobe), bending the interhemispheric fissure toward the right (Figure 1). As a consequence, structures surrounding the right Sylvian fissure are also torqued forward relative to their counterparts on the left.

Figure 1 Petalia asymmetry. (Left) A three-dimensional rendering of the inferior surface of the human brain exaggerated to illustrate prominent asymmetries found in the gross anatomy of the two brain hemispheres. Noticeable protrusions of the hemispheres, anteriorly (R > L) and posteriorly (L > R), are observed, as well as differences in the widths of the frontal (R > L) and occipital lobes (L > R). A twisting effect is also observed, known as Yakovlevian torque, in which the left occipital lobe is splayed across midline and skews the interhemispheric fissure in a rightward direction. (Right) The magnitude and direction of hemispheric shape differences, which are estimated by measuring distances from a central point (origin) in the brain to thousands of spatially equivalent cortical surface locations in each hemisphere and by comparing these distances using an asymmetry index. The color scale illustrates anterior protrusions of hemispheric shape in the right hemisphere and posterior protrusions of hemispheric shape in the left hemisphere in one individual.

Sylvian Fissure and Related Asymmetries

At the posterior limit, the right Sylvian fissure curves upward more anteriorly than the left Sylvian fissure in the majority of brains. The Sylvian fissure also typically follows a steeper trajectory in the right hemisphere, whereas it extends further posteriorly and is longer in horizontal length in the left hemisphere (Figure 2). In addition to shape asymmetries in the Sylvian fissure, neuroscientists have noted that on the superior surface of the temporal lobe, buried within the Sylvian fissure, there is typically only one transverse gyrus in the left hemisphere, whereas there are two on the right. These transverse gyri (Heschl's gyri) constitute primary auditory cortex. In addition, the extent or area of the cortical surface posterior to the first gyrus of Heschl, a brain region known as the planum temporale (PT), exhibits a hemisphere-specific gross morphology. The PT, a structure involved in the analysis of sound amplitude and frequency, is commonly observed as larger in the left hemisphere. This leftward asymmetry appears to be related to the degree of handedness, with right-handers exhibiting stronger leftward asymmetries than left-handers. Finally, Broca's area (the pars opercularis and pars triangularis of the inferior frontal gyrus, respectively) has been shown to be larger in volume in the left hemisphere than its homolog in the right hemisphere, although opposing results exist.

Notably, the structural asymmetries of Heschl's gyri, the PT, and Broca's area – all brain regions involved in auditory processing or speech perception and production – might constitute the anatomical substrate for language lateralization. In support of this hypothesis, investigators have observed that verbal fluency and the asymmetry of the pars triangularis are correlated in subjects with above average intelligence. In addition, language lateralization appears to follow the direction of the PT asymmetry. Moreover, others have demonstrated a strong leftward PT asymmetry among subjects with left hemisphere speech representation but no consistent PT asymmetry among subjects with right hemisphere speech representation in a sample of left-handers only.

Central Sulcus and Related Asymmetries

The postcentral gyrus is shown to exhibit structural hemispheric asymmetries in the majority of individuals, where the trajectory of the postcentral sulcus

Figure 2 Sulcal asymmetry. From a lateral view, the average shape of the major sulci and fissures for 15 subjects are shown for both the left and the right hemisphere by looking through the brain. The color bar further indexes the magnitude of shape differences between matching sulci in each hemisphere. Note the typical hemispheric differences of the Sylvian fissure (longer in the left (L) and steeper and curving upward more anteriorly in the right (R)), where these asymmetries are largely mirrored in the superior and inferior temporal sulci. Finally, the trajectory of the postcentral sulcus appears to shift more anteriorly in the right hemisphere as opposed to the left hemisphere.

appears to shift more anteriorly in the right hemisphere as opposed to the left (Figure 2). This asymmetry may be associated with slope and horizontal length asymmetries of the Sylvian fissure and temporal sulci and may reflect asymmetries in the parietal operculum that complement PT asymmetries in right-handed subjects.

Whereas some neuroscientists have reported that the central sulcus is generally deeper and larger in the right hemisphere, other investigators have observed a rightward asymmetry of the central sulcus in left-handers only, or even a pronounced leftward asymmetry in right-handers. In fact, this latter macrostructural leftward asymmetry was complemented by a microstructural leftward asymmetry in neuropil volume (i.e., tissue compartment containing dendrites, axons, and synapses) in the primary motor cortex located in the precentral gyrus.

Other asymmetries have been detected in subcortical regions that are more proximal to the motor effectors. For example, the right cortical spinal tract is found to be larger than the left in 75% of subjects, and the left pyramid crosses more rostrally and is larger than the right in 82–87% of subjects. Possibly related to asymmetries in regions that supplement motor function, a rightward asymmetry in callosal regions that contain predominantly projections from the motor cortices (e.g., callosal anterior body) has been reported. Finally, anterior cerebellar volumes have been observed as larger in the right hemisphere, whereas posterior cerebellar volumes are reported as larger in the left.

Ventricular Asymmetries

Some hemispheric differences in brain structure may go unnoticed in individual subjects due to the high intersubject variability of anatomy. Population-based brain atlases overcome this problem by averaging three-dimensional models of anatomy across hundreds, or even thousands, of subjects while storing statistics on anatomic variation. Ventricular asymmetry is an example of a statistically significant effect that becomes clear in a group average brain map but is not universally apparent in individual subjects. As demonstrated in Figure 3, the left lateral ventricle is typically wider and larger than the right, and the left posterior horn is longer in normal adults. This finding is consistent with volumetric measures and may reflect rapid, asymmetric growth in the overlying language systems; it can occasionally be seen in the embryonic brain, using ultrasound, as early as 29–31 weeks postconception.

Tissue Component Asymmetries

Investigators have also examined the asymmetry of brain tissue compartments; they observed significant hemispheric differences of gray matter (GM) in frontal, temporal, parietal, and occipital regions, that include Heschl's gyrus, the PT, the amygdala, and the hippocampus (L > R), as well as in inferior and medial temporal gyrus regions, the lateral thalamus, and the anterior cingulum (R > L). Recent analyses have shown hemispheric differences with respect to the thickness of the cortex, where some regions

Figure 3 Ventricular asymmetry. The anatomy of the lateral ventricles is shown across subjects ($N = 40$) in three-dimensional view. These maps of average ventricular anatomy show that the left ventricle is larger than the right ventricle. The anatomic asymmetry is clearly localized to the occipital horn, which extends (on average) 5.1 mm more posteriorly on the left than the right. This is consistent with the petalia and torque effects described previously. This asymmetry may go unnoticed in individual subjects due to the high intersubject variability of anatomy.

Figure 4 Cortical thickness asymmetry. Statistical maps demonstrating significant hemispheric differences of cortical thickness in a large sample of subjects ($N = 60$). The left brain demonstrates leftward (L > R) asymmetries in the anterior temporal lobe, including the inferior, middle, and superior temporal gyri and the precentral gyrus extending anteriorly to adjacent regions. Two additional larger clusters favoring the left are apparent in the middle frontal gyrus and superior parietal lobe (extending more diffusely inferiorly, covering the inferior parietal lobe and supramarginal gyrus). Smaller clusters of leftward asymmetry are evident in superior frontal regions very close to the midline extending along the longitudinal fissure and in the orbital gyrus. The right brain demonstrates significant rightward asymmetries (R > L) in the posterior inferior temporal lobe and inferior frontal gyrus (comprising the pars orbitalis, triangularis, and opercularis and extending into the extreme anterior tip of the temporal lobe) and near the frontal pole. In general, leftward asymmetries are spread over larger regions than rightward asymmetries.

exhibit pronounced thickness asymmetries that resemble GM asymmetries while other regions reveal distinct asymmetries (Figure 4).

Determining Factors of Brain Asymmetries

Heredity versus Environment

Perisylvian asymmetries are already present in children. Their magnitude, however, appears to increase throughout childhood and the teenage years, even after adjusting for developmental increases in brain volume. This suggests that there may be hemispheric differences in white matter maturation, perhaps during the many regional growth spurts in myelination that occur in childhood. It is not certain which factors determine the initiation or amplification of cerebral asymmetries. It appears unlikely that hemispheric differences are solely genetically predetermined. For example, an individual's genotype may not be the only determinant for laterality because many identical twins are discordant for handedness and differ considerably in their expression of PT asymmetry. However, genetic factors appear to influence hemispheric volumes twice as strongly in right-handed

twin pairs than in twin pairs with at least one left-hander (non-right-handers). Investigators have hypothesized that the decrement in genetic control of cerebral volumes in non-right-handed twin pairs supports the existence of a 'right-shift' genotype in the majority of the population (expressed as a right hand/left hemisphere bias) that is lost in non-right-handers. Thus, genes appear to be significant contributors to brain and behavioral asymmetries, where the degree of genetic determination also depends on brain structure. For example, GM volumes in perisylvian areas are reported to be under predominantly genetic control, whereas gyral and sulcal patterns have been demonstrated as much less heritable. A number of potential nongenetic contributors to variations in brain asymmetry, including fetal orientation, hormones, and functional adaptations, are discussed later. In addition, gender-specific asymmetries and disturbances in asymmetries as may be associated with some specific diseases are explained.

Fetal Orientation

Asymmetric influences in the prenatal environment may lead to perceptual and motor asymmetries. Two-thirds of fetuses are confined to a leftward fetal position in the third trimester, with their right side facing outward. Lateralization of language perception may result from asymmetries in their auditory experience. For example, the right ear may be better positioned to discriminate high-frequency speech sounds. It has also been argued that asymmetrical vestibular stimulation *in utero* may produce behavioral motor asymmetries later in life. Finally, the exposure to ultrasound in fetal life has been suggested to increase the chances of being left-handed by approximately 30%.

Hormones

In male rats, the right neocortex is thicker than the left. Female rats, on the other hand, display a non-significant trend toward the opposite pattern. Notably, castration at birth, which prevents the flow of androgens from the testis to the brain, blocks the formation of the normal rightward brain asymmetry in male rats. Similarly, neonatal ovariectomy reverses the female pattern to the male pattern. Interestingly, maternal environmental or nutritional stress has been demonstrated to reverse the male-typical asymmetry in fetal male rats to the female pattern by both shifting and depressing a testosterone surge that normally occurs on gestational day 18. These findings suggest that levels of androgenic and ovarian sex steroids, before and after birth, play a role in modulating brain asymmetry, at least in rodents.

In humans, the hormonal determinants for sex-specific symmetries are less understood. In their widely cited theory of cerebral lateralization, Geschwind and Galaburda suggested that elevated testosterone levels might be responsible for deviations from the normal dominance pattern (i.e., right-handedness and leftward language dominance, as well as rightward visuospatial dominance). According to this theory, if testosterone levels are higher than normal *in utero*, consequences include a smaller left hemisphere and even anomalous dominance due to a delay of left-hemispheric growth. This model has been posited to explain the different maturational rates of the sexes (with females generally maturing faster) and also to explain the relative advantage males show for right hemisphere visuospatial tasks and that females show for left hemisphere linguistic tasks. It has also been used to explain the greater incidence of left-handedness in males. Finally, hormonal influences might largely determine gender-specific structural asymmetries, as outlined next.

Gender-Specific Asymmetries

Gender differences in structural asymmetries, with larger interhemispheric differences in males compared to females, have been widely replicated where sex-dependent patterns appear to be complemented by behavioral and neuroactivational scores. To explain greater functional lateralization in men compared to women, it has been suggested that either the functions of the hemispheres are less sharply differentiated in women than in men or, alternatively, that larger commissural systems in women may act to reduce the difference in lateralized response scores between hemispheres. Sex differences in brain organization, both within and between hemispheres, are thought to underlie sex differences in motor and visuospatial skills, linguistic performance, and vulnerability to deficits following stroke and other focal lesions.

With emphasis on structural asymmetries, a larger right hemisphere volume has been identified in male fetuses, but no equivalent pattern has been reported in adults. Other studies have shown a significantly deeper central sulcus in the left hemisphere than in the right, but only in male right-handers; interhemispheric asymmetry was reported absent in female right-handers. Similarly, a larger leftward GM asymmetry in males compared to females has been observed in a region posterior to the central sulcus. Possibly related to these findings, pronounced rightward parasagittal asymmetries have been detected in the anterior callosal body in males but appear to a much lesser degree in females (Figure 5). Other

Figure 5 Callosal asymmetry. Statistical maps demonstrating significant gender-specific asymmetries in a large sample of subjects (30 men and 30 women). Differences between callosal thicknesses were measured in the left and right hemispheres several millimeters apart from the midsagittal plane. Rightward asymmetries are largely increased in men, supporting the assumption of a sexually dimorphic organization of male and female brains that involves hemispheric relations and is reflected in the organization and distribution of callosal fibers.

observations of sexually dimorphic cerebral asymmetries include pronounced rightward asymmetries of the planum parietale in right-handed men compared to right-handed women, whereas left-handed subjects demonstrate the opposite pattern. Gender-dependent asymmetries of the inferior parietal lobe and PT, with males having significantly larger leftward asymmetries and females showing reversed, diminished, or no asymmetries, have also been reported. Greater lateralization of right frontal petalias (in right-handers and left-handers) and occipital petalias (in left-handers only) in men compared to women further confirm previous findings of greater frontal and occipital asymmetries in men and reductions of the typical asymmetries in women.

Although the majority of studies suggest diminished asymmetries in female brains, a number of studies also exist that either failed to detect significant gender effects with respect to hemispheric differences or revealed even more pronounced asymmetries in females. A study that analyzed hemispheric differences with respect to the thickness of the cortex observed asymmetry profiles that were similar in both sexes. Notwithstanding, hemispheric differences appeared slightly pronounced in males compared to females, albeit a few regions also indicated greater asymmetry in females compared to males.

Functional Adaptation

Experience-dependent plasticity and asymmetric behaviors may also induce different neuronal changes in the two hemispheres. In rats, the asymmetric use of only one forelimb in the postweaning period induces an asymmetrically larger neuropil volume and lower cell packing density in the motor cortex. In mice with a hereditary asymmetry in their whisker pads, a dominant right whisker pad has been associated with left paw preference. Limb preference may therefore be associated with asymmetries in sensory input, although it is not known whether this relationship is causal.

In humans, professional right-handed keyboard players who had received intensive bimanual training from early childhood are more symmetrical in hand skill tests. Moreover, the absolute length of the central sulcus appears related to the age of commencement of musical training such that those musicians who had started early in life with musical training exhibited the longest sulcus on both sides. These findings suggest that some brain asymmetries are not necessarily genetically determined and may result from lateralized motoric activity and/or sensory stimulation.

Aberrant Asymmetries and Disease

Reduced or even inverted volume asymmetries of the PT have been reported in some subjects with reading disorders or developmental dyslexia, as well as in some people with unusual right-hemispheric dominance for speech. Analogously, functional magnetic resonance imaging studies have shown a pattern of brain activation in stutterers that is shifted toward the right in both motor and auditory language areas. This may suggest an inherent difference in the way in which normal subjects and stutterers process language.

Controversy surrounds reports of altered brain asymmetry in schizophrenia. For example, it has been proposed that altered anatomical and functional asymmetries in schizophrenia constitute a genetic and evolutionary basis for the disease that has developed in concert with hemispheric specialization for language. It has also been suggested that schizophrenia

Figure 6 Cortical thickness asymmetry in schizophrenia. Statistical maps show significant hemispheric differences in cortical thickness within groups defined by sex and a diagnosis of schizophrenia ($N = 150$). The patterns of cortical thickness asymmetries appear similar in all groups (leftward asymmetries of thickness in sensorimotor and perisylvian cortices and rightward cortical thickness asymmetries in posterior temporopariteal cortices). Notably, these patterns were not shown to differ statistically in patients with schizophrenia compared to demographically similar healthy comparison subjects.

is due to an anomaly of cerebral dominance, in which an agnosic right shift gene is suggested to be a major contributor toward schizophrenia pathophysiology. Observations of altered structural asymmetries in patients with schizophrenia include the reversal of normal petalias; disproportionately reduced left hemisphere temporal lobe volumes; reduced asymmetries of the PT, the superior temporal gyrus, and the Sylvian fissure; and alterations in hemispheric gyrification indices. Findings indicating intact structural lateralization in schizophrenia, however, are not uncommon. For example, one study failed to detect schizophrenia-related changes in cortical thickness asymmetries in a large sample of schizophrenia patients compared to demographically similar healthy comparison subjects (Figure 6). Thickness asymmetries, however, were shown to vary by disease status in non-dextrals.

Some diseases appear to progress asymmetrically. Patients with semantic dementia generally show asymmetric anterolateral temporal atrophy (typically worse on the left side) with relative sparing of the hippocampal formation. In Alzheimer's disease, a spreading wave of GM loss emerges initially in entorhinal and temporal-parietal cortices, sweeping into frontal and ultimately sensorimotor territory as the disease progresses. This sequence occurs in both hemispheres, but left hemisphere regions are affected earlier and more severely. The right hemisphere follows a similar pattern approximately 2 years later (Figure 7). Furthermore, cerebrospinal fluid volumes in the Sylvian fissure appear to rise more sharply on the left than the right in patients with dementia compared to normal controls. Additional left-greater-than-right metabolic dysfunctions in a group of patients with early dementia have been observed using positron emission tomography. These disease-related asymmetries suggest either that the left hemisphere is more susceptible than the right to neurodegeneration in Alzheimer's disease or that left hemisphere pathology results in greater structural change and lobar metabolic deficits.

Evolutionary Origins of Anatomical Asymmetries

Brain Size Expansion

Increasing brain size in humans is possibly one of the driving forces in the phylogeny of hemispheric specialization. For example, it has been suggested that the massive evolutionary expansion of the brain may have resulted in a level of complexity where duplication of structures was no longer efficient. Functional incompatibility or the need for simultaneous parallel processing related to increasing cognitive capacities during the course of evolution might also constitute driving forces for the emergence of functionally separated systems. Due to competition for space within the brain, different functions might have been confined to different hemispheres (rather than to different networks within a hemisphere). As a possible consequence, the right hemisphere in humans outperforms the left in the analysis of spatial relations and also shows a tendency for global processes (e.g., with respect to attention and memory storage). The left hemisphere,

Figure 7 Asymmetrical progression of Alzheimer's disease. These maps show the average profile of GM loss in a group of patients with mild to moderate Alzheimer's disease ($N = 17$) compared to a group of healthy age- and gender-matched controls ($N = 14$). Initially, the right hemisphere (R) is much less severely affected than the left (L), but after 1.5 years the deficit progresses to encompass more of the right hemisphere.

on the other hand, is specialized in language and shows superiority in categorizing (as opposed to global processing).

Time limits associated with the transfer of information across the corpus callosum between the brain hemispheres may also favor development of unilateral networks in larger brains. It has been reported that more asymmetrical brains have a corpus callosum with a reduced midsagittal area relative to more symmetrical ones. In addition, there exists an inverse relationship between forebrain size and relative callosal size accounting for relatively smaller callosal areas in larger brains. Since smaller callosal areas may reflect fewer or thinner fibers connecting the two hemispheres, this suggests the degree of interhemispheric connectedness decreases with increased brain size.

Left-Hemispheric Dominance for Language

The evolutionary development of language in humans may have led to marked volume asymmetries in structures crucial for speech production and perception as well as for motor dominance. For example, in humans, the left PT – an extension of Wernicke's posterior receptive language area – is up to 10 times larger than its right hemisphere counterpart and is perhaps the most functionally significant human brain asymmetry. Language is commonly lateralized to the left hemisphere, and some argue that this is advantageous: (1) it avoids competition between hemispheres for control of the muscles involved in speech, and (2) it may be more efficient to transfer language information between collections of focal areas in a single hemisphere. The main pitfall in arguing that left hemisphere dominance provides an evolutionary advantage is that bilateral language representation, or rightward dominance, is also common. In addition, leftward dominance does not, in general, provide a cognitive advantage.

Left-Hemispheric Dominance for Handedness

A hypothesis first proposed by Condillac in 1746 suggests that the left hemisphere's dominance for language processing evolved from its control of the right hand. The left-hemispheric programming of skilled movement and gesture may have evolved to encompass control of the motor systems involved in speech. Broca's area, in particular, is a premotor module that sequences complex articulations that are not limited to speech. Great apes, including chimpanzees and gorillas, also have an enlarged area 44 (Broca's area). This area controls muscles of the face and vocal tract but is not as well connected with the homolog of Wernicke's area as it is in humans. It has been suggested that nonhuman primates developed a homolog of Broca's area due to a link between primate vocalization and gesture: captive apes usually gesture with the right hand as they vocalize. Research on indigenous gestural languages invented by children in Taiwan and in Nicaragua provides some evidence for the innate relation between gesture and language. Functional neuroimaging studies also suggest that deaf subjects using a gestural sign language activate many of the

systems involved in verbal language production. These congruencies in functional anatomy may support the hypothesis that verbal language evolved from gestural language as an outgrowth of the already asymmetric motor control system. It was proposed that language is a relatively recent evolutionary adaptation (not more than 200 000 years old), where the Neanderthal vocal tract was incapable of articulating the range of modern human speech sounds.

Brain Asymmetries in Nonhuman Species

Functional asymmetries in the brain were initially thought to be uniquely human, reflecting unique processing demands required to produce and comprehend language. Nonetheless, functional and structural asymmetries have been identified in nonhuman primates and many other species. For example, Japanese macaques exhibit a right ear advantage for processing auditory stimuli, passerine birds produce song primarily under left hemisphere control, and frogs utilize their left hemisphere to control clasping vocalizations. Moreover, with respect to structural asymmetries, cerebral petalias are seen in phylogenetically older primates (and other species), as evidenced by endocasts from fossilized cranial bones. Similarly, the PT asymmetry also appears in higher nonhuman primates. In most great apes, the Sylvian fissure is longer and straighter on the left side than on the right. It has also been observed that the right hemisphere is generally larger than the left in rats, mice, rabbits, and cats. Although asymmetries in nonhuman species can be strikingly similar to those in humans, asymmetries defined in animal studies may not be easy to extrapolate to humans because the precursors of language-related asymmetries in humans may not be present in other species. The mechanisms that underlie some cerebral asymmetries in humans might differ substantially from those that underpin brain asymmetry in other mammals. Notwithstanding, the existence of hemispheric differences in nonhumans indicates that brain asymmetry is neither unique to humans nor completely dependent on the development of language.

At the cellular level, age-related neurological diseases including Alzheimer's disease (AD), Parkinson's disease, and Down syndrome share the characteristics of oxidative stress. Oxidation of lipids, DNA/RNA, and proteins produces a variety of toxic compounds, protein modifications, and DNA damage. AD is the leading cause of senile dementia, and there are more than four million AD patients in the United States alone. It is estimated that by 2050, fourteen million people will be inflicted by this disease. The familial form of AD worldwide accounts for 5–10% of the cases, whereas the sporadic form ranges from 90% to 95%. The brains of sporadic as well as familial cases of AD are characterized by extensive neuronal loss, deposition of extracellular senile plaques consisting of amyloid-β (Aβ) peptide aggregates, and intracellular neurofibrillary tangles (NFTs) consisting of hyperphosphorylated tau proteins.

Aβ40–42 peptides (Aβ40–42) are formed *in vivo* through the consecutive action of β-secretase and γ-secretase on Aβ protein precursor (AβPP), whose physiological function is not yet clear. Presenilin 1 and 2 are the intermembrane aspartyl proteases that process many diverse proteins in the lipid bilayers and form the active centers of the γ-secretase enzyme. Transition metal-mediated oxidative stress plays a key role in the formation of Aβ aggregates and NFTs. Further, cell cycle re-entry followed by abnormal mitotic alterations in some neuronal cells (less than one in 10 000 at a given time) leads to their apoptosis.

Protein modifications as a result of glycation and lipid peroxidations also play a major role in the regulation of oxidative stress at sites of the lesions of AD. Antioxidants such as vitamin C and α-tocopherol (vitamin E) as well as nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin have limited protective effects against AD. In addition, metal ion chelators may also have beneficial effects for the control of the progression of neurodegenerative diseases. Among the most commonly used drugs for the treatment of the symptoms of AD are Donepezil and galantamine (also called as Razadyne; galantamine hydrobromide), which are acetylcholinesterase (AChE) inhibitors. Donepezil shows concentration-dependent inhibition of cellular proliferation in human neuroblastoma cell lines, and thus approaches in targeting cell cycle abnormalities for the treatment of AD are promising. Cholesterol and other lipids also aid in the secretion of Aβ from AβPP. Thus, cholesterol/lipid-lowering drugs are also being considered for the treatment of AD. Statins inhibit enzymes involved in the biosynthesis of cholesterol, and in addition show anti-inflammatory effects and show other beneficial effects by modulating α-secretase and β-secretase enzymes. Further, stereoisomerization of the naturally occurring L-amino acid residues of the long-lived proteins *in vivo* to D-amino acids results in the formation of proteolysis-resistant toxic peptides which may also contribute the etiology of the age-related diseases. To date, treatment effectiveness has been modest and variable among patients. While any improvement or delay of disease progression is viewed positively by families and caregivers, all drug treatments require careful monitoring and consideration of the risks and side effects.

Lipids

Lipid oxidation (also called lipid peroxidation) has consequences in aging and age-related diseases including neurological diseases such as AD and Parkinson disease. Membrane- and lipoprotein-associated polyunsaturated fatty acids upon reactive oxygen species (ROS) or reactive nitrogen species (RNS)-mediated oxidations give rise to a variety of toxic molecules including malondialdehyde, glyoxal, acrolein, *trans*-4-hydroxy-2-nonenal (HNE), and *trans*-4-oxo-2-nonenal (ONE). HNE and ONE are particularly toxic compounds to the surrounding biomacromolecules, as they can react relatively readily with cysteine-derived thiol groups and ε-amino groups of lysine units, which may result in enzyme deactivation. They can also deplete levels of intracellular glutathione, a cellular antioxidant, by Michael reactions involving the thiol group of the glutathione. Similarly, HNE deactivates glutathione peroxidase enzyme, which is responsible for detoxifying hydrogen peroxide. HNE and ONE also react with amino groups of nucleic acid-bases in DNA forming a variety of adducts, resulting in transversion mutations. HNE-derived propano adducts have been shown to exist in cerebellum and cortex of cases of AD (Figure 1).

There is strong evidence for the modulation of the activity of the γ-secretase as a function of the concentration of cholesterol and other lipids: higher cholesterol levels lead to the enhanced formation of

Figure 1 HNE-derived propano adducts are found in the brain of patients with AD.

the Aβ peptide and vice versa. Hypercholesterolemia is a risk factor for AD, as elevated concentrations of cholesterol are found in the brains of AD patients during the progression of AD, and thus cholesterol-lowering drugs are currently being developed for the treatment of AD. Statins (3-hydroxy-3-methylglutaryl-CoA reductase inhibitors) have well-established cholesterol-lowering properties and inhibit the Aβ-induced expression of interleukin-1β and inducible nitric oxide synthase (iNOS). Statins also have anti-inflammatory properties that are independent of their cholesterol-lowering effects. Although at present there are no reliable clinical data to show the effectiveness of statins in AD therapy, they are expected to attenuate the symptoms of AD by cholesterol-lowering as well as anti-inflammatory properties. Apolipoprotein E (ApoE) deficiency in AD brains impairs the lipid transport system, thereby altering lipid homeostasis in cases of AD. The cholesterol-lowering drug Probucol increases the concentrations of cerebrospinal fluid (CSF) ApoE levels and decreases the CSF Aβ1–42 levels.

Metals and Oxidations

Transition metal ions, for example, Fe^{2+} and Cu^{+}, although essential in maintaining the central nervous system, induce neuronal damage when present in excess quantities. Fe^{2+} and Cu^{+} are sources of ROS (e.g., hydrogen peroxide, hydroxyl radical, and superoxide radical anion) and RNS (e.g., nitrous acid, nitric oxide, peroxynitrite) through Fenton and related reactions. Metal ion-catalyzed reduction of molecular oxygen gives the superoxide radical anions, which are further reduced to hydrogen peroxide (H_2O_2). Although $O_2^{\bullet -}$ and H_2O_2 by themselves are relatively nontoxic, H_2O_2 may lead to the production of hydroxyl radicals (HO•) through metal ion-catalyzed Fenton reactions. The hydroxyl radicals are highly toxic to neurons and the surrounding medium. Aβ may be a source of the ROS, as it binds to Cu^{2+} and Fe^{3+}. In the presence of biological reducing agents, Cu^{2+} and Fe^{3+} are reduced to Cu^{+} and Fe^{2+}, which are mediators of the Fenton reaction forming hydroxyl radicals (Figure 2). In agreement with this, when Aβ is pretreated with the iron chelator desferrioxamine, neuronal toxicity is significantly reduced. In various animal models, the addition of trace amounts of copper, but not zinc or aluminum,-resulted in increased Aβ deposition. However, copper ions bound to Aβ can cause conformational changes that confer to it a superoxide dismutase activity, maintaining oxidative balance. Thus, the role of Aβ in the cause of oxidative stress in AD may be dependent on the metal ion homoeostasis in the surrounding medium. It is notable that although aggregated Aβ peptide in combination with associated metal ions can induce oxidative stress, the formation of Aβ itself is triggered by enhanced cellular oxidative stress, through activation of β-secretase and expression of AβPP by the activation of the AP-1 transcription factor.

There is abundant evidence showing that the oxidative stress mediated by ROS and RNS precedes the onset of the formation of Aβ and NFT in cases of AD. Serving as markers of oxidative damage during aging

and in age-related diseases such as AD, Parkinson's disease, and Down syndrome, 8-hydroxydeoxyguanosine (8-OHdG), 8-hydroxyguanosine (8-OHG), protein carbonyls, and nitrotyrosine are abundantly formed in neuronal cells, decades before the onset of the disease hallmarks, such as Aβ plaques or NFTs. Abnormal mitochondria are the source of the majority of the ROS produced in cells, and metal ions are intrinsically involved in their formation. Iron and copper ions have been demonstrated histochemically to be localized in Aβ plaques and NFTs, the main constituents of the brains of AD. Desferrioxamine (Fe^{3+} chelator), tetrathiomolybdate (Cu^{2+} chelator), and mercaptopropanol (Pb^{2+} and Hg^{2+} chelator) suppress the expression of AβPP, thus lowering the Aβ peptide secretion. Desferrioixamine and clioquinol, a Cu^{2+} chelator, have found limited therapeutic applications for AD (Figure 3). Oxidative stress may contribute to the irreversible protein aggregation associated with neuronal degeneration. For example, HNE binding to phosphorylated tau protein facilitates the *in vitro* formation of filaments. Also, oxidative stress and reactive oxygen species bring about the covalent cross-linking of tau filaments to form large aggregates that are resistant to proteolytic cleavage.

Figure 2 Reactions involving the detoxification of reactive oxygen species (ROS).

Racemization

The amino acid residues of long-lived proteins in biological tissues are progressively racemized with time, and the racemization process may be abnormally accelerated in age-related diseases. Long-lived proteins such as lens crystallin show increased amounts of D-amino acid residues, which is due to the slow racemization of the L-amino acids over time. Aspartic acid residues are especially prone to racemization. D-Asp concentrations increase with age in tissues such as dentine and may serve as estimates of the age of the individuals. In lens crystallin proteins, amino acid residues Asp151 and Asp58 are relatively more stereochemically labile. Racemization of the native L-amino acids in proteins results in the change of their conformations, resistance to proteolytic degradation, and loss of enzyme activity of the involved enzymes.

There are several reports of racemization of the Ser and Asp residues of the insoluble Aβ1–40 peptides *in vivo* during the aging process, over a 20–30 year duration. The secondary structures of the [D-Asp23] Aβ20–29 and [D-Ser26]Aβ20–29 have been shown to differ from the corresponding unracemized peptides by vibrational circulation dichroism. Purified amyloid was found to contain relatively large amounts of D-aspartate and D-serine, which may be derived from the long-lived AβPP. The Aβ peptide with racemized Ser or Asp residues, but not the unracemized peptide, is hydrolyzed by chymotrypsin-like enzymes to form soluble peptide fragments, for example, [D-Ser26]Aβ25–35, which are neurotoxic and are involved in the degeneration of hippocampal neurons in AD brains. The latter peptides are also resistant to brain proteinases.

Figure 3 The metal chelators, clioquinol, and deserioxamine, have both shown promise in clinical trials for the treatment of AD.

Conclusions

Aging and age-related diseases, in particular AD, have oxidative stress as an important pathogenic factor. ROS, derived through abnormal mitochondrial metabolism involving transition metal ions, and lipoxidation-derived aldehyde products (also implicating transition metal ions in their generation) oxidatively modify cellular proteins and exert DNA/RNA damage. Oxidative stress precedes the formation of the Aβ plaques and NFTs in AD, which in turn, through associated transition metal ions, further exacerbate the oxidative stress. Further, racemization of amino acids in the long-lived proteins, for example, AβPP in AD, may result in the formation of proteolytically stable, toxic peptides. Antioxidants and agents that would sequester the ROS and lipid peroxidation endproducts may be useful targets in the identification of drugs for age-related diseases.

Brain Connectivity and Brain Size

Types of Connectivity in the Brain

The various parts of the brain differ in their macroscopic layout and internal structure. They can have the shape of flat pieces of gray substance – such as the cerebral and the cerebellar cortex, the dentate nucleus of the cerebellum, the tectum opticum of nonmammalian species, and the vagal lobe in some fishes – or that of globular structures, such as the many thalamic nuclei or parts of the striatum. The neurons of which they are composed differ in shape, size, and patterns of ramification. Particular synaptic arrangements, such as the glomeruli in the cerebellum or the triads in the lateral geniculate body of the thalamus, can occur. In addition, the various parts of the brain differ in their internal connectivity. For example, the neurons in the cerebral cortex form a rich network among themselves, as do the neurons in the striatum. However, the two kinds of networks differ in one decisive point: the cerebral cortex forms a predominantly excitatory network, whereas the network within the mammalian striatum is mainly inhibitory. In contrast to the cortex and the striatum, most of the neurons of the main cell type in the thalamus seem not to form a network among themselves but to relay their input directly to the cortex. A similar situation is found in the cerebellar cortex: the neurons of the most numerous cell type, the granule cells, do not make any synapses with each other but relay their input to the output neurons, the Purkinje cells. These, and other characteristic features, reflect the specific function of a given part of the brain.

Brain Size and Number of Neurons

The weight of the brain of different vertebrates ranges over six orders of magnitude. In mammals, the range is five orders of magnitude: the smallest mammalian brain is that of the pygmy white-toothed shrew (*Suncus etruscus*), weighing 0.062 g, and the largest is found in the sperm whale (*Physeter macrocephalus*), weighing approximately 9500 g.

In most organs, an increase in volume is due to an increase in the number of cells, whereas the size of the cells remains nearly constant. In the brain, however, the increase in the number of neurons is much less than the increase in its volume (Figure 1). Here, the brain as an interconnected network of cells departs from the general trend of size increase in other organs. This is related to a more than proportionate increase in the fiber mass connecting the neurons in larger brains.

In this article, we elaborate on some aspects of connectivity and on their relation to brain size. We focus on two parts of the brain – the cerebral and the cerebellar cortex. A comparison of the two cortices may provide us with general rules underlying brain enlargement, and deviations thereof may hint at the specific requirements of different computational schemes.

Cerebral Cortex

Basic Connectivity

All sensory systems end up in the cerebral cortex. As in some other parts of the brain, such as the thalamus, information from different modalities enters separate regions of the cortex. However, unlike other parts of the brain, an essential feature of the cerebral cortex is its rich internal connectivity, which allows for ample mixing of the signals reaching the cortex from sensory or other systems. This is due to the fact that (1) most cortical neurons are 'interneurons' in the sense that they receive signals from cortical neurons and, in turn, relay them to other cortical neurons, and (2) most cortical neurons are excitatory and therefore capable of relaying excitation from their afferents to the neurons to which they are connected.

Two kinds of excitatory connections can be distinguished in the cortex: most of the excitatory neurons (pyramidal cells) seem to provide both – axon collaterals, which spread in the region in which the cell body is located, and distant connections to another part of the cortex via a main axon which usually runs through the white matter. Thus, there is a continuous, mainly excitatory, network consisting of axons within the cortical gray matter, as well as distant connections via the white matter.

Functional Implications

The self-connectedness of an excitatory system is unique among the major subdivisions of the brain. Functionally, it is suited for representing correlations in the outside world by correlated activity in the cortex and to incorporate these correlations (i.e., 'to learn') into the cortex by strengthening the synapses between neurons which tend to be active together, as postulated by the psychologist Hebb in 1949.

Figure 1 Brain weight as a function of total number of neurons. (All data in this article are plotted in double logarithmic coordinates.) The two data sets are based on different methods but show a similar pattern of behavior: with the exception of the human brain, the average contribution of individual neurons to the volume (weight) of the brain increases at approximately the 3/2 power of number of neurons. Circles: these data were calculated on the basis of density and volume measurements from various sources in the literature. From Braitenberg V (2001) Brain size and number of neurons: An exercise in synthetic neuroanatomy. *Journal of Computational Neuroscience* 10: 71–77. Squares: these data are based on the isotropic fractionator method. From Herculano-Houzel S, Mota B, and Lent R (2006) Cellular scaling rules for rodent brains. *Proceedings of the National Academy of Sciences of the United States of America* 103: 12138–12143.

The actual ability of a cortex to learn all possible kinds of correlations and then combine them in new ways will strongly depend on the degree of its self-connectedness, between both individual neurons and separate cortical regions. In this context, it is important to note that the ramification patterns and the distribution of synapses along the dendritic and axonal arborizations are such that individual pyramidal cells make synapses with thousands of different cortical neurons. In the mouse, the average neuron is connected to approximately 5000 other neurons. This is a small proportion of the approximately 1.6×10^7 neurons in the whole cortex of the mouse (total number in both hemispheres of neo- and allocortex), but it would theoretically suffice to connect each neuron to every other cortical neuron in two steps ($5000 \times 5000 = 2.5 \times 10^7$). In reality, a few more steps are required as has been shown by tracer injection. How is the degree of self-connectedness affected by brain size?

Number of Cortical Neurons and Connectedness

If the number of neurons contacted by an individual neuron remains constant, the fraction of neurons reached by an individual neuron decreases with an increase in the total number of neurons. In reality, this is partially compensated by an increase in the average size of the neurons with brain size – that is, an increase in the total length of axonal and dendritic ramifications and a corresponding increase in the number of synapses per neuron. The evidence for this is as follows: (1) a decrease in the density of neuronal cell bodies in the gray matter with brain size, indicating an increase in the fibers associated with each neuron; (2) no indication of a substantial change in the thickness of the fibers filling the space between the neuronal cell bodies, indicating that the length of cell processes is the main determining factor of volume; and (3) a relatively constant density of synapses in the neuropil. The exact quantitative relationships are not clear since there are few quantitative data on points 2 and 3. Point 1, the density of neurons in brains of different size, has been investigated extensively for more than 50 years but the exact relationship is still a matter of debate. However, most studies report a decrease in the density of neurons (D) with an increase in brain volume (B) of approximately $D \sim B^{-1/3}$(Figure 2). A study on rodent brains, using a method completely different from those of previous studies (Figure 2(a)), corroborates this figure. A decrease in the density of neurons with the $-1/3$ power of brain volume is compatible with an increase in the length of cell processes as the cubic root of brain volume (i.e., as the linear dimensions of the brain).

It should be mentioned, however, that the density of neurons may differ somewhat between orders or families: primates seem to have a higher density than other mammals with similar brain size (Figure 2(b)).

In the motor cortex, the average number of synapses per neuron has been found to be approximately 4.6 times higher in the macaque than in the mouse. Since the macaque has approximately 10^9 cortical neurons, this is not enough to maintain the degree of connectedness at the level of that in the mouse. After two synaptic steps, only approximately 50% of the total number of neurons could be reached from an individual neuron (in the ideal case of maximum divergence). One more synaptic step would be required in the monkey to connect each neuron to every other.

However, a constant degree of connectedness between the individual neurons in different species may not be required for a well-functioning cortex. It might be sufficient to maintain a constant degree of

connectedness between groups of neurons. An increase in the size of the groups would make this possible, as envisaged in the Braitenbergian scheme of square root compartments – a network consisting of N neurons subdivided into $\sqrt{N}$ compartments, each containing $\sqrt{N}$ neurons. Every compartment could then be connected to every other via one neuron. To maintain the same degree of connectedness between compartments in large brains, the number of neurons in each compartment would need to increase at the same rate as the number of compartments (i.e., as the square root of the total number of cortical neurons). It is interesting to note that the volume of the white matter in small and large brains is compatible with this theoretical scheme, indicating that a constant degree of connectedness

Figure 2 Continued

between groups of neurons might possibly be maintained in large brains.

Horizontal Connectivity of the Cortex and Brain Size

The increase in the volume of the cortical gray matter is mainly due to an increase in surface area. This leads to the folding of the neocortex in large brains. By contrast, the thickness of the cortex tends towards an asymptotic value of only a few millimeters with brain size. How does the large increase in cortical surface area influence the horizontal connectivity of the cortex?

In large brains, the connectivity of the cortex in its tangential plane is served by three kinds of fibers: (1) axon collaterals running tangentially within the cortical gray matter and connecting the cortex in itself up to distance of a few millimeters, (2) the U-fiber system of the white matter which follows the gyri and sulci and connects the cortex in itself up to a few centimeters, and (3) the long-distance fibers which run more deeply in the white matter and connect the various cortical lobes and the two hemispheres to each other. Figure 3 shows the approximate number of fibers in each of these three groups in the human brain. Broadly speaking, the number of fibers in each group is inversely proportionate to their average length. This suggests that they are all part of one system connecting the subdivisions of the cortical plane with each other.

Indeed, in small, lissencephalic brains, a clear-cut division into these three groups cannot be made. In some species, the distances to be bridged hardly exceed a few millimeters. In this case, much of the horizontal connectivity can be accomplished via the gray matter, and the white matter is correspondingly thin. As the number of neurons increases with brain size, both the number and the average length of fibers in the white matter increase. Correspondingly, the volume of the white matter increases considerably more than that of the gray matter with brain size (Figure 4).

It is not clear how these quantitative relations of the white substance in brains of different sizes are related to another observation, namely, that in larger

Figure 3 Distribution of the lengths of fibers connecting the human cortex in the horizontal plane. A, number of horizontal axon collaterals running within the gray matter (see inset). B, number of fibers in the peripheral white matter which follows the gyri and sulci (U-fiber system). C, cortico-cortical fibers in the remaining white matter, connecting the cortex over larger distances (including the callosal fibers). There is an inverse relationship between number of fibers in the three categories and their length. From Schüz A and Braitenberg V (2002) The human cortical white matter: Quantitative aspects of cortico-cortical long-range connectivity. In: Schüz A and Miller R (eds.) *Cortical Areas: Unity and Diversity*, pp. 377–385. London: Taylor & Francis.

Figure 2 Density of neurons as a function of brain volume. (a) Measurements by six different authors. The slopes of the individual regression lines are shown in brackets. Most regression lines show a remarkably similar slope around -1/3, despite systematic differences in density between individual studies (see data for mouse and humans). All correlations are significant. The steeper slope in the study by Herculano-Houzel et al. can be explained by the fact that the white substance was included in the density measurements. Data by Shariff refer to the motor cortex of primates, those by Bok to rodents and a rabbit, those by Stolzenburg et al. to insectivores, those by Herculano-Houzel et al. to rodents, and those by Tower and by Barasa to species from a variety of mammalian orders. Tower (from left to right): mouse, rat, guinea pig, rabbit, cat, dog, macaca, beef, man, elephant, and whale. Barasa: mouse, rat, guinea pig, rabbit, cat, dog, sheep and goat, pig, cow, horse, and man. (b) Measurements by one author (Haug) are shown for a particularly large variety of species. Regression lines are shown separately for some taxonomic groups. The overall regression line is flatter than the regression lines in a, but a slope of approximately −1/3 can also be found within cetaceans and prosimians. Higher primates show a higher density of neurons than other groups. Copyright (1987, Wiley-Liss). Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

Figure 4 Volume of the cortical white matter plotted against volume of the cortical gray matter. The increase of white matter is more than proportional to that of the gray matter. From Zhang K and Sejnowski TJ (2000) A universal scaling law between gray matter and white matter of cerebral cortex. *Proceedings of the National Academy of Sciences of the United States of America* 97: 5621–5626.

brains, both the size and the number of cortical areas are increased. The number of patches of axonal ramifications observed after a localized tracer injection also seems to increase. By contrast, the size of the patches changes only slightly.

Fiber Thickness and Conduction Time

Conduction times constitute an additional point to be considered in the discussion about connectivity and brain size. Due to the fact that the diameter of the mammalian brain varies between a few millimeters and a few hundred millimeters, conduction times should differ by the same proportion, unless they were compensated by thicker axons and correspondingly higher conduction velocity. However, this is only partially the case. Observations on the corpus callosum of mouse and monkey show that some fibers are indeed several times thicker in the monkey than the thickest fibers in the mouse. However, the majority of fibers have a similar distribution of diameters in both species, with most of the fibers having diameters less than 1 μm. As shown in 1994 by Ringo and associates, keeping conduction times in large brains as short as those in small ones in all fibers is rendered impossible by the fact that thicker axons lead to a further enlargement of brain volume. This, in turn, leads to longer conduction times and the necessity of still thicker axons. According to their calculations, in order to reduce conduction times in the human corpus callosum by 50%, the volume of human brain would have to increase by 50%.

Cerebellar Cortex

Cerebellar Connectivity

The cerebellum is present in all vertebrates but undergoes a remarkable expansion in the orders of birds and mammals. Since most of our knowledge about the cerebellum is derived from mammals, we focus on this animal class. The mammalian cerebellum is composed of a strongly folded cerebellar cortex which engulfs the white matter and the deep cerebellar nuclei. The cerebellar cortex consists of three layers: the granule cell layer adjacent to the white matter, the molecular layer at the cerebellar surface, and, in between these two, a thin layer mainly consisting of a two-dimensional array of large cell bodies, the Purkinje cells. The cerebellar cortex receives two kinds of afferents, mossy and climbing fibers, which mediate a wide variety of vestibular, somatosensory, visual, and auditory sensory modalities, as well as tectal and cerebral cortical afferents. Mossy fibers contact the granule cells that send their axons to the molecular layer where they make T-shaped ramifications, the so-called parallel fibers. The parallel fibers are unmyelinated and form excitatory synapses on their postsynaptic targets. They contact the dendritic trees of the Purkinje cells and the inhibitory interneurons of the molecular layer (the so-called basket and stellate cells) up to a distance of 2 or 3 mm from the site of bifurcation. The climbing fibers, which have their origin in the inferior olive, contact the Purkinje cells directly. The Purkinje cells, which mediate the only output of the cerebellar cortex, project to the deep cerebellar nuclei and to the vestibular nuclei.

Compared to the cerebral cortex, the cerebellar cortex stands out by virtue of its particular geometry. Externally, the parallel arrangement of the folds of the cerebellum is notable, with all of them running in a latero-lateral direction. Internally, the parallel fibers take the same course, with all of them running along the folds. In contrast, the dendritic trees of the Purkinje cells and the dendrites and axons of the basket and stellate cells ramify only in the direction perpendicular to the folds.

The majority of cell types in the cerebellum are inhibitory. However, the granule cells with their parallel fiber axons are the most numerous cells in the cerebellum and are excitatory. In contrast to the excitatory pyramidal cells in the cerebral cortex, the granule cells do not form any contacts with each other. In fact, the division of the cerebellar cortex into two major layers (the granular layer and molecular layer) has the important consequence of keeping the granule cell dendrites and their axons separate (i.e., the dendrites in the granule cell layer and the axons in the molecular layer), thus preventing them from making synapses among themselves.

Functional Implications of Cerebellar Microcircuitry

The microcircuitry of the cerebellar cortex has some important functional implications. First, the cerebellar network is a feed-forward network that hinges on the activity of the afferents that reach the cerebellum. In marked contrast to the cerebral cortex, the lack of any excitatory cerebello-cerebellar connections does not allow for sustained reverberating excitatory loops within the cerebellar cortex. Second, the parallel fibers are thin and unmyelinated and, hence, slow-conducting axons (conduction velocity of 0.3–0.5 $m\,s^{-1}$). With their branches, they contact rows of hundreds of Purkinje cells in succession, with conduction delays depending on their distances from the point of entry of the granule cell axon. Third, the spread of excitation and inhibition matches the anatomical anisotropy described previously: While parallel fibers mediate excitation along the folds, the

basket and stellate cells pass on their inhibition to Purkinje cells in a direction across the folds. The axons of these inhibitory cells are also short ranged and do not exceed 1 mm. In summary, the cerebellar circuitry performs operations on its inputs that are short ranged both in space (a few millimeters) and in time (approximately 10 ms). The short range of interaction is certainly an important feature of the computations for which the cerebellum is responsible.

Scaling of the Cerebellum with Brain Size

The surface of the cerebellum increases in parallel with the surface of the cerebral cortex (Figure 5). However, whereas the volume of the cerebral neocortex (including its white matter) increases during mammalian evolution from 15% to 75% of total brain volume, the volume of the cerebellum remains relatively constant (10–20%). Despite this lower contribution to brain volume, if the number of neurons is considered, cerebellar neurons actually comprise the majority of neurons in the brain (60–80% of all neurons from mouse to human). This discrepancy is due to two factors. First is the high density of cerebellar neurons. The density of cerebellar neurons (i.e., the granule cells) is approximately 10 times higher than the density of neurons in the cerebral cortex (e.g., in a small rodent, 10^6 granule cells mm^{-3} compared to approximately 10^5 cortical neurons mm^{-3}). Furthermore, the granule cell density is remarkably similar in brains of different size (Figure 6), in contrast to the decrease in the density of cerebral cortex neurons in larger brains. Second, the relative increase in the total volume of the cerebral cortex with brain size is largely

Figure 5 Proportional increase in the surfaces of the cerebellar and the cerebral cortex. The regression line has the following equation: $\log Y = 1.02 \log X - 0.52$ ($r = 0.95$, $p < 0.0003$). From Sultan F (2002) Brain evolution: Analysis of mammalian brain architecture. *Nature* 415: 133–134.

Figure 6 Density of granule and Purkinje cells in relation to cerebellar weight. The density of granule cells mm^{-3} does not show a significant dependence on brain size in these data (a slight decrease with brain size has been reported). By contrast, the density of Purkinje cells mm^{-2} shows a significant decrease with cerebellar weight, with a slope of approximately $-1/3$. The data for both kinds of neurons range from mouse to man and are taken from several sources. The densities of granule cells are from Smolyaninov VV (1971) Some special features of organization of the cerebellar cortex. In: Cohen MM and Snider RS (eds.) *Morphological and Biochemical Correlates of Neural Activity*, pp. 112–141. New York: Harper & Row. The data by Mwengele et al. concern total numbers of Purkinje cells. Densities were obtained by dividing these numbers by total cerebellar surface, taken from Sultan F and Braitenberg V (1993) Shapes and sizes of different mammalian cerebella. A study in quantitative comparative neuroanatomy. *Journal für Hirnforschung* 34: 79–92.

due to the strong increase in its white matter. By contrast, cerebellar white matter remains an almost constant fraction of brain volume (Figure 7).

The size and shape of granule cells are remarkably conserved across phylogeny. Granule cell soma size does not change much with brain size, in contrast to many other neuron types. The dendrites and axons of these cells are also remarkably conserved across species. The axons of the granule cells, the parallel fibers, have a constant length in different species (chicken, rat, monkey, and human) and a similar diameter. The constant size of granule cells is therefore probably an important feature related to the computations which the cerebellum performs.

Figure 7 The white matter of neocortex and cerebellum show different scaling to brain volume. The white matter of the neocortex increases more than proportionally with brain size, probably reflecting the necessity for maintaining cortico-cortical connectivity with the increase in neuron number. In contrast, cerebellar white matter comprises solely input and output fibers, which may be expected to increase proportionally with the number of cerebellar neurons. White matter volumes were obtained from Bush EC and Allman JM (2003) The scaling of white matter to gray matter in cerebellum and neocortex. *Brain, Behavior and Evolution* 61: 1–5. Total brain volumes were obtained from Brauer K and Schober W (1970) *Katalog der Säugetiergehirne*. Jena, Germany: VEB Gustav Fischer; Hofman MA (1988) Size and shape of the cerebral cortex in mammals: II. The cortical volume. *Brain, Behavior and Evolution* 32: 17–26; and Stephan H, Frahm H, and Baron G (1981) New and revised data on volumes of brain structures in insectivores and primates. *Folia Primatologica* 35: 1–29.

In contrast to the granule cells, Purkinje cell density does scale with brain size (Figure 6). The number of Purkinje cells per unit area of cortex (and therefore, to a first approximation, also per volume of cortical gray substance) decreases with brain size, with an exponent of approximately −1/3. This is similar to the decrease in neocortical neuron density described previously. It correlates with an increase in the size of the Purkinje cells with brain size, which may have to do with the fact that the Purkinje cells are the output neurons of the cerebellar cortex (i.e., they have to project over larger distances in larger brains).

The particular microcircuitry of the cerebellar cortex is also reflected in the anisotropic shape of the unfolded cerebellar surface and in the different scaling of cerebellar width and anterior–posterior length, as shown in Figure 8. Cerebellar volume increase accompanying brain size increase is mainly effected by an increase in anterior–posterior length.

Summary of Cerebral and Cerebellar Scaling

The most significant feature that the two parts of the brain have in common is their similar increase in surface area with brain size. This may partially reflect the fact that the two cortices are connected with each other both ways (via pontine nuclei and thalamus, respectively).

The main differences between the two parts of the brain are as follows:

1. Whereas in larger brains, the cerebral cortex increases in both dimensions of its surface, the cerebellar cortex increases much more in its anterior–posterior than in its latero-lateral extension. This reflects the internal isotropy of the cerebral cortex as opposed to the internal anisotropy of the cerebellar cortex. In the case of the cerebral cortex, this makes sense in connection with the two-dimensional topographic representation of space via the sensory surfaces and equal operations on them in both dimensions. In the case of the cerebellum, the spread of activity is a one-dimensional affair, suggesting a role in time phenomena. In larger cerebellar cortices, it seems to be more important to add new excitatory beams rather than to increase their length.

2. The granule cells in the cerebellar cortex are remarkably constant in the size of their cell bodies and length of their cell processes. This indicates a roughly constant number of synapses per granule cell with brain size. By contrast, the neurons in the cerebral cortex have, on average, a larger number of synapses in larger brains.

Figure 8 (a) Length and width of the unfolded cerebellar surface depend in different ways on the size of the cerebellum. Cerebellar width scales with the 1/3 power, whereas cerebellar length scales with the 2/3 power of cerebellar volume. (b) Three unfolded cerebella of a cat, sheep, and human are shown. The width of the cerebellum corresponds to the direction of the parallel fibers, whereas cerebellar length corresponds to the rostrocaudal extension of the unfolded cerebellar cortex. Data from Sultan F and Braitenberg V (1993) Shapes and sizes of different mammalian cerebella. A study in quantitative comparative neuroanatomy. *Journal für Hirnforschung* 34: 79–92.

3. One of the most striking changes with brain size is the strong relative increase in the white matter of the cerebral cortex. Although the white matter of the cerebellar cortex also increases slightly more than its gray matter with brain size, it remains a nearly constant fraction of the whole brain. This difference between the two cortices reflects the important role of cortico-cortical connections in the case of the cerebral cortex and their complete absence in the white matter of the cerebellar cortex.

Brain Damage: Functional Reorganization

J Grafman, R Zahn, and E Wassermann, National Institute of Neurological Disorders and Stroke, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

Recent research in cognitive neuroscience has made great strides in assigning behavioral functions to discrete areas of the brain and describing the knowledge, representational elements, and processes that are subserved by the tissue within their borders. Although much work remains to be done to provide a complete functional atlas of the thinking brain, one fact is generally accepted about how representational knowledge is stored. That is, the brain appears to be composed of modular networks within which a particular representational element is homogeneously represented. Such elements may range in complexity from the edge detectors, used in visual processing and stored in the occipital cortex, to high-level plan representations used to guide behavior and stored in the prefrontal cortex. To perform a cognitive or perceptual function, sets of modules are activated in concert. Thus, the human brain can be subdivided into functional modules, which must be combined to perform a task.

Neuroplasticity is a term used to describe structural and functional changes at the genetic, molecular, neuronal, system, and behavioral levels. Such changes may reflect new experience and learning or can occur as a reaction to brain damage. Although a great deal of scientific literature describes neuroplasticity at the molecular, structural, and system levels in animals, we focus on neuroplastic changes at the system level that can be observed in humans. Current thinking about systems neuroplasticity suggests that at least four kinds of neuroplastic changes operate at the representational module level after brain damage: (1) homologous area adaptation, (2) cross-modal reassignment, (3) potentiation of topographic representations, and (4) compensatory masquerade.

Homologous Area Adaptation

One form of neuroplasticity, homologous area adaptation, appears to prevail before children reach puberty and underlies the observation that damage to a particular brain region can be compensated for by shifting its functions to other brain areas, often to the homologous region of the opposite hemisphere. An implication of this mechanism is that the brain area accepting the new operation will be more 'crowded' with functional representations (both the new and the 'usual' representations are now stored in a region that before stored only the usual representation). This crowding leads to a sparser or 'lower resolution' representation of knowledge or sensory input within both modules and makes degraded performance or interference likely when the two functions are activated simultaneously. This form of neuroplastic change is reported less often in adults. This may be because regions of the developing brain are less 'committed' to specific cognitive processes, because they have not yet been encountered in school (e.g., mathematics) or demanded by the environment (e.g., complex social interactions).

We studied an adolescent who had incurred a severe right parietal lobe brain injury as a young child. Despite the severity and location of the injury, evaluation showed that the boy had developed essentially normal visuospatial function but had impaired arithmetic skills. We inferred that at the time of injury, the left parietal region assumed some of the functions normally stored in the right parietal lobe. Because most calculation skill is acquired in school, the injury and plastic change occurred before the age of arithmetic acquisition. Thus, we argued, spatial processes had claimed the left parietal region before arithmetic instruction, making it more difficult for the patient to learn and store mathematical facts. Functional magnetic resonance imaging (fMRI) of his brain activity during arithmetic processing indicated that he activated the left parietal lobe (among other regions). This finding implied that that the left parietal lobe was still programmed to store arithmetic facts even though it was now also committed to spatial processing, leading to the degradation of the subject's arithmetic ability.

Some investigators have claimed that the proportion of a functional region that is damaged determines the amount of homologous region adaptation that occurs. The underlying principle is as follows. Neighboring and homologous cortical regions have primary and secondary, or latent, functional assignments. Usually the secondary function is inhibited competitively by output from the nearby or contralateral brain region where that function is primary. Therefore, cortical regions are only able to express their secondary functions when competitive inhibition is removed. Given this logic, plasticity might be promoted by incurring complete rather than partial damage to a particular brain region, because when the damaged region is completely incapacitated, it cannot

inhibit the expression of its usual function elsewhere in the brain.

We studied another patient who suffered a large infarction that destroyed most of the left cerebral hemisphere, although he had some spared and functionally active islands of tissue in the left parietal and frontal areas. This patient could read words but not nonwords, and he had great difficulty calculating. On fMRI, word reading activated a broadly distributed network of areas in the right hemisphere. Attempts to read nonwords were unsuccessful and did not produce significant activation in either hemisphere. This suggested that the right hemisphere had assumed some functions of the left hemisphere. However, although the left hemisphere substrate for reading known words was destroyed, allowing the right hemisphere to assume its function, the additional ability to read nonwords (a crucial skill reflecting the ability to learn to read new words) did not transfer and was lost with the injury. This indicates that functional neuroplasticity may be more limited in adults. Interestingly, during fMRI scanning, while the patient was performing arithmetic fact verification, both right and left parietal lobe activation was found. However, the left parietal activation was found in locations around the periphery of the area in the brain devoted to this ability. Even with this pattern, the patient performed poorly, although his accuracy increased slightly after a week of training with a concomitant increase in cortical activation. We suspect that the remaining left parietal tissue was inadequate for accurate calculation but still inhibited the right parietal cortex from assuming more of a role in calculation.

Cross-Modal Reassignment

A second form of neuroplasticity, cross-modal reassignment, involves the introduction of new sensory inputs to a brain region that has been deprived of its main sensory input. For example, positron emission tomography (PET) and fMRI studies of tactile discrimination have shown that adults who became blind early in childhood have somatosensory input to area V1 of the occipital cortex, whereas sighted controls do not. Presumably, in the blind, such input succeeds in activating the representations stored in area V1, because the cognitive operations in that area are somewhat independent of the modality of input, and their function is helpful in making the discriminations between geometric patterns required for reading Braille characters. In this study, only tactile discrimination of Braille letters, as opposed to simply palpating fields of nonsense dots or performing verbal language tasks, activated V1 in the early blind. In contrast, in sighted people exposed to the same stimuli and tasks, the V1 activation was absent and there was evidence of decreased activation in area V1 (suggesting that recruiting the brain regions that usually process the tactile input (e.g., parietal cortex) ordinarily inhibits or depotentiates the visual system). The fact that visual cortex activation is important in Braille reading and may account for the superior ability of blind subjects was demonstrated in a study in which transcranial magnetic stimulation (TMS) was delivered over the occipital cortex. This stimulation, designed to interfere with cortical processing, dramatically impaired the performance of the early blind but not sighted or late-life blinded individuals. The fact that such cross-modal sensory plasticity is possible and requires an early lesion suggests that afferent connections from multiple sensory sources may be latent in cortical areas such as V1, which is considered by most clinicians to be rigidly assigned to visual processing. Presumably these secondary inputs atrophy over time under the competitive influence of the primary input. Undoubtedly, limits exist to this form of neuroplasticity. For example, color processing cells in the occipital cortex are so specialized for visual input that they would be unlikely to accept other forms of sensory input.

Potentiation of Topographic Representations

This form of neuroplasticity involves changes within brain regions devoted to a particular kind of knowledge or operation. Studies in the motor cortex indicate that the intracortical connections devoted to a processing function may become temporarily enhanced or even enlarged with skill acquisition or frequent exposure to a stimulus. This enhancement may, in turn, result in topographic expansion of the area of cortex devoted to the function or representation. In two studies using two different techniques (TMS and electroencephalography (EEG)), we demonstrated that repetition of a cued sequence of key presses caused increasing excitability of neurons in the representation of the performing hand in the early stages of learning while the pattern was still implicit (i.e., the subjects did not become aware of the pattern, but their responses were becoming faster). When learning became explicit (i.e., the subjects could produce it without cueing), the excitability of the hand representation returned to baseline. This type of change, measured as a larger EEG potential before movement and a larger muscle response to TMS of the hand representation, could result from topographic expansion of this representation by unmasking of latent connections within the cortex or from the cortex to the spinal cord. Although EEG

and TMS cannot measure motor map size, changes seen in fMRI studies during, and even weeks after, motor learning seem to bear this out. Evidence suggests that rapid enlargement of cortical maps can persist in individuals who develop or are trained in a particular skill that they use routinely. The meaning of map expansion is still unclear. One possible explanation for a change in map size is that continual input may overload the processing capacity of a local cortical network and signal it to expand by recruiting new neurons from adjacent tissue into the network to handle the increased load. Another possibility is that before enough synaptic change has occurred for the minimal necessary volume of cortex to perform the skill, an enlarged area of the network is recruited. With increasing practice, the system becomes more and more efficient, restricting activity to a few highly dedicated and stimulus specific neural elements.

Compensatory Masquerade

The fourth form of neuroplasticity, compensatory masquerade, means the novel use of an established and intact cognitive process to perform a task previously dependent on an impaired cognitive process. This can be a subtle change detectable only with fine-grained cognitive tasks. For example, there may be a single route from home to the office. One way to navigate that route may depend most upon spatial processes, is implicitly stored, and is performed rapidly. Another way to get to work would depend on verbal labeling of landmarks that are remembered explicitly and processed more deliberately. A large brain injury may affect both way-finding processes, but typically one is relatively spared. The patient may then be able to use the spared strategy to navigate the same route that was previously dependent on the impaired strategy. Unless a neuropsychologic study carefully evaluated both processes in some detail, an observer could be misled into thinking that a more fundamental form of neuroplasticity had occurred (e.g., homologous area adaptation).

Discussion

We have reviewed four major forms of neuroplasticity that can be studied and promoted in healthy human volunteers and patients after brain damage. The neurophysiologic processes that underlie plasticity continue to be studied at the level of synaptic physiology and ultrastructure after repeated stimulation.

Recently it has become clear that neurogenesis, synapse formation, and remodeling of axons and dendrites occur in adult human brains. Neurogenesis in adulthood appears to occur in both the hippocampus and subventricular zone. It is unclear what functional role new neurons play in previously existing networks. It would appear that neurogenesis and cortical rewiring would be ideal mechanisms to assist brain regions partially damaged by stroke and other lesions to recover their functions. However, because recovery of function after brain injury is rarely if ever complete, their contributions to recovery of function appear to be restricted. The neuroanatomical, physiological, and molecular bases of these restrictions to plasticity are the focus of intense investigation.

By focusing on the four forms of plasticity previously outlined, fundamental questions about how functional cooperation between brain regions is achieved can be asked. Why does the ability to shift functions between sites decline over development and aging? This may be the result of the necessity to stabilize connectivity between maturing brain areas dedicated to particular functions. The increasing degree and stability of this connectivity suggests that the networks themselves make a commitment to a particular functional representation. If functional substitution was permitted beyond the early stages of the formation of these networks, then continuous and substantial reorganization of distributed networks would be required for their efficient operation. Therefore, it is likely that the increasing connectivity required for learning is directly related to the increasing functional commitment of brain areas throughout life.

A second question about plasticity emerges from the observation of cross-modal activation of V1 in the early blind. Traditional notions about deafferentation lead one to expect atrophy and or 'denervation hypersensitivity' of a maladaptive kind in the visual areas of the blind. Instead, evidence suggests that the modality-independent processing capabilities of the visual cortex (e.g., discrimination of width, angles, feature conjunctions) can be used to process spatial information from more than one source. This is a remarkable departure from the idea that cortical functions are assigned to areas entirely based on input routing rather than processing architecture.

Clinical approaches to enhancing recovery of cognitive function in patients recovering from brain injury have historically been implemented in an atheoretical way. Early approaches relied simply on massed repetitive practice in various domains of function (e.g., memory, attention). More recent efforts at rehabilitation have begun to use treatments motivated by cognitive theory. Despite this increasing sophistication, there have been too few clinical trials that included large numbers of subjects or adequate controls, and most rehabilitation studies have compared programs of stimulation to supposedly neutral

interactions or to no intervention at all rather than investigating the validity of specific interventions on specific outcomes. Furthermore, the therapeutic strategies used in these studies were not always developed with systems and cognitive neuroscience findings in mind. Although some recent counterexamples exist, the rehabilitation field has often lagged behind other specialties in clinical neuroscience in adapting laboratory findings to the clinic.

Fortunately, many conceptual frameworks for neuroplasticity exist that could lead to new rehabilitation methods. We suggest that proven methods for inducing changes in the cortical topography at the network level and rerouting or unmasking latent input and output to the affected network should guide the development of new rehabilitation techniques. Testing of paradigms designed to cause and manipulate neuroplasticity in healthy volunteers and patients will help investigators find the optimal conditions for neuroplastic change. Such paradigms may also lead to 'challenge' studies using pharmacologic and other agents to enhance or prevent neuroplastic changes. Indeed, the future looks promising as we probe the limits of functional neuroplasticity in adult humans while answering fundamental questions about the stable and dynamic topography of information processing.

Brain Development: The Generation of Large Brains

S Herculano-Houzel, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

What Larger Brains Are Made Of

More Neurons

One century of comparative studies has led to the notion that larger mammalian brains are built with larger numbers of neurons whose average size increases only modestly as brain size increases. Although technical difficulties preclude precise estimates of average neuronal size, changes in this parameter can be inferred from changes in neuronal density. Compared to the large volumetric expansion of structures such as the cerebral cortex, the relatively small decrease in neuronal density (presumably a result of larger neuronal size) in the structure across species indicates that increasing neuronal size is a factor in the generation of large brains, but one that is less important than increasing numbers of neurons. For example, the brain of the capybara, a giant Amazonian rodent, is 180× larger than the mouse brain, contains 22× more neurons, but its density of neurons per unit of tissue is only 8× smaller than in the mouse. The discrepancy may be even greater in primates: although the human brain weighs 175× more than a marmoset brain and has a 162× heavier cerebral cortex, the neuronal density in this structure is only about 3× smaller in humans. This indicates that the increase in average neuronal size contributes to increasing cortical size, but is a minor factor compared to increased number of neurons, in making the human cortex much larger than the marmoset cortex. Therefore, the generation of larger brains, at least within mammalian orders, requires the generation of larger numbers of neurons during development.

More Surface

The larger cerebral and cerebellar cortices of larger brains are increased mostly in their surface area, rather than in thickness. For example, the gray matter of the human cerebral cortex is roughly 1000× larger in surface area than the gray matter of the mouse cortex, but only about 2× thicker than the latter. The addition of larger numbers of neurons to cortical structures during brain development must thus proceed in a way that privileges surface expansion rather than greater thickness of the cortical wall.

More Glia

In contrast to the decreasing neuronal density, and therefore presumably increasing average neuronal size, large brains have densities of nonneuronal cells that are fairly similar to those found in smaller brains. This suggests that the average size of nonneuronal cells does not vary much with brain size, although their total number must increase rapidly in larger brains. In rodents, the total nonneuronal cell density in the brain is only 2× smaller in the capybara than in the mouse, even though the 180× larger brain of the former species has 85× more nonneuronal cells than the latter, suggesting that nonneuronal cells are not much larger in larger brains. Thus, besides the generation of larger numbers of neurons of moderately larger neurons, the development of larger brains requires the formation of an even larger number of glial cells whose size is presumed to vary little.

Neurons First, Glia Later

Brain development follows a series of well-documented steps. Early in development, the progenitor cells that compose the proliferative zones that line the ventricles undergo a series of symmetrical divisions, which expand exponentially the number of progenitors that will eventually give rise to neurons and glial cells in the brain. These symmetrical divisions establish the size of the founder population of progenitor cells that will build the brain.

Asymmetrical divisions ensue, in which one progenitor gives rise, for instance, to one self-renewing progenitor and one proliferating cell, which will give rise to the neurons that migrate outward to form the cortical plate and the parenchyma of other brain structures. Regressive events also occur in development, and may drastically reduce the neuronal population. According to some estimates, the total number of cortical neurons may be cut in half during development due to cell death.

The glial population of the brain is formed only once the neuronal population is already in place, as cell-intrinsic mechanisms eventually promote a switch from neuronal to glial production by progenitor cells. Neurogenesis is mostly prenatal; gliogenesis extends into postnatal life.

How to Add More Neurons

If large brains have an increased number of neurons, their generation must involve the production of larger

numbers of neurons during development. This may be achieved in at least three ways: by increasing the number of progenitors, by increasing the number of neurons generated by each progenitor, and by decreasing the number of neurons lost to cell death. These processes necessarily take time, so it seems logical that large brains take longer to develop than small brains. Indeed, the neuronal population of the mouse cortex is generated over about 6 days, while it takes about 55 and 100 days to generate all neurons in the macaque and human cortex, respectively. Gestation time increases coordinately with brain size at birth, among various mammalian orders.

More Progenitors Expand the Cortical Surface

Clonal analysis has shown that the neurons generated from one single progenitor are often clustered radially in the cerebral cortex. Since larger cerebral cortices are increased mostly in surface rather than in thickness, they should be generated by a larger number of radial clusters of neurons. If each radial cluster is derived from one progenitor cell, it follows that, all other things being equal, a larger number of progenitor cells should give rise to a larger surface of cerebral cortex of an unchanged thickness, containing a larger number of radial clusters of neurons. This is the essence of the 'radial-unit hypothesis,' proposed by Pasko Rakic in 1985.

Since the population of progenitor cells is expanded exponentially by symmetric cell division, small increments in the number of divisions will give rise to much larger numbers of progenitors. With only $3\times$ extra rounds of cell division, for instance, a $2^3 = 8\times$ larger number of progenitors would be generated. If all other factors remain unchanged, these three extra rounds will generate a brain with $8\times$ more neurons. In this scenario, the $22\times$ larger number of neurons in the capybara brain could be achieved by an average 45 extra rounds of symmetric division of the early progenitor cells, prior to the generation of neurons.

Experimental data have shown that X-ray irradiation of monkey embryos during the period of symmetric division of progenitors results in a decrease in cortical surface, with little effect on its thickness. Moreover, genetic manipulations that increase the number of progenitors early in development do lead to animals with an abnormally large cortical surface.

However, the expansion of the progenitor symmetrical division is unlikely to be the sole factor that increases the number of neurons in brain structures. The radial-unit hypothesis is based on the proposition by Rockel, Hiorns, and Powell in 1980 that there is a constant number of close to 150 000 neurons underneath 1 mm^2 of cortical surface of any mammalian species. This proposed uniformity has been contested by several groups, who argue that the number of neurons underneath a given surface may vary by as much as $8\times$ among species. While the expansion of the cortical surface is a major factor in building larger brains, and may be achieved by mechanisms that increase the population of founder progenitor cells, other factors must also contribute.

More Neurons per Progenitor Thicken the Cortical Surface

If increased symmetrical divisions expand the number of radial clones that will compose the cortical surface, increased asymmetrical divisions should expand the number of neurons that compose each clone, and thus increase the thickness of the cortical wall. Accordingly, there is evidence that experimental manipulations that increase the number of neurons generated per neuronal progenitor cell do lead to thickening of the cortical wall within a single species. Comparative studies addressing the number of neurons generated per progenitor across species, however, are lacking in the literature.

Decreased Cell Death Enlarges the Brain

Cell death is a normal mechanism that regulates the number of neurons in the brain. Differentiated neurons are subject to cell death, which is generally expected to cut the neuronal population of the brain in half, but the number of progenitor cells has also been shown to be regulated by cell death. Experimental genetic manipulations that delete genes required for cell death lead to animals with abnormally large brains. However, these mutations are lethal, and it is not known whether more subtle, natural genetic modifications of the cell-death pathway are an actual mechanism in the development of large brains. Interestingly, chemical manipulations that diminish but do not abolish progenitor cell death lead to both, expansion of the cortical surface and thickening of the cortical wall. This shows that the regulation of cell death is a possible mechanism in the generation of brains of different sizes in evolution.

Natural Mechanisms Are Still Unknown

Overall, it is possible that cortical surface and thickness be regulated both independently and coordinately, by developmental mechanisms that seem to apply to other brain structures as well. However, despite the relative wealth of data on experimental manipulations that affect proliferation, differentiation, and cell death and lead to the development of abnormally larger brains, it is still unclear whether

and how these processes vary naturally among species of different brain size.

More Glia Follow

Larger brains tend to have an increased ratio of glial cells to every neuron, or g/n ratio, compared to smaller brains. Fin whales, for example, have a gray matter g/n ratio of 454, while that ratio in humans is 178. Since glial cells appear in development only once the neuronal population is formed, mostly postnatally, mechanisms that adjust the number of glial cells to the number of neurons already present in the cortical wall must be in place in development.

Glial proliferation can be influenced by neuronal activity. Because it has been widely believed that the relative glial expansion has trophic and metabolic meaning for the neuronal population, the increase in the g/n ratio with increasing brain size has often been hypothesized to be regulated directly by neuronal activity. This would take place during gliogenesis, in postnatal development. Accordingly, the neuronal activity-regulated generation of large numbers of glial cells would further expand brain size beyond the enlargement due to the generation of larger numbers of neurons.

However, the numeric expansion of glial cells relative to neurons seems to contradict the observation that the neuronal need for metabolic support remains similar across species. Moreover, the increased g/n ratio of larger brains is not accompanied by any systematic variation in glial density, as large brains have glial cells distributed as densely as in small brains. These discrepancies could be settled if, during development, gliogenesis were regulated not by neuronal activity, but mainly by the overall neuronal mass in structures such as the cortical wall. This is in line with the observation that the proliferation of glial progenitors is controlled by contact inhibition with glial cells. Gliogenesis would thus presumably ensue until the entire cortical wall was occupied by evenly distributed glia. The higher the number of neurons in the cortical wall, the larger the latter would become, and thus the larger would be the volume of tissue to accommodate proliferating glial cells. Since increasing neuronal size also contributes to making brains larger, the cortical volume to be invaded by newly born glial cells is presumably yet larger in large brains. A larger number of glial cells would thus be generated for every neuron, leading to the increased g/n ratio observed in large brains.

Genetic Regulation of Brain Size

As mentioned above, changes in brain size can be generated experimentally through the manipulation of several genes controlling cell proliferation, differentiation, and death during development. Although it is unclear how these processes vary among species, it is already established that there is variability in genes that regulate brain size across primate species, humans included. For example, cell cycle genes associated with microcephaly (MCPH1, ASPM, CDK5RAP2, CENPJ) and caspase genes controlling cell death have higher evolutionary rates in primates, particularly in great apes and humans, than in rodents or carnivores, and seem to have undergone positive selection. It is unclear, however, how these gene changes are related to brain size.

Brain Evolution: Developmental Constraints and Relative Developmental Growth

B L Finlay, Cornell University, Ithaca, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Components of the brain in mammals enlarge in large part by regular power laws based on the size of the brain overall. To transform the brain of a mouse to the brain of a chimpanzee, we can imagine that the volume or cell number of each brain component (for example, midbrain or cerebellum) or cell class (such as Purkinje cells of the cerebellum or rods in the retina) is each set by its own independent, nonlinear dial. The neocortex and the cerebellum grow with 'positive allometry' with respect to the rest of the brain, so that the larger brains become in absolute size, the progressively greater the proportion of the brain constituting neocortex and cerebellum. Conversely, the proportion that is medulla or midbrain decreases (Figure 1). The direct mechanistic cause of this conserved pattern of disproportionate but predictable growth is conservation of the order of neurogenesis across species such that structures or cell groups produced last experience the greatest expansion of the numbers of stem cells in their precursor pools in species with extended developmental periods.

Whether this conserved and disproportionate pattern of expansion of brain components is a metabolic and structural load that evolving brains must bear because of a maladaptive uniform application of a developmental program, as the word 'constraint' would suggest, is very suspect. Particularly so in that variation in size is one of the major ways that brains vary! Such conservation might better be interpreted as a mechanism that permits graceful scaling of brain function with brain size. In the same way that components of the body scale nonlinearly with body mass to compensate for the functional requirements of each organ that change lawfully at different body sizes, the brain must also scale appropriately. For example, skeletal mass in terrestrial mammals increases at a greater exponent than total body mass, particularly for supporting limbs (consider the deer, cow, and elephant), not because skeleton production is trapped by a developmental constraint requiring the animal to generate useless volumes of skeleton in supporting limbs at large body sizes, but because proportionately more cross-sectional skeletal mass is required to support the body. For skeletons and body mass, the reasons for allometric predictability are reasonably self-evident; for the relative scaling of medulla versus cortex, the underlying reasons may not be so clear and are the subject of this article.

The basic phenomena of brain component scaling will be discussed first, and then the properties of conservation and variation in developmental mechanisms that underlie conservation and variation in brain component scaling. Finally, several examples of conserved processes in neuroembryology that have the property of permitting flexible and robust conformation to commonly encountered evolutionary challenges will be considered.

Brain Scaling

Brain versus Body

The brain scales regularly with the size of the body, with an allometric exponent of about 0.75, an exponent whose cause has been the source of numerous academic debates. Therefore, as the body increases in size, the brain also increases in size, but so as to become an even smaller percentage of the body mass. As any cursory examination of office information processing devices will demonstrate that the sizes of a controller and the thing controlled are not obligatorily linked, why is there such a regular relationship in the case of the brain and the body? An obvious peculiarity of biological devices compared with engineered devices is that biological devices are composed of the elemental unit of cells, whose size is limited by diffusion and intracellular transport mechanisms, and not by the size of the body they compose. As the brain's most basic function is to move the body, and the larger bodies will be composed of a larger number of muscle units, an increase in the number of neurons will be necessary to innervate larger musculature (though axonal and dendritic arbors have a considerably greater range in possible size than a cell body does, and account for some of the range of neuromuscular scaling). Similarly, if large animals attempt to maintain the absolute spatial resolution of their skin sensation at some acceptable value (which seems reasonable, as things to be detected and localized, such as insects, cannot be depended on to scale with their prey animal's body size), the number of receptors and associated neurons transmitting information to the brain should scale with body size as well. There is no need whatever, however, to scale other sensory systems, such as eyes, ears, and vestibular organs, with body size, and yet they do scale. Larger organs

Figure 1 Comparison of the relative volumes of neocortex and brain stem in mouse (*Mus musculus*) and chimpanzee (*Pan troglodytes*) for comparable coronal brain sections. Scale bar = 0.5 cm for each. From Comparative Mammalian Brain Collections, http://brainmuseum.org.

can permit greater spatial resolution, but that causes improvement, not just maintenance, of quality. This issue will be mentioned again in the section titled 'Employment of "late equals large" to gracefully scale the retina.'

Body size does not entirely control brain size, however; at any particular body size, considering all the vertebrates, there is a possible range of about 40 in the ratio of brain to body size, and within the bony fish, birds, reptiles, and mammals, about a factor of 10 in the same ratio. While there is some arguable association of absolute brain size with behavioral complexity, in fact the two can be quite dissociable. For example, while a hummingbird could fly, collect nectar, and conduct social interactions within a space of the size of the brain case of a baleen whale, the length and complexity of the list of behaviors hummingbirds and whales might exhibit somewhat favors the hummingbird. It is relative size of the brain with respect to the body, variously measured as various ratios or statistical residual variance compared with the animal's taxon, that corresponds best to behavioral complexity or intelligence.

Brain Component Scaling

While it is relative brain size, measured best by the 'encephalization quotient,' or residual deviation from the mean brain–body size value from the appropriate taxonomic group, brain component architecture is best measured with respect to absolute brain size. This was first noted for the relative size of the cortex compared with the rest of the brain; since the cortex has predictable positive allometry with respect to the brain, the larger the brain becomes, the more it comes to be composed of cortex. As humans have the largest encephalization quotient, but not the largest brain, this means that absolutely larger brains, such as the brains of elephants and many cetaceans, are composed of proportionately more cortex than are human brains.

The cortex is not a special case of predictable scaling, however. Each identifiable brain part has its own exponent, as can be seen in the different slopes of each structure in Figure 2, which plots the slopes of six structures versus 'brain core' – medulla, pons, midbrain, and thalamus. In fact, each identifiable region of the cortex, such as visual cortex, other primary sensory cortices, and parietal or frontal cortex has its own exponent as well, which has caused a great deal of confusion about whether components of the human cortex, particularly the frontal cortex, are as large as should be 'expected.' Many would expect a simple ratio, such as the human brain as the chimpanzee brain multiplied by three, and would predict that a deviation from such a ratio should represent special selection or adaptation. A multiplicative ratio, however, is rarely the nature of the relationship between brain parts – in fact, it occurs only in the special case when the ratio of the allometric exponents of the two parts happens to be one. If the frontal cortex has a positive allometry with respect to the cortex overall, as the cortex enlarges in absolute terms, the frontal cortex will come to comprise a greater percentage of the entire cortex. Thus humans have an entirely predictable, but disproportionate, amount of frontal cortex in their brain compared with other primates.

The Limbic Factor

In the various first investigations of brain component scaling of the large data set collected by Stephan and associates, it was observed by many researchers that primates, compared with bats and insectivores, showed a 'grade shift' with respect to the amount of cortex their brains contained, producing more cortex per unit brain but relatively less olfactory bulb, olfactory cortex, and hippocampus, as well as some other components of the extended limbic system. Knowing whole brain volume captures about 94% of the variability in brain component scaling in mammals overall, and adding a second limbic component gains another 4% of the variance. Until recently, it was unclear

Figure 2 The sizes of six brain structures relative to brain stem and basal ganglia core size, across 160 species in nine taxonomic groups. The six structure sizes have been adjusted by the indicated arbitrary constants (listed on the right of the figure) to separate the six scatterplots visually. Both scales are natural log scales. The regression slopes are paleocortex (olfactory cortex), 0.826; septum, 0.847; hippocampus, 0.912; schizocortex, 0.963; cerebellum, 1.150; and neocortex, 1.441. Natural logarithm, ln. From Reep R, Darlington RB, and Finlay BL (2007) The limbic system in mammalian brain evolution. *Brain, Behavior and Evolution* 70: 57–70.

whether this differential allocation of tissue in the brain was specific to the primate–insectivore contrast or whether it was characteristic of mammalian brain variation more generally. With a sample that included marine mammals, known to have smaller olfactory bulbs, and also some species that would appear to be unusually dependent on chemosensation, such as anteaters, substantial variation along the limbic–cortex tissue allocation axis (Figure 3) has been found to be characteristic both between and within mammalian orders. This relationship was not an obligatory reciprocal relationship, however; it is possible for some animals (such as carnivores) to have both a relatively large neocortex and a relatively large olfactory bulb–hippocampus complex with respect to the brain core, or to be reduced in both (like bats), but variation on this dimension dominates the data. Unusually large amounts of variation on this same axis are true of individual variation within species as well, for species as diverse as swine, minks, and mice.

The Developmental Structure of the Observed Species Differences

A basic, conserved pattern of neurogenesis proved to underlie the consistency observed in mammalian brain component scaling. Those structures which became disproportionately large as brains became absolutely larger were the same structures and cell groups whose 'birthdays' were late. That is, those structures whose precursor pools had an extended time to enlarge before the first of their cells exited the precursor pool and differentiated as neurons were the same ones that became differentially large. We call this relationship 'late equals large,' and it falls directly out of the kinetics of cell proliferation in the developing embryo, which we represent in its most generalized form in Figure 4. This figure represents the empirical observation that cell division begins roughly simultaneously in all parts of the neural tube that will give rise to the mammalian brain, but neurogenesis terminates in some parts earlier than others. When neurogenesis is extended from the 21 days or so required to generate a mouse brain to the 100 or so required for a monkey, the consequences for different brain components are not uniform: the regions withdrawing neurons the latest from their precursor pools allow those regions to see more cell divisions and become substantially larger.

The strength of this relationship brings forward some essential regularities about mammalian brain development observed empirically. First, the brain acts as if it is a rate-limiting step in development overall. Early embryos are composed of a large percentage of brain by volume, and the literal bulk of somatic development occurs later, in some species predominantly postnatally. If brain weight is plotted against gestational length in days across diverse eutherian mammalian species, an extremely straight line results, as if a fixed amount of brain can be produced per day. No evidence to date points to locally variable rates of neuron or precursor development; to

Figure 3 Relationship between limbic and isocortical (neocortical) components of the telencephalon. Plotted are residual variance in the volume of limbic and isocortical components, referenced to brain core volume, for 160 species in nine taxonomic groups. Overall there is a push–pull arrangement between the limbic and isocortical components, indicated by the preponderance of values in the upper left and lower right quadrants. However, some carnivores represent a balanced expansion of both components, and most chiropterans exhibit reduction of both components. iso, isocortex. From Reep R, Darlington RB, and Finlay BL (2007) The limbic system in mammalian brain evolution. *Brain, Behavior and Evolution* 70: 57–70.

Figure 4 'Late equals Large': a schematic of the consequences for eventual size of a structure generated early (A), intermediate (B), or late (C) in the order of neurogenesis for a species with a short period of neurogenesis and a small brain, like a mouse, versus one with a long period of neurogenesis and a large brain. In the long-development species, the precursor pool for late-generated structures has a longer time to multiply and becomes disproportionately large.

produce more brain, precursors are generated, not more quickly, but over a longer time. (In marsupials, noneutherian mammals, however, the overall pace of brain production is considerably slowed compared to placental mammals, so it is possible to change rate wholesale.) Finally, there is a spatial organization, derived from the initial segmental structure of the neural tube, to the order in which structures enter terminal neurogenesis, and this spatial organization accounts for about half the variation in date of termination of neurogenesis (Figure 5). Those areas that are the most anterior in the neural tube, and most lateral with respect to the original neural tube, that is, the alar plate, are the ones that enter terminal neurogenesis the latest. In fact, for two of the three most anterior and lateral division of the neural plate, which give rise to the hippocampus, neocortex, and olfactory bulb, neurogenesis does not terminate at all.

Limbic System Reduction and Amplification

For primates, evidence exists about how the wholesale reduction of the olfactory bulb, olfactory cortex, hippocampus, and several other nuclear limbic structures, as well as the enlargement of the neocortex, is produced: if the schedule of rodent neurogenesis is appropriately transformed and lined up against the schedule of the rhesus monkey, it is obvious that the distributed limbic structures in the monkey all appear to commence terminal neurogenesis on the same day, and all of them earlier than would have been expected for the same structures in a rat (Figure 6). Conversely, all the layers of the cortex begin terminal neurogenesis later in development than would be predicted from the rat schedule. Those structures that do not differ in their expected size – midbrain, basal ganglia,

Figure 5 Prosomeric model of the forebrain, showing the embryonic spatial relationships of the areas of the brain which undergo the most protracted neurogenesis: olfactory bulb, neocortex, and hippocampus.

and cerebellum – line up at the equivalent times predicted. It is a very interesting research question as to what the genomic alteration might be in monkeys that alters the onset of neurogenesis forward and backward in this distinctive way. It is not yet known whether the other animals that differ on the same axis, like marine mammals, have altered their onsets of neurogenesis in equivalent ways.

The animals whose schedules of neurogenesis have been examined include rodents, the rhesus monkey, cat, ferret, and possum – not an extensive comparative base, but a corpus that has been examined closely to see whether any other potential units of covariation in brain might be observed in any one species or across species (for example, functional systems, such as visual or auditory systems, or parts of brain geometry such as midbrain or hindbrain). Thus far, no such covarying units that could explain more interspecific variation in brains have been identified.

Developmental Constraint, or a Useful Reservoir of Variation for Brain Evolution?

Many aspects of early brain segmentation and genetic specification are highly conserved across vertebrates. The most reasonable interpretation of the extremely conserved fundamental body plan in vertebrates, one of many examples, is not that it is a crystallized 'constraint' on vertebrate organization, but rather a robust and flexible system that by its nature permits graceful variation. The fundamental mechanisms of the specification of body plan are 'evolvable.' How might this argument be extended to a segmental pattern of neurogenesis that permits by its nature systematic variation in the duration of the genesis of precursor pools for neurons, and that has the further property of systematically and disproportionately amplifying the numbers of certain populations of precursor pools with respect to each other as neurogenesis is extended? As discussed earlier, if a mammal is to be selected for a larger brain, it must take longer to make it. In mammals, the principal way brains differ in size is across, not within species. Since this type of size variation has happened so commonly, the property of graceful scaling should be viewed as a historical filter on the kinds of developmental programs that can undergo selection and that are preserved today. It should be noted, however, that mammals are unusual with respect to most vertebrates in that most of their neurogenesis is confined to early development. In many other animals, both brain and body grow throughout life and must be scaled 'on line,' coupling scaling of the two structures in the life of an individual animal.

Employment of 'Late Equals Large' to Gracefully Scale the Retina

The retina is a case in which, in order to maintain functionality in a system of different scales, cell groups must (and do) scale with different exponents. Rods and cones must scale at different slopes with eye size in order to hold constant their particular functions. If an eye becomes twice as large in diameter, no change is necessary in the number of cones to retain the same visual acuity; since the retina is flooded with photons in diurnal vision, a single cone will have no difficulty encountering a photon in the visual angle it represents regardless of the angle the cone itself subtends. More cones could of course be added, to improve acuity, but we are discussing here what is required to maintain equivalent, not improved, function over different eye sizes.

Figure 6 Using the 'translating time' functions described at http://www.translatingtime.net/ (Translating Time Across Developing Mammalian Brains), the schedule of neurogenesis of the monkey is translated to the duration of a rat's for direct comparison. Cessation of neurogenesis for limbic structures begins simultaneously and earlier than expected in the monkey, and the generation of the neocortex later.

The same solution will not work for rods. Working at low light levels and low photon numbers, a single rod located in a larger absolute retinal angle will fail to detect most photons, even allowing for biologically plausible increases in the size of a single rod. Rods must tile the surface of the retina to maintain sensitivity, increasing in number approximately at the square of change in retinal diameter. The scaling of rods and cones in diurnal primates in fact conforms closely to this functional requirement; for example, the human eye, larger than the marmoset eye, has only about 1.2 times the number of cones and retinal ganglion cells in the marmoset eye but 8 times as many rods (Figure 7). How is this consistent within- and across-species disproportional scaling necessity executed in the schedule of neurogenesis of the

Figure 7 The hypothesized consequences of extended neurogenesis in the retina of *Homo sapiens* versus *Callithrix iacchus* for their relative numbers of cones and rods. The positioning of rod proliferation late in neurogenesis allows dispropotionate proliferation of rods in a larger retina to maintain sensitivity. Areas under the curves for rod and cone numbers are drawn to reflect empirically determined values in each species. Reproduced with permission from figure 2.5 in Finlay BL, Silveira LCL, and Reichenbach A (2005) Comparative aspects of visual system development. retina? While the precise kinetics are being worked out, the schedule of neurogenesis in the retina is arranged such that extension of the period of embryogenesis should automatically produce the desired differential scaling, in that cones go into terminal neurogenesis early, and rods late. Those cell types that must change in number with a high exponent with eye diameter, rods and their attendant bipolar cells, are located last in order of differentiation, and those that need not change are produced first. This obligatory, coordinated scaling of retinal cell classes to match functional requirements is an example of the idea of 'evolvability.' The retina offers a potential source of variability in the onset of photoreceptor differentiation by cell class, some of which might gracefully scale with eye size, and some not. Those potential ancestors with perhaps a reversed order of neurogenesis in the retina, rods first, cones last, who might have enjoyed a selective advantage at a larger brain size, but which had ineffective vision in the dark as a result, presumably would enjoy less reproductive success. Common selection points, such as variable body and brain size, will naturally gravitate to coordinate with predictable aspects of embryogenesis. The retina is a nice example of order of neurogenesis adapted to permit several contrasting functional constraints in a single sensory system.

Using Continuing Neurogenesis to Permit Rapid Memory Acquisition and Loss in the Hippocampus

The hippocampus and the neocortex present another possible example of the siting of a function with respect to a favorable location for continued neurogenesis, the most lateral aspect of the alar plate. Both structures are involved in the integration of multisensory information and in memory but are distinct in that the hippocampus is specialized for immediate short-term memory and the transfer of the short-term store to the long-term storage of the neocortex. New neurons are generated in the hippocampus throughout life, but this unusual maintenance of neurogenesis is well suited to hippocampus function: the 'noise' introduced into the connectivity of a structure whose memories are continually overwritten does not represent a problem for the maintenance of any particular memory and in fact may be useful in

memory erasure. The component of the brain important for short-term memory might function best and survive millions of bouts of selection if the appropriate circuitry and cellular processes were sited in a brain location where the pattern of protracted neurogenesis was favorable.

Why Does the Cortex Get Big and the Spinal Cord and Sensory Thalamus Stay Small? A Network Hypothesis

This argument follows the same lines as that described for the rods and cones of the retina and for the hippocampus: over evolutionary time, important functions in the brain are likely to site themselves where the pattern of neurogenesis is permissive for optimal function, in this case, optimal scaling of its network architecture. The pattern of selective enlargement of the telencephalon and constraint on spinal cord and thalamus contrasts with a type of brain evolution essentially unseen in mammals. Consider that a star-nosed mole, with its specialized end organ for palpation, does not generate a dedicated processing center of cortical proportions for its new sensory system in the spinal cord, but rather in the neocortex, where mouse whiskers, primate hands, and elephant trunks all locate themselves as well. If brain evolution could truly be mosaic, that is, any structure could be the target of differential selection on size, why are integrating structures of the size of the cortex not situated in the spinal cord, the hindbrain, and the midbrain?

The answer to the question of coordination of brain, sensory systems, and body scaling and the preferential enlargement of the cortex may be found in the nature of what is likely to be represented in a larger brain and the particular nature of networks in the brain, particularly the cortex. A common hypothesis about brain evolution is that an animal might specialize or improve function by adding a new 'module,' by which is meant a specialized processing system, relatively encapsulated, like bat echolocation, palpation of the earth by the star nose of the mole, or human language. Minimal consideration of even these systems shows that all must constantly integrate motor output with sensory input, which must then further direct muscle effectors, and even the most committed sensory system has multimodal components. Chemosensory information must be integrated with somatosensory, and in current fMRI studies in human language processing, it has been shown that generating the words for tools activates primary somatomotor cortex. So it is obvious that elaboration of sensory, cognitive, or motor capacities should be situated in locations where multimodal integration is possible.

Why body, brain, and sensory systems should covary so regularly, even though neural tissue is metabolically expensive, may have its answer in the distributed nature of neuronal connections. Particularly in the cortex, each neuron receives thousands of synapses, none of which has a 'command' nature; not only that, there are small assemblies of neurons, such as the cortical column, with high local interconnectivity and which almost certainly participate in multiple disparate computations, such as in the language example above. In modeling studies, if the size of just one component of a multicomponent system is increased differentially, the excessive input–output (I/O) requirements of the single larger component when communicating with other system components propagates itself throughout the neural net, leaving the remaining systems with far fewer computational resources than they would have if the large system had simply been deleted from the resources of the net. It is a peculiar and not much noticed fact that the primary sensory and motor nuclei are the first-generated ones in the thalamus, causing them to scale with negative allometry with respect to the rest of the thalamus. The primary sensory nuclei and their inputs act as a significant bottleneck on input to the cortex – for example, the human retina has only about 6 times as many retinal ganglion cells contributing optic nerve axons to the thalamus as a gerbil's! The primary sensory and motor areas of the cortex are also the ones that appear to be the most specified in terms of location and size in the developing brain. Further, in all the primary sensory areas, if an animal develops a specialization, such as an auditory, acoustic, or somatosensory 'fovea,' the increased allocation of cortical area to the specialization takes its place within the primary cortex and does not appear to enlarge it. Rather, the effect of the specialization is seen primarily in the proliferation of new cortical areas. It is interesting that the two large neural systems that show evidence of decoupling, the neocortical and limbic, do not directly combine primary sensory inputs in the thalamus, which may be permissive for diverging allometric scaling that these two systems show (**Figure 4**).

These anatomical observations, initial modeling studies, and hypotheses are here combined to suggest that the fundamental kinetic of cytogenesis described as 'late equals large' may be employed repeatedly as a natural substrate for graceful scaling in vertebrate development and evolution, whether to defend the functional requirements of rods versus cones in sensitivity or acuity, respectively, or the I/O requirements of an associative net with multiple separate inputs. Thus, the conservation seen in the scaling of body, sensory, and motor inputs and brain components does probably represent a constraint, although not a constraint that development places on function but rather functional constraints that exploit to best purpose the intrinsic nonlinearities of neurogenesis.

Brain Evolution: The Radiator Theory

D Falk, Florida State University, Tallahassee, FL, USA

© 2009 Elsevier Ltd. All rights reserved.

Two remarkable facts characterized the evolution of hominins since their ancestors split from those of living chimpanzees approximately 5–7 million years ago (Ma): Unlike chimpanzees, hominins evolved and refined habitual bipedalism, and during the course of their evolution mean brain size increased to three times that expected for chimpanzees of equivalent body sizes. Although the primary selective pressures that resulted in habitual bipedalism and enlarged brains in hominins remain a matter of intense speculation among paleoanthropologists, it is generally recognized that bipedalism evolved before brains became significantly enlarged. According to the radiator hypothesis, selection for bipedalism kicked off a cascade of events that eventually resulted in the evolution of a network of cranial veins that contributed to selective cooling of brains (SBC) under conditions that stimulated hyperthemia in certain species of hominins, much as the radiators of cars prevent their engines from overheating. This vascular mechanism for regulating brain temperature released a thermal constraint that had previously kept brain size in check, thereby paving the way for the natural selection of enlarged brains (for whatever behavioral reasons) that occurred in the direct ancestors of *Homo sapiens*.

Evolutionary Changes in Posture Altered Human Vascular Systems

The hemodynamics of blood circulation in animals fluctuate in response to a variety of factors, including action of the heart, changing respiration, and gravitational (hydrostatic) pressures that alter with varying body postures. Data from arboreal snakes and long-necked giraffes suggest that animals that evolved changes in their habitual body postures did so in conjunction with adaptive changes in their circulatory systems (especially the venous system) in the face of altered hydrostatic pressures. Humans are just as subject to gravity as other animals and retain a replumbed cranial vascular system that differs from those of other primates, which they evolved in conjunction with selection for bipedalism. As a result, cranial blood flow in modern humans is highly dynamic and alters with an individual's posture, breathing, exertion, and thermal state. In monkeys, the internal jugular veins are the major pathway of cerebral venous return. In upright (but not supine) humans, however, the delivery of blood fluctuates with respiration and exertion between the internal jugular vein and a large valveless vascular network (the vertebral plexus) that extends from the cranium to the coccyx. Because of the habitual upright posture of humans, the vertebral plexus is believed to be a major pathway for cerebral venous return. Emissary veins help to deliver blood to the vertebral plexus of veins in upright humans.

Emissary Veins Facilitate Selective Brain Cooling in *Homo sapiens*

Brains are extremely metabolically active and are very sensitive to heat. Brain temperature is determined by the temperature of arterial blood supplying the brain, the rate of blood flow, and the rate of metabolic heat production of the brain. When animals exercise, the temperature of the brain may be kept below that of the body by SBC, which is facilitated in numerous carnivores and ungulates (including dogs, cats, wolves, hyenas, oxen, sheep, and lambs) by cooling arterial blood as it flows through a complex network of arteries (the *rete mirabile*, or marvelous net) that is immersed in cooler venous blood within the cavernous sinus at the base of the brain. Thus, in those animals that have them, retia mirabilia act as countercurrent heat-exchange networks that transfer heat from inside to outside their crania.

Human brains have relatively greater cooling needs than other animals because of the increased ratio of cerebral to resting metabolic rates that is associated with comparatively big bodies and makes brains more susceptible to neurological disturbance (and even death) from hyperthermia and because human brains are comparatively large and thus generate a good deal of heat. Nonetheless, the question of whether human brains are subject to SBC has been controversial because people (and other primates) lack carotid retia. However, a number of other animals, including horses, rabbits, rats, flying bats, and pigeons, have been shown to experience SBC despite their lack of carotid retia. Although it would be unethical for experimenters to measure brain temperature directly in human subjects exposed to hyperthermic conditions, mounting experimental evidence suggests that SBC occurs in humans via cooling of the airways (ventilation through the buccal cavity and nose), fanning of the face, and by evaporation of sweat from the head. The latter mechanism employs a widespread network of emissary veins that pass through various openings in the skull to form connections between the venous sinuses of the dura

inside the skull, the veins within the diploë of the cranial bones, and the veins on the exterior of the skull. The existence of SBC in humans was proposed more than 20 years ago by Michel Cabanac and Heiner Brinnel based on their experiments comparing blood flow in two large emissary veins located near the posterior top and sides of the skull (the parietal and mastoid, respectively) and a third vein at the front of the skull (the ophthalmic) that passes through a foramen to form connections between the cavernous venous sinus internally and facial vein externally (Figure 1). Direction of blood flow within these valveless veins was determined in subjects experiencing two conditions – hypothermia and exercise-induced hyperthermia. During hypothermia, the blood did not flow or flowed slowly from the brain out to the surface of the skull. During hyperthermia, on the other hand, blood that had been cooled by vasodilation in conjunction with evaporation of sweat from the scalp and forehead flowed rapidly from the surfaces of the crania into the cranial cavity. These reversals of blood flow are a consequence of reversed blood pressure gradients between the exterior and internal cranial venous networks, which are controlled by the sympathetic nervous system. The authors hypothesized that the three veins were part of a rich system of innumerable subcutaneous veins (many of them microscopic) that collects cooled blood from the vasodilated skin of the heads of hyperthermic humans and delivers it into their braincases.

Although the hypothesized existence of a widespread network of cranial emissary veins that facilitates SBC in humans initially met with skepticism, in 1996 Wolfgang Zenker and Stefan Kubik published a detailed analysis of human vascular anatomy that is capable of facilitating a bulky transfer of cooled venous blood from the skin of the head, nasal, and paranasal mucous membranes through the skull to the rich network of veins in the dura mater, which in turn may transmit temperature changes to the cerebrospinal fluid and, from there, to the brain (Figure 2). This finding lends support to (and broadens) the hypothesis that convective SBC involving an elaborate network of tiny veins that perforate the cranial vault occurs in humans when the blood in the skin is cooled by evaporation during intense sweating from the head.

Figure 1 Venous sinuses and parietal (P) and mastoid (M) emissary veins in humans. When humans are lying down, intracranial blood flows preferentially from the sigmoid sinus to the internal jugular vein. Upright humans deliver cranial blood preferentially to the vertebral plexus. These emissary veins are part of a much more extensive network of smaller emissary veins that penetrate the skull. Cranial Blood Flow in Early Hominins

Because the large named emissary veins pass through observable foramina and venous sinuses leave traces that are imprinted within the braincase, cranial blood flow has been studied in three genera of fossil hominins (*Paranthropus*, *Australopithecus*, and early *Homo*). Fossils of so-called robust australopithecines (*Paranthropus*) date from approximately 2.5 to 1.0 Ma and are known from South and East Africa. Although robust australopithecines were bipedal, they are believed to have been too specialized in many aspects of their anatomy to have been direct ancestors of *Homo*. One of these specializations involves cranial blood flow. To date, all 12 of the *Paranthropus* skulls that are complete enough to score manifest an enlarged route at the back of the skull for delivering blood from the braincase. This enlarged occipital/marginal (O/M) venous sinus (Figure 3) appears to have had connections with the vertebral plexus of veins that was presumably as important for receiving cranial blood in upright (bipedal) *Paranthropus* as it is for upright humans. It is important to note, however, that unlike humans (and like apes), *Paranthropus* appears to have lacked a high frequency of emissary veins and therefore an evolved adaptation for SBC.

In contrast to *Paranthropus*, the African great apes, *Australopithecus*, early *Homo*, and humans have very low frequencies of enlarged O/M sinuses and instead rely on the transverse/sigmoid sinuses for delivering cranial blood to their internal jugular veins. These groups differ markedly, however, in their frequencies of named emissary veins. Like robust australopithecines, the African great apes have very low frequencies of emissary foramina. Comparative studies on the frequencies of numerous named emissary foramina show that their frequencies increased dramatically during hominin evolution. Specifically, data for the parietal and mastoid foramina suggest that since branching off from *Australopithecus* prior to 1.6 Ma, *Homo* has experienced a steady increase in the vascular network of emissary veins that facilitate SBC under hyperthermic conditions. Significantly, elaboration of the emissary network of veins in the lineage leading to *Homo sapiens* correlated with an ongoing trend for enlarging brain size.

Figure 3 Occipital views of typical cranial venous sinus systems in *Australopithecus*, early *Homo*, and modern humans (left) and robust australopithecines (*Paranthropus*) (right). In the former, a major exit for cranial venous blood is through the transverse (T)/sigmoid (S) sinuses, which deliver blood to the internal jugular veins. Although this system was sometimes retained in robust australopithecines, all of them drained a significant amount of cranial blood through an enlarged occipital/marginal (O/M) sinus system that was present on one or both sides. Copyright Dean Falk.

The Evolution of Brain Size and Cranial Blood Flow

Brain size remained conservative during the course of evolution in *Paranthropus*, which evolved an enlarged O/M sinus for draining cranial blood but not an elaborate network of emissary veins entailed in SBC (Figure 4). On the other hand, accumulating evidence suggests that brain size increased in the lineage leading from *Australopithecus* to *Homo sapiens* in conjunction with elaboration of the vasculature entailed in SBC in living people (Figure 5). This is not surprising in light of the fact that larger brains have greater cooling needs (discussed previously). As noted, *Paranthropus* and *Australopithecus* both evolved habitual bipedalism that necessitated replumbing of vascular systems in response to hydrostatic pressures, similar to other animals that experience major shifts in habitual posture and locomotion. Evidence suggests that, like the earliest hominins known from the fossil record, *Paranthropus* was not adapted to thermally stressful open grasslands or lifestyles, which is consistent with a cranial vascular system that lacks cooling capabilities. By approximately 1.9 Ma, however, brain size and frequencies of emissary foramina had begun to increase in other hominins compared to contemporaneous *Paranthropus*. According to the radiator hypothesis, this happened because the particular way the cranial vascular system in the lineage leading to *Homo* was evolving benefited SBC, thereby releasing a thermal constraint that had previously kept brain size in check. What, then, were these other hominins doing to bring about such a departure?

The Impact of Environment and Behavior on SBC in Hominins

Not too long ago, paleoanthropologists believed that earliest hominins that lived in Africa were adapted to open or partially wooded grassland savannas that were characterized by high predator pressures and other challenges associated with daily travel to seek

Figure 4 Cranial capacity (as a surrogate for brain size) plotted against time for a variety of fossil hominins and extant *Homo sapiens*. (Top) Brain size remained conservative over time in *Paranthropus*, which evolved an enlarged O/M sinus for draining cranial blood but not an elaborate network of emissary veins entailed in SBC. (Bottom) mounting evidence suggests that brain size increased in the lineage leading from *Australopithecus* to *Homo sapiens* in conjunction with elaboration of the vasculature entailed in SBC in living people. Copyright Dean Falk.

food, water, and sleeping sites. Such difficult savanna habitats were thought to be crucial for the initial evolution of bipedalism as well as for the eventual shaping of advanced cognitive abilities and social complexity in hominins. This view has changed, however. Relatively recent discoveries of bipedal hominins that lived approximately 7.0–6.0 Ma in Chad and Kenya were associated with forested or wooded habitats rather than open savannas, as is now recognized to be the case for australopithecines that lived in Ethiopia slightly before 3.0 Ma, including the famous fossil known as Lucy (*Australopithecus afarensis*). *Homo* is currently thought to have arisen in East Africa at some point between 2.7 and 1.7 Ma, which coincides with a climate that was growing drier and vegetation that was becoming increasingly open – circumstances that were conducive for the savanna living in East Africa once envisioned for earlier hominins. This timeframe coincided with the departure of brain size from that of *Paranthropus* in hominins that appeared to be transitional between *Australopithecus* and *Homo* (Figure 4), as well as the first instances of hominin migration out of Africa.

In contrast to *Paranthropus* and *Australopithecus*, a modern body build had evolved in early *Homo* by 1.5 Ma, as evidenced by the skeleton of a tall, slim 10- to 12-year-old boy from Kenya who had humanlike rather than apelike limb proportions (KNM-WT 15,000 or WT 15K) (Figure 6). The boy's brain volume of approximately 900 cm^3 would have been close to the adult value, and it was twice the average for both types of australopithecines and two-thirds the mean volume of 1350 cm^3 for living people. WT 15K's linear body build is ideal for dissipating heat in hot climates and remains the norm for that area of the world. In addition to walking, humans are adapted for sustained running and most of the structural bases for the latter are indicated by

Figure 5 Frequencies of mastoid (blue diamonds) and parietal (green triangles) emissary foramina and enlarged O/M sinuses (black squares) plotted against mean cranial capacities (CC) expressed as percentages of the 1350 cm^3 mean for modern humans (red circles). Dashed lines indicate fossils that have not been scored; robust = *Paranthropus*; gracile = *Australopithecus africanus*. Chimpanzees are included for comparative purposes; hominins are arranged in approximate chronological order from left to right. In Hadar and robust specimens, O/M is fixed; in the latter, emissary foramina occur in low apelike frequencies. The reverse is true for the *Australopithecus* (gracile)–*Homo* lineage in which O/M frequencies fluctuate around those of apes, whereas those for emissary foramina increase through time in conjunction with brain size. Sketch by Brian Worthington; permission by Dean Falk.

WT 15K's skeleton. It is therefore reasonable to hypothesize that *Homo* evolved anatomical specializations that facilitated both walking long distances and endurance running in a thermally stressful climate, perhaps in conjunction with scavenging and chasing down prey (persistence hunting). The increase in emissary foramina associated with increased brain size in the direct ancestors of *Homo sapiens* strongly suggests that SBC was among these specializations.

Summary

Selection for habitual bipedalism in early hominins necessitated a reconfiguration of their cranial vascular systems in response to altered hydrostatic pressures, which was achieved in *Paranthropus* and *Australopithecus* by different adaptations. The former lived in relatively covered environments and evolved an enlarged O/M sinus system for delivering blood from the cranium which was not associated with SBC. Brain size remained conservative throughout the evolution of this now-extinct group. On the other hand, a network of emissary veins began to evolve at some point after 2.7 Ma in association with refinement of bipedalism (and possibly selection for endurance running) in the descendants of early *Australopithecus* that had shifted from relatively closed to more open and thermally stressful environments. This incipient cranial 'radiator' permitted SBC in these hominins, thereby releasing a thermal constraint that had previously kept brain size in check. Brain size continued to enlarge in this group and their *Homo* descendants in conjunction with ongoing elaboration of a venous apparatus for SBC. It is important to note that the evolution of mechanisms for SBC did not directly cause brain size to enlarge in the human lineage; rather, it released a thermal constraint that had previously constrained natural selection for larger brains.

Figure 6 The skeleton of KNM-WT 15 000 is from a young *Homo erectus* boy who lived in Kenya 1.5–1.6 Ma. The 10- to 12-year-old would have grown to more than 6 feet tall and had a brain that was twice the size of the average for *Paranthropus* and *Australopithecus*. Copyright Dean Falk.

Brain Fossils: Endocasts

R L Holloway, Columbia University, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The human brain, as any other part of our body, has an evolutionary history, no more or less remarkable than the evolutionary histories that have fashioned the nervous systems of millions of other living organisms on our planet. Yet it remains to be seen whether the trillions of potential neural states that can, through a singular human adaptation, namely, language, link with other brains of the same species and either maintain or exterminate our existence. After all, hundreds of thousands, if not millions, of species have met their terminal fates, extinction, during the past 500 or so million years. The human species, as we recognize ourselves, has had an evolutionary life span of only a few hundred thousand years, at most, whereas many animal genera have had life spans averaging 5–10 My. As a genus, we might have an ancestry of perhaps 2 My; what is left is largely up to our collective use of our brains, and another 5 My seems rather unlikely.

How did we emerge as the primate with the largest brain in absolute size and complexity? What does the fossil record tell us about the evolutionary journey our ancestors embraced during just the last 3–5 My, when we became hominids?

Evolutionary Approaches

Paleoneurology, the Direct Evidence

There are three important approaches to these questions, only one of which we will explore here in more detail. The line of evidence that is direct is paleoneurology, the study of the fossil evidence of the central nervous system, as found on the surface of endocasts. Endocasts are not fossilized brains, but rather the casts of the insides of crania of fossil animals, which in our case mean the hominids of the past 3–5 My known from Africa, Asia, and Europe. Endocasts come in three flavors: natural, artificial (or human-made), and 'virtual' (as generated by a computer from computed tomography (CT) scan data).

Some of the earliest hominid endocasts, such as those from South Africa, such as the infamous Taung child, and known as *Australopithecus africanus* and/or *robustus*, are known from natural endocasts, fashioned over thousands of years by fine sediments entering the postmortem crania, and gradually being compacted and infiltrated by calcareous solutions to become a rock-hard external replica of whatever neuroanatomical details existed on the internal table of cranial bone. Note that in this natural process, the state of the crania will determine how good the replication of surface details will be, that is, how complete the cranial portions are, and whether or not they are distorted by postmortem geological changes, fractures, and/or plastic flow. No thalami, amygdala, hippocampi, cerebellar nuclei, mirror neurons, or fiber tracts such as the corpus callosum, or arcuate fasciculus will ever be preserved. In hominids, then, and indeed, even most primates, fossil or extant, endocasts can only show the surface features of the cerebral cortex, posterior cerebellum, and some of the brain stem to the level of the foramen magnum (Figure 1).

Man-made endocasts are usually made by applying rubber latex, or silicon rubber to the internal cranial surfaces of fossil crania, and these then become the casts which are studied. More recently, because of technical advances in computer imaging and scanning techniques, 'virtual' endocasts can be made, and an endocast model literally carved out of a plastic block using the data set of scanned coordinates collected from CT scans. The same sorry set of restrictions is applicable to these endocasts. Additionally, the resolution of the scans is variable (usually between 1 and 0.5 mm); thus not all details can be collected from a 'virtual' rather than an 'actual' endocast.

So what, then, are the potential valuable insights one can derive from the direct evidence for human brain evolution if one studies endocasts?

Comparative Neurology, Indirect Evidence

Before answering this question, it is important to look at other kinds of evidence. First, there is the study of comparative neurology. It is the most important line of evidence for understanding the relationships between neural and behavioral variation. It compares the size and structures of various animal brains and attempts to relate the differences and similarities to behavior. Most importantly, however, is that the objects of study, the brains, are simply the current end products of past evolutionary events: the comparative record is not an evolutionary sequence or record. Nevertheless, monkeys, chimpanzees, rats, mice, etc., are routinely compared to modern humans as if these were in some way an evolutionary record. They are not. Nevertheless, without comparative neurology, it would be impossible to study paleoneurology (the reverse does not necessarily hold).

Figure 1 Lateral view of a modern human brain cast and the accompanying endocast. It is obvious that much detail is lost in the endocast.

Molecular Neurogenetics

Another source of information regarding brain evolutionary histories is so new, that little can be said, except that it could well become an important source of direct evidence regarding the evolutionary history of any living animal's brain. This source is molecular neurogenetics. Here, we are beginning to unravel not only what the genetic elements are, but which ones have been under selective pressures in the past.

Data Provided by Endocasts

First, and perhaps of most importance and interest is size, meaning the endocast's volume in cubic centimeters or milliliters. This volume is of course somewhat larger than the volume of the brain, as the endocranial volume (EV) also includes meninges, cerebrospinal fluid, and cranial nerves. The EV is about 8–12% more than the actual brain volume. It is most intriguing to realize that the modern human brain varies in size from about 900 to 2000+ g (remember the old chestnut of Anatole de France at 900 and Swift and Turgenev at about 2000+?), which represent about 1000 g (or cc) which is the total evolutionary change from early australopithecines at 400 ml, to modern human average of about 1400 ml. The average brain weight for modern *Homo sapiens* is 1330 g. Intriguing or not, we now know that there is some correlative relationship between brain size and cognitive abilities at an R of about 0.3, and the fossil evidence for complex cognitive behavior surely shows an increasing complexity through the 2.6 My of hominids' tool productions and later, art works. That said, one cannot, with any degree of certainty, establish connections between selection for brain sizes in hominids and their tools. One reason is that there is a relationship between body size and brain size, and it could well have been the case that selection favored increased body size at certain times and the brain, because of its allometric relationship with body size, simply increased in size, eventually bestowing greater cognitive ability on the hominids so endowed. While rarely the case, postcranial remains are found with crania, and these can provide biological anthropologists some estimates of body size, which in turn can lead to estimates of relative brain size, and when placed within a comparative data set (say all mammals, or all primates) can lead to the calculation of encephalization coefficients (EQs). For example, *A. africanus*, which existed about 2–3 Ma, had an average brain size of about 400–450 cc, roughly the same as chimpanzees, and less than gorillas, yet their body sizes suggest slightly higher EQs than these living apes. However, when we examine these relationships in *Homo erectus* hominids, we find that their body weights were essentially the same as our own, yet their brain sizes were on the order of 750–850 cc. Clearly, there must have been selection pressures operating in the Pleistocene to increase brain size without increasing body size, thus making it reasonably clear that human brain evolution was a mosaic affair, at least as far as brain and body sizes were concerned. Furthermore, it does appear that Neandertal hominids living 200 000 to about 28 000 years ago did have, on average, larger brains than we do, but we also believe that their body sizes were also larger, with more lean muscle mass related to adaptations to colder temperatures. Table 1 provides a listing of hominid brain sizes, by taxonomic group, and their respective EQs. EQs are a relative measure of a species' degree of encephalization calculated from some known allometric data-base. For example, Martin's EQ in Table 1 is calculated from the equation, EQ Martin = brain weight of an animal/0.0991 × (body weight)$^{0.762\ 37}$. The data comes from 88 species of primates where the allometric equation for this data set becomes the denominator of the above equation. The EQ Homo is based on the equation: EQ Homo = brain weight/1.0 (body weight)$^{0.649\ 06}$. Since

Table 1 Hominid brain sizes, by taxonomic group, and their respective EQs

Taxa	*Mean vol.* (cm^3)	*N*	*Range* (cm^3)	*Mean* (*Ma*)	*Body mass* (*kg*)	*EQ Martin*	*EQ Homo*

N, number of specimens.

Figure 2 This chart shows the changes through time of hominid EV. It is important to realize that each point itself takes up many thousands of years, and that such a rendition can have little to suggest in terms of actual evolutionary forces and resultant brain changes.

H. sapiens has the highest EQ (whatever method or data set is used), this immediately provides an EQ for an animal as a percentage of modern *Homo*'s value, which is 1.00 or 100. (This equation is based on plotting the log 10 of modern *Homo*'s 1330 brain against his body weight of 65 000, and the intercept is 1.0, since if body weight is zero, so is the brain.)

If the brain sizes of our hominid ancestors of the last 3 My are plotted against time (Figure 2), one finds a curve that appears curvilinear, but which has so many gaps in the fossil record, that it cannot truly represent the complexity of selective forces that operated both on brain and body sizes during the Pliocene and Pleistocene. Of interest, there are data which show that brain size in modern humans has decreased over the last 10 000 years, and should the protein resources of this planet suffer severe degrading, it can be reasonably speculated that brain size would show a further decrease in those regions severely affected. What effect this would have on cognition is not certain.

Second, endocasts provide information about cerebral asymmetries. As LeMay and Galaburda *et al.* showed, cerebral petalias (projections of cerebral cortex into the surrounding cranial table of bone) correlated at roughly 90% with handedness in living modern humans. For example, a torque-like pattern of a protrusion of the left occipital cortex and a rightward greater width of the prefrontal lobe was highly concordant with right-handedness. The opposite pattern correlated with left-handedness, and both patterns could be found with ambidextrous subjects. Again, these relationships were correlations, and the relationships were clearly not 100% obligate. As we know from many neurological studies, including split-brain research, each hemisphere appears to show specializations for cognitive processing, the left hemisphere usually credited with greater analytical reasoning, the right with more holistic, gestalt-like processing. While it is true that asymmetries are found in many different animal brains, this particular pattern of a torque-growth process appears relegated to humans alone, although more research needs to be done with the chimpanzee, our closest animal relative (Figure 3).

Here is where the principle of uniformitarianism is important: if we find similar cerebral patterns on fossil hominid endocasts, are we reasonably entitled to suggest that they also had some degree of cerebral specialization and cognitive processing either very similar to, or identical to our own? Since behavior does not fossilize, it is unlikely we will ever know the full answer. Many archeologists and paleoanthropologists believe, for example, that there could not have been any hominids with language until one finds evidence for symbolic art, as found in the caves of France and Spain, dating to roughly 20 000–30 000 years ago. Others, including this author, conclude that if one finds evidence for cerebral asymmetries, including those for left/right Broca's regions, then one must consider that language could well have been present, at least by 1.8 Ma, since the fossil hominid, *Homo rudolfensis* (KNM-ER 1470, with an EV of 752 cc),

Figure 3 A dorsal view of a modern brain cast and the accompanying endocast. Note that the left occipital lobe extends further posteriorly than the right side, while the lateral width of the right frontal lobe is greater than the left. This is the typical torque-like petalial pattern associated with right-handedness.

shows such asymmetries very clearly. Similarly, such asymmetries can be found in some of the *H. erectus* specimens, and also Neandertals. No art is known for the so-called Clovis peoples of 12 000 years ago in the Americas, just beautifully fashioned spear points. Would one argue that these members of modern *H. sapiens* lacked language? Australian Aborigine stone tools are primitive, but anthropologists still struggle to understand their complex social relationships, learned by Aborigines through their languages. As the author and de LaCoste-Lareymondie showed, the petalial patterns of a combination of left-occipital and right prefrontal width were not found in a large sample of chimpanzees and gorillas, but were found in many of the fossil hominid endocasts. We conclude, that language, surely more primitive than our

own, has been around for at least a million years, if not well before that.

Third, endocasts sometimes do show cerebral morphology, that is, convolutional details that suggest reorganizational changes as well as size increases of the whole brain. For example, relevant to the above suggestions regarding Broca's region, the various endocasts of australopithecines do not show a Broca's cap region (areas 44, 45, 47) that is like our own, whereas later fossil hominids, such as KNM-ER 1470, and all subsequent fossils of the genus *Homo*, do appear to have such a region like our own, at least in terms of endocast morphology. (What the actual cytoarchitecture was is anyone's guess.)

Another important landmark, at least in primate neuroanatomical terms, is the lunate sulcus, which in great apes (as well as all anthropoids) is a sulcus delimiting the anterior extent of primary visual striate cortex (PVC), area 17 of Brodmann from adjacent parietal association cortex. As we know from allometric studies, the modern human PVC is about 120% less in volume than would be expected for a primate of its brain size, and the lateral geniculate body is about 144% less. The question is, when did this reduction take place, and what part of the cortex had to expand relatively to make up for the lost PVC volume? The answer to the latter is evident, and that is that parietal association cortex probably expanded relatively in hominids. The first question, however, has been largely controversial. When Dart published his epochal paper in *Nature* (1925), part of his reasoning for naming the small natural endocast, and fossil crania and mandible as *A. africanus*, was that the endocast showed a lunate sulcus in a relatively posterior position compared to apes, that is, more of a human-like posterior position. This led Dart, a student of Grafton Elliot Smith, the neuroanatomist who helped define the lunate sulcus, to conclude that even a couple of million years ago, the hominid brain had undergone some cerebral reorganization from an ape-like ancestor. Modern humans seldom show a complete lunate sulcus, and, when present, it is mostly fragmented, and is not a completely perfect delimiter of PVC, although it does occur in a relatively posterior position (Figures 4 and 5).

As mentioned earlier, not all convolutions impress onto the internal table of cranial bone, and reading some of the dim imprints can be very challenging, and controversial. The sulcus in question is not without ambiguity, but the placement of the lunate sulcus in more anterior positions either converts the Taung hominid to a monkey, or violates the remaining morphology. As we showed in several publications, placing the lunate in a typical chimpanzee position violates the remaining morphology. Nevertheless, these two examples, Broca's regions and the lunate sulcus, demonstrate that the hominid brain became reorganized to a human-like pattern early in hominid evolution, and well before the final enlargement of the cerebral cortex as in modern *H. sapiens*.

Fourth, one can measure the endocasts using CT scans or plain calipers, rendering large data sets with chord and arc measurements, and then apply sophisticated multivariate analyses to the data sets, in the hope that combinations of measurements might reflect some taxonomic shape differences that might

Figure 4 This shows a typical allometric relationship between total brain size and a part of the brain, primary visual striate cortex (area 17 of Brodmann). The log–log relationship is obviously linear, and the human point is about 121% lower than would be expected based on the rest of the primate data.

Figure 5 (a) This shows the contrast between a typical chimpanzee (*Pan troglodytes*) brain and that of the natural endocast of the Taung fossil (*Australopithecus africanus*) from South Africa. When the typical chimp position for the lunate sulcus (LS) is placed on the Taung endocast, it violates the sulcal morphology, indicating that the lunate was not in a typical ape position on the Taung child. Placing the LS more anteriorly reduces the Taung child to a monkey status, which is clearly wrong. (b) Views (oblique, occipital) of the new Stw 505 *A. africanus* endocast, showing a true lunate sulcus in a relatively posterior position, thus indicating reorganization of the cortex prior to any significant brain enlargement.

be in turn related to function. Alas, this is not the case. All of the measures and the resulting indices largely, if not completely, reflect the fact that the measurements are completely correlated to the endocasts' volumes. Still, to the extent that endocast shape might have some taxonomic value, or help with reconstructions of missing regions, these measurements do have value.

Fifth, the meningeal patterns of blood supply to the meninges through the middle meningeal artery (mostly) do show variability between hominid groups. In general, as the brain enlarged, the pattern of meningeal imprints on hominid endocasts shows an increase in complexity. Unfortunately, these patterns have no known association with behavioral variables.

These five sets of data are what one can find by studying endocasts. As animals differ more, say between mammals, reptiles, amphibians, birds, and fish, brain endocasts show very different patterns of neurological structures, and the interested reader will

Figure 6 These boxes represent some possible scenarios of brain changes from 'time 1' to 'time 2'. Scenarios (b–e) suggest reorganizational changes that may not be visible on endocasts, although (b) and (d) are variably present on endocasts. (b), For example, symbolizes a reduction of primary visual striate cortex, with a posteriorly placed lunate sulcus, and (d) shows the typical torque-petalial pattern we associate with right-handedness. Neither (c) or (e) are likely to show details on the cortical surface, as the changes could be related to fiber connections, or to subcortical structures not appearing on endocasts.

find a rich literature of comparative neuroanatomy covering these and many invertebrate species (Figure 6).

Conclusions

Clearly, with so few fossil remains discovered thus far, and these spanning a time period of perhaps 5 My, our understanding of how our brains evolved must be incomplete, and largely speculative. In the past, and continuing today, it is brain size that appears to capture most scientists' minds. The direct paleoneurological evidence tells us, however, that our brain evolution picture had to have been far more complex, as we have clear evidence of reorganizational changes interspersed with brain size changes, some of which were absolute, and some relative, that is, dependent on body size increases or decreases. The picture, most importantly, is not a lineal one, but one in which the rates of change were not constant but shifting with selection pressures, immigration, genetic drift, mutations, and environmental challenges involving a most complex interplay of climates, ecologies, prey and predators, as well as social and material interactions within and between groups. Brain evolution in hominids was a mosaic of mosaics. Measuring the size of brain endocasts is the least difficult task in unraveling the evolutionary changes through time. Far more difficult, yet equally important, is discovering the organizational changes that occurred, and when these occurred. The picture starts out with brain sizes within the range of our closest relative, the common chimpanzee, *Pan troglodytes*, with an average brain size of about 385–400 cc. This is apparent in australopithecine hominids, starting with *Australopithecus afarensis* at about 3–3.5 Ma. However, one of these endocasts shows a lunate sulcus in a posterior position quite different than the anterior position found in apes, including the Miocene *Proconsul africanus* fossil. The frontal lobes of this australopithecine, as well as the later derived *A. africanus* group, are narrow, and the Broca's region is not human like. That reorganizational change occurs much later, being present in *Homo* lineages (such as *H. erectus*, *H. ergaster*, *H. antecessor*, *H. habilis*, *H. rudolphensis*, *H. georgicus*, *H. heidelbergensis*, and *H. sapiens neandertalensis*) at about 1.8 Ma, with a brain size of 752 cc. Thus, two critical reorganizational changes took place before the major increase in brain and body size occurred. The author believes that those changes relate to social skills including primitive language being evolved, setting a positive feedback pattern, in which behavioral complexity and brain size are inextricably linked. After ~1 Ma, brain sizes increase to modern values, while the body size remains similar to our own, and the archeological records suggest increasing social and material (stone tools, etc.) behavioral complexity occurring through this time. Perhaps other reorganizational changes in the brain, refinements of cortical structures, acquisition of specific socially relevant behavioral modules accompanied these size increases. What these were cannot at this time be gleaned from the direct endocast evidence. On these questions, the evidence is mute and perhaps forever moot.

Technical Issues in Brain Glucose Metabolic Imaging in Aging and Degeneration

The cerebral metabolic rate of glucose (CMRglc) can be measured *in vivo* using positron emission tomography (PET) imaging with [^{18}F]-2D-fluoro-deoxiglucose (FDG) as the tracer. Before we present FDG-PET findings in aging individuals and Alzheimer's disease (AD) patients, some technical issues relevant to the use of PET in these populations should be described.

First, FDG is taken up in the brain at a gray matter: white matter ratio of 5:1. The cortical gray matter ribbon thickness varies between 1 and 4.5 mm, with an average of approximately 2.5 mm, which is well below the 4.25 mm spatial resolution of current state-of-the-art PET scanners. Therefore, the FDG-PET signal in the cortex spills out to the surrounding low-activity regions (white matter and cerebrospinal fluid, CSF). This effect is called partial volume effect (PVE). PVE can be thought of as a blurring of higher-activity gray matter structures with the surrounding lower-activity spaces. PVE generates an artifactual reduction of FDG-PET activity as the cortex gets thinner (Figure 1). This is relevant to elderly subjects and AD patients, whose brains may show cortical atrophy (i.e., cortical thinning due to neuronal loss) and ventricular enlargement. It is possible to correct for PVE using mathematical models and co-registration with magnetic resonance imaging (MRI), which offers a structural image of the distribution of gray and white matter and the CSF. Partial volume correction adjusts FDG uptake values as a function of the underlying tissue volume, therefore increasing CMRglc values in atrophic regions, and provides a measure of metabolic activity per gram of brain tissue. Despite the technical importance of PVE, several FDG-PET studies have shown that CMRglc reductions in AD patients compared to controls remain significant after PVE correction and therefore reflect true reductions of CMRglc.

Second, AD is associated with a phenomenon called selective neuronal vulnerability, in which specific regions are vulnerable to neurodegeneration and others are spared. CMRglc reductions are found in the brain regions most affected by AD pathology (i.e., amyloid-beta and tau pathology, and neuronal loss), for example, the medial temporal lobes (MTLs), including the hippocampus (HIP), entorhinal cortex (EC) and transentorhinal cortex, and parahippocampal gyrus; the posterior cingulate cortex (PCC); the parieto-temporal cortex (PTC); and the frontal association cortex (FC). Traditionally, FDG-PET scans in aging and AD were sampled using manually drawn regions of interest (ROI) of the brain structures known to be selectively involved, either on PET-co-registered MRI or directly on PET. However, the method is subject to high inter- and intra-operator variability. To overcome some of these issues, several methods of automatic ROI extraction and cross-modality co-registration have been developed, and their application guarantees a better reproducibility and higher anatomical accuracy of the results.

A totally different approach is based on voxel-based analysis (VBA), a family of techniques that analyzes brain images at the single voxel (the image-unitary 3D element) level to identify regions showing significant CMRglc reductions between groups of subjects by means of intrasubject or intersubject statistical comparisons and generation of statistical parametric maps. Because human brains differ in size, shape, and orientation, VBA methods adequately modify these features by virtue of warping and spatial normalization algorithms so that all images conform to a standardized brain shape in the stereotactic space (i.e., a template image) (Figure 2). After spatial normalization, statistical analysis is performed on a voxel-by-voxel basis, correcting for confounding variables known to affect CMRglc (e.g., age, gender, and education) by standard multiple linear regressions (Figure 3). Among these methods, the most widely used for FDG-PET analysis in dementia are Statistical Parametrical Mapping (SPM) (Wellcome Department of Neurology, London, UK) and NEUROSTAT (University of Washington, Seattle, WA, USA). Moreover, diagnostic VBA methods have also been developed to perform an automated comparison of a single patient's scan to a database of reference FDG-PET scans to facilitate clinical decision (see the sections titled 'Brain glucose metabolic alterations: operating characteristics in Alzheimer's disease and mild cognitive impairment' and 'FDG-PET: Work in progress').

Figure 1 Visual depiction of partial volume effect in the temporal–occipital region of a representative middle-age normal subject: (a) MRI; (b) co-registered MRI and FDG-PET; (c) FDG-PET. FDG uptake is represented on a green to red color scale, with red indicating high FDG uptake (i.e., high local metabolic activity). Among other factors, visualization of FDG uptake is related to the thickness of the cortex. Thinner cortical gyri show lower signal intensities (solid arrows) than do thicker cortical gyri or areas of convergence of different gyri (dotted arrows), which show higher metabolic activity. CMRglc may, in fact, be comparable in the two regions, and the apparent difference in intensity depends on the response of the PET scanner to the different thickness of the activity source (the cortex). CMRglc, cerebral metabolic rate of glucose; FDG, [^{18}F]-fluoro-2-deoxiglucose; MRI, magnetic resonance imaging; PET, positron emission tomography.

Figure 2 Spatial normalization with voxel-based analysis (VBA): (a–b) raw images from two subjects, S1 and S2; (c) FDG-PET template from the Montreal Neurological Institute; (d–e) normalized images using SPM2. Spatial normalization is the key point to apply VBA. In (a) and (b), the two brains differ in their size, shape, and orientation. The VBA software contains a mathematical algorithm (usually very complex) which resizes, reshapes, and reorients the brain, minimizing, as the cost function, the differences using a FDG-PET template (c). After normalization (d–e), the subjects' brain images have the same size, shape, and orientation, but the metabolic differences are maintained (white plain arrow in (a) and (d), showing S1's brain cortical region with low metabolism). FDG, [^{18}F]-fluoro-2-deoxiglucose; PET, positron emission tomography; S1r, subject 1 raw images; S1t, subject 1 transformed images; S2r, subject 2 raw images; S2t, subject 2 transformed images; SPM, Statistical Parametrical Mapping.

Molecular and Cellular Factors Involved with Glucose Hypometabolism in the Aging Brain and Alzheimer's Dementia

There seems to be very little or no relationship between CMRglc decreases and the density of pathological hallmarks of AD: amyloid-beta plaques and neurofibrillary tangles. Neuronal loss is thought to be the most likely cause of decreased FDG uptake, although CMRglc decrease seems to be an early event in AD, possibly occurring prior to neuronal loss. Moreover, there is a significant CMRglc decrease during normal aging, whereas age-related neuronal loss is minimal.

Another molecular factor that has been implicated in aging and AD, and their related CMRglc reductions,

Figure 3 Statistical analysis of the effects of aging on metabolic activity: (a) the basic components of the analysis, the proposed contrast and the groups; (b) the region(s) in which the metabolic activity is significantly different in accord with the proposed contrast; (c) CMRglc in each subject's ACC, normalized to the mean cortical value, plotted versus the subject's age. The second phase of voxel-based analysis (VBA) is the statistical analysis, performed after spatial normalization. This figure presents a basic SPM analysis. The example is a comparison of two groups of normal subjects, a group A of 16 subjects with mean age 34.3 ± 6.1 (range 21–44 years) and a group B of 15 subjects with mean age 64.9 ± 3.0 (range 60–71 years). The analysis is a *t*-test. The contrast applied in the study is shown at the top of (a) by the two small gray labels (1 and 2). In the lower part of (a), the two large white columns (A and B) indicate the subjects of the two groups. The two white columns indicate the number of subjects in each group (*y*-axis). The two gray labels indicate the direction of the contrast. In this study, the regions searched for are those in which the metabolism is higher in the younger group than in the older one (upward direction of the gray label 1 and downward for label 2). In (b), the regions in which the metabolic activity is significantly different in accord with the proposed contrast are shown in a scale which reports the value of *t* (0–5 in the color bar). In this example, the anterior cingulate cortex (ACC) fulfills the contrast and is colored yellow. The colored region is represented on a magnetic resonance template. As shown in (c), the slope of the regression line is 6.9% per decade. CMRglc, cerebral metabolic rate of glucose.

is oxidative stress (OS). OS is the result of a complex of damaging events correlated with the energetic production in neurons and astrocytes, and its disruptive effects may be differently expressed depending on individual brain compensatory capacity, which in turn is determined by genetic, environmental, and lifestyle factors. Over time, OS can impair cellular energy production at the mitochondrial level. Such impairment has been supposed to be the primary cause of CMRglc decreases on FDG-PET, a hypothesis contradicted by the known activity of allosteric (due to feedback activity) mechanisms which are activated by cellular energy demand and increase cellular glucose intake. Actually, AD neurons *in vitro* show an increased, not a decreased, glycolytic consumption to compensate for decreased energy production.

Synapse dysfunction and loss are instead currently seen as the most probable cause of CMRglc reduction in aging and AD. First, synapse molecular impairment, structural changes, and loss are early events in AD, as well as, to a lesser extent, in normal aging and senescence. Hippocampal synapse loss and dysfunction have been detected before neurofibrillary tangles in human tau transgenic mice. Second, there are sound observations linking local glucose intake with the activity of glutamatergic synapses, which constitute 80% of total brain synapses. A decline in synaptic function decreases local glutamate release and may therefore reduce glucose intake. Third, synaptic loss, like FDG uptake, closely correlates with cognitive deficits in AD. Finally, animal studies with synaptophisin (i.e., a presynaptic vesicle membrane protein used as a marker of synaptic density) have shown a significant positive correlation between synapse density and regional FDG uptake. Overall, these findings strongly support the hypothesis that resting-state CMRglc measures on FDG-PET reflect integrated synaptic activity and suggest that FDG-PET imaging may be ideal tool for investigating changes in brain function in aging and AD.

Several other factors may be implicated in FDG-PET changes in aging and AD. For example, amyloid-beta is deposited in the walls of cerebral arterioles in normal individuals and AD patients, causing vascular damage that may in turn impair glucose supply. Moreover, although it is generally accepted that FDG-PET measures are an index of neuronal activity, it is still debated whether and to what extent astrocytes play a role in the observed signal. Astrocytes, or neuroglial cells, are hypothesized to be responsible for the anaerobic component of the glycolytic path, converting glucose into lactate, which is then shuttled into neurons for further metabolism. This hypothesis is currently being tested. In this case, FDG uptake in the brain is limited to astrocytes, and FDG-PET images represent astrocytic, instead of neuronal, glucose metabolic rate. The observation of a tenfold prevalence of glial cells with respect to neurons in the brain and the poor understanding of nerve versus glial energy metabolism need further investigation.

Brain Glucose Metabolism Changes with Aging

Aging is the most important risk factor for late-onset sporadic AD (LOSAD). Therefore, aging has been a point of interest since the beginning of FDG-PET studies in AD. Early FDG-PET studies that visually compared healthy elderly with young or middle-age normal subjects failed to show significant FDG-PET changes associated with age. The negative reports are probably due to the fact that age-related CMRglc changes are subtle and difficult to identify by visual inspection (Figure 4) on low-resolution PET scanners, such as those used in the early years. More recently, with improvements in PET spatial resolution and the use of more sophisticated analytical methods like VBA, age-related CMRglc changes have been detected. Cross-sectional FDG-PET studies have shown that normal elderly subjects, compared to young controls, show CMRglc decreases in the association neocortex, particularly in the FC and the anterior cingulate cortex (ACC) (Figure 3), and also in the PTC regions that are usually hypometabolic in clinical AD. On the other hand, the PCC, which is usually hypometabolic in AD, is apparently not affected by aging. These regional changes are paralleled by global CMRglc reductions of approximately 6% per decade (Figure 3), as demonstrated by quantitative CMRglc measurements. Interestingly, this rate of CMRglc decrease is consistent with the estimated rate of decrease in synaptic density measured postmortem in healthy elderly brains. This correspondence further suggests that FDG-PET measures and synaptic density are strongly related.

Longitudinal FDG-PET studies that monitored changes in cognitive performance in normal healthy subjects showed that CMRglc changes in the PTC correlate with cognitive decline over time. Moreover, there is evidence that CMRglc reductions in the EC and HIP among normal elderly accurately predict future decline from normal cognition to mild cognitive impairment (MCI), often a prodrome to AD, and dementia. These studies were based on the detection of group differences and did not examine whether individual patterns of baseline FDG-PET alterations may be predictive of clinical outcome in individual subjects. Nonetheless, longitudinal FDG-PET studies of normal elderly individuals followed for 6–14 years with serial FDG-PET exams have shown that the rate of CMRglc decline per year is highly predictive of clinical outcome. Longitudinally, in stable normal individuals the rate of hippocampal CMRglc reductions was less than 1% per year, whereas patients who declined to MCI and AD had significantly higher rates of CMRglc reductions of 2.4% and 4.4% per year, respectively. A similar effect was also found in the PCC in patients who declined to AD.

Overall, these data show that age-related CMRglc changes are found also in the brain regions showing CMRglc deficits in AD and that metabolic differences between healthy brain aging and AD may be more quantitative than topographic in nature (i.e., the magnitude rather than the site of CMRglc decrease may be important). Important issues stem

Figure 4 FDG-PET changes in the brain with age: (a) young control (35 years old); (b) elderly control (65 years old). Axial FDG-PET images of the two subjects are shown from vertex (left) to cerebellum (right). The color scale is from blue (low activity) to white (high activity.) A visual search for differences between two subjects is not able to find differences. The brains were spatially normalized with SPM2. FDG, [^{18}F]-fluoro-2-deoxiglucose; PET, positron emission tomography; SPM, Statistical Parametrical Mapping.

from this consideration. First, deviations from age-associated CMRglc declines and CMRglc declines related to MCI and AD may be determined, on an individual basis, by the imbalance between damaging events and protective capacity, a theory currently at the basis of the pathogenesis of AD. Second, in operative terms, it is necessary to take into account the effects of age in any clinical FDG-PET studies aimed at identifying AD as opposed to normal aging.

Brain Glucose Metabolic Alterations in AD: Pathophysiology

In the early 1980s, the clinical use of FDG-PET was restricted to epilepsy and brain tumors. But its potential in the study of degenerative brain diseases became clear as soon as an AD-specific distribution pattern of the CMRglc deficits was discovered.

Afterward, a more systematic approach to the examination of AD was made possible by the development and application of automated image analysis procedures, which enriched the FDG-PET evaluation of more objective criteria based on the statistical detection of CMRglc differences between AD and normal subjects. AD patients exhibit early CMRglc reductions in the PCC and in the PTC (Figure 5), followed by FC hypometabolism found in severe dementia. Quantitative measurements of CMRglc with FDG-PET have also shown that a widespread metabolic reduction underlies regional changes, partially sparing the basal ganglia and cerebellum. These signs are like a signature of AD in the brain and may

Figure 5 Population study comparing brains of normal controls (NCs) and Alzheimer's disease patients (ADs), with age and education as confounding covariates: (a) significantly hypometabolic regions in ADs are depicted in red-to-yellow scale on a magnetic resonance template; (b) design matrix with age and education as confounding covariates and the classical SPM glass-brain presentation; (c) results table. Twenty-five NCs (age 61.3 ± 5.2 years, education 11.2 ± 4.1 years) ($Group_1$) and 25 ADs (age 72.2 ± 9.4 years, education 6.7 ± 3.2 years) ($Group_2$) were compared using SPM. In (a), the parietal and temporal regions are hypometabolic bilaterally. Metabolic involvement of the frontal lobe is shown on the left hemisphere. In the medial surface of the brain, severe hypometabolism in the posterior cingulate cortex is bilaterally shown. Lower left panel: In (c), the characteristics of each brain region are reported. Ke reports the extension (in voxels) of the regions. The column 'coordinates' reports (in millimeters) the peaks in the region, localized with *x* (left to right side, respectively, negative to positive values), *y* (back to front, respectively, negative to positive values), and *z* (above to below the intercommisural plane, respectively, negative to positive values) in Talairach space. The third and fourth columns are the names of the functional areas and the Broadman areas (BAs).

be used to diagnose and to differentiate AD from other dementias. In addition to differential diagnosis, the magnitude and extent of the CMRglc reductions on FDG-PET predict with high accuracy clinical progression and correlate with disease severity.

Despite the well-known early pathological involvement of the MTL in AD, only recently did clinical FDG-PET studies demonstrate CMRglc reductions in the MTL as an additional specific and consistent sign of early and advanced AD. This finding is in agreement with the finding of MTL synapse loss at a very early stage of AD. In contrast to the MTL, the PTC is affected by pathology in a later phase of AD, although PTC CMRglc decline is a relatively early event which does not seem to strictly correlate with local pathology. It has been suggested that PTC CMRglc reductions may be a distant effect of deafferentation of this region from the MTL, due to the disruption of neurons connecting the MTL to the PTC. Lesional studies in experimental animals demonstrated that the interruption of HIP and EC input/output connections can produce CMRglc decreases in the PTC. Moreover, a functional (metabolic) connectivity has been shown between the EC and PCC with FDG-PET in normal subjects and AD patients. In this model, damage to the MTL is a likely source of remote neocortical CMRglc impairment, or a sort of metabolic diaschisis due to the interruption of MTL inputs to the associative cortex. Later on, axonal transport dysfunction could participate in further decreasing cortical metabolic activity in the PTC and induce pathological changes such as synaptic and neuronal loss.

Brain Glucose Metabolic Alterations: Operating Characteristics in AD and Mild Cognitive Impairment

The clinical diagnosis of AD may be difficult to make at the early stages of disease when symptoms are not fully expressed and are hard to differentiate from physiological age-related declines. There is a great need for an accurate and early AD diagnosis because several clinical entities exist that share similar symptoms with AD but that, unlike AD, are potentially treatable (e.g., dementia syndrome of depression) or have a different response to specific treatments (e.g., frontotemporal dementia, FTD, and anticholinesterase inhibitors). The increasing availability of medications for symptomatic treatment of mild to moderate AD, which may be most effective in the early phases of disease, and the potential for protective/reparative treatments for preclinical AD phases, namely MCI, represent an additional reasons for developing early image diagnostic tools.

Several studies have put forth FDG-PET as a candidate tool for the preclinical detection of dementia. The largest published study with pathologically verified cases showed that bilateral PTC hypometabolism on FDG-PET has a sensitivity of 94% and a specificity of 73% in distinguishing AD from normal aging and other neurodegenerative diseases (Figures 6–8). Therefore, the presence of PTC CMRglc alterations appears to be relatively specific to AD. In the same study, the presence of PTC hypometabolism was shown to have prognostic value in predicting the progressive course of dementia with 93% sensitivity and 76% specificity. In 2004, these results prompted US Medicare to approve the reimbursement of FDG-PET scans performed in patients with documented cognitive decline of at least 6 months and a recently established diagnosis of dementia that meets diagnostic criteria for both AD and FTD.

For clinical and strategic reasons, it is also important to develop early diagnostic procedures to forecast on an individual basis who among MCI subjects will eventually decline to AD. Recently, FDG-PET capability to predict a decline from MCI to AD has been tested by several research groups. A clear sign predictive of decline has not been found in the general population of MCI patients. By restricting the evaluation to amnestic MCI patients, who show higher rates of decline to AD (up to 50% in 3 years compared to other MCI subtypes), it appeared clear that CMRglc reductions in the PCC and PTC are present in the future decliners at least 1–3 years prior to the clinical diagnosis of AD, with prediction accuracies between 75% and 90%.

FDG-PET can attain diagnostic power in MCI when, in addition to the typical cortical pattern already described, it is used to also evaluate the MTL metabolism, which is more visible with the use of oblique axial projections (Figures 9 and 10). When the severity of hypometabolism of the PTC and PCC is associated with that of the MTL, FDG-PET is able to differentiate MCI patients from normal subjects with a 85% sensitivity and 71% specificity and from AD patients with a 100% sensitivity and 77% specificity.

FDG-PET: Work in Progress

The most common approach to the diagnosis of AD with FDG-PET is by visual inspection, but visual analysis requires expert examiners. To obviate the need for expert readers, several automated diagnostic tools have been developed. They are based on the availability of a normal FDG-PET database and of VBA software. Thereafter, either the statistical parametric images are reviewed by the reader or the algorithm itself expresses a probabilistic attribution of the subject to a class of disease (AD, AD Lewy body variant, or FTD). The diagnostic performances of

Figure 6 FDG-PET brain pattern in a patient affected by Alzheimer's disease (AD): (a) axial FDG-PET images; (b) automated analysis in which the classic SPM display shows the hypometabolic regions in comparison with a database of normal controls. The patient is a woman 63 years old, with AD onset at 57 years old, MMSE 17. The images in (a) show bilateral parieto-temporal hypometabolism (white arrows). Metabolism is relatively high in the occipital cortex and in the basal ganglia. The display in (b) confirms the presence of symmetrical parieto-temporal and posterior cingulate cortex hypometabolism. Figure 7 FDG-PET brain pattern in a patient with frontal dementia: (a) axial FDG-PET images; (b) automated analysis in which the classic SPM display shows the hypometabolic regions in comparison with a database of normal controls. The images in (a) show bilateral frontal hypometabolism (white plain arrows). The display in (b) confirms the presence of symmetrical frontal hypometabolism. Parietal hypometabolism on the left side might be due to sulcal enlargement (dotted arrow). FDG, [^{18}F]-fluoro-2-deoxiglucose; PET, positron emission tomography; SPM, Statistical Parametrical Mapping.

Figure 8 FDG-PET brain pattern in a patient with AD Lewy body variant. (a) axial FDG-PET images; (b) automated analysis in which the classic SPM display shows the hypometabolic regions in comparison with a database of normal controls. The images in (a) show bilateral frontal and parietal hypometabolism (white arrows). In addition, occipital hypometabolism is shown (white dotted arrows). The display in (b) confirms the presence of symmetrical parieto-temporal hypometabolism and the involvement of occipital cortex. FDG, [^{18}F]-fluoro-2-deoxiglucose; PET, positron emission tomography; SPM, Statistical Parametrical Mapping.

Figure 9 Hippocampal visualization in which MRI images are used to show the different orientations applied at brain volume for examining cortical metabolism and hippocampal metabolism: (a) orientation commonly used with functional images; (b) orientation used for visualizing hippocampal bodies. In (a), the horizontal plane is oriented so as to include anterior and posterior commissurare (intercommisural plane). This is called bicommisural or fronto-occipital orientation. With this orientation, hippocampal bodies, surrounded by white arrows, are cut out of their major axis plane. In (b), the sagittal image (middle) clearly shows the different horizontal plane. The hippocampal bodies are cut in the plane (white arrows). Images are prepared with MIPAV. MRI, magnetic resonance imaging.

Figure 10 Co-registered MRI FDG-PET images of a normal subject, 30 years of age: (a) MRI and FDG-PET fused images; (b) FDG-PET images; (c) MRI images. Hippocampal metabolism is usually lower than cortical metabolism. Images are prepared with MIPAV. FDG, [^{18}F]-fluoro-2-deoxiglucose; L, lateral; MRI, magnetic resonance imaging; P, parietal; PET, positron emission tomography.

the automatic diagnostic systems are comparable with that of visual inspection by experts. We caution the reader that the use of automatic diagnostic systems for AD has not been approved by regulatory institutions and that clinical application is not recommended. Examples of the application of VBA to single-case studies are given in Figures 6–8.

FDG-PET has also been proposed as a surrogate endpoint in AD clinical trials. A surrogate endpoint is a biological marker, laboratory measurement, or physical sign used as a substitute for a clinically meaningful endpoint that measures directly how a patient feels, functions, or survives. Using FDG-PET as surrogate endpoint in clinical trials in AD could substantially reduce the sample size necessary to detect a treatment effect, the trial duration, and the expense. Other analyses have shown that the use of FDG-PET as surrogate endpoint after a treatment to slow or halt the progression of AD could allow a tenfold reduction in the number of subjects needed to enroll in a clinical trial. FDG-PET is not currently recommended as a surrogate endpoint in phase III drug trials in AD because it has not been demonstrated that halting or hindering CMRglc reductions corresponds to improving the patient's health.

Genetic Factors in Relation with Brain Metabolism Changes in Aging, Mild Cognitive Impairment, and AD

Correlative studies of CMRglc changes and genetic factors have been performed in normal individuals and in AD and MCI patients. The interest of these studies is twofold: to discover in genetically predisposed

subjects the earliest metabolic signs of AD and to better investigate the cellular and molecular factors of regional metabolic reduction.

Few cross-sectional studies with FDG-PET have been done in subjects carrying autosomal dominant mutations which determine an early-onset familial AD manifestation (EOFAD). These genes are *APP, PS1*, and *PS2*, and their proteins are involved in the production and metabolism of amyloid precursor protein. The importance of these studies is that they may be performed long before the emergence of cognitive clinical symptoms and may help to better define the metabolic continuum among normal brain, aging, senescence, MCI, and AD. In these studies, the same regions affected by CMRglc decrease in MCI and AD (i.e., the PTC and HIP) were already hypometabolic more than a decade before subject's expected time of overt clinical dementia (Figure 11). Despite possible biological differences with nonautosomal AD, the finding of this specific endophenotype in autosomal EOFAD subjects, although cognitively normal, strengthens the importance of the CMRglc impairment in the PTC and HIP as a research and diagnostic marker of the evolution from normal brain function to dementia; also it may be proof of a direct relationship between the amyloid metabolism and CMRglc decrease, an issue currently still largely debated.

FDG-PET changes in relation with the major genetic risk factor of AD, the ε4 allele of apolipoprotein E (ApoE) gene, have been investigated in AD patients at the onset of cognitive symptoms. The AD-specific hypometabolic pattern does not differ among the different ApoE genotype groups (with 0, 1, or 2 ε4 alleles). Anyway, when researchers compared the AD genetically different groups directly, hypometabolic differences were evident within the brain areas adjacent to those typically hypometabolic in AD, in a ε4-related fashion, suggesting that the metabolic damage of AD might be exacerbated by the dose of the ε4 allele. This effect of ApoE ε4 on CMRglc is consistent with the less efficient protective role of ApoE ε4 protein toward synapses in Aβ mouse models, as well as with the possibility that the ApoE ε4 protein directly damages the synapses, the main factor of FDG uptake in the brain. Moreover, the dose-dependent relationship between the number of copies of ε4 and the severity (extension) of CMRglc reduction in PTC is consistent with the known relationship of the ε4 dose and the age of onset of AD, such that ε4/ε4 subjects have an earlier onset than do heterozygous ε4 subjects.

The growing interest in the association of CMRglc and genetic factors in MCI patients derives from the compelling need to select the patients for protective/reparative interventions. Indeed, a genetic predisposition due to ApoE ε4 allele by itself is a predictor of conversion from MCI to AD with a good sensitivity (75%) but poor specificity (50%). When the genetic predisposition is considered together with FDG-PET hypometabolism in specific areas (the ACC and inferior FC), the capacity to predict conversion attains a sensitivity of 75% and a specificity of 89%.

An interesting issue is the study of brain metabolism in normal aging in association with the ApoE ε4 allele in order to select as early as possible the at-risk subjects for treatment and for protection against AD. In middle-age and older healthy subjects with normal memory performance, a single copy of the ApoE ε4 allele was associated with lowered PTC and PCC

Figure 11 Metabolic impairment in a preclinical AD genetic case. Metabolic reduction in temporoparietal cortex in a subject 35 years old with a genetic mutation PS1 Leu392Val. At the time of this FDG-PET study (right) the subject was cognitively normal (MMSE 30). MRI-coregistered image (left) does not show any atrophy in the corresponding regions.

metabolism, which predicted the degree of cognitive decline after 2 years of longitudinal follow-up. This does not occur in the absence of the ApoE ε4 risk factor, representing possible proof that PTC hypometabolism might be a consequence of a genetic impairment of brain cells and, thus, might be causative of (instead deriving from) the cognitive impairment.

Although the ApoE ε4 allele by itself may account for a large fraction of genetic risk of developing AD, the role of several other susceptibility genes is suspected. Therefore, studies in AD patients have focused on LOFAD patients in which these unknown AD susceptibility genes may act in concert with epigenetic events to determine AD. In these patients (approximately one-third of all late-onset AD), there is a reduction of CMRglc in the PCC, HIP complex, and occipital regions compared with LOSAD patients, balanced for the presence of the ApoE ε4 allele. This finding suggests that these unknown susceptibility genetic factors may participate in the protective/reparative cellular functions against OS because they decrease CMRglc in brain regions in which a reduced capacity to compensate for stress and damages at the cellular level is known to be present.

Brain Injury: Functional Recovery After

D G Stein, Emory University School of Medicine, Atlanta, GA, USA

© 2009 Elsevier Ltd. All rights reserved.

Conceptual Issues

Functional recovery after brain injury is generally thought of as the behavioral concept that cognitive, sensory, or motor impairments gradually diminish or are eliminated over time. This concept implies that, after a brain injury or stroke, acute or chronic behavioral and motor deficits disappear spontaneously or are reduced by pharmacological, physiological, surgical, or behavioral rehabilitation strategies. Functional recovery can also be defined by changes at the molecular level of the neuron. For instance, after an injury, neural transmission or release of transmitters at the synapse may be disrupted and 'functional recovery' can be defined as a return of neurotransmission to preinjury or even higher than preinjury levels. Indeed, many studies of plasticity and recovery of cell membrane or nuclear functions, such as the expression or inhibition of genes which control cell metabolism and growth, never examine whether the behavior of the organism is directly affected – in either an adaptive or maladaptive way. Dramatic changes in central nervous system organization and metabolic activity could be disruptive to, or even prevent, further recovery of function, so it is critical to have detailed behavioral outcome measures to correlate with physiological alterations in brain activity associated with injury and subsequent repair. For example, very high levels of glutamate, an excitatory neurotransmitter in normal circumstances, can overstimulate vulnerable neurons to the point of killing them off at sites remote from the injury, disrupting complex behaviors. Furthermore, psychological 'functions' that are initially lost and then recovered are not always clearly defined, and as a result, both function and recovery can mean different things to different people. Thus, in laboratory rats with frontal cortex lesions, cognitive functions involved in learning are said to be preserved if the animals can run through a maze to get to a goal box. No attention is paid to the possibility that there could be abnormalities in their gait or shifts in the hierarchy of sensory cues they use to remember where they are going in the maze. By ignoring the question of how the animals get to the goal box, recovery may be assessed as complete, although the underlying physiological processes mediating the behavior may be very different from those seen in intact animals. Thus, 'recovery' can be defined in terms of attaining a goal, regardless of how that goal is achieved.

In the clinic, such an ends-based definition of functional recovery is more difficult to accept. Many in the field of rehabilitation still hold to the idea that 'true' recovery of function does not exist. When brain-damaged patients succeed in activities of daily living by substituting new, different behavioral strategies to accomplish goals, as they often do, this is assumed to reflect a process of 'compensation.' The goal for rehabilitation, in this view, is to help patients learn to live more effectively with their impairments – to get around them. Although the brain-damaged patient may accomplish the same goal as an intact person, the behavioral strategies used may be very different. Without measurements of specific physiological correlates, it is circular to argue that if no deficits are observed, it is because the patient has learned to 'compensate,' the tests are insensitive, or the wrong tests have been used, rather than because any true recovery of function has occurred.

Although 'compensation' is a phenomenological construct that can be evaluated only by identifying and measuring behavioral changes, underlying changes in cerebral physiology and structure must be present to mediate the behavior. Many studies show that rehabilitation training and general learning experiences can directly modify cortical maps in dramatic and long-lasting ways. These new maps, which are basically aggregates of neurons, can respond to sensory inputs that did not activate them before the injury-induced reorganization. Extensive reorganization leading to behavioral compensation is inconsistent with the idea that specific areas of the brain are hardwired to 'control' or 'mediate' behaviors – and thus that the destruction or perturbation of a center in which a specific function is localized must lead to a permanent loss (or permanent impairment) of that function. The notion of substitution of function, or compensation, after brain damage is consistent with the idea that intact parts of the brain are structurally modifiable to take over the functions of tissue lost after injury or disease. From this point of view, remaining healthy tissue is said to modulate its physiological activities in response to damage to a specific brain region.

In restitution or sparing of function, initial behavior is intact or returns to preinjury performance. Such recovery is thought to be due to the equipotentiality or vicarious capacity of cerebral areas. Equipotentiality is the capacity of anatomically distinct, sometimes

distant, areas of the brain to mediate disparate functions. Such plasticity is thought to be more likely when the brain is developing and not yet specialized for particular activities, such as speech or patterned movement. Recovery of motor and sensory functions and sparing of language and cognition is sometimes complete when injury occurs at certain critical periods in early development.

Even the mature central nervous system has redundant or 'backup' subsystems that participate in this takeover of function. The term for this is neural vicariation. 'Parallel' and perhaps even widely (spatially) distributed 'systems' can sometimes mediate the behaviors of concern. However, the mechanisms by which area 'a' could 'take over the function' of damaged area 'b' and still perform function 'a' are usually not well described.

Injury-Induced Reorganization of Cerebral Maps

Until the development of sophisticated imaging and electrophysiological techniques, it was not possible to determine whether such equipotential, vicarious, or pluripotent systems did or did not exist, so the concept of neuronal plasticity in adults was largely dismissed until near the end of the twentieth century. Clinical researchers now use functional magnetic resonance imaging (fMRI), positron emission tomography, scanning and microelectrode stimulation, and recording from multiple brain sites to show that functional compensation is the result of extensive reorganization of activity in the damaged brain. For instance, after an infarct in the striatum of human patients, a number of subcortical areas both ipsilateral and contralateral to the injury site become activated as behavioral recovery progresses. Such activation, measured by increases in cerebral blood flow and glucose metabolism, is not observed when normal volunteers perform the same motor tasks. Thus, if 'tricks' are being used to compensate for lost functions, they may be mediated by extensive shifts in the neuronal and metabolic activity of cerebral structures that are not activated or thought to be generally involved in the behaviors (or not in the same way) in normal circumstances. This type of reorganization can occur rapidly after an injury or take weeks, months, or years, making prognoses for recovery complex and difficult.

Microelectrode recording techniques have demonstrated that in primates, certain brain areas such as the sensory motor cortex are capable of very rapid electrophysiological reorganization in response to injury. Within very short periods of time after lesions of the afferent pathways or even after cortical damage, tissue adjacent to the affected areas reorganizes or expands its receptive fields to capture and mediate at least some of the original physiological activities that were destroyed by the injury. For example, if the visual (occipital) cortex is deprived of its inputs from the optic nerves, that same cortex can now be stimulated by auditory input – the 'visual' cells are 'taken over' by the auditory nerve fibers. The auditory cortex could be said to expand into the territory previously occupied and controlled by visual inputs. Likewise, if the auditory cortex is destroyed or the auditory nerve is cut, the auditory cortex will be 'captured' by visual inputs that have expanded into the deafferented zone. However, if the visual cortex is now activated by auditory input, it may be a clear example of neuroplasticity, but is it 'functional recovery'? This demonstrates again why functional assessment of recovery is so important in a clinical and practical context. Rapid reorganization tends to be more robust during early development. This may be one reason why young subjects with brain damage recover better than older counterparts with the same injury.

Imaging and electrophysiological techniques have also been used to support the historical idea of diaschisis (injury-induced functional inhibition) proposed by Constantin von Monakow at the beginning of the twentieth century. In diaschisis, brain injury triggers a form of long-lasting depression of neural activity. Recovery of function was thought to occur as diaschisis dissipated over time, whereas permanent deficits, due especially to subcortical strokes, were said to be the result of permanent diaschisis. Although the logic appears circular, current research shows that injury to the brain does produce chronic suppression of activity associated with behavioral impairments, often in the area of the brain contralateral to the injury, showing that the process of injury involves many more structures than just the directly traumatized area.

At the very least, the notion that the 'rewiring' of neuronal pathways can be achieved by drugs or environmental stimulation needs to be approached carefully because the wiring diagram for each individual is heavily influenced by early experience and training. Standardized rehabilitation therapies might result in the formation of maladaptive connections and the prevention of functional recovery. For instance, if the current paradigm of structure–function relationships proves valid, it is difficult to imagine how the capture of auditory input by visual fibers would automatically lead to an adaptive outcome.

In conjunction with the electrophysiological experiments in primates, computer-assisted rapid fMRI studies in humans have shown that multiple systems throughout the brain become activated during selected

cognitive tasks, such as naming objects or performing mathematical calculations. Many neuroscientists now accept the view that widely distributed neural 'modules' and parallel processing are involved in even simple cognitive or sensory processing; however, there is much less agreement regarding the number of modules (brain areas) that are required to mediate even a simple behavior such as reaching for a piece of food. A corollary of this assumption is that focalized damage would cause widespread changes both serially and in parallel throughout the brain. Therefore, recovery of behavioral functions may depend on equally widespread changes in synaptic connectivity and their nuclear and metabolic consequences.

Therapies for Brain Injury

In the search for new therapies to treat traumatic brain damage, it has become clear that the injury itself is not a monolithic or isolated event. Brain injury is now seen as a very complex cascade of biochemical and morphological processes of varying duration, each of which may contribute to neuronal death and/or repair and regeneration. Until recently, head trauma research focused on what happens to neurons and their transmitters. Now it is becoming increasingly clear that the repair of the vascular system and blood–brain barrier and the posttraumatic activities of different types of glial cells, macrophages, T cells, and other inflammatory agents all contribute significantly to the prognosis for recovery.

During the past 40 years, clinical trials have failed to find a successful treatment for traumatic brain injury (TBI). For stroke victims, only one agent, tissue plasminogen activator, is available, and it is used infrequently (in only 3–5% of patients) because of its risks. Most current drug interventions for brain damage are categorized into two classes: (1) those that can be given early in the injury cascade to inhibit inflammation and cytotoxicity in vulnerable neural cells and (2) those that are given later to agonize or antagonize the synthesis, release, and reuptake of neurotransmitters and neuromodulators, which can produce a state of overexcitation and oxidative stress leading to loss of nervous tissue. Such agonist drugs which increase neurotransmitter activity or block inhibitory neurotransmitters to overcome diaschisis have been used to promote functional recovery after stroke in both animal and human subjects. However, clinical trials with these agents have had limited success. Another category of treatment, behavioral therapy, such as forcing patients to use an affected limb by restricting the use of the good limb (the forced-use paradigm), or treatment with stimulants (e.g., amphetamine) may reduce or eliminate the diaschisis caused by the injury. Do these therapies work because other brain areas take over the function of the area of stroke? Current evidence can be cautiously interpreted to suggest that this may be the case, but the issue is still the subject of much research and debate.

Neuroprotective Agents

There are three main types of therapies to increase functional recovery from brain injury. First is the use of neuroprotective compounds to reduce the initial inflammatory cascade that can destroy injured neurons. This phase is followed by necrosis of tissue in the area of the injury and then by programmed cell death (apoptosis) that can continue for weeks or months after the initial injury. Many of these changes are not limited to the injury site but, rather, take place throughout the brain. The sometimes subtle and persistent changes in personality, motivation, and daily performance seen in brain-injured patients may be due to the widespread changes in brain physiology that are not always detected with current noninvasive assay techniques.

The neuroprotective agents that reduce cytotoxicity tend to absorb damaging molecules such as free radicals. Free radicals react with many sensitive organelles in nervous tissue, including cellular membranes, DNA, and proteins, changing their conformation and affecting their function. Unfortunately, brain injury clinical trials using free radical scavengers have not had successful outcomes. Other therapies which block the hyperexcitation of the receptors for glutamate have been studied extensively in the laboratory. As with free radical scavengers, many of these compounds have also proven ineffective in improving clinical outcome after TBI.

One additional category of agents that does show promise for reducing the early stages of vascular and neuronal tissue destruction are the neurosteroids progesterone and estrogen. These steroids appear to produce beneficial effects through actions at several levels of the injury cascade. Both can reduce lipid peroxidation, excitotoxicity, and inflammatory immune reactions. Progestins and estrogens have the advantage that they are natural substances that can be injected systemically or given orally beginning immediately after the onset of injury. In laboratory investigations, progesterone was effective in reducing cerebral inflammatory factors, edema, and secondary neuronal degeneration caused by necrosis and apoptosis. Thus, as cerebral edema is reduced, neuronal sparing can also be observed in those areas of the brain that have reciprocal connections to the zone of injury. The onset of cerebral edema also appears to be related to the

production of free radical lipid peroxidation. Postinjury treatment in male rats given progesterone can markedly reduce the formation of 8-isoprostane (a prostaglandin-like substance used as a marker for peroxidation reactions) in the first 24 h after contusion of the medial frontal cortex. This change is highly correlated with behavioral recovery, reductions in the size of the lesion, and enhanced neuronal sparing, which endure long after the treatments have terminated. These data suggest that neuronal and behavioral recovery may be due to the scavenging of free radicals and reduction of inflammation in the injury zone. In one study, researchers found that males with severe brain injury have more than twice the levels of lipid peroxidation reactions to injury compared to females. This may be one reason why brain-injured females tend to recover better than males with the same extent of damage.

Although many still regard progesterone only as a female sex hormone, its use in males in the acute period after brain injury produces the same beneficial morphological and behavioral consequences as in females. One clinical trial found that postinjury administration of progesterone could decrease mortality in severely brain-injured patients by more than 50% and significantly reduce functional deficits in moderately brain-injured patients.

Drugs that can modulate γ-aminobutyric acid (GABA)ergic synapses have been implicated in the recovery process. GABA is thought to be primarily inhibitory in the cortex, and substances that increase GABA synthesis appear to block recovery from cerebral injury, especially in the somatosensory system, when administered chronically. Interestingly, progesterone stimulates the $GABA_A$ receptor to reduce excitatory mechanisms, and in this role it could prevent postinjury epilepsy and excitotoxicity during the early stages after brain injury.

The problem with managing levels of neurotransmitters as a means of promoting functional recovery is that pharmacological manipulations are extremely sensitive to the elapse of time after the injury. Therefore, increased levels of inhibition that may be needed to block excitotoxicity in the damaged area may in fact disrupt recovery if treatment is maintained throughout the course of rehabilitation.

Neural Regeneration

Another approach to treatment is chronic administration of pharmacological agents or the transplantation of various types of embryonic stem or progenitor cells directly into the brain tissue to enhance or stimulate regenerative neuronal and vascular mechanisms of repair after the injury cascade has subsided. Most of these techniques are still in the experimental stage and have not been successfully applied in large-scale clinical testing. As mentioned previously, neuroprotective agents act by protecting the brain from secondary injury in the immediate period after trauma. Research has started to focus on stimulating the regeneration of neural tissue. Such therapies consist of administration of trophic factors – agents that stimulate the repair, regeneration, elongation, and reconnection of damaged axons or dendrites – and transplantation of stem cells, which can migrate to areas of damage to replace lost neurons and glial cells. However, neuronal sprouting may not always be beneficial. For example, lesion-induced sprouting of new afferents into the hippocampus can lead to increased seizure activity, whereas some sprouting in the injured spinal cord can produce spasticity.

Until only a few years ago, glial cells or embryonic stem cells received scant attention as treatments for brain damage. Now, glia have been shown to secrete neurotrophic factors that can stimulate sprouting and regeneration, contribute to axonal repair by remyelinating damaged nerve fibers, and directly modify and contribute to neural transmission in response to brain injury. Neuroscientists have shown that progenitor cells lining the walls of the cerebral ventricles, and stem cells, can give rise to new neurons in the hippocampus, an area consistently implicated in memory processing.

Stem cells also morph into glia, which are now known to play a role in stimulating the growth of new blood vessels and capillaries – processes that are also critical to neural repair after injury. In developing new therapeutic agents to promote functional recovery, it would be advantageous to focus some research on the effects of drugs or stem cell lines on the enhancement of this glial and vascular response to injury. Such effort would be especially important if glia can be shown to contribute to neurogenesis or regeneration in the adult brain.

A class of proteins and peptides showing some promise in preclinical head injury research are neurotrophic factors produced by the brain during development and after injury. During the past decade, advances in molecular biology have made it possible to produce human trophic factors in genetically engineered bacteria. One problem with their use as therapeutic agents in human patients is that they do not appear to pass through the blood–brain barrier in sufficient quantity to be clinically effective. However, rats given intracerebral or intraventricular brain-derived trophic factor, nerve growth factor, and basic fibroblast growth factor have shown significant functional and morphological recovery after lesions of the nucleus basalis magnocellularis, the septal nucleus, the hippocampus, and the entorhinal cortex, among others. Despite good results with laboratory animals, high-quality clinical trial data with these proteins are

still lacking. Despite their potency, delivery of trophic proteins directly into the brain appears to be the limiting factor because systemic administration by injection seems to have unwanted side effects.

Another new area of research is the use of neural stem cells to repopulate the injured nervous system with tissue that has the capacity to develop into a variety of different organs, including brain cells. In one study, researchers showed that when cells from a mouse neural stem cell line were injected into cholinergic basal forebrain areas of mice with fimbria–fornix lesions, these implanted cells differentiated into a neuronal phenotype that expresses choline acetyltransferase and the p75 neurotrophic factor receptor. Other investigators have injected bone marrow stromal cells into the internal carotid artery after TBI in rats. In this study, the injected cells were able to enter the brain parenchyma at the site of injury and differentiate into both neuronal- and astroglial-like phenotypes. Rats treated with these stromal cells had improved neurological scores compared to their injured controls.

Behavioral Rehabilitation Therapies

Behavioral rehabilitation therapies combined with antidepressants, antispasmodics, anticonvulsants, or other agents are used to help brain-injured patients readapt to activities of daily living. One of the more successful rehabilitation approaches has been the 'forced-use paradigm' mentioned previously, in which stroke patients, even years after their injury, have been trained to withhold the use of their unaffected limbs while being required to manipulate aspects of their environment with their stroke-affected limb. Multicenter testing with this approach has demonstrated moderate to good recovery that appears to be sustained after the training has been terminated.

Investigators have also shown that reorganization and expansion of functional cortical maps can be induced by intensive training in normal animals. In brain-damaged subjects, specific kinds of sensory training may be beneficial as rehabilitation therapy because they directly enhance the pace and extent of reorganization and recovery of functional plasticity. Furthermore, there are apparently marked individual differences in normal individuals in the location and size of cortical receptive fields which vary in their degree of modifiability according to the subject's experiential history. An interesting example of experiential modification of the brain is found in London cabbies. Using MRI scanning, University College of London investigators found that compared to the general population, cabbies have a larger hippocampus (a part of the brain associated with long- and short-term memory storage and spatial learning). The 'extra' learning required to memorize the streets of London supposedly accounts for the additional hippocampal growth.

Conclusion

The injury process is a complex cascade of events that can be influenced by many variables, including sex, age, severity and momentum of injury, hormonal state, health history, and time of trauma. Other therapies may include treatments that do not directly affect neural tissue but instead promote recovery of function by working indirectly on the immune system to reduce inflammation or on the vasculature to increase blood flow and brain metabolism. Because brain injury in its various forms is a major public health problem, more attention is now being paid to research in this area. Meanwhile, older paradigms which held that the mature brain is incapable of inherent plasticity and repair are being replaced by a more optimistic vision of central nervous system plasticity, which will eventually translate into more effective and enduring treatments and therapies. Policy changes at the National Institutes of Health suggest that there will be more focus on 'translational' research to bring new drug therapies and better care to TBI victims, but only time will tell whether such policies prevail and prove effective.

Brain Injury: Magnetic Resonance Studies of Metabolic Aspects

R Vink, University of Adelaide, Adelaide, SA, Australia

© 2009 Elsevier Ltd. All rights reserved.

Brain injury may result in the development of irreversible tissue damage through both primary and secondary injury mechanisms. Primary injury is caused by the mechanical events associated with the initial injury to the brain, whereas secondary injury is the chemical and metabolic changes initiated by the original insult. These secondary changes then develop over minutes to days after the primary event to cause further brain injury. This gradual development of secondary injury with time provides a window of opportunity to attenuate, or even prevent, the secondary injury process and subsequently improve the outcome. However, the factors that contribute to secondary injury first need to be identified before appropriate 'antifactors' can be developed. One of the major difficulties associated with the identification of secondary injury factors has been the use of invasive physiological and biochemical techniques that by their nature destroy tissue. Moreover, such techniques are limited to single time points and do not permit the correlation of measurements of physiological and metabolic changes with the ultimate survival and neurological outcome following brain injury. One class of techniques that has gained increasing acceptance as a valuable tool in the study of brain injury is magnetic resonance (MR) spectroscopy (MRS) and magnetic resonance imaging (MRI). These MR techniques are noninvasive and permit the repeated monitoring of various metabolic and physiologic changes over time. Moreover, at an experimental level, a brain-injured animal can be allowed to recover and evaluated with regard to long-term neurological outcome and histopathology. Thus, each animal serves as its own control, and correlations can be made between early metabolic and physiological changes and chronic behavioral recovery or tissue damage.

Magnetic Resonance

The application of MR techniques to the study of biological systems was first performed in the 1950s, but it was not until the advent of surface coil techniques in 1980 that the technology was successfully applied to the study of organ metabolism *in vivo*. Since then, the investigation of brain metabolism by MR techniques has resulted in literally thousands of medical and scientific research studies. Although a number of nuclei can be evaluated with MR, most MR studies in brain injury have concentrated on either phosphorus or proton resonances. It is not the intention of this article to discuss the basic principles of MR, and interested readers can find more detailed information from some excellent online resources.

Phosphorus MRS

Phosphorus MRS allows the monitoring of metabolic events involving phosphorus metabolites. Because many of the critical energetic processes occurring in the cell are essentially phosphate transfer reactions, phosphorus MRS has grown to be the most widely used MRS technique in the study of metabolism. A typical phosphorus MRS spectrum obtained from the brain of a rat is shown in Figure 1. Several metabolites can be identified, including phosphomonoesters (PME), inorganic phosphate (Pi), phosphodiesters (PDE), phosphocreatine (PCr), and the three phosphates of adenosine triphosphate (ATP). The integrated area under each peak is directly proportional to the concentration of that metabolite, whereas the chemical shift (i.e., position) of the peak provides information about the ionic environment of that metabolite. For example, the Pi peak is commonly used to determine the intracellular pH, the chemical shift of the Pi peak being dependent on the dissociation state of HPO_4^{2-}. Similarly, intracellular free magnesium concentration (Mg^{2+}) can be determined on the basis of the chemical shift of βATP, which is dependent on the relative concentrations of Mg^{2+}-bound ATP and Mg^{2+}-free ATP. Thus, change in the position of the peaks provides valuable information about the intracellular ionic environment, whereas change in the intensity of the peaks provides an indication of the relative concentrations of the metabolites.

Proton MRS

Application of proton MRS to the study of the brain has been somewhat slower than that of phosphorus MRS because of difficulties inherent in this method. The relative concentration of the intracellular metabolites is in the millimolar range, whereas the concentration of water approaches 40 M, which is equivalent to 80 M in protons. Thus, to observe the less-concentrated metabolites, effective suppression of the dominant water peak is essential. Furthermore, the difference in chemical shifts between metabolites is far less than that observed in phosphorus

Figure 1 Typical phosphorus MRS spectrum obtained from the brain of an anesthetized rat. PME, phosphomonesters; Pi, inorganic phosphate; PDE, phosphodiesters; PCr, phosphocreatine; ATP, adenosine triphosphate (α, β, and γ peaks).

MRS. For example, the normal phosphorus spectrum extends over approximately 40 parts per million (ppm), whereas most observable proton resonances occur within a 10 ppm range. Thus, there is significant overlap between metabolites in a proton spectrum that makes identification of individual resonances somewhat difficult. Nevertheless, proton MR techniques have been developed that allow for the monitoring of certain metabolites, including lactate, *N*-acetyl aspartate (NAA), total creatine (creatine plus phosphocreatine), total choline, lipids, and amino acids. Furthermore, as higher field magnets are developed and applied to brain studies, the degree of overlap between individual resonances will be reduced providing greater chemical shift dispersion and improved detection sensitivity such that more metabolites will be visible.

Proton MRI

MRI differs from MRS in that total signal intensity is mapped against location, giving an image of the signal distribution. Most studies have mapped the proton intensity of water, whose concentration varies by 14% between tissues, thus giving excellent soft tissue contrast, particularly in brain (Figure 2). In addition to anatomical images of brain structure, the technology can also be used to obtain information on vascular anatomy, blood flow, edema development, water diffusion and perfusion, and glucose turnover. Also, metabolic information has been obtained by using an exciting MRI development termed functional imaging, which provides information on the relationships between brain structures and their function.

MRS in Brain Injury

Noninjured Brain

Numerous MRS studies have reported 'normal' values for various parameters in brain. From phosphorus studies, intracellular pH is approximately 7.1, and intracellular free Mg^{2+} concentration ranges from 0.3 to 0.6 depending on age, gender, and species. Although absolute concentration values of metabolites in brain have been reported, these values vary depending on the methods used. Therefore, it is usual in phosphorus MRS to report ratios that avoid the pitfalls of absolute quantitation. The ratios so far reported are somewhat species dependent; the PCr:Pi ratio ranges from 2.0 in humans to 4.0 in rats, and the PCr:ATP ratio ranges from 1.0 to 2.0, respectively. It should be noted that these are adult values, and ratios are lower for neonatal brain. ADP concentration has been calculated from the creatine kinase equilibrium reaction to be approximately 20–30 $\mu mol\, g^{-1}$ tissue wet weight. This calculation uses *in vitro* values for PCr and ATP and the MRS measured values for pH and free Mg^{2+}. Because this value for ADP concentration is significantly less than previous values determined using *in vitro* techniques, it is thought to represent the free cytosolic pool and not the total ADP pool.

In water-suppressed proton MR spectra of normal brain (Figure 3), NAA is the dominant metabolite, with a concentration of approximately 13 mM, although the exact value is dependent on age and, to a small degree, location (gray matter vs. white matter). Originally used as an internal standard, it is now known that the NAA concentration varies with pathophysiological state and cannot be used as a concentration standard. Indeed, it is widely accepted that NAA is a neuronal marker reflecting both neuronal integrity and neuronal metabolic activity. It is commonly expressed in terms of a ratio with other visible metabolites, including total choline (NAA:Cho) or total creatine (NAA:Cr), with the latter being the more frequently used. The normal value for NAA:Cr is approximately 1.35 and varies according to brain location and age. The degree of water suppression affects peak intensities of those metabolites closest to the water frequency, and this should be borne in

Figure 2 MRI image through the human brain.

mind when examining relative metabolite concentrations. Although very important after brain injury, lactate is normally not visible in normal brain because it is present at submillimolar concentrations.

Ischemia

Many of the early MRS studies of brain metabolism following central nervous system (CNS) injury evaluated changes caused by cerebral ischemia. Ischemia results in a loss of high-energy phosphates such as PCr and ATP and an increase in Pi. A profound decrease in intracellular pH from 7.1 to approximately 6.4 was invariably associated with loss of high-energy phosphates. Under conditions of normoglycemia, proton MRS studies have shown that the decrease in pH is linearly correlated with accumulation of lactic acid, although studies in hypoglycemic animals suggest that factors other than lactate accumulation may contribute to brain acidosis. Studies of ischemia in various animals have combined MRS with electroencephalography (EEG) and simultaneous measurement of cerebral blood flow. These studies have reported that whole brain blood flow must decrease to less than 20 ml per 100 g per min before any changes occur with respect to phosphorus metabolites, pH, lactate accumulation, or the EEG. Chronic ischemia studies have shown that although total phosphorus content of the injured tissue decreases,

Figure 3 Typical proton MRS spectrum obtained from human brain. Cho, total choline; Cr, total creatine; NAA, *N*-acetyl-aspartate.

the pH and relative concentrations of the metabolites recover to normal values. It has been suggested that this may reflect tissue heterogeneity with necrotic tissue failing to contribute to the MRS spectrum. This loss of signal is also detected in proton spectra in which NAA has been observed to decrease in injured tissue as opposed to lactate, which shows significant increases. MRS studies of ischemia have focused on reflow phenomena and pharmacologic or physiologic intervention of secondary damage, particularly the effects of calcium antagonists, alkalinizing agents, and hypothermia. Although relatively few studies have been reported, it appears that restoration of intracellular pH and bioenergetic state is associated with improved tissue survival after ischemia.

Trauma

Changes in MRS metabolites following experimental brain trauma are very different from those observed in ischemia. For example, trauma that results in mild to severe levels of motor dysfunction does not cause loss of ATP or sustained lactic acidosis. Only when very severe levels of trauma are induced is there a depletion of ATP reserves, most likely as a result of secondary ischemia caused by the extreme nature of the insult. Nonetheless, there are significant changes in the MRS spectra following less-severe levels of traumatic brain injury (TBI). Brief acidosis is apparent in the immediate posttraumatic period, although the acidosis is slight (pH decreases to a minimum value of 6.8) and transient, recovering by 1.5 h after the injury. The development of intracellular acidosis is correlated with accumulation of lactic acid, which, as shown in ischemia studies, is linearly related to intracellular acidosis. Cellular bioenergetic state also decreases following trauma as reflected in declines in PCr:Pi ratio and calculated cytosolic phosphorylation potential. This decline in the bioenergetic state is thought to reflect an increased energy demand in response to attempts to maintain ionic gradients after trauma.

Phosphorus MRS has also shown that the brain intracellular free Mg^{2+} concentration decreases by as much as 60% after brain injury. In addition to being mandatory for all energy-producing and energy-consuming reactions, the magnesium ion is essential for membrane stability; modulation of K^+, Ca^{2+}, and *N*-methyl-D-aspartate channel activity; protein synthesis; RNA aggregation; DNA synthesis; regulation of vascular tone; and apoptosis. Thus, a decline in the free and tissue concentration of this ion may be involved in many of the reported secondary events following trauma. The evidence demonstrating that intervention which restores Mg^{2+} levels following CNS trauma improves neuronal survival and improves functional outcome suggests that Mg^{2+} may be a critical early factor leading to irreversible tissue damage after CNS trauma. Although the importance of the magnesium ion has long been recognized, MRS studies have now provided evidence, at least in trauma, stroke, migraine, and substance abuse, that free Mg^{2+} may play a central role in metabolic regulation *in vivo*.

Proton MRS studies have demonstrated that NAA declines following trauma in a manner similar to that observed in ischemia. Moreover, the decline in NAA, and particularly gray matter NAA, has been reported to predict outcome after trauma and, specifically, overall neuropsychological performance. Because NAA is restricted to neurons, it has also been proposed that the loss of this metabolite is a marker for neuronal cell death. However, observations suggest that NAA decline may also occur through metabolic depression or in response to altered osmolar state. As such, the use of NAA as an assay of neuronal numbers should be discouraged, although its use as an indicator of neuronal status seems valid. Decreased levels of NAA, or of NAA/Cr ratios, are indicative of a poor prognosis.

Choline levels following trauma have also attracted interest, with studies suggesting that higher levels of this metabolite in the frontal lobe of children may be related to arithmetic ability. Whether this relates to the fact that choline is a precursor to the neurotransmitter acetylcholine is still unknown and requires further investigation. For this reason, changes in individual metabolites are sometimes difficult to interpret, and it has been suggested that combinations of changes may better indicate specific metabolic events. For example, macrophage recruitment in the posttraumatic inflammatory response may be reflected in combined changes of lactate, alanine, glutathione, and polyamines. The difficulty in this approach is that with all the potential permutations, it may be

impossible to establish what specific event is associated with each 'metabolic fingerprint.'

MRI in Brain Injury

Numerous studies have used MRI in the examination of brain injury, particularly with respect to characterizing lesion location and size after insult, as well as overall size of the brain and its substructures. Studies in both traumatic and ischemic brain injury have demonstrated a correlation between lesion size and histopathology, with experimental and clinical studies showing that the MRI-detected lesion size is correlated to outcome. Indeed, a reduction in lesion size by pharmacological means has been noted to result in an improvement in outcome. Trauma studies have further demonstrated that it is not only the size of the lesion but also the location of the lesion that is related to posttraumatic motor outcome, cognition, and memory performance. Childhood brain injury often resulted in white matter atrophy and reductions in hippocampal volume that impacted on outcome, whereas MRI-detected white matter injury, ventriculomegaly, and intraventricular hemorrhage in brain-injured premature infants was associated with abnormal outcome. Taken together, these results clearly demonstrate a promising application of MRI in the clinical management of head injury. A novel application of MRI involves biomechanical characterization of injury; rapid MRI acquisitions permitted the estimation of tissue strains and strain rates following TBI, thus providing the foundation for the development of protective devices and measures against primary injury.

Diffusion-weighted imaging (DWI) and the related diffusion tensor imaging (DTI) have been used to characterize the time course of lesion development and tissue microstructural changes after injury. This application of DWI can detect lesion development within minutes of the insult (Figure 4), whereas DTI can provide information on the integrity of neuronal fiber tracts (fiber tracking). When used to characterize edema formation, DWI provides information on and can differentiate between cytotoxic

Figure 4 MRI scan of human brain showing the superior ability of diffusion-weighted MRI to detect lesions not readily visible by conventional MRI techniques.

and vasogenic edema. Findings to date have shown that cytotoxic edema is always present in ischemia, whereas vasogenic edema is present in the initial stages of mild to severe brain trauma. Although the reasons for this difference are still unclear, it has been proposed that cellular energy status may be a contributing factor. Another MRI application to brain injury is vascular angiography, which can provide information on blood vessel anatomy and restriction of flow on the basis of blood flow through the vessels. The rate of tissue perfusion can then be determined using perfusion-weighted imaging. Hemorrhage as a result of brain injury is easily detected by MRI (Figure 5), although it is the ability to detect nonhemorrhagic diffuse axonal injury that sets MRI apart from computed tomography. The presence of hemorrhage in diffuse axonal injury-type lesions is a poor prognostic sign, with lesions in the deeper brain regions being more strongly associated with poorer neuropsychological performance. These hemorrhagic diffuse axonal injury lesions are best detected with the recently developed susceptibility weighted MRI techniques, although the gradient-echo techniques are still routinely used with good success.

Although applications of functional MRI (fMRI) in brain injury have been limited, there are a number of encouraging reports suggesting that the technique may become particularly useful in monitoring the brain's ability to recover function as it attempts to repair damaged connections. For example, decreased activity of the anterior cingulated cortex in TBI patients was potentially related to neural network damage most likely associated with diffuse axonal injury. Moreover, in a separate study, the magnitude of fMRI signal change during sensorimotor tasks in TBI patients was correlated to the magnitude of subsequent clinical impairment. In perinatal stroke, functional recovery in the visual cortex was correlated with the recovery of structural integrity in major pathways of the visual system. Clearly, significantly more studies are required before fMRI techniques become routinely utilized in patient care, although the technique shows promise far beyond the original applications in the 1990s.

Figure 5 MRI scan of human brain illustrating the presence of hemorrhage.

Future Directions

It is clear that the unique ability of MR techniques to noninvasively monitor physiological and metabolic processes over time permits the investigation of basic mechanisms involved in brain injury and the efficacy of drug treatments to promote recovery. Furthermore, with the development of improved localization techniques, it may soon be possible to determine the selective vulnerability of specific brain regions to injury. Progress in MR technique development has also opened the way for a number of exciting studies. In particular, fMRI techniques are being increasingly utilized to illustrate disorders of brain activation, including speed of information processing, that may be correlated to posttraumatic lesion development. Reports are also appearing that describe the measurement of local oxygen consumption using MRI and MRS-determined rate of glucose consumption in human brain. Furthermore, the development of routine chemical shift imaging techniques will permit the neuroscientist to examine the distribution of a metabolite across the brain in a manner similar to how a radiologist examines anatomical proton images. It appears that future applications of MR techniques will initiate a number of exciting new studies that will further assist in the characterization of the pathophysiological events associated with brain injury.

Brains Evolved

The only plausible scientific explanation for the existence of what Charles Darwin termed "organs of extreme perfection and complication," such as the brain, is that they evolved over millennia by natural selection. The human brain contains millions or even billions of neurons organized into a variety of interacting but distinct neural systems. Neuroscience has predominantly approached the problem of understanding this complex organization without explicit reference to how it evolved. Yet the functional organization of a system must reflect both the adaptive problems to which it is a solution, and the combined evolutionary and developmental processes from which it emerges. The way that brains are organized is thus intrinsically related to the way that they evolved.

Using Extant Species to Study Brain Evolution

Because the internal structure of brains does not fossilize, their evolution can be studied only indirectly. One indirect method is to analyze the patterns of surface convolutions whose imprints are visible on the internal surface of fossilized crania (or on endocasts of the crania). While useful for documenting evolutionary changes in gross morphological features and certain fine details of cortical surface structure, these data are of limited use in understanding how neural organization evolved, as they reveal nothing about internal structural changes.

The second indirect method is potentially more useful in this respect. It reconstructs evolutionary changes by analyzing comparative anatomy of extant species within a phylogenetic context. A variety of phylogenetic techniques for the analysis of comparative data are now available. The basic rationale for all of these techniques is that the way a trait evolved can be reconstructed by mapping character states in extant species (e.g., the size of a particular nucleus) onto a phylogenetic tree of those species. Reconstruction of the evolution of two or more traits allows evaluation of the patterns of correlated change among the traits (see Figure 1). For example, the hypothesis that two brain nuclei are components of an integrated system implies that they underwent correlated evolution, in terms of their overall size, number of neurons, synaptic connectivity, or other neural characteristics. Whether any such correlated evolution reflects a specific neurobiological relationship between the nuclei, that is, whether it exists independently of more general evolutionary changes, such as those in overall brain size, can be tested by using statistical methods for controlling the effects of confounding variables. Hence, comparative tests of neural organization are based on analyses of the way in which brain structures evolved in relation to one another.

Why is it necessary to use information on the phylogenetic relationships among species in comparative analyses, rather than just correlating the raw species values? The answer is that species are not independent data points in analyses that aim to test hypotheses about how traits evolved. Closely related species are more similar to one another than are distantly related species, because closely related species have undergone less evolutionary divergence. If we are interested in the way in which traits (e.g., the sizes of brain nuclei) evolved in relation to one another, evolutionary changes, rather than species differences, are the most relevant data. Phylogenetic methods explicitly take into account the branching patterns and divergence times between species, and consequently allow valid inferences about trait evolution. These methods are currently little known within neuroscience, despite the fact that neuroscientists often make evolutionary inferences, either explicitly or implicitly, based on comparisons among species.

The process of reconstructing trait evolution on phylogenetic trees emphasizes that extant species do not represent ancestor–descendant relationships. Each extant species is the endpoint of both shared and independent evolutionary histories over an identical period of evolutionary time since their common ancestor. The significance of this point is that no extant species can be treated as an embodiment of the ancestral traits of any other species. Although this point has been made repeatedly, it is still possible to find either implicit or explicit reference in the neuroscience literature to evolutionary pathways between supposedly 'primitive' and 'advanced' extant species. Invariably, such interpretations of species differences are anthropocentrically biased, with phylogenetic affinity to humans being cast as a primitive–advanced continuum (the so-called *scala natura*). This way of thinking about species differences is wrong, and it distracts attention from the ways in which brains have become specialized in different kinds of ways

Figure 1 Basic rationale for the phylogenetic analysis of comparative data, using the method of independent contrasts. Independent contrasts are calculated as differences between pairs of species, between species values and an ancestral node, or between higher nodes. (a) Beginning at the tips of the tree, contrast *a* is calculated as the difference between species i and ii, while contrast *b* is calculated as the difference between species iv and v. Then, contrasts are calculated using higher nodes (the 'mixed' contrast *c* and internal contrast *d*; pairs of values at internal nodes are the reconstructed ancestral values of traits A and B). Contrasts are thus calculated up the tree, maximizing the number of possible contrasts while using each branch no more than once. The direction of subtraction for calculating contrasts is arbitrary but it is usual to force the independent variable to be positive. These contrasts are independent of one another and can be analyzed using standard statistical techniques. Strictly, the contrasts should be standardized according to the amount of time since evolutionary divergence. In this simplified example, however, unstandardized contrasts are plotted against one another for illustrative purposes (b). Here, traits A and B show positively correlated evolution.

in different lineages. In contrast, studying the patterns of brain evolution across numerous independently changing lineages has the potential to illuminate general aspects of brain organization.

Modularity and Brain Evolution

The different components of organisms tend to evolve in a coordinated fashion. Hence, as overall body size increases, so does the size of limbs, muscles, tendons, and internal organs, and this is necessary for the animal to function well. At the molecular level, such coordinated evolutionary change may involve regulatory genes that determine overall patterns of growth, such as the rate and duration of cellular division. However, the very fact that separate components of organisms can be differentiated implies that they have a degree of structural and functional independence. The concept of modularity refers to the idea of integration within, and relative autonomy among, the different components. Modularity may refer to the way that particular structures function, to the way in which they evolve, or to the way in which they develop during ontogeny. These types of modularity are conceptually distinct yet often related. For example, the idea that a set of components comprises a functional module implies that they are structurally integrated to perform the function. If the integrity of such a functional module is to be preserved when it is modified by natural selection, the constituent components must change together. Such coordinated evolutionary change is facilitated if there is developmental modularity, allowing relatively few genetic changes to cause a cascade of coordinated structural changes. On the other hand, developmental modularity may act as a constraint on 'evolvability': the evolutionary changes that are developmentally possible or likely.

Modularity in organism design is associated with mosaic evolution: to the extent that modules are functionally and developmentally dissociable, organisms can be expected to evolve in a mosaic fashion, with different modules changing in response to different selection pressures. For example, testes are structurally and histologically distinct tissues with the specific functions of sperm and testosterone production. While the size of the testes correlates closely with the size of other organs and overall body size, comparative studies have shown that testes of promiscuously mating species are large relative to body size, as an adaptation to sperm competition. Hence, testes evolved in part independently of changes in the size of other organs and in overall size. Such mosaic evolutionary change appears to have been ubiquitous, and other well-known examples include increased heart and lung size as an adaptation to the energetic costs of flying in bats and birds, variation in relative spleen size associated with degree of exposure to nematode infection, and relatively elongated loops of Henle in the kidneys of desert mammals.

Unlike bodily organs, individual brain components are extensively – even massively – interconnected to support the integrated processing of information and coordinated behavior, potentially limiting the importance of mosaic evolution. The extent to which modularity and mosaic evolution apply to the systems of the brain has, therefore, proved relatively contentious. Nevertheless, much evidence suggests that individual brain components are grouped within structurally, functionally, and developmentally differentiated neural systems specialized for handling particular cognitive operations. Indeed, systems neuroscience is largely predicated on such modularity.

Although there is little argument that the brain is at least partly modular, the nature, extent, and developmental causes of this modularity are still hotly debated. It has also been suggested that, once the fundamental structure of the central nervous system was established early in the evolution of the chordates, the extent of mosaic change in the brain may have been limited by developmental constraints. The fact that all major brain structures tend to show highly correlated size variation across species has been taken as evidence for this developmental constraint hypothesis. Recent evidence from comparative studies, however, provides evidence for mosaic evolution of brain structure.

Comparative Evidence for Mosaic Evolution of Brain Structure

Relative Size Change in Major Brain Structures

The extent to which brain structure appears to have evolved in a mosaic fashion depends on the anatomical level at which the analysis is done. Analyses of variation in the size of major brain subdivisions, such as the telencephalon, tectum, cerebellum, and medulla, generally indicate a pattern of strongly coordinated evolutionary change, with 90% or more of the variance in a brain structure being attributable to overall size. Even at this crude level of analysis, however, there are striking examples of variation that is independent of overall size. Among teleost fishes, specializations for different modes of foraging and sensory processing are associated with dramatic differences in the relative sizes of relevant brain structures (Figure 2). In mammals, the superior colliculus is approximately 10 times larger in ground squirrels than in rats, despite the fact that overall brain size is very similar. And also among mammals, primates have neocortices that are, on average, 5 times larger than in insectivores of similar brain size, with some comparisons again indicating tenfold differences.

These examples of relative size differences are impressive, particularly given that the structures involved connect with many other brain regions and process a variety of types of information. The mosaic evolution hypothesis implies that the differences reflect size changes in specific components within these structures. For example, the neocortex is a highly heterogenous organ, processing information from all the senses and being involved in many different aspects of sensory, motor, and cognitive processing. Concordant with the concept of mosaic evolution, differences in neocortex size are related to the evolution of specific sensory regions. Primate visual specialization provides an example. Primates exhibit a range of peripheral and central specializations for vision, including highly convergent orbits supporting binocular vision, large eyes, trichromatic vision (in Old World monkeys and apes), a concentration of ganglion cells in the central retina; a greatly expanded representation of the central field in visual cortex; a distinctive pattern of projections between eye and brain; a distinctly laminated lateral geniculate nucleus (LGN) within which information from the same hemifield of each retina is brought into visuotopic register in separate layers, before converging on numerous single binocular neurons in the visual cortex; and relatively numerous and extensive visual cortical regions. This suite of visual features was a fundamental component of the adaptive shift in the evolution of the first primates, but there is variability in most or all of these features within the order. Both variation in neocortex size within

Figure 2 Mosaic brain evolution in teleost fish. Dorsal views of brains on the left, transverse sections on the right. VL, vagal lobes; FL, facial lobes; Tec, tectum; Tel, telencephalon; Cbl, cerebellum; EL, electrosensory lateral line lobe. Sensory specializations are associated with dramatic differences in the size of associated brain structures. Goldfish have enlarged vagal lobes (involved in taste and processing of food). Catfish have large facial lobes (processing gustatory information from the barbells), and relatively large electrosensory lateral line lobes, though the latter are not as large as in electric fish such as the glass knifefish. Figure 3 Visual specialization underlies the evolution of large neocortex size in primates. Graph (a) shows the results of a phylogenetic analysis indicating positively correlated evolution between the relative volumes of the whole neocortex and of the LGN, after removing the effects of variation in other brain structures. Graph (b) plots surface areas of visual cortices against those of somatosensory cortices for primates and two other taxonomic groups (red circles are primates, blue diamonds are marsupials, green squares are insectivores). (a) Data from publications by H Stephan and colleagues. (b) Data provided by P Kaskan (Kaskan PM, Franco ECS, Yamada ES, Silveira LCD, Darlington RB, and Finlay BL (2005) Peripheral variability and central constancy in mammalian visual system evolution. *Proceedings of the Royal Society of London B* 272: 91–100).

the primates and differences in neocortex size between primates and nonprimates are related specifically to size change in visual cortices relative to other cortical regions (Figure 3). The data in Figure 3(b) are plotted in log–log coordinates for analytical convenience, masking the absolute size differences. For example, tamarin monkeys have somatosensory cortices slightly smaller than do hedgehogs (22.5 vs. 28.5 mm^2, respectively), but their visual cortices are approximately 9 times larger (158 vs. 17.4 mm^2, respectively). Hence, primates are relative visual specialists, while insectivores are relative somatosensory specialists, reflected in the mosaic nature of neocortical evolution.

Correlated Evolution between Components of Functional Systems

Because neural systems are extended networks with connections that cut across the major structures of the brain, mosaic evolution should be evident in correlated evolutionary changes among connected components, independent of changes in other systems. Quantitative phylogenetic comparative analyses strongly support this prediction: anatomical and functional connections closely predict patterns of correlated evolution among nuclei in a range of neural systems, including the hippocampal complex, amygdala, olfactory system, auditory system, and motor system (Figure 4). In some cases, it has been possible to test the prediction of correlated evolution at the level of individual nuclei. In the corticocerebellar system, evolutionary changes in the size of connected nuclei in the hind-, mid-, and forebrain correlate strongly after controlling for variation in other brain structures. Of the four main vestibular nuclei and three cerebellar nuclei, the two with direct connections (the lateral vestibular and middle cerebellar nuclei) are those that show correlated evolution after controlling for the size of the other nuclei. Hence, anatomical connections predict detailed patterns of correlated evolution, substantiating the hypothesis of mosaic change at the level of neural systems.

Comparative Studies Inform Systems Neuroscience

The cases cited above are examples of testing predictions of evolutionary hypotheses derived from experimental neurobiological data. The fact that brain nuclei co-evolved according to their functional connections also allows us to carry out the reciprocal program, that of testing hypotheses about brain organization using comparative data. A recent example concerns debate about the structural and functional integrity of the amygdala. On the basis of anatomical, pharmacological, and electrophysiological data, Swanson and Petrovich questioned the existence of the amygdala as a structurally and functionally coherent unit, arguing that the term 'amygdala' refers to a collection of disparate nuclei that are really parts of different neural systems. Some other researchers, however, emphasize the dense connections between nuclei within the amygdala. The problem here is in deciding what constitutes sufficient evidence to conclude that the amygdala either does or does not exist as a structurally and functionally integrated entity, hence breaking the cycle of claim and counterclaim based on affinities among nuclei and differences between them respectively.

Accepting that, like all complex biological organs, neural systems exist because they evolved by natural selection, the question of whether particular components constitute components of such a unified system is intrinsically an evolutionary question. The crux of the matter is thus how such nuclei evolved: did they evolve together, in a coordinated fashion,

	Rest of brain	Olfactory bulb	Entorhinal cortex	CBL amygdala	Cerebellar nuclei	Visual cortex
Olfactory cortex	0.18 n.s.	0.31 **	0.09 n.s.	0.32 *	0.23 n.s.

Lateral geniculate	1.04 n.s.	–0.52 *	0.49 n.s.	–0.40 n.s.	–0.70 n.s.	0.83 *

Figure 4 Correlated evolution among primate brain structures is predicted by functional and anatomical connections. Each cell in the figure contains the results of a phylogenetic analysis of the volumes of the corresponding structures. The figures are partial regression coefficients for pairs of structures, after controlling for evolutionary change in all of the other structures in the table. Asterisks indicate statistical significance (*, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$; ****, $p < 0.0001$; n.s., nonsignificant). Predicted correlations are in the diagonal line of blue boxes. Negative correlations between visual and olfactory systems reflect evolutionary differentiation into nocturnal and diurnal niches. The positive correlation between amygdala and olfactory cortices is unsurprising on anatomical and functional grounds (see below). Hence, there are only two correlations that would not be predicted (both between the amygdala and the cerebellar–vestibular system). Overall, these analyses and similar ones for insectivores indicate a clear pattern of strongly and positively correlated evolution among structures within systems, and a lack of such correlated evolution among structures in different systems. and in a way that cannot be attributed merely to their integration within a larger, more global system (e.g., the limbic system, or even the brain as a whole)? Phylogenetic analysis of comparative data in primates and insectivores clearly shows that the amygdala coheres as an evolutionary unit. After controlling for variation in a range of other brain structures, including other limbic structures, separate groups of nuclei in the amygdala show significantly correlated evolution, hence refuting the claim that they are parts of entirely different neural systems (Figure 5).

Figure 5 Evolutionary coherence of the amygdala in two mammalian groups. Phylogenetic comparative analysis indicates strongly correlated evolution between separate amygdala components, even after removing the effects of a variety of other limbic and nonlimbic structures. Bars between structures represent significant partial regression coefficients, with bar width reflecting strength of the correlation (**, $p < 0.01$; ***, $p < 0.001$). AOB, accessory olfactory bulbs; BL, basolateral nuclei; CM, centromedial nuclei; NLOT, nucleus of lateral olfactory tract. Summarized from analyses in Barton RA, Aggleton J, and Grenyer R (2003) Evolutionary coherence of the mammalian amygdala. *Proceedings of the Royal Society of London B* 270, 539–544.

Correlated Evolution between Brain Structure and Ecology

If, as suggested, neural system evolution is a result of natural selection on modular information-processing capacities, brain structure should correlate with relevant aspects of animals' ecology and behavioral specialization. Comparative studies have begun to reveal such correlates of mosaic brain evolution. In birds, the relative sizes of the HVC nucleus and of the hippocampus correlate with song repertoire size and spatial memory demands (food caching), respectively. In primates, visual and olfactory system evolution are both associated with ecology, though in different ways: diurnal habits correlate with increased relative volume and cell number in parvocellular, but not magnocellular layers of the LGN, and with decreased

olfactory system size. The evolutionary dissociation between parvo- and magnocellular pathways accords with experimental data on functional segregation within the visual system and on behavioral attributes of different species. Parvocellular projections to visual cortex mediate fine-grained, acute, and color vision, abilities that are characteristic of diurnal primates. Relative parvocellular LGN size and visual cortex size also correlate with foraging behavior and with social group size, independently of the correlation with activity period, suggesting that visual system evolution may have been affected by several aspects of lifestyles. The size of the accessory olfactory bulbs, which mediate pheromonal processing, are correlated with social variables, such as social group size (in New World monkeys) and spatial dispersion (in nocturnal lemurs and lorises), whereas the main olfactory bulbs correlate more strongly with nonsocial variables such as diet. In carnivores, relative olfactory bulb size also correlates with ecological variables. In bats, wing area and habitat complexity correlate with the relative size of the auditory inferior colliculi (among echolocating species) and with relative hippocampus size.

Neural System Evolution and Brain Size

The adaptive and cognitive significance of brain size has been much debated. If brains are mosaics of independently evolving neural systems, it should be possible to document at least broad types of information processing that have been enhanced during brain expansion (or compromised during brain size reduction). Primates' visual specialization again provides an example. Evolutionary changes in the volumes of both the LGN and primary visual cortices correlate positively with brain size relative to body size after removing the effects of evolutionary changes in other structures. One specific visual factor implicated in brain size evolution is stereopsis, because the degree of convergence of the orbits also correlates with brain size. Thus, brain size evolution in primates is specifically associated with modifications of the visual system. Similar evidence is emerging for mammals (in which the size of the optical input to the brain correlates with brain size) and birds (in which eye size correlates with brain size). These recent results provide the first explanations of brain size variation in terms of specific neural systems. Broader understanding of mammalian brain size evolution will, however, require investigation of mosaic size change across a variety of neural systems and phylogenetic lineages.

Conclusions

The components of any adaptive complex, such as the brain, by definition undergo coordinated evolution. At the same time, functional differentiation of neural systems within the mammalian brain potentially creates scope for a mosaic pattern of evolutionary change overlying the allometric covariation of individual components. Comparative analyses unequivocally show that specific systems and structures have evolved in part independently of change in overall brain size, and that such system-specific change correlates with behavioral ecology. The brains of different species evolved under different selection pressures and mediate different behavioral adaptations. These differences caution against making sweeping inferences about 'the brain' based on study of any one model species, and provide strong justification for comparative studies of brain structure informed by evolutionary principles. By studying how natural selection modified brains, we can derive insights into their functional organization.

Brain Na,K-ATPase

J-D Horisberger and K Geering, University of Lausanne, Lausanne, Switzerland

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Na,K-ATPase, the Na^+ pump, is a transmembrane protein belonging to the P-type ATPase family. Its primary physiological role is the maintenance of large gradients, inward for sodium (Na^+) and outward for potassium (K^+), across the plasma membrane of all animal cells. Na^+ and K^+ gradients are necessary for the control of resting membrane potential, cell volume, intracellular pH, and calcium concentration, and for import or export of many solutes by means of various coupled transport systems. Na,K-ATPase is also the target of a group of drugs and toxins known as 'cardiac steroids' (e.g., digoxin, ouabain) because of their structure and use in the treatment of congestive heart failure.

Na,K-ATPase: Genes, Subunits, and Isoforms

A functional Na,K-ATPase results from the association of two subunits, α and β (see Figure 1). The main α subunit (~100 kDa), also called the catalytic subunit, contains the cation- and nucleotide-binding sites and the catalytic site responsible for the hydrolysis of ATP and the transfer of the γ phosphate of ATP to an aspartic residue of the α subunit (the phosphorylation site). The β subunit a smaller (~30–40 kDa) glycoprotein, is essential for the maturation and the expression of a stable protein at the plasma membrane. In mammals, there are four known isoforms of the α subunit ($\alpha1$, $\alpha2$, $\alpha3$, and $\alpha4$) and three isoforms of the β subunit ($\beta1$, $\beta2$, and $\beta3$). Except for the $\alpha1$ and $\beta1$ isoforms, which are ubiquitous, the expression of the other isoforms is tissue specific.

There is a good understanding of the structure of the Na,K-ATPase α subunit (see Figure 1), thanks to determination of the high-resolution structure of sarco/endoplasmic reticulum Ca^{2+}-ATPase (SERCA) by X-ray crystallography. The sequences of these two proteins are sufficiently similar to allow reliable molecular structure predictions by homology. In contrast, the three-dimensional structure of the β subunit is not known.

In many tissues, the α/β complex is found associated with a third small protein of about 14 kDa, called FXYD protein because of the presence of a conserved motif FXYD (phenylalanine, any amino acid, tyrosine, and aspartic acid) in its extracellular domain. Seven different FXYD proteins are known (FXYD1–FXYD7). They are also expressed in a tissue-specific manner and they appear to modulate the functional characteristics of Na,K-ATPase.

Na,K-ATPase Isoform Distribution in the Central Nervous System

α Subunit

The central nervous system expresses $\alpha1$, $\alpha2$, and $\alpha3$ Na,K-ATPase isoforms. In adult brain, all three α isoforms are present in all brain regions. $\alpha1$ levels are highest in cerebrum and cerebellum relative to the two other isoforms. On the whole, there are only subtle differences in the macroscopic distribution of the three α isoforms in the brain. The expression pattern in the eye has received particular attention. In the lens epithelium, which is thought to conduct Na^+ and K^+ transport for the entire lens cell mass, $\alpha1$ and $\alpha2$ isoforms are present, whereas in lens fibers, which have a poor ion transport capacity, only the $\alpha1$ isoform is expressed. On the other hand, in the rat retina, the $\alpha1$ and $\alpha3$ isoforms account for greater than 97% of the Na,K-ATPase mRNA. Finally, in the ocular ciliary epithelium, which contributes to the production of aqueous humor, the $\alpha2$ isoform is expressed at high levels in the nonpigmented epithelium, and $\alpha1$ is expressed in the pigmented epithelium. Significantly, Na,K-ATPase α subunits are located in the apical membrane of the retinal pigment epithelium and the choroid plexus, in contrast to the typical basolateral expression of Na,K-ATPase in kidney and intestinal epithelia.

The expression pattern of the different α isoforms in neurons and in glial cells is complex. It is mostly accepted that the $\alpha1$ isoform is expressed in neurons and glia, $\alpha2$ is expressed in glia, and $\alpha3$ isoform is restricted to neurons. However, this does not exclude that some neurons predominantly express the $\alpha3$ isoform and others express $\alpha1$ and $\alpha3$ isoforms. Moreover, despite a preponderance of the $\alpha2$ isoform in astrocytes, some neurons may express $\alpha2$ as well.

α Isoform expression is regulated by various mechanisms. The expression of all α isoforms increases during development, reflecting the increased specific Na,K-ATPase activity observed during brain development. Neuron-specific expression of $\alpha3$ is mediated by a silencer and another *cis*-acting element in the $\alpha3$ subunit promoter. $\alpha3$ expression is only observed in fully differentiated neurons and not in undifferentiated

Figure 1 Na,K-ATPase structure. The left-hand panel shows the structure of the α subunit of Na,K-ATPase, obtained by homology modeling with sarco/endoplasmic reticulum Ca^{2+}-ATPase (SERCA; Protein Database code 1SU4). The solid cylinders represent α-helical structures. The plasma membrane (m) is shown in yellow. The transmembrane part of the protein is formed by 10 transmembrane helices. The right-hand panel is a scheme of the two constitutive subunits, α and β, together with the associated small FXYD (phenylalanine, any amino acid, tyrosine, and aspartic acid) protein. The respective position of the subunits is still hypothetical.

pluripotent embryonic stem cells, which express only α1 isoforms. In mature neurons, the α3 isoform contributes to about one-third of the total Na,K-ATPase activity. Its appearance coincides temporally with essential neuronal functions such as outgrowth of axonal and dendritic processes, synaptic events, and responses to neurotransmitters, suggesting that this isoform has a specialized function in neuronal physiology. Polarized as well as nonpolarized distributions of α1 and α3 isoforms in neurons have been described, suggesting that cellular localization of the isoforms may not be fixed but may vary with specific functional demands. As to the glial expression of the α2 isoform, it is thought to be dependent on contact with neurons. Unlike in the adult brain, where α2 is mainly present in glial cells, late in the gestation period of mice, α2 is widely expressed in neurons. This result indicates that α2 may be important in the modulation of neuronal activity in the neonate and could explain why mice lacking α2 isoforms die immediately after birth from lack of breathing. In conclusion, the expression patterns and the contributions of α isoforms to total Na,K-ATPase activity in the brain are likely to be under complex control by neurotransmitters, hormones, and developmental processes.

β Subunit

β1, β2, and low levels of β3 isoforms are expressed in mammalian brain. The β2 isoform has in particular been identified in choroid plexus, retina, vestibular dark cells, and ampullary crests of the inner ear's semicircular ducts, whereas the β3 isoform is expressed in the retinal photoreceptor. In general, the β1 isoform predominates in neurons and β2 predominates in astrocytes, making α1–β1 and α2–β2 Na,K-ATPase isoenzymes the most abundant isoenzymes in neurons and glial cells, respectively. The presence of β3 isoforms has also been observed in oligodendrocytes. β1 isoforms in neurons and in astrocytes show no developmental regulation. The β2 isoform, on the other hand, is observed in cellular processes of astroglia and in soma of neurons in newborn mice, but its expression decreases during maturation and is absent in neurons of adult animals. The differential expression and cellular localization of these isoforms suggest a complex regulation of their gene expression and their cellular distribution. Moreover, the distribution pattern of α and β isoforms is consistent with the possibility that all combinations between different α and β isoforms may exist and may produce different Na,K-ATPase isoenzymes with different functional properties.

The picture is even more complicated by the fact that β2 isoforms in the brain may have two functions. β2 isoforms are partner subunits of α2 subunits, but β2 isoforms are also adhesion molecules on glia (AMOG), which are specifically involved in neuron–astrocyte interactions and promote neurite outgrowth. It is not known whether the β2 isoform exerts two independent functions or whether there is a link between cell adhesion and modulation of the ionic milieu.

FXYD Proteins

Of the auxiliary subunits of Na,K-ATPase, the FXYD proteins phospholemman (FXYD1), phosphohippolin (FXYD6), and FXYD7 are expressed in brain. Both absence and presence of the γ subunit (FXYD2) has been reported, whereas Mat-8 (FXYD3), CHIF (FXYD4), and Ric (FXYD5) are absent from the brain. FXYD1 is mostly expressed in heart and skeletal muscle, but moderate levels of FXYD1 mRNA levels are found in the brain. The FXYD1 protein is particularly enriched in choroid plexus and in cerebellum, where it is expressed in both neurons and glial cells and is associated with all three Na,K-ATPase α isoenzymes. On the other hand, FXYD6 is highly expressed in brain compared to other tissues. FXYD6 is widely distributed in different brain regions and is exclusively expressed in

neurons. Expression of FXYD6 is higher during development than in adult brain and is differentially regulated in different brain regions during development. Finally, FXYD7 is exclusively expressed in brain neurons and glial cells, where it is associated specifically with Na,K-ATPase $\alpha 1$–β isoenzymes. FXYD7 protein expression is observed in several regions of the brain, with lowest expression in the hypothalamus. Overall, the expression of several FXYD proteins in brain, which are associated with Na,K-ATPase, and potentially can modulate its transport properties, adds to the possibility for an extremely fine and complex control of Na^+ and K^+ transmembrane gradients by Na,K-ATPase in the central nervous system.

Functional Role of Na,K-ATPase in the Brain

Role in Neurons and Glia

The neuronal action potential is due to the time-controlled flows of Na^+ and K^+ ions along their electrochemical gradients, and the activity of Na,K-ATPase in neurons is absolutely essential to any neuronal activity because it is the sole transport mechanism responsible for the maintenance of these Na^+ and K^+ gradients across the neuronal membrane. The resting membrane potential, a key determinant of neuronal excitability, is also mainly due to the K^+ gradient across the neuronal membrane. In addition, because Na,K-ATPase works by an asymmetrical exchange of three Na^+ ions for two K^+ ions, it carries a small outward current that tends to hyperpolarize the cell membrane. This effect is small (a few millivolts) under steady-state conditions, but can reach a physiologically significant level (e.g., after a train of action potentials that results in Na^+ loading of the neuron and an increase of the extracellular K^+ concentration).

During a period of high neuronal activity with long trains of action potentials, large amounts of K^+ flow out of the neurons during the repolarization phase of the action potentials. Excess K^+ must then be cleared from the narrow intercellular spaces because a high extracellular K^+ concentration would depolarize the neuronal resting membrane potential. K^+ clearance is performed not only by Na,K-ATPase in the neuronal membrane but also by Na,K-ATPase in the plasma membrane of glial cells surrounding the neuronal membrane.

In neurons and in glial cells, the gradients of Na^+ and K^+ are also essential for the function of secondary active transport systems that allow the import of many organic molecules, including the precursors of neurotransmitters, and particularly for the recapture of neurotransmitters released at synapses, mostly by astrocytes. In fact, a significant part of the energy generated by oxidative metabolism in astrocytes is used to restore the Na^+ and K^+ gradients that are 'consumed' by the neurotransmitter reuptake coupled-transport systems. The phenomenon of glial reuptake of the excitatory neurotransmitter L-glutamate has been studied in great detail (see Figure 2). After its release in the synaptic cleft, L-glutamate can be taken up by several coupled transport systems, in particular by the excitatory amino acid transporters EAAT1 (GLAST) and EAAT2 (GLT-1), both expressed in the astrocyte plasma membrane. These coupled-transport systems have a complex stoichiometry: 1 glutamate + 2(or 3) Na^+ and 1 H^+ entering the cell in exchange for 1 K^+. The reuptake of L-glutamate thus depends on both the Na^+ and K^+ electrochemical gradients and is therefore doubly dependent on adequate function of Na,K-ATPase. Failure of glutamate clearance and its persistence in the synaptic cleft result in excessive glutamate receptor stimulation, a pathological phenomenon named excitotoxicity that has the potential to lead to neuronal damage and death.

The increased workload on Na,K-ATPase following reuptake of L-glutamate triggers glucose uptake by the astrocytes, its metabolic processing, and release of lactate, providing an energy metabolite for neurons. Thus Na,K-ATPase not only maintains the cation gradients but is also part of a metabolic signaling pathway between glia and neurons.

Gradients of Na^+ and K^+ are also important to many other cellular functions not specific to neurons

Figure 2 Physiological role of Na,K-ATPase in neurons and glia. This schematic illustrates the role of Na,K-ATPase in the extrusion of Na^+ out of the neuronal and glial cells, in the uptake of K^+ from the intercellular spaces, and in the regeneration of the Na^+ and K^+ gradients used by coupled transport systems such as the Na^+/Ca^{2+} exchanger or the excitatory amino acid transporter (EAAT) (see text for details).

but nevertheless essential to neuronal physiology; these include the maintenance of intracellular pH and Ca^{2+} concentration, thanks to secondary active transporters (Na^+/H^+ exchangers, Na^+/Ca^{2+} exchanger) and the maintenance of cell volume. The α2 isoform appears to have a specially important role in the maintenance of intracellular Ca^{2+}, probably because the Na^+/Ca^{2+} exchanger and the Na,K-ATPase isoforms, including the α2 isoform, may be present together in restricted subdomains of the plasma membrane. This close interaction between the α2 isoform and the Na^+/Ca^{2+} exchanger has been extensively studied in heart muscle, but seems also to be true in astrocytes.

Thus, a reduced function of Na,K-ATPase – due to insufficient energy (ATP) supply because of anoxia or ischemia, inhibition by toxic substances or drugs, or defect of genetic origin – is expected to result in multiple neuronal dysfunction: depolarization of the resting potential, increased excitability, slower conduction velocity, intracellular acidosis or calcium overload, or insufficient reuptake of neurotransmitter (which, in the case of excitatory amino acid neurotransmitters such as L-glutamate, may lead to excitotoxicity). Failure of the transport function of Na,K-ATPase may thus be extremely detrimental for neuronal function and survival.

Pharmacological inhibition of Na,K-ATPase by cardiac steroid drugs results in a wide variety of neuropsychological symptoms when excessive dosage or reduced clearance result in toxic blood levels of these drugs. Common symptoms are visual disturbances (mostly altered color vision due to retinal toxicity), depression, mental confusion, hallucinations, and sometimes delirium. Although these toxic effects are clearly due to Na,K-ATPase inhibition-related neuronal dysfunction, their exact mechanisms are not known in detail. In contrast, some neuroprotective effects of cardiac steroids have been reported in experimental animal ischemia models; in this case the protective effect has been attributed to a reduced energy expenditure.

Information from Animals Models

The first observation of a phenotype resulting from a genetic alteration of Na,K-ATPase was described in *Drosophila melanogaster*. Insertion of a P element in the Na,K-ATPase α subunit locus resulted in a 'bang' phenotype, which is a short-term (a few seconds) paralysis upon exposure to a loud noise. It was shown that these flies had a reduced expression of Na,K-ATPase and also displayed an increased sensitivity to Na,K-pump inhibition by ouabain. More recently, several mutations in the α subunit locus have been described to be associated either with a gain of function or a loss of function of Na,K-ATPase and to result in various phenotypes of temporary paralysis upon exposure to high temperature or mechanical shock, and also age-dependent neurodegeneration. Similar phenotypes can be observed after pharmacological inhibition of Na,K-ATPase activity with ouabain. Taken together, all of these data show that a normal and well-regulated Na,K-ATPase function is required for neuronal function and survival, especially under stressful conditions.

Considering the central role of Na,K-ATPase in cell physiology, it is not surprising that homozygous gene inactivation for the ubiquitously expressed α1 gene is embryonically lethal. Homozygous inactivation of the α2 isoforms prove also to be lethal: $\alpha2^{-/-}$ mice die soon after birth. The cause of death appears to be a deficiency in the control of respiratory movements by the brain stem breathing center, a defect probably due to neuronal development alterations. Mice heterozygous for α1 or α2 gene inactivation display mostly cardiac and skeletal muscle phenotypes, and it is mostly their cardiac functions that have been investigated in detail, but neither heterozygosity shows obvious neuronal phenotypes. Gene inactivation of the α3 and α4 isoforms has not been reported.

Concerning the β subunit, targeted deletion of the β2 isoform results in severe and progressive neurological defects starting at about 2 weeks of age, with tremor and limb paralysis, leading to death within a few days after the onset of symptoms. Pathological alterations are mainly found in astrocytes of the brain stem, with swelling of astrocytic end-feet. In these mice, there is also an accelerated rate of cell death of photoreceptor cells in the retina. Remarkably, replacement of β2 protein by the β1 isoform (β2/β1 knock in) prevents at least a large part of the alterations observed in the $\beta2^{-/-}$ mice, allowing a normal life span in these animals, but the rate of apoptotic death of photoreceptor cells is still increased when compared to wild-type mice.

Human Diseases Associated with Genetic Alterations of Na,K-ATPase Genes

Genetic alterations in Na,K-ATPase function have long been incriminated in cardiovascular diseases such as hypertension, but it is only recently that mutations in Na,K-ATPase genes could be demonstrated to be responsible for human genetic diseases. Mutations in two Na,K-ATPase α subunit genes, encoding α2 and α3, were found linked to essentially neurological phenotypes. Outside the neurobiological domain, mutations in the *FXYD2* gene (Online Mendelian Inheritance in Man (OMIM) database entry #154020) have been shown to lead to hypomagnesemia due to urinary

magnesium loss, probably associated with a dysfunction of Na,K-ATPase in Henle's loop.

Familial Hemiplegic Migraine Type 2

Familial hemiplegic migraine type 2 (*MHP2* (*FHM2*); OMIM #602481) is a rare genetic disease transmitted in the autosomal dominant mode and characterized by the typical symptoms of a migraine with aura; this aura often includes hemiparesia. While other symptomatically similar forms of migraine can be caused by mutations in a gene encoding a Ca^{2+} channel subunit (*CACNA1A* (*FHM1*)) or in a gene encoding a voltage-gated sodium channel (*SCN1A* (*FHM3*)), *MHP2* (*FHM2*) is associated with a number of (at least ten different) mutations in the gene (*ATP1A2*) encoding the $\alpha 2$ isoform of Na,K-ATPase. Several of these mutations have been shown to result in strong decrease or abolishment of Na,K-ATPase transport function. Some mutations result in a failure of stable expression of the protein at the cell surface, in some cases probably because of a defective association with the β subunit, and some other mutations result in expressed but functionally dead mutants. Although the physiopathological mechanism linking the Na,K-ATPase functional alteration to the phenotype is not fully understood, the main hypothesis involves either a defect in the reuptake of excitatory neurotransmitters or a failure of the control of intracellular Ca^{2+} (this last hypothesis being supported by the similar phenotype in *CACNA1A*, linked to gain of function mutations in a calcium channel subunit). Both mechanisms can be causally linked to reduced Na^+ (and K^+) gradients across the plasma membrane.

Rapid Onset Dystonia Parkinsonism

This autosomal-dominant genetic disease, also called dystonia 12 (*DYT12*; OMIM #128235), is characterized by the very rapid onset (over a few hours), in previously asymptomatic patients, of dystonia with signs of parkinsonism. This sudden onset often follows a trauma, a febrile episode, or another kind of stressful triggering event. Dystonia 12 has recently been shown to be linked with several missense mutations in the gene (*ATP1A3*) encoding the $\alpha 3$ isoform of Na,K-ATPase. Each of these mutations results in the modification of residues that are highly conserved in Na,K-ATPase genes throughout the animal kingdom, suggesting that they are functionally important residues. The essential functional role of these residues has been confirmed by showing that each of the *DYT12*-associated mutants is unable to sustain life in a ouabain-resistance test.

Brain Scaling Laws

Introduction

The mammalian brain varies over five orders of magnitude in volume from shrew to whale, and large mammalian brains do not look like small mammalian brains. For example, large neocortices have lower neuron density, are more convoluted, have disproportionately more white matter, and possess a greater number of specialized cortical areas. Knowing the manner in which brains change as a function of size is important in our attempt to understand the fundamental principles governing the brain. In particular, the hope is to find fundamental brain properties that are kept invariant as a function of brain size, the idea being that the brain changes as it does because it has been selected to maintain important invariants. Here, many of the broad ways the neocortex changes as a function of brain size are reviewed, and the principles that may explain these scaling relationships are discussed.

Before proceeding, note that bigger mammals appear to require bigger brains (brain mass increases as the 3/4 power of body mass), whether or not the animal is any more intelligent. (There is currently no accepted explanation for this brain–body scaling relationship.) Larger but similarly intelligent mammals have bigger brains, and their brains will differ from those found in smaller but similarly intelligent mammals, and therefore these differences are not due to differences in intelligence. The brain scaling relationships discussed here are, for this reason, likely to be explained by fundamental dilemmas encountered by trying to build a larger, highly interconnected brain, not explained by principles for building a 'smarter' brain.

Number of Neurons and Neural Connectivity

A first question one might reasonably ask is, how fast does the number of neocortical neurons increase as a function of brain size? The number of neurons increases disproportionately slowly as a function of brain volume, increasing approximately proportional to the 2/3 power of brain volume (i.e., number of neurons $\propto V_{\text{brain}}^{2/3}$) or, equivalently, neuron density decreases as the 1/3 power. In other words, brain volume (and also gray matter volume) increases disproportionately quickly as a function of the number of neurons, namely as the 3/2 power of the number of neurons, so that quadrupling the number of neurons requires an eightfold increase in brain size. (See Figure 1(a) for the approximate scaling relationships.)

How does the number of synapses per neuron vary with brain size? It is known that synapse density appears approximately constant as a function of brain size (on the order of $10^9\,\text{mm}^{-3}$). Bigger brains, then, have lower neuron density but approximately the same synapse density. Because every synapse, of course, belongs to a neuron, it immediately follows that the number of synapses per neuron is larger in larger brains. In particular, the total number of synapses in the brain increases proportional to brain volume (because synapse density is invariant), and the total number of neurons increases proportional to the 2/3 power of brain volume, from which it follows that the average number of synapses per neuron is proportional to $V_{\text{brain}}/(V_{\text{brain}}^{2/3}) = V_{\text{brain}}^{1/3}$. That is, it follows that the number of synapses per neuron increases approximately as the 1/3 power of brain volume (Figure 1(a)).

Because the number of neurons increases as $V_{\text{brain}}^{2/3}$ and the number of synapses per neuron increases as $V_{\text{brain}}^{1/3}$, it follows that the number of synapses per neuron, δ, increases as the square root of the number of neurons, N; that is, $\delta \propto \text{N}^{1/2}$. Assuming that the neocortex is small world (i.e., having sufficiently many axons connecting otherwise separated parts of neocortex that the network diameter can be approximated as that of a random network), the network diameter (i.e., the average number of axons that must be traversed to get from any neuron to another) may be approximated as $\Lambda \approx (\log N)/(\log \delta)$, which can be manipulated into $\Lambda \approx 2 \times [1 + (\log c)/(\log N)]$, where c is the proportionality constant in the equation $\delta = c\text{N}^{1/2}$. For sufficiently large brains, then, the network diameter approaches 2. Also, estimates of c are on the order of 1, meaning that perhaps network diameter may be approximately 2 in actual neocortices, despite the number of synapses per neuron scaling up much more slowly than the total number of neurons (namely as a square root of the total number of neurons) (Figure 1(a)).

We have just reported the approximate empirical scaling relationship for the number of neurons, the number of synapses per neuron, and the network diameter but have not given any hint as to why the brain might conform to these scaling relationships. This will be discussed later, where it will be shown that increasing the number of synapses per neuron as the square root of the number of neurons is the slowest rate of increase possible while still allowing high intra-area connectivity and high area–area connectivity.

Figure 1 Various neocortical features as a function of brain mass. The number in the square bracket indicates the scaling exponent in each case; for example, for # neurons in (a), the '2/3' in square brackets indicates that the number of neurons varies with brain volume to the power of 2/3. The four plots respectively show the scaling relationships concerned with (a) number of neurons and neural connectivity, (b) gray matter convolutedness and thickness, (c) white matter volume and axon caliber, and (d) specialized areas and area–area connectivity.

Convolutedness and Thickness

One of the most salient differences between small and large brains is that the neocortical surface is smooth in small brains and convoluted in large brains. In fact, the surface area of the gray matter increases as approximately the 8/9 power of brain volume, more quickly than the 2/3 power expected for geometrically similar objects. This difference between 8/9 and 2/3 serves to quantify the rate at which larger brains become increasingly convoluted (Figure 1(b)).

Given that gray matter surface area increases as the 8/9 of brain volume, and given that gray matter volume obviously equals its surface area multiplied by its thickness, it follows that thickness increases as the 1/9 of brain volume, or very slowly (Figure 1(b)).

From this slow increase in gray matter thickness, it is possible to derive an interesting invariant feature of mammalian brains. Recall that (volumetric) neuron density decreases as the 1/3 power of brain volume. Because linear dimensions are the cube root of volumes, the linear neuron density decreases as the 1/3 power of the volumetric neuron density. Therefore, it follows that the linear neuron density decreases as the 1/9 power of brain volume. In other words, the linear dimensions of some fixed number of neurons along a line will increase as the 1/9 power.

In this light, one can see that the slow increase in gray matter thickness is explained entirely by the neuron density decrease in larger brains, meaning that the number of neurons through the cortical thickness (from pia to white matter) is approximately invariant as a function of brain size. Minicolumns are thin neuroanatomical structures consisting of neurons extending from pia to white matter, and we can conclude – and there is evidence – that the number of neurons per minicolumn does not vary as a function of brain size (**Figure 1(b)**). (There is also evidence for another invariant-sized computational unit, the module, which includes larger structures such as column, blobs, barrels, and stripes.)

This suggests an important potential principle underlying why surface area and thickness scale as they do. Namely, gray matter appears to be built out of minicolumns which are repeating computational units of invariant size – that is, computational units possessing a number of neurons that does not vary as a function of brain size – extending through the thickness of the neocortex gray matter. From this principle of invariant-size computational units, and from the neuron density decrease discussed previously, it follows that thickness increases as the 1/9 power of brain volume, entailing, in turn, that surface area scales as the 8/9 power. This explanation for why brains become increasingly convoluted at the rate that they do relies also on the neuron density decrease, and we have not yet provided an explanation for it; this explanation will complete the explanation for why surface area and thickness scale as they do.

Axon Caliber and White Matter

For nearly all biological trees, arbors with more leaves possess thicker trunks. The same is true for neurons: neurons with more synapses tend to have thicker early arbor segments (e.g., the soma or the near-soma axon segment). We have previously seen that larger brains have neurons with a greater number of synapses, and we should not be surprised to find thicker trunked neurons in bigger brains. Although there is large variability in axon caliber, evidence supports that axon caliber tends to slowly increase with brain volume, namely approximately as the 1/9 power (e.g., for white matter axons and for spinal motor neuron somas) (**Figure 1(c)**).

White matter consists of axonal wiring connecting disparate parts of neocortex, and its volume depends, in part, on the caliber of the axons. White matter scales disproportionately quickly as a function of brain size, namely approximately with a scaling exponent of approximately 4/3 (**Figure 1(c)**), although sometimes it has been measured to be as low as approximately 1.2.

What explains these scaling relationships for axon caliber and white matter volume? Let us start with axon caliber; why an exponent of 1/9, rather than some other positive exponent? This exponent is consistent with a law that appears to apply to neural arbors concerning how the diameter of a parent segment relates to the diameter of the daughter segments downstream. In particular, evidence suggests that the cube of the diameter of the parent is equal to the sum of the cubes of the daughter segments (e.g., $R_{\text{trunk}}^3 = R_1^3 + R_2^3$), which is called Murray's law (and has been found to apply to a variety of kinds of natural arbor), and is the power-efficient diameter setting for laminar flow through pipes and also the optimal setting for simultaneously optimizing volume and transmission speed. The 1/9 exponent is derivable from Murray's law as follows: each of the terms in the summation of Murray's law is for one daughter segment and can be replaced by the sum of the cubes of that daughter's daughters, and so on, until reaching the synapses so that $R_{\text{trunk}}^3 = \delta \times R_{\text{synapse}}^3$, where δ is the number of synapses and R_{synapse} is the linear dimensions of synapses. Because synapse density is invariant, R_{synapse} must be invariant, and therefore the equation becomes the proportionality $R_{\text{trunk}}^3 \propto \delta$. However, recall that the number of synapses per neuron scales as the 1/3 power of brain volume, and thus $R_{\text{trunk}} \propto V_{\text{brain}}^{1/9}$.

The 1/9 scaling law for axon caliber is key for understanding white matter volume scaling. The volume of white matter is proportional to the product of the number of white matter-projecting neurons, N_{white}, the length of the average connection, L, and the square of the axon caliber, R; that is, $V_{\text{white}} \propto N_{\text{white}} \times L \times R^2$. Supposing that the number of white matter-projecting neurons scales proportionally with the total number of neurons, and treating the average connection length as proportional to the linear dimensions of the white matter (and recalling that axon caliber scales as the 1/9 power), one may derive that the volume of white matter increases as the 4/3 power of brain volume. If, instead, the average connection length is proportional to the linear dimensions of the brain (rather than to the white matter), white matter volume scales as the 11/9 power of brain volume. White matter volume, then, scales up disproportionately quickly because white matter axon caliber increases as it does, and this, in turn, is due to the increasing number of synapses per neuron and due to Murray's law. If white matter axon caliber were constant (which would require that the number of synapses per neuron be constant), then white matter volume would scale proportionally with brain size. Although we now understand why white matter volume scales the way it does given that the number of synapses per neuron scales as it does, we have not

yet addressed why the number of synapses per neuron scales the way it does, something crucial to brain scaling which we discuss later.

Areas and Area–Area Connectivity

The neocortex is parceled into specialized areas, and the number of areas increases approximately as the 1/3 power of brain volume. Recalling that the number of neocortical neurons increases as the 2/3 power of brain volume, it follows that the number of areas increases as the square root of the number of neocortical neurons. It immediately follows that the average number of neurons per area increases as the square root of the number of neocortical neurons, or as the 1/3 power of brain volume (Figure 1(d)).

We are now in position to notice an important invariance. Recall that the number of synapses per neuron increases as the 1/3 power of brain volume, and therefore the number of synapses per neuron scales proportionally with the number of neurons per area. Therefore, when a neuron connects to an area (either to its own area or to another), it is able to connect to a certain fraction of the neurons there (approximately on the order of 10^{-4}), and this fraction does not appear to vary as a function of brain size (Figure 1(d)). This invariance property is referred to as invariant area infiltration because, independent of brain size, neurons have, on average, sufficiently many synapses to 'infiltrate' an invariant fraction of the neurons in an area. Thus, there appears to be strong selective pressure across mammalian neocortices for the average number of synapses per neuron to scale up just fast enough that neuron interconnectedness within areas can remain invariant and that, when an area connects to another area, the average neuron making the connection has sufficiently many synapses to infiltrate an invariant fraction of the neurons in the area.

Concerning area–area connectivity, evidence suggests that the average number of areas to which an area connects scales proportionally with the 1/3 power of brain volume or, again, as the square root of the number of neurons (Figure 1(d)).

An important invariance principle follows from this. Recall that the number of areas scales as the 1/3 power of brain volume, and therefore the average number of areas to which an area connects scales proportionally with the number of areas. That is, no matter the size of the brain, each area is able to connect to a certain fraction of the areas in that brain (probably approximately 30%), and that fraction does not appear to vary as a function of brain size (Figure 1(d)). This invariance property is referred to as invariant area interconnectedness. There appears, then, to be strong selective pressure across mammalian neocortices for the number of area connections per area to scale up just fast enough that area networks can maintain an invariant level of area interconnectedness. Equivalently, there is selective pressure for the total number of area–area connections to scale as the square of the total number of areas.

We have seen that the number of areas and the number of area connections per area each scale as the 1/3 power of brain volume, but we have not yet provided an explanation. Recall that we have also not yet provided any explanation for why neuron density and the number of synapses per neuron scale as they do. The next section discusses how these are connected and how they may be explained.

Economical Well-Connectedness

Previously, we described that neuron density decreases, and the number of synapses per neuron increases, in larger brains; this fact was crucial for understanding why brains become increasingly convoluted (and the principle of invariant computational units was also key), and it was also crucial for comprehending why white matter volume increases disproportionately quickly (and Murray's law was also key). We have not yet provided an explanation for the neuron density and number of synapses per neuron scaling, nor have we provided an explanation for why the number of areas and the number of area connections per area increase.

In the previous section, we noted that the mammalian neocortex maintains two important invariants – invariant area infiltration (or it could have been named invariant area intraconnectedness) and invariant area interconnectedness. The first states that the number of synapses per neuron increases just fast enough that neurons can connect to an invariant fraction of the neurons within a cortical area. In particular, both quantities increase in larger brains, namely as the 1/3 power of brain volume. This means that no matter the brain size (and no matter the size of the areas), each area maintains constant intra-area connectivity; also, when an area sends an axon to communicate to another area, it is able to synapse to some constant fraction of the neurons there. Invariant area interconnectedness, on the other hand, states that the number of area connections per area increases just fast enough that areas can connect to an invariant fraction of the areas in the neocortex. In particular, both quantities increase as the 1/3 power of brain volume. This means that no matter the brain size (and no matter the total number of areas), the neocortex area network maintains a constant area–area connectivity or, equivalently, the number of area–area edges scales as the square of the number of areas.

That is, the neocortex appears to take a two-tiered approach to high interconnectivity: invariant neural connectivity for the neural network within areas and invariant area connectivity for the entire neocortical area network. It is not understood why the neocortex takes a two-tiered approach of this kind. Why not a one-tiered design in which the number of synapses per neuron scales proportionally with the number of neurons? A one-tiered design would lead to brain size increasing much faster as a function of the number of neurons – and thus a brain of any given size would have to have many fewer neurons – but such a brain would be much more fully connected. It is difficult to state why a one-tiered design would be worse than a two-tiered design, for how does one balance the costs of having fewer neurons against the benefit of having them much more highly interconnected? Alternatively, why not a take a three-tiered design? Again, the advantages of a two-tiered design are not well understood.

Given that the neocortex follows a two-tiered design, is it possible to explain some of the yet unexplained scaling exponents discussed previously (namely why neuron density decreases and why the number of areas increases as it does)? Invariant area infiltration tells us that $\delta \propto W$, where δ is the number of synapses per neuron and W is the number of neurons per area. Invariant area interconnectedness tells us that $D \propto A$, where D is the number of area connections per area and A is the number of neocortical areas. The problem is that these two proportionalities do not tell us how W relates to A. If we knew that, then we could compute how these variables relate to the total number of neurons (which is the product of W and A). Thus, the answer is "no," the two invariance principles are not sufficient to explain everything. The reason is that there are many ways of implementing a two-tiered design. For example, a two-tiered design could just possess two areas no matter the brain size, in which case the number of neurons per area would increase proportional to the total number of neurons. Alternatively, a two-tiered design could try to keep the number of neurons per area low by compartmentalizing as fast as possible.

Although there is a continuum of two-tiered designs (parameterized by how quickly the number of neurons per area increases), some designs are more economical than others in terms of the amount of wire required. If the neocortex requires conformance to invariant area infiltration – as it appears to – then the lower the number of neurons per area, the lower the number of synapses per neuron. Fewer synapses per neuron means less arborization for each neuron and thinner wires, which in turn leads to lower distances for the neurons to travel because the brain can be more compactly organized. That is, the lower the number of neurons per area, the less wiring volume is required. Such a 'save wire' desideratum has turned out to be very successful at predicting nervous system organization at many levels, and appears critical for comprehending why the neocortex scales as it does. Recall that invariant well connectedness referred to the pair of invariants: invariant area infiltration and invariant area interconnectedness. Consider now the hypothesis that the neocortex satisfies invariant well connectedness economically, which we may call economical well connectedness for short. As previously mentioned, this hypothesis expects the number of neurons per area to scale up as slowly as possible, which in turn is to say that the number of areas should increase as quickly as possible. The number of areas cannot scale up faster than the number of neurons per area because if it did, then there would not be enough neurons in an area to connect up to an invariant fraction of all the areas, violating invariant area interconnectedness. Thus, the fastest that the number of areas can increase is proportional to the number of neurons per area, or $A \propto W$. However, because $N = W \times A$, where N is the total number of neurons, it immediately follows that W and A each scale as the square root of the number of neurons. But then the number of synapses per neuron, δ, and the number of area connections per area, D, also scale as the square root of the number of neurons. That is, $\delta \propto W \propto A \propto D \propto N^{1/2}$. We see, then, how the area and area connection relationships discussed previously are explained. Also, given that synapse density is invariant, gray matter volume (and brain volume) scales as the total number of synapses, or $\propto \delta \times N$, and this is proportional to $N^{3/2}$, or $N \propto V_{\text{brain}}^{2/3}$. That is, this explains the neural density (and number of synapses per neuron) scaling relationships discussed previously – relationships that were also part of the story in understanding convolutedness, axon caliber, and white matter volume.

Conclusion

Despite the large variety of scaling relationships in Figure 1, they can be understood in terms of a relatively small number of principles. Economical well connectedness is the principle that the neocortex maintains an invariant two-tiered design (satisfying invariant area infiltration and invariant area interconnectedness) and does so economically. We saw that from this principle the scaling relationships can be derived for the number of neurons, the number of synapses per neuron, the number of areas, the number of neurons per area, and the number of area connections per area. The result for the total number of

neurons was crucial for understanding why bigger brains become increasingly convoluted, but also crucial was the principle of invariant computational units (stating that the neocortical gray matter consists of invariant-sized minicolumns), without which the convolutedness (or surface area) scaling relationship would not have followed. Finally, in order to understand why axon caliber and white matter volume scale as they do, it was necessary to understand Murray's law, which governs the rate at which neural arbors become thinner as they near the synapses.

Introduction

Traumatic brain injury (TBI) is responsible for nearly 2 million emergency room admissions annually in the United States, affecting 2% of the population per year. These injuries range from mild concussions necessitating only observation to large hemorrhages requiring emergent surgery. Approximately 250 000 of these patients require hospitalization, and nearly half of these will undergo surgery for evacuation of a hematoma. Despite significant advances in our understanding of the pathophysiology involved and improved therapy, mortality remains high, at 20%, with significant long-term neurological deficits in 35% of survivors. As a result of this significant morbidity and mortality, a joint task force of the Brain Trauma Foundation and the American Association of Neurological Surgeons (AANS) has developed evidence-based guidelines in an attempt at systematizing the care of patients with TBI. The results of collaborative efforts such as these have focused management emphasis on both the primary injury – that which occurs from the initial traumatic insult – and the secondary injuries, the pathophysiologic events occurring in subsequent minutes, hours, and days after the primary insult.

In this article, we review current concepts in TBI. We first address the areas of classifications and assessment of TBI. Second, we focus on the pathophysiology and management strategies of both primary and secondary brain injury. Common themes across different types of head injuries are emphasized.

Assessment and Classification of Traumatic Brain Injury

Glasgow Coma Score

Developed in 1974 by Jennett and Teasdale, the Glasgow Coma Score (GCS) (Table 1) is the most widely used method of determining the severity of TBI. Included in the assessment are a patient's eye opening, verbal response, and motor response, giving a general gauge of the level of consciousness. Although it has been widely criticized as being excessively simplistic and not accurately reflecting the complete clinical picture of an acutely injured patient, the GCS remains the primary assessment tool in the TBI population. Its simplicity is what has made it so valuable, allowing accurate communication between observers with different levels of expertise in the field. In our experience, the combination of the GCS with a quick but systematic assessment of brain stem function, particularly pupillary reactivity, gives an accurate clinical picture of the neurologically injured patient.

The GCS has been used to help classify injuries according to their clinical severity. Each GCS criterion is assigned a point value. Two broad categories include minor head injury, encompassing injuries that yield total GCS scores from 9 to 15, and severe head injury, with total GCS scores from 3 to 8. Each category of head injury is treated differently. A simple guide to the management of minor head injuries is shown in Figure 1 (severe head injuries are discussed in greater detail later). Minor head injuries may be further divided into minimal, mild, or moderate head injury. With minimal injuries (GCS = 15), patients are neurologically intact and have suffered no loss of consciousness or amnesia. These patients usually do not require computed tomography (CT) scanning except in select cases (see Figure 1 for CT indications) and are discharged home with instructions to return should signs or symptoms of brain injury develop (including headache, nausea/vomiting, seizure). With GCS =14, patients have mild brain injury and may be associated with a brief (<5 min) loss of consciousness or memory impairment. Our institution routinely obtains CT scans on these patients; in one of the largest retrospective studies of mildly head-injured patients, 16% of patients with a GCS of 14 had abnormal CT scans, with 1.6% of patients requiring surgery according to Culotta's study. A GCS score of 9–13 indicates moderate injury wherein patients are able to follow commands at the time of examination but have had longer periods of loss of consciousness (>5 min) and neurologic findings on exam. This group of patients requires careful monitoring, as over 30% of patients in this subgroup have abnormal CT scans, with Stein's group reporting 8% of patients requiring surgery. For this reason, patients should have emergent CT scans with prompt neurosurgical consultation should findings be abnormal (Figure 1). GCS scores from 3 to 8 indicate severe TBI with worse outcomes. Nearly 80% of patients with an initial hospital GCS of 3–5 have an eventual outcome of death, severe disability, or vegetative state; patients with an initial GCS of 3 have a 65% mortality rate. Management of severe brain injury is discussed in greater detail in subsequent sections.

Primary and Secondary Traumatic Brain Injury

Significant morbidity and mortality results not only from the original injury sustained during TBI, but also from ensuing pathophysiologic processes evolving over a period of hours to days. This has prompted the differentiation between what has been termed 'primary' brain injury and 'secondary' brain injury.

[a]GCS score = E + V + M; range from 3 (or 3T) to 15.

Primary Brain Injury

Primary brain injury, referring to the clinical sequelae resulting directly from the initial injury, can be broadly divided into focal and diffuse injuries (Table 2). Focal injuries are related to a narrow force vector delivered to a reduced intracranial region. We see this with epidural hematomas located under a skull fracture caused by a force vector delivered usually in one plane. This type of injury tends to produce intracranial hemorrhages such as epidural or subdural hematomas, or cerebral contusions and intracerebral hematomas. Diffuse injuries are more often related to wider vector and higher acceleration/deceleration injuries, as seen with motor vehicle accidents. Diffuse injuries comprise the clinical spectrum from concussion to diffuse axonal injury (DAI) with widespread long tract signs and posttraumatic coma.

The first critical step in the management of traumatic brain injury is to determine the severity of the primary injury using clinical exam and radiographic evaluation. It is during this assessment of the primary injury that the decision for emergent surgical intervention is required. Once this decision is made and the primary injury is addressed, then the patient moves into the phase of prevention of secondary injury. Management of TBI may thus be considered in two phases: identification and management of primary brain injury followed by the prevention of secondary brain injury. We consider these phases in turn.

Surgical intervention in TBI is unequivocally indicated in a number of clinical scenarios and is primarily indicated in patients with intracranial hemorrhage of sufficient size to compromise neurologic status. Indeed, Pickard and colleagues observed that craniotomy

Diffuse	Concussion
	Multifocal contusion
	Diffuse axonal injury

for acute epidural hematoma is one of the most cost-effective interventions among all surgeries, based upon calculations of long-term disability expenses averted and years of productive life gained after surgery. Surgical indications in TBI and traumatic hemorrhages and skull fractures are briefly addressed in the following sections.

Hemorrhages Acute blood can be readily identified on noncontrast CT of the head, an important component in the initial evaluation of a patient with TBI. The main types of traumatic brain hemorrhage requiring surgery are epidural, subdural, and intracerebral. When surgically appropriate, acute epidural hematomas are typically removed by craniotomy due to the gelatinous consistency of an acute blood clot, making it difficult to manage without complete exposure of the area of bleeding. Characteristics of traumatic blood on CT can help guide indications for surgery, although always in the context of a patient's neurologic status. In a group of 158 patients followed prospectively, Servadei et al. reported that over 90% of patients with epidural hematoma with thickness greater than 15 mm and midline shift greater than 5 mm underwent operative intervention with good outcomes. Another study by Bezircioglu et al. analyzed 80 patients with epidural hematoma and observed that patients exhibiting hematoma of volume less than 30 cm^3, hematoma thickness less than 20 mm, and no neurological deficit could be managed nonoperatively in the vast majority of cases (94%), but with close monitoring. Expectant management can be a reasonable option if the mass effect is minimal and the patient's neurological status is normal, especially in the pediatric population. However, the cost of conservative management is that the patient must be monitored carefully in the intensive care unit for several days.

Accumulation of blood in the subdural space can occur in an acute or chronic manner, and the surgical management of each subgroup differs considerably, owing mostly to the consistency of evolving blood. The acute subdural hematoma can be surgically treated by craniotomy or craniectomy, and in a subset of individuals can be allowed to liquefy to a chronic state and then drained by burrhole evacuation in a delayed fashion. The advantage of the burrhole is the lower surgical risk, as some cases may even be performed under local anesthesia at the bedside. But depending on the acuity and severity of the neurologic compromise due to the subdural blood, delayed or expectant management may not be appropriate. In distinction to the epidural hematoma, predominantly a disease of younger patients (mean age, 20–30 years old), a strong correlation exists between poor outcome and age in patients with subdural hematomas. Indeed, in Howard's study of 23 patients 66 years old or greater with a GCS of less than 9, 74% of patients died. As with epidural hematoma, decreasing the time to surgery improves outcome; Haselsberger and colleagues noted that those patients whose subdural hematomas were surgically evacuated within 2 h of onset of coma had a substantially lower mortality (47 vs. 80%) compared with those operated on 2 h after coma.

An entity that is observed with increasing frequency in the era of modern medicine is the acute-on-chronic subdural hematoma. Often the consequence of anticoagulation for a heart condition such as atrial fibrillation, this group of subdural hematomas can have a significant and sudden acute component on top of an otherwise indolent and inconsequential chronic subdural in the setting of even trivial trauma. The first step in the management of these patients is to stop ongoing bleeding by discontinuing the anticoagulation and correcting the coagulopathy. Although infusion of fresh frozen plasma is a reasonable means of achieving the latter goal, such patients often have comorbidities, including arrhythmias and heart failure, that decrease their tolerance for fluid loads. An alternative that is still undergoing evaluation for traumatic intracerebral hemorrhage is recombinant factor VII, a treatment that Mayer et al. demonstrated as having clear benefits with in limiting the growth of spontaneous intracerebral hemorrhage. The low-volume bolus afforded by factor VII and its efficacy in correction of the coagulation profile make its use plausible in the setting of anticoagulated patients with traumatic intracranial blood, but this issue has thus far been studied in a only a limited number of case reports.

Intraparenchymal hemorrhages occur commonly in TBI, and most are treated nonoperatively. Often these intraparenchymal hemorrhages present as contusions on the inferior frontal lobe surface and the pterional region of the anterior temporal region, sites where the

parenchyma strikes the bony margins upon cerebral displacement. They can initially be small to moderate-sized contusions, which over the course of the ensuing 48–72 h may increase dramatically in size, creating significant mass lesions where only small lesions were present. Consequently, small contusions seen on initial CT scans should be followed closely for the first 3 days, as this represents their period of maximal swelling and increase in size. Even after this period, contusions tend to continue to grow in size, but at a substantially slower rate. This problem is made much more dramatic in elderly patients on traditional anticoagulation or even on antiplatelet agents or in patients with coagulopathy secondary to liver disease or other systemic disorders. When considering surgery, the patient's neurological status, comorbidities, and response to medical therapy are considered, as no clear radiological thresholds have been defined for determining surgical intervention with contusions. Dominant among these issues in considering surgery are the patient's preoperative clinical status and the amount of intracranial mass effect, shift, or herniation that exists. Surgical approaches include craniotomy or craniectomy with evacuation of clot and/or lobectomy.

In all of the aforementioned hemorrhage types, subsequent brain edema and high intracranial pressure (ICP) may not respond to standard medical measures. In these cases, decompressive craniectomy may be attempted during the initial surgical intervention as a measure to assist in the subsequent management of postoperative cerebral edema and potential secondary injury.

Skull fractures Skull fractures are often associated with intracranial hemorrhage and are an important component of the patient evaluation in TBI. Open skull fractures – those that have an overlying scalp laceration – have traditionally been managed with expedited operative debridement with or without removal of bone fragments. Indeed, Jennet and Miller reported that operative debridement of open skull fractures within 48 h was associated with an infection rate of 4.6%, whereas the infection rate jumped to 36.5% with an operative delay greater than 48 h. In such cases, immediate bone replacement may obviate the need for a second surgery (cranioplasty) but, based on first principles, may be predicted to increase infection risk. However, retrospective studies do not support an increased risk of infection with primary bone replacement unless gross contamination is present. A fracture with depression greater than the thickness of the skull has also been argued to be an indication for surgical management, which includes bone elevation or removal. Although on cosmetic grounds this logic is sound, elevation of closed depressed fractures does not necessarily alter the clinical course. For instance, the risk of posttraumatic epilepsy between elevated and nonelevated skull fractures is indistinguishable in Jennett's large retrospective series.

Secondary Brain Injury

Surgery typically is undertaken in response to the primary brain injury. Secondary brain injury, however, refers to cellular processes which take place over hours to days after the initial brain injury and which compound the effects of the initial injury. Secondary brain injury results not only from the delayed effects of primary brain injury, but also from aggravating factors such as hypotension, hypoxia, intracranial hypertension, and inadequate cerebral perfusion pressure (CPP). Untreated, the ultimate results are intracranial hypertension and cerebral ischemia, which can significantly compound the effects of the initial injury.

Intracranial hypertension

Pathophysiology Intracranial hypertension is a common complication of severe head injury; along with the prevention of cerebral ischemia, its management is essential to the arrest of secondary injury. Nearly 50% of head-injured patients with intracranial mass lesions and 33% of patients with DAI have persistently elevated ICP. ICP is determined by the contents of the intracranial vault, the physiology of which was codified by the Monro–Kellie doctrine: the total volume available for intracranial contents is constant and an augmentation in one compartment must be accompanied by a diminution in the other. An uncompensated increase in one or more compartments results in ICP above the normal range of 5–15 mmHg. In the absence of a mass lesion, increased ICP in severe TBI results from alterations in cerebrospinal fluid (CSF) flow, cerebral blood volume (CBV), and the development of vasogenic and cytotoxic edema. Physiologic volume-buffering mechanisms exist and involve alterations of blood and CSF volume and include arteriolar vasoconstriction, increasing cerebral venous outflow, and downward CSF displacement through the foramen magnum or into expanded root sleeves. Once these mechanisms are exhausted, ICP rises in an exponential fashion. The very step nature of the volume–pressure curve complicates ICP management, since once a rise in ICP is noted, it signifies a significant reduction in intracranial compliance (**Figure 2**). Identification of a measure of intracranial compliance that would assist as a predictor of changes in ICP has been a subject of much interest. Sustained ICP readings of greater than 20 mmHg are abnormal. ICP readings above

Figure 2 Intracranial pressure (ICP) and volume relationships. Classic pressure–volume curve depicts the exponential rise in ICP once compensatory mechanisms of handling additional intracranial volume are exhausted. In the severely head-injured patient, additional volume may take the form of increased cerebrospinal fluid from poor absorption; increased cerebral blood volume, vasogenic edema from a compromised blood–brain barrier, and cytotoxic edema.

20 mmHg are considered elevated; elevations above 30 mmHg are considered severe in our institution and are treated aggressively. Extensive research has shown that at these pressure levels the patients can readily enter into plateau waves, during which pressures can rise to between 30 and 60 mmHg, creating significant intracranial ischemia and severe secondary injury. ICP readings greater than 40 mmHg represent severe preterminal intracranial hypertension.

The two principal consequences of elevated ICP are cerebral herniation and impaired cerebral perfusion, as denoted by the formula CPP = mean arterial pressure (MAP) – ICP. The two principal forms of cerebral herniation are uncal herniation and central diencephalic herniation. Uncal herniation is produced by medial displacement of the temporal lobe by middle fossa lesions in which the ipsilateral oculomotor nerve, cerebral peduncle, reticular activating system, and, with severe compression, contralateral cerebral peduncle (Kernohan's phenomenon) are compromised. The resulting clinical syndrome involves coma, ipsilateral fixed and dilated pupil, and contralateral hemiparesis. Should the contralateral peduncle be compressed against the contralateral tentorial edge, ipsilateral motor function may also be compromised. Central or downward herniation may result from globally increased ICP and is defined by progressive caudal displacement of the diencephalon through the tentorial incisura with progressive deformation and dysfunction of the diencephalons, progressing to the midbrain and pons. The sequence of events in this progression was eloquently described by Plum and Posner and leads to coma from involvement of the reticular activating system. Basilar artery perforators are stretched and often cause hemorrhages (Duret's hemorrhages).

Cerebral ischemia The avoidance of cerebral ischemia is one of the pillars in the modern management of severe head injury. Management principles center on maintaining an adequate CPP and avoiding systemic hypotension, hypoxia, and anemia so as to ensure adequate cerebral blood flow (CBF). Important in discussing CBF in TBI is CPP, defined as the MAP minus the ICP. Normally, CBF is relatively constant in a range of CPPs between 40 and 150 mmHg. A dynamic system of arterial vasoconstriction and dilation exists to preserve CBF and oxygen delivery. At low perfusion pressures within this range, the arteriolar bed dilates to reduce cerebral vascular resistance (CVR) and increase blood flow to normal levels. At higher perfusion pressures, arteriolar constriction occurs to protect the vascular bed from overperfusion. At perfusion pressures below the autoregulatory threshold, arterioles passively collapse and CBF falls. At pressures above the autoregulatory limits, vessels are maximally dilated and CBF increases.

Pressure autoregulation is lost in many patients following TBI. Bouma and colleagues reported in a series of 117 patients that autoregulation was lost in 49% of patients. Even when pressure autoregulation is intact, the parameters at which autoregulation occurs were often shifted, with significant therapeutic implications. The lower limit of autoregulation may increase from the 40–50 mmHg range to the 70–90 mmHg range, meaning that normally adequate perfusion pressures may cause ischemia in these patients, even when autoregulation is intact.

Given these findings, the clinician must assume that in patients with severe TBI, CBF has a linear relationship to CPP. To prevent cerebral ischemia and maximize outcome, CPP must be closely monitored and maintained. Prospective studies have demonstrated a mean mortality rate of 21% in patients with severe TBI (GCS of 3–7) when CPPs are maintained above 70 mmHg, as compared with a 40% mortality rate among patients with a GCS of 3–7 whose CPPs were not managed as such (the Traumatic Coma Data Bank series). While targets may differ among various researchers, there is consensus that CPP less than 60 mmHg is harmful. The Brain Trauma Foundation currently supports maintaining CPP above 60 mmHg, while other centers advocate a CPP above 70 mmHg.

Aside from the fact that increased ICP can decrease CPP, it is also true that drops in CPP can increase ICP. As CPP decreases, pial arterioles vasodilate and accommodate larger CBVs, diagrammed in Rosner's vasodilatory cascade (Figure 3). This increased blood volume can increase ICP. When CPP is restored, pial arterioles can constrict and ICP will often decrease. Furthermore, adequate cerebral oxygenation is threatened by systemic hypotension and hypoxia. Miller and colleagues showed a 150% increased risk of mortality in patients with severe TBI who had at least one episode of hypotension as defined by systolic blood pressure (SBP) <90 mmHg when compared with patients without hypotension. Similarly, Stochetti and colleagues showed that severe TBI patients with hypoxic episodes prior to intubation had a 77% mortality rate, and 100% of survivors were severely disabled.

Anemia may also decrease tissue oxygenation, and the hematocrit deserves particular attention in the head-injured patient. While an optimal value has not been established, Kee has suggested that brain tissue oxygen delivery begins to decrease below a hematocrit of 33%. Most centers transfuse packed red blood cells in patients with hematocrits below 30%. As with all trauma patients, a hematocrit refractory to blood transfusion should prompt a search for extracranial bleeding sources. Several methods exist to assess oxygenation of brain and blood in trauma patients.

Monitoring

Consensus has emerged regarding indications for placing an ICP monitor in patients with TBI, based on the identification of groups at risk for developing intracranial hypertension. At highest risk are patients with a GCS <8 and an abnormal CT scan; up to 60% of these patients develop elevated ICP readings according to Eisenberg and colleagues. While patients with a GCS <8 with normal-appearing CT scans on admission have a 10–15% chance of developing elevated ICPs, there is a subgroup with a 60% chance of intracranial hypertension: those with age >40 years, SBP <90 mmHg, and unilateral or bilateral motor posturing. We place ICP monitoring devices in all patients with a GCS <8, unless there is a coexisting coagulopathy. We also consider placement in some patients with a GCS >8 who are undergoing extensive anesthesia for extracranial surgery. Ventriculostomy permits drainage of CSF in addition to ICP monitoring, and is especially indicated in patients with hydrocephalus and intraventricular hemorrhage (IVH), or whenever intracranial hypertension is expected to be a significant problem.

Figure 3 Cerebral perfusion pressure (CPP), intracranial pressure (ICP), cerebral blood volume (CBV), and vasodilatation relationship in preserved autoregulation.

Management of Raised Intracranial Pressure

The goals of intracranial hypertension management are the maintenance of satisfactory CPP and the avoidance of intracranial herniation. The clinical justification for ICP reduction is that elevated ICP is an independent predictor of poor neurologic outcome in patients with severe head injury. While this management principle is well supported, the particular threshold at which treatment is initiated varies. More recently, Marshall's group found that initial or sustained ICP readings above 20 mmHg were effective predictors of poor neurologic outcome among patients with severe head injury. The Brain Trauma Foundation supports initiating treatment at ICP readings between 20 and 25 mmHg, while preserving adequate CBF. A caveat in the rigid adherence to these oft-quoted values is that herniation may occur at ICP readings below 20 mmHg, particularly with temporal lesions. On the other hand, a therapeutic CPP target may be reached with ICP readings as high as 25 mmHg. At our institution, we initiate treatment for ICP readings greater than 25 mmHg, unless CPP is compromised at lower levels. We employ a stepwise approach, beginning with techniques to optimize venous outflow from the brain (head elevation), followed by pharmacotherapy and CSF drainage (Figure 4).

Physical Positioning

We advocate elevating the head of the bed to 30° and maintaining a neutral head position in order to maximize venous return from the brain and thereby

Figure 4 Stepwise protocol for intracranial pressure management.

reduce CBV. While some advocate keeping the head of the bed flat to maximize CPP, Feldan et al. have shown that CPP and CBF may be preserved and ICP reduced by elevating the head of the bed to 30°.

Avoidance of Hypoventilation: CO_2 Reactivity

Changes in arterial carbon dioxide (CO_2) affect CBF and vascular caliber. Hypoventilation leads to an increase in arterial partial pressure of CO_2 ($PaCO_2$), resulting in vasodilatation and an increase in CBF and ICP. While pressure autoregulation may be deranged in severe head injury, carbon dioxide reactivity is preserved. The routine measurement of $PaCO_2$ in head-injured patients is strongly recommended. Hypoventilation raises $PaCO_2$ and ICP, while $PaCO_2$ levels below 35 mmHg may lower ICP but compromise CBF. The ideal $PaCO_2$ level in head-injured patients is normocapnia, to avoid elevations in ICP from hypoventilation and decreased CBF and ischemia from hyperventilation. The only circumstance in which mild chronic hyperventilation may be considered is when cerebral hyperemia – more prevalent in the pediatric population – is demonstrated by either jugular bulb venous saturation ($SjVO_2$) or CBF measurements. Even in these circumstances, however, treatment with chronic hyperventilation is hazardous and should be carried out with the aforementioned monitoring and using extreme caution, as hypoperfusion can be devastating in these patients.

Adequate Sedation and Analgesia; Neuromuscular Paralysis

Sedation and analgesia may blunt the sympathetic stimulation provided by pain from traumatic injury or agitation from brain injury, endotracheal irritation, or routine nursing care, all of which if untreated may increase ICP. The short-acting sedative–anesthetic propofol is being used with increasing frequency because its short half-life permits frequent neurologic examinations and because it appears to have superior effects on ICP reduction compared to narcotic-based regimens. Propofol is a potent vasodilator and careful attention must be paid to MAP and CPP during its administration. When intracranial hypertension becomes severe, patients may require pharmacologic paralysis by neuromuscular blockade for maximum muscle relaxation.

CSF Drainage by Ventriculostomy

CSF drainage via an external ventricular drain (EVD) or ventriculostomy is a highly effective and physiologic method of ICP reduction in head-injured patients. The utility of the ventriculostomy catheter, however, may be compromised in the presence of considerable brain edema and subsequent ventricular collapse. When a ventriculostomy is in place, we use it to drain CSF to its maximal capacity for increased ICP control prior to starting osmotherapy. When an intraparenchymal monitor is in place, however, osmotherapy may be instituted first. In our experience, however, we have found that even when patients present with small ventricles secondary to significant cerebral edema, that a ventricular catheter can be successfully placed. In these circumstances, it becomes invaluable in managing elevated ICP. We, therefore, recommend the use of a ventricular catheter, wherever possible, prior to the use of osmotherapy and paralysis, and certainly before the institution of barbiturate coma.

Osmotherapy

Mannitol is a mainstay in the control of elevated ICP. An osmotic diuretic, mannitol was commonly thought to reduce ICP by reducing intracranial water, but, as first shown by Barry and others, is now recognized to also expand plasma volume and decrease viscosity. Canine and human studies have demonstrated that mannitol increases CBF and decreases ICP by autoregulatory vasoconstriction. Furosemide, which can inhibit the production of CSF, may potentiate the effects of mannitol. When given together, a greater and more sustained decrease in ICP has been observed.

When using mannitol, intravascular volume status, serum osmolarity, sodium, and blood urea nitrogen (BUN) and creatinine must be monitored for possible adverse effects. When the serum osmolarity is raised above 320 Osm, mannitol, particularly in large doses, may precipitate acute tubular necrosis. With prolonged use, mannitol can also disrupt the blood–brain barrier, and it may pass into the brain parenchyma and cause a rebound effect, with subsequent increases in ICP.

Hypertonic Saline Solutions

Hypertonic saline solutions may be used as an adjunct or alternative to mannitol. One advantage of these agents compared to mannitol is a lower risk of rebound intracranial hypertension and renal failure. In hyperosmolar concentrations, sodium chloride creates a gradient which drives water from its interstitial and intracellular compartments into the intravascular space, reducing brain water and ICP. More recent work by Christou and colleagues have suggested that hypertonic saline also has antiinflammatory properties.

Data on the effectiveness of hypertonic saline solutions in the management of raised ICP in head-injured patients have been gathered only in small case series and controlled groups. Quereshi's group reported that 23.4% saline in doses of 30–60 ml over 20 min can markedly reduce ICP when standard treatments fail. Hartl et al. demonstrated that 7.5% hypertonic saline was particularly effective in ICP reduction and CPP elevation in patients with severe TBI whose ICPs were refractory to standard therapy. Hypernatremia is commonly observed but usually resolves as renal free water clearance is reduced. Potential adverse consequences include central pontine myelinolysis and seizures, as well as hypernatremia, congestive heart failure from fluid shifts, and coagulopathy.

Intracranial Hypertension Refractory to Standard Treatment: Other Measures to Consider

The measures described in preceding sections are routinely used to manage intracranial hypertension. When ICP begins to increase despite maximal treatment, other measures are considered, such as hyperventilation with the use of appropriate CBF monitoring, decompressive craniectomy, or barbiturate-induced burst suppression. Prolonged hyperventilation can actually be harmful, and barbiturate-induced burst suppression has not demonstrated to improve outcomes, despite its ability to control reduced cerebral metabolic rates for oxygen ($CMRO_2$). The role of decompressive hemicraniectomy has not been fully defined, as initial studies showed little benefit, but a recent revival in the popularity of the procedure purports to show improved outcomes. Therefore, we use these measures in select situations only, after careful consideration and discussion with family members regarding the advantages and disadvantages of each.

Barbiturates

Barbiturates potentiate the effects of γ-aminobutyric acid (GABA) at GABA receptors, and reduce $CMRO_2$ by globally inhibiting neuronal transmission. Barbiturates may also decrease ICP by limiting free-radical-mediated lipid peroxidation and limiting resultant cerebral edema. The routine use of barbiturates as the prophylactic treatment of ICP is not indicated. In one study, over half of the treated group developed clinically significant hypotension during pentobarbital administration. Nevertheless, barbiturates decreased ICP in two early studies. In a prospective randomized trial, Eisenberg et al. showed that pentobarbital coma in patients with refractory intracranial hypertension had a 2:1 benefit in the control of ICP. Plasma and CSF pentobarbital levels correlate poorly with physiologic effects, and pentobarbital dosing and effects are best followed by electroencephalogram (EEG) monitoring, with dose titration to achieve burst suppression. The most frequently cited and clinically important side effects of barbiturate administration are hypotension and global oligemic hypoxia, followed by hypokalemia, respiratory depression, hepatic dysfunction, and renal dysfunction. For these reasons, this treatment should only be used in conjunction with a Swan–Ganz catheter.

Hyperventilation

Hyperventilation was at one time routinely used as a prophylactic means of reducing intracranial hypertension. However, ICP reduction by hyperventilatory vasoconstriction carries with it the significant risk of inducing cerebral ischemia through inadequate CBF, particularly in the first 24 h after injury, when CBF is already severely compromised. These physiologic effects have been tied to outcome, with Muizelaar et al. reporting an improved outcome at 3 and 6 months when prophylactic hyperventilation was avoided for 5 days after injury. The routine use of hyperventilation should therefore generally avoided, but it remains a rapid method of reducing ICP in emergency situations with acute neurologic deterioration and impending herniation, In such situations, hyperventilation should be maintained only as long as necessary to initiate other treatments.

Decompressive Hemicraniectomy

Delayed decompressive hemicraniectomy, where the bone is removed and the dura is opened to increase

the size of the intracranial compartment, can lower ICP. The first large series of such intervention was the bifrontal decompressive craniotomy reported by Kjellberg and Prieto in 1971; outcomes, however, were generally poor. Gaab et al. reported their prospective results on the use of bifrontal or hemicraniectomy with more stringent inclusion criteria, in which they excluded patients over 40 years of age and those with GCS <5. They reported a 14% mortality rate and a 38% rate of 'full restitution.' Jane's group reported favorable outcomes in 60% of patients undergoing a modified Kjellberg procedure within 48 h of injury, with a GCS between 3 and 8 and intractable hypertension, but with ICP less than 40 mmHg. A recent Cochrane Systematic Review of decompressive craniectomy for refractory ICP identified only one small, randomized, controlled trial addressing this issue in the pediatric population (<18 years old). In this trial containing 27 patients, Taylor and colleagues demonstrated a risk ratio reduction of 0.54 for death, as well as for death, vegetative state, and severe disability 6–12 months after the event in those patients who underwent bitemporal decompressive craniectomy for high ICP. Other studies without direct comparisons with patients that did not have the procedure have also noted favorable outcomes. The particular timing and indications for intervention have yet to be codified.

Management Paradigms

The principal goal of severe TBI management is the limitation of secondary brain injury from cerebral ischemia and intracranial hypertension after any primary injury has been addressed. The avoidance of intracranial hypertension is essential to this goal and has as its physiologic basis the prevention of brain herniation and reduced CPP. This ICP-based approach to patients with severe TBI centers on the maintenance of a normal ICP, with stepwise measures taken as shown in Figure 4.

Others have stressed the importance of CPP-based management, in which maintenance of a particular CPP is central to management, rather than the avoidance of a particular ICP. The guiding physiologic underpinnings of this approach are that a decrease in CPP – whether by an increase in ICP or a decrease in MAP – leads to compensatory vasodilatation and an increase in CBV, which further increases ICP and, in turn, even further compromises CPP (Figure 3). Initial favorable outcomes have led to the widespread adoption of CPP preservation in the management algorithms of severe TBI.

Given these considerations, the three cornerstones of an integrated management paradigm which monitors and controls both ICP and CPP include (1) rapid identification and potential management of intra- or extra-axial mass lesions, (2) ICP monitoring and treatment of intracranial hypertension, and (3) CPP preservation and avoidance of cerebral ischemia (Figure 5). Also crucial in management schemes is meticulous systemic medical management of these patients, including appropriate seizure prophylaxis.

Hypothermia, Neuroprotection, and Restorative Therapies

Future directions in brain injury management include the formulation of strategies to 'protect' the head-injured brain from further secondary injury and to repair injured neural tissue. An early attempt at neuroprotection was hypothermia, which produces proportionate reductions in energy production, use,

Figure 5 Cornerstones of severe traumatic brain injury management. CPP, cerebral perfusion pressure; ICP, intracranial pressure.

$CMRO_2$, and CBF. While early pilot studies demonstrated favorable outcomes in head-injured patients, a multicenter prospective randomized-controlled trial by Clifton and colleagues failed to show improvement in outcomes. However, a follow-up study in a subgroup of patients that may have benefited is currently in progress.

Therapeutic strategies have also been developed to antagonize the glutamate excitotoxic pathway at the level of the *N*-methyl-D-aspartate (NMDA) receptor to reduce calcium entry into injured neurons, but no convincing effect on outcome has been demonstrated to date. Tirilazad, a 21-aminosteroid that inhibits lipid peroxidation, and the free radical scavenger polyethylene glycol–superoxide dismutase were both studied in large clinical trials, with no benefit to outcome reported.

Another exciting possibility is the stimulation of endogenous neurogenesis or engraftment of exogenous neural stem cells to repair damaged brain by cell replacement or growth factor release. In the coming years, current TBI management paradigms will surely be complemented by highly selective neuroprotective and neurorestorative strategies to enhance the likelihood of meaningful functional recovery.

Brain Volume: Age-Related Changes

G Bartzokis and P H Lu, University of California School of Medicine, Los Angeles, CA, USA

Introduction

The popular concept of postnatal human development separated into three stages (development/maturation, adulthood/stability, and aging/degeneration) may be appropriate to human physical characteristics such as height but has distorted the understanding of human brain biology. Over the life span, the human brain is in a continuous state of change roughly defined as periods of development/maturation followed by degeneration/repair. The popular concept of a stable, unchanging 'adult' life stage for the brain is misleading and biologically invalid (Figures 1, 2, and 3). The concept of a stable adult stage (defined as ages 18–55) is valid only when whole brain volume is considered (Figure 1(c)) but fails to capture the underlying infrastructural changes to our brain's 'Internet' (see section titled 'The myelin model of the human brain' and Figures 1(b), 2, 3, and 4(b)). Our very nature as a species depends on optimizing the performance of our brain's Internet, and this performance is dependent on the extensive and protracted process of myelination (see next section and Figure 5).

Magnetic resonance imaging (MRI) can provide images with appropriate resolution and tissue contrasts to quantify *in vivo* the brain's developmental and subsequent degenerative changes. MRI images can measure white matter volumes. When myelin-sensitive inversion-recovery and heavily T1-weighted MRI sequence images are used, they likely include some of the deeper layers of cortical gray matter as myelination spreads into the cortex (lower panels of Figure 2). Thus, these imaging methods measure white matter (WM) volumes that can be better conceptualized as 'myelinated WM volume,' which includes deeper layers of cortex. Not surprisingly, these imaging methods have replicated and extended postmortem observations using myelin stains (Figures 2 and 3). In other words, such sequences are the MRI equivalent of myelin stains, which is the likely reason MRI studies using these methods correspond so closely with postmortem myelin stain data (Figures 2 and 3). Using such images, MRI can detect the shift of the gray matter–myelinated WM boundary into cortical gray matter caused by the process of 'intracortical' myelination (lower panels of Figure 2). This intracortical myelination, together with continued myelination of unmyelinated subcortical fibers (Figure 6(a)) and addition of myelin lamellae in the subcortical myelinated fibers, form the myelinated WM volume. The term 'myelinated WM volume' may therefore be a more appropriate description of the volume measured with inversion-recovery and heavily T1-weighted sequences than simply 'WM volume.' Although this way of conceptualizing MRI data helps explain the similarities between MRI data and postmortem studies, the usual term of 'WM volume' will be used throughout this article except for specific discussion of the impact of intracortical myelination (e.g., Figure 2).

In humans, the disproportional contributor to the enlargement of the late-maturing structures such as the frontal and temporal lobes is their higher WM and myelin content compared to other species (Figure 5). Going against popular belief, recent studies show that compared to primates, adult humans have neither disproportionately enlarged frontal lobes for our overall brain size nor disproportionate increase in gray matter. Rather, human brain has disproportionately more (approximately 20%) WM. These findings are consistent with the overall evolutionary trend to have increasing cognitive abilities associated with disproportionate increases in glia rather than neuron numbers. During brain evolution, glial cell numbers have increased disproportionately compared to neurons; from 10–20% of all brain cells in the nematode to 25% in the fly, 65% in the rodent, and 90% in human. The higher number of oligodendrocytes results in the disproportionately higher percentage of brain dry weight accounted for by myelin in humans (30% higher), compared with rodents.

The Myelin Model of the Human Brain

The human brain is unique in its high myelin content as well as its long developmental (myelination) phase. On average, the myelination phase continues until approximately age 50–60 (Figures 1 and 3) and thus spans our entire evolved life span (before modern medicine, few individuals lived beyond that age). The popular analogy of the brain to a computer is misleading as it ignores the WM (axons, or 'wires,' plus their myelin, or 'insulation') that composes approximately half the adult human brain. A more useful analogy for the human brain is thus the Internet, where speed, bandwidth, and an online connection are the paramount attributes of optimal function. All these attributes of the brain's Internet depend on myelin.

Axon myelination results in saltatory conduction of action potentials that markedly increases (>tenfold) signal transmission speed. Speed makes it

Figure 1 MRI volumes in frontal plus temporal lobes of healthy individuals across the life span. (a) Gray matter. Linear: $r = -0.62$, $p < 0.0001$; Quadratic: not significant (NS), $p > 0.94$. (b) White matter. Linear: NS, $p > 0.84$; Quadratic: $t = 4.56$, $p < 0.0001$, Peak = 45 years. (c) Gray plus white matter. Linear correlations for adults (18–54) and older age (55–76), confirming stable adult brain volume (gray plus white matter) observed in postmortem studies. For details on methods, see Bartzokis G, Beckson M, Lu PH, Nuechterlein KH, Edwards N, and Mintz J (2001) Age-related changes in frontal and temporal lobe volumes in men: A magnetic resonance imaging study. *Archives of General Psychiatry* 58: 461–465.

Figure 2 Quadratic (inverted U) myelination trajectories of human brain over the life span. Myelination (*y*-axis) vs. age (*x*-axis) in (a) frontal and (b) temporal lobes of normal individuals. Figures (a) and (b) are *in vivo* MRI data reproduced from Bartzokis G, Beckson M, Lu PH, Nuechterlein KH, Edwards N, and Mintz J (2001) Age-related changes in frontal and temporal lobe volumes in men: A magnetic resonance imaging study. *Archives of General Psychiatry* 58: 461–465, copyright ©(2001) American Medical Association. Figures (c) and (d) are, respectively, frontal and temporal cortex postmortem intracortical myelin stain data from Kaes, 1907; adapted and reproduced in Kemper T (1994) Neuroanatomical and neuropathological changes during aging and dementia. In: Albert M and Knoefel J (eds.) *Clinical Neurology of Aging*, 2nd edn., pp. 3–67. New York: Oxford University Press, with permission from Oxford University Press. The data depicted in (a) and (b) were acquired some 100 years later than the data depicted in (c) and (d), yet the two samples of normal individuals show remarkably similar myelination trajectories in the two regions. Note that different brain regions have significantly different myelination trajectories even when the regions are similar, as is the case with these two association regions. Frontal lobe peak myelination is reached at age 45, but peak myelination is reached even later in the temporal lobe.

possible to integrate information across the highly spatially distributed neural networks that underlie our higher cognitive functions. Myelination also decreases the refractory time (time needed for repolarization before a new action potential can be supported by the axon) by as much as 34-fold. Thus, if the brain were to be compared to the Internet, myelination not only increases its speed (e.g., transforming it from a telephone line system to a T1 line system) but also its 'bandwidth,' increasing the actual amount of information that can be transmitted per unit of time. This allows myelinated axons to support 'high-frequency bursts' of signals, on which processing speed and long-term potentiation depend, and further facilitates information processing by allowing for precise temporal coding of neuronal activity. However, until a network or circuit is fully myelinated (from neuron body to neuron body), it will not be 'online' to immediately affect ongoing cognition and behavior. Figure 2 demonstrates that from a biological standpoint, becoming a healthy middle-aged adult involves intracortical myelination all the way to the neuron body that brings networks or circuits online. Thus, humans' extensive process of myelination markedly increases cognitive

Figure 5 Coronal myelin stains of (a) human, (b) chimpanzee, and (c) rodent brains. Brains are not to scale. Chimpanzee and rodent brain are enlarged to approximate human brain in order to more easily demonstrate the striking differences in the proportion of myelin (stained black) in each brain. Human brain has approximately 20% more white matter than the chimpanzee's.

Figure 6 Corpus callosum regional differences in size and myelination of axons. (a) Genu: many small, thinly myelinated axons and clusters of unmyelinated axons (20–30% of axons in this structure connecting late-myelinating frontal regions). (b) Larger, more heavily myelinated axons and far fewer unmyelinated axons (<7%; none in this image) observed in regions like ventral splenium which connect primary sensory (visual) early myelinating regions. information-processing speed and underlies many of our brain's unique capabilities, such as language, memory, inhibitory control, and higher cognitive functions. This interpretation suggests that the brain could experience neurodevelopmental arrest, even in adulthood, if pathological states (e.g., brain trauma, schizophrenia, severe stress, substance abuse, etc.) alter the normal age-related pattern of structural changes.

The widely distributed neural networks on which the brain's organization is based make speed of processing paramount for higher cognitive functions. The impact of myelin on information processing speed makes the production and maintenance of myelin essential for normal brain function. The vulnerability of the oligodendrocytes and the myelin they produce to genetic and environmental insults likely also underlies our brain's unique susceptibility to highly prevalent and often unique human disorders of development, ranging from autism and learning disabilities to schizophrenia. In older age, such vulnerabilities likely also underlie the exponential increase in degenerative disorders such as Alzheimer's and Parkinson's diseases, whose prevalence is such that they may be considered 'normal' (i.e., affect the majority of the population above the age of 90).

Functional Implications of the Myelin Model

The view of development and aging as a continuum of interactive structural and functional developmental trajectories fosters the examination of multiple factors that promote or inhibit myelination throughout the protracted process of human brain development. Quadratic-like patterns of change over the life span similar to the myelination trajectory have been demonstrated in neurophysiologic and cognitive models of brain function and are also observed in studies of clinical symptomatology in a variety of neuropsychiatric disorders.

Such quadratic-like life-span trajectories have been repeatedly documented in age-related changes of cognitive speed that increase throughout childhood and early adulthood and then decrease with an accelerating rate in old age. Salthouse delineated the hypothesis that a basic parameter such as speed is directly related to biological factors and is essential for higher-order cognitive processing. Similar quadratic trajectories are also apparent in paradigms that test inhibitory control. These quadratic trajectories also resemble the trajectory of some neurophysiologic (electroencephalogram) parameters. The myelin model described above would suggest that the principal underlying biological factor to consider as an explanation for all such life-span trajectories is the process of myelination (Figures 2, 3, and 4).

In the context of the myelin model, the occurrence of all these changes in the structure and function of

the normal human brain peaking at roughly the same midlife stage can be viewed as indirect evidence that after infancy, myelination is the central biologic process underlying human aging-related changes. It is important to point out that the age-related cognitive improvements in processing speed and inhibitory control peak in adulthood. Thus, these developmental trajectories do not temporally 'fit' (by more than a decade) the regressive processes of neuronal, synaptic, axonal, and dendritic pruning and elimination that occur primarily before mid-adolescence.

Brain Development during Childhood to Adolescence

The focus on myelin and myelination is not intended to diminish the importance of other early brain developmental processes such as neurogenesis (primarily intrauterine but whose disruption can cause catastrophic abnormalities that are usually evident at birth or in early infancy). The focus on myelin is especially not intended to dismiss the drastic processes of neuronal, synaptic, axonal, and dendritic pruning and elimination that appear to reduce the 'connectivity' of the child's brain by as much as two-thirds as it develops into adulthood. These processes, which have been hypothesized to affect several childhood disorders, are in large part completed by puberty or mid-adolescence.

These regressive pruning processes occur in concert with a precisely regulated but highly vulnerable and sometimes ignored process of myelination. The regressive pruning processes occur in a heterochronous pattern in primary process areas (motor, sensory) before association areas (frontal, temporal, and parietal lobes; see example in Figure 2). This pattern of heterochronous, volume-reducing, regressive pruning matches the pattern of the heterochronous, volume-increasing, developmental process of myelination (Figure 1). The human skull becomes rigid in late childhood, eliminating the possibility of further expansion of the brain. Thus, it can be argued that the regressive pruning processes of childhood described above occur in large part to provide the 'room' (intracranial volume) and possibly other resources necessary to support the crucial process of myelination.

How can it be that a process that produces such tremendous losses of synapses and axons does not result in dementia in this young age range? To return to the Internet analogy, the pruning of the neurons, and synaptic loss is equivalent to the reduction in capability of the computers of the Internet (e.g., reduced random access memory). The dramatic gains in processing speed (transmission speed, bandwidth, and online connectivity) and other possible benefits, such as reduced energy consumption, provided by myelination likely more than compensate (functionally) for the regressive pruning processes. Instead of reducing 'connectivity' between different parts of the brain suggested by the regressive pruning processes, the myelination process markedly increases the functional potential (connectivity) of the remaining neural networks and circuits. It is thus possible to continue human cognitive, emotional, and behavioral development without the loss, and in fact with the addition, of functional capacity that in middle age culminates in healthy adults with better emotional regulation and inhibitory control underlying what is commonly referred to as wisdom.

Studies examining brain development in children and adolescents have demonstrated increasing WM volume and decreasing gray matter volume in later childhood and adolescence. These findings were recently confirmed in prospective MRI studies of brain development which demonstrated that WM volume increases linearly between ages 4 and 20, a period characterized by increased myelination. Unlike the WM changes, cortical gray matter changes were quadratic rather than linear and exhibited region-specific patterns of change (heterochronous) within this age span. Gray matter reached maximum volume at about age 12 in the frontal lobes but not until age 16 in the temporal lobes. The myelination process continues this regional developmental trajectory, resulting in the same regional pattern of maximal myelination reached 30 years later in the frontal lobe (in the mid-40s) and in the temporal lobe (in the late 40s; Figure 2).

Brain Development Continues during Adulthood until Middle Age

The history of research on age-related changes in adult human brain structure has been immersed in confusion and controversy. Much of the confusion stemmed from the long-standing dogma that in normal adulthood (18–55 years of age), large reductions in cortical neuron numbers occur. This erroneous conclusion was based on data showing that neuronal density in young adults was higher than in middle-aged and older adults. The age-related reductions in cortical neuronal density were subsequently shown to be caused by an age-related tissue fixation shrinkage artifact that caused cortices of younger individuals to shrink more than those of older ones. Together with the assumption that neuronal density was equivalent to number, the dogma took hold that beginning in young adulthood, neuronal numbers decreased with

age. Recent postmortem data based on unbiased stereologic assessments have demonstrated that there is minimal, if any, neuronal cell loss or cortical thickness decrement before the age of 55.

The confusion was also promoted by the underappreciation of the fact that in primate brain, postnatal development is primarily driven by the protracted process of myelination. Unlike other brain cell lines, oligodendrocyte numbers continue to increase into old age to support the process of subcortical and intracortical myelination. The excess cortical shrinkage of younger brains that occurs on fixation is likely due to the lower levels of intracortical myelin at younger ages (Figure 2). Intracortical myelination increases during adulthood to peak in the mid- to late fifth decade of life in association regions such as the frontal and temporal lobes (Figure 2), and the presence of lipid-rich myelin reduces the amount of dehydration-related shrinkage that occurs in older compared to younger brains. The lower the myelin content of any cortex, the more shrinkage would be expected on fixation and the higher the neuronal density (as opposed to numbers) would be.

With the advent of MRI, the dogma was reinforced that in healthy aging, intracortical neuronal numbers and presumably gray matter thickness decline beginning in the teens. This occurred because the vast majority of imaging studies observed an apparent reduction in gray matter volume in adulthood (ages 18–55). The two largely erroneous conclusions (the excess cortical shrinkage of younger brains that occurs with fixation and the imaging findings of an apparent cortical volume loss with age) are likely both due to the process of increasing intracortical myelination. Thus, as Figure 1 demonstrates, the apparent decrease in gray matter volume from ages 18 to 55 (Figure 1(a)) is offset by the increase in myelinated WM volume (Figure 1(b)), to result in a stable brain volume in this age range (Figure 1(c)), as established by postmortem studies. The shift in the gray–white border created by intracortical myelination (Figures 1 and 2) can also help explain why some studies of structure–function relationships in healthy developing individuals report improving function with faster rates of gray matter volume decline. From the framework of the myelin model, such findings can best be interpreted as improved function with increasing intracortical myelination.

With few exceptions, however, most of the early MRI studies reported that WM volume remains constant into the seventh decade, as if it were unaffected by the aging process. This is in contrast to later imaging studies using improved methods to demonstrate continual WM expansion into middle age. The failure of early imaging studies to detect age-related WM volume increase in adulthood may be accounted for by many methodological issues. These include the use of axial images aimed at studying the brain in its entirety rather than focusing on regions such as the frontal and temporal lobes, which complete maturational changes later (in middle age) than the primary sensorimotor and occipital areas (Figures 7(a) and 7(b)). The age-related trajectory of structural changes can also depend on the age range examined because different regions differ in their age-related trajectory of myelination (Figures 2 and 7(a)). Finally, the use of automated procedures for gray and WM segmentation and suboptimal contrast can contribute to misclassification of tissues, and slice thickness greater than 3 mm can increase partial volume effects.

The difference in gray–white contrast obtained with various imaging parameters deserves special focus as it can help clarify discrepant imaging results. This focus can also highlight how consistent imaging and postmortem results can be when appropriate imaging contrasts are employed. When myelin tissue stains or myelin-sensitive brain imaging sequences are used to assess whole brain changes with age, the process of myelination (including intracortical myelination) results in similar quadratic (inverted U) age-related changes in the gray to WM ratio in the adult age range (Figure 3). As outlined above, the process of intracortical myelination can alter both the amount of fixation shrinkage of the cortex and the location of the gray–white border detected on brain imaging studies (Figure 2). Since most imaging sequences are sensitive (in varying degrees) to myelin and water content, they will detect an apparent age-related decrease in cortical volume as the process of age-related intracortical myelination causes the border between gray and WM to 'track' the process of intracortical myelination and be placed higher into the cortex (Figure 2). The slope of the apparent gray matter volume decline will depend on the region being evaluated (e.g., the average of the heterogeneous cortical areas included in the measure – see Figure 7), and the age ranges examined as different regions differ in their age-related pattern of myelination. Thus, many factors can influence imaging findings, but in general, inversion recovery and heavily T1-weighted images are most strongly influenced by the myelin content of the tissues.

Figure 3 demonstrates how myelin-tracking postmortem and *in vivo* imaging of two samples of normal individuals over the life span produce consistent results. Regression lines from the 1980 'gold standard' myelin stain study of AK Miller and colleagues evaluating whole brain gray/WM ratio (Figure 3(b)) estimate a value of approximately 1.3 for the gray/WM ratio of healthy individuals at the age of 20. In MRI measures that were limited to the evaluation of frontal plus temporal regions, a higher ratio would

Figure 7 (a) The myelogenetic fields numbered according to the time of myelination. From Flechsig, 1920; reproduced in Meyer A (1981) Paul Flechsig's system of myelogenetic cortical localization in the light of recent research in neuroanatomy and neurophysiology: Part II. *Canadian Journal of Neurological Sciences* 8: 95–104. This is one of the few works attempting to map the sequence of myelination. It illustrates the developmental heterogeneity (heterochronic timing) of brain myelination, with sensory and motor regions (shaded) myelinating first (in very early childhood) and temporal and frontal regions myelinating last – confirmed by Yakovlev PI and Lecours AR (1967) *Regional Development of the Brain in Early Life*. Boston, MA: Blackwell Scientific. (b, left) The image shows three zones of cerebral myelination which differ (are heterochronic) by age at myelination. Medial zone, light gray; paramedial zone, dark; dorsolateral zone, opercular and paralimbic areas – cross hatching; supralimbic association areas – diagonal hatching. (Left) Adapted from Yakovlev PI and Lecours AR (1967) *Regional Development of the Brain in Early Life*. Boston, MA: Blackwell Scientific, with permission from Blackwell Publishing. Showing the 'supralimbic association areas' (diagonal hatching of the frontal and temporal cortices) as these regions continue myelinating into 'older age.' This is graphically depicted in the lower left graph where the cortical supralimbic zones (lowest horizontal graph) continue myelinating well beyond the first decade. On the right, MRI image used to measure myelinated white matter volume in the same frontal and temporal 'supralimbic association areas', demonstrating myelination continues late into the fifth decade (also see **Figure 2**). In the MRI image the outer border of the brain and 'islands' of lighter material seen in the frontal gray matter are cerebrospinal fluid areas that are eliminated from computation using a coregistered T2-weighted image. Inversion recovery MRI reproduced from Bartzokis G, Beckson M, Lu PH, Nuechterlein KH, Edwards N, and Mintz J (2001) Age-related changes in frontal and temporal lobe volumes in men: A magnetic resonance imaging study. *Archives of General Psychiatry* 58: 461–465, copyright © (2001) American Medical Association.

be expected since, as described in myelin stain studies (**Figures 5 and 7**), myelination is continuing in these lobes beyond age 20 although it is complete in many other primary brain regions (e.g., motor, visual). From inversion recovery MRI images, a gray/WM ratio of 1.55 for the frontal plus temporal lobes at age 20 (estimated from regression lines – **Figure 3(a)**) is thus consistent with the gold standard myelin stain post-mortem gray/WM ratio results (**Figure 3(b)**). In addition, the minimum (trough) gray/WM ratio is reached

at age 50 in the postmortem whole brain data and at age 54.6 for *in vivo* data. The trough is again strikingly consistent given that the brain frontal and temporal lobe regions continue to develop in adulthood, which would tend to push the trough to older ages.

Thus, during healthy postadolescent development and maturation of the prefrontal and association areas, apparent gray matter volume reduction observed on imaging studies occurs in concert with an expansion in myelinated WM volume that continues into middle age (**Figure 2**), when peak myelin brain levels are reached. Myelin-sensitive imaging sequences produce data that are strikingly similar to postmortem myelin stain data (**Figures 2 and 3**). The myelinated WM expansion volumetrically cancels out the apparent gray matter reduction; thus, both imaging and postmortem studies show minimal, if any, changes in total brain (gray plus WM) volume in normal individuals during adulthood (18–55 years of age) (**Figure 1(c)**). In older age, the cortex undergoes additional changes consisting primarily of shrinkage of large neurons and increase in the proportion of small neurons. What effect such changes, combined with the increased number of oligodendrocytes and intracortical myelin growth and eventual loss, have on imaging results remains to be fully elucidated.

The biology of brain myelination shows that the life span can be appropriately conceptualized as dynamic, roughly quadratic (inverted U) trajectories that differ (are heterochronic – have different developmental/age trajectories) by brain region (**Figure 2**) and function. The trajectory of intracortical myelination with a shift in the gray/WM separation can help explain the quadratic trajectories in life span WM volumes (**Figure 2**). It can also help explain the complementary, U-shaped gray matter life span trajectories that emerge when people in their ninth and tenth decades are included in aging studies. At advanced ages, the loss of intracortical myelin with a shift of the gray–white border toward the WM could make the cortex appear to be getting 'thicker' or maintaining its volume with age while the overall WM volume continues to decline. This trend will also create a U-shaped curve in a gray–white ratio analysis (**Figure 3**), where the trough represents the point at which loss in myelinated WM volume surpasses the change in gray matter volume produced (at least in part) by the loss of intracortical myelin.

Aging and Myelin Breakdown

In addition to gross volume changes in myelinated WM, the loss of myelin integrity in older age has profound effects on brain function and age-related cognitive decline in human and nonhuman primates. The breakdown in the structural integrity of myelin sheaths can be measured indirectly *in vivo* with MRI using multiple methods. One such method uses transverse relaxation rate (R_2) measures (R_2 is directly associated with transverse relaxation times [T_2] by the formula $R_2 = 1/T_2 \times 1000$). These measures are markedly sensitive to small changes in the amount of tissue water. Ultrastructural electron microscopy studies demonstrate that age-related myelin breakdown results in microvacuolations consisting of splits of myelin sheath layers that create microscopic fluid-filled spaces and increase MRI-'visible' water, thus decreasing R_2. These microvacuolations are ultrastructurally very similar to reversible myelinopathies produced by certain toxins. Animal studies have confirmed that this type of myelin breakdown can be detected with MRI in circumscribed susceptible regions and that the histopathologic changes produced by toxins as well as the recovery process can be tracked by changes in MRI relaxation rates. In asymptomatic individuals, focal WM regions of R_2 decrease (T_2 increase) have also been associated with myelin pallor on histological stains (**Figure 8**). Although R_2 has not been directly correlated with myelin breakdown due to normal aging (as opposed to the reversible toxin-induced myelin breakdown and focal regions described above), in humans and primates, healthy aging is not associated with neuronal loss. On the other hand, the process of myelin breakdown and loss has been repeatedly demonstrated. In this article, the term 'myelin breakdown' will therefore be used to refer to the R_2 findings.

In addition to being heterochronic, the brain's myelination process is highly heterogeneous (**Figures 2 and 7**). For example, the myelination process for primary sensory and motor regions such as the visual system occurs primarily in infancy and consists of large axons myelinated very heavily by a single oligodendrocyte per myelin segment (**Figures 6(b) and 4(a)**). In the late-myelinating association regions such as frontal lobes and corpus callosum regions that connect them (such as the genu – **Figures 6(a) and 4(a)**), the myelination process continues into early middle age (**Figure 4(b)**) and consists of myelination of much smaller fibers by thinner myelin sheaths (**Figure 6(a)**). In these late-myelinating regions, one oligodendrocyte myelinates multiple axons (as many as 50–60 in the latest myelinating regions in the frontal and temporal lobes).

Peters and others have shown in both primate animal models and human postmortem and *in vivo* data that myelination is followed by a degenerative process consisting of progressive myelin breakdown and loss (**Figures 2 and 4**). Published observations from a primate model of aging show that myelin breakdown begins to occur while active myelination

and myelin volume expansion is still continuing. The same sequence has been shown to occur in human aging. Analysis of data for 68 normal men for whom both frontal lobe WM (FWM) volume (Figure 2) and relaxation rate (a measure sensitive to changes in tissue integrity which produce increased tissue water – Figure 4(b) were available showed that, as would be expected, the beginning of WM integrity decline in Fwm (at age 38) (Figure 4(b)) precedes the age at which Fwm volume decreases begin (at age 45; Figure 2).

These imaging data are also consistent with postmortem data from human brain that show a 45% loss of myelinated fiber length during aging, affecting primarily thinner and less heavily myelinated fibers such as the ones seen in the frontal lobe WM and genu of the corpus callosum (Figure 6(a)). These declines are also consistent with age-related ferritin iron declines in these WM regions. It is postulated that age-related myelin breakdown and oligodendrocyte loss (Figure 8) release the considerable iron stores of oligodendrocytes and their myelin, which are then redistributed and contribute to the age-related increase in brain iron levels observed in heavily-myelinated subcortical gray matter regions.

Functional Implications of Age-Related Myelin Breakdown

Neuroimaging and postmortem data have demonstrated that the process of myelination peaks in middle age, followed by myelin breakdown and loss (Figures 2, 3, and 6(b)). Age-related slowing in speed of information processing, particularly after middle age, has been repeatedly documented in the neuropsychological literature and is a well-accepted clinical phenomenon. Salthouse and others have demonstrated that the slowing in cognitive processing speed (CPS) with age likely underlies the age-related decline observed in most, if not, all human cognitive functions.

Investigations of CPS performance across the life span reveal a trajectory that parallels myelination and subsequent myelin breakdown. The similarity in these trajectories supports the hypothesis that in older age, myelin breakdown may be the cellular mechanism underlying the age-related decline in cognitive speed. Thus, the uniquely extensive myelination of the human brain makes myelin maintenance and repair especially critical for sustaining our high CPS. Myelin breakdown may result in a progressive 'disconnection' of widely distributed neural networks that eventually contributes to age-related cognitive decline and Alzheimer's disease (AD).

Apolipoprotein E (ApoE) 4 genotype, coded on chromosome 19, is second only to advancing age in its influence as a risk factor for developing AD. Epidemiological studies have demonstrated that ApoE4 genotype shifts the age of onset for AD by more than a decade, thus accounting for the vast majority of observed cases of AD. Conversely, the onset age is delayed in carriers of the ApoE2 allele.

The physiologic role of ApoE suggests that myelin may be a central biological link between the presence of this gene and AD. In nonhuman primates, myelin

Figure 8 White matter 'hyperintensities' on MRI are often the center of much larger areas of diffuse myelin breakdown. Small patchy hyperintense white matter lesions on T2-weighted MRI (arrows, (b)) are often the very center of much more widespread and diffuse regions of myelin breakdown, as shown in the postmortem myelin stain of (c) – see arrows. The panels are different MRI images through the same slice of tissue; (a) is a T1-weighted image, (b) is a T2-weighted image, and (c) is a histologic section (luxol fast blue staining for myelin) through the same slice of the same brain (showing the boxed region in left panel). Adapted from Takao M, Koto A, Tanahashi N, Fukuuchi Y, Takagi M, and Morinaga S (1999) Pathologic findings of silent hyperintense white matter lesions on MRI. *Journal of the Neurological Sciences* 167: 127–131, with permission from Elsevier.

repair and remyelination is an essential process that continues into old age. ApoE is the primary transporter of endogenously produced lipids such as cholesterol and sulfatide, entirely produced by oligodendrocytes and essential for myelin production and function. ApoE coordinates mobilization and transport of such lipids for uptake and use in repair, growth, and maintenance of myelin as well as other membranes, including synapses and dendrites essential for brain plasticity and learning. ApoE is essential to the extensive process of 'recycling' lipids such as cholesterol released when damaged myelin is degraded and supplying these lipids for rapid membrane repair and biogenesis. This process of 'remyelination' has been demonstrated in the primate model. The quantity of ApoE molecules necessary for this recycling process is lowest in ApoE4 carriers and highest in individuals with the ApoE2 allele. Thus, it has been hypothesized and imaging data have supported that the disruption of myelin repair secondary to insufficient ApoE molecules results in greater age-related myelin breakdown and contributes to the association between ApoE4 and AD as well as the associated influence of ApoE genotype on age-related cognitive decline.

Studies testing the myelin model have demonstrated that healthy older individuals possessing the ApoE4 genotype displayed more myelin breakdown with age. This relationship was absent for participants with the ApoE2 genotype, and ApoE3 individuals displayed an intermediate slope of decline. This genetic effect was specific to late myelinating regions and was not observed in early myelinating regions such as the splenium of the corpus callosum (**Figures 6 and 4**). Furthermore, CPS performance (as assessed by Trails A and Digit Symbol neurocognitive tasks) was significantly associated with R_2 in late myelinating regions (frontal lobe WM, $p < 0.0001$, and genu, $p < 0.004$) but not in the early myelinating splenium region ($p > 0.2$). These data suggest that myelin breakdown in healthy older individuals underlies the age-related cognitive decline that ultimately progresses to AD.

Conclusions

Postmortem and *in vivo* imaging evidence can be integrated to suggest that an understanding of brain aging and the aging-related processes of myelin production and subsequent breakdown may be directly relevant to deepening our understanding of the biology and function of the human brain. The lifelong quadratic trajectories of myelination and eventual myelin breakdown and loss of different networks, circuits, and regions can help explain the lifelong trajectories of cognitive, behavioral, and emotional changes that define our everyday lives, from the impulsiveness of youth to the wisdom of older ages. More important, the focus on the myelination trajectories of the human brain may help explain many of the unique but highly prevalent and devastating diseases that plague our species over its entire life span.

This myelin model of the human brain posits that the uniquely pervasive and protracted myelination process creates a continuum of vulnerability among the myelin-producing oligodendrocytes and their myelin that culminates in the latest developing oligodendrocytes. Genetic and/or environmental effects that affect myelin development and breakdown will manifest as risk factors (or protective factors) for both developmental disorders such as autism and schizophrenia and aging-related disorders such as AD and Parkinson's disease.

The creation and maintenance of myelin is at the core of the earliest changes involved in both postnatal brain development and, in older age, the aging process itself and the subsequent emergence of degenerative disorders such as AD. Myelin deficits disrupt brain functions that depend on highly synchronized timing of high-frequency bursts of action potentials and eventually result in functional 'disconnections' of association cortical regions. The eventual progression to frank neuronal loss results in permanent deficits. This model suggests that many pathological states (e.g., genetic and hormonal states, head trauma, hypertension, hypercholesterolemia, and substance abuse) can affect the normal age-related pattern of myelin development, resulting in developmental disorders that at older ages can also affect the pattern of myelin breakdown and the manifestations of degenerative disorders. This life-span model of a seamless transition from brain development and its dynamic interaction with degenerative processes can be directly tested using prospective *in vivo* imaging studies.

The focus on myelination provides a conceptual framework for considering and developing novel myelin-centered treatments with wide spectra of efficacy that likely will extend to many disorders that share derangements in myelin health. The model suggests that the current focus on neuronal neurotransmitter 'imbalances' that much of neuropsychopharmacology is attempting to correct may be too narrow. It suggests that expanding the research focus to include interventions that affect vulnerable structural developmental processes and specifically the process of myelination may provide opportunities for novel and powerful interventions. Interventions that affect myelination may be effective in strengthening inhibitory controls of cognition in developmental disorders of younger ages as well as providing preventive opportunities for age-related degenerative disorders. As briefly outlined

above, the tools (imaging, genetic, molecular, clinical, etc.) to perform such medication development work directly in humans are either already available or being developed at a rapid pace. The model suggests that interceding early in dysregulated developmental and accelerated degenerative trajectories may increase the effectiveness of treatments, decrease the need for more aggressive interventions later, and thus be accomplished with reduced risk to patients.

Introduction

In the nearly 80 years since Hans Berger first recorded electroencephalographic activity from the scalp, the electroencephalograph (EEG) has been used primarily for clinical diagnosis, for exploring brain function, and to a very limited extent for therapy. At the same time, many people have speculated that the EEG or other reflections of brain activity might be useful for another purpose as well: to serve as an alternative method for the brain to send messages and commands to the outside world. While the brain's normal communication and control capabilities depend on nerves and muscles, the existence of easily recordable brain signals, such as the EEG implied the possibility of establishing nonmuscular communication and control based on brain–computer interfaces (BCIs).

In spite of recurring scientific and popular interest in the idea of BCIs, and despite a few encouraging initial efforts, it is only in the past 20 years that sustained research has begun, and only in the past 12 years that a recognizable field of BCI research and development has emerged. The field is now populated by a large and rapidly growing number of research groups throughout the world. This new surge of interest and activity is due largely to the combination of four important elements.

The first element is greater appreciation of the needs and the abilities of people paralyzed by disorders such as cerebral palsy, spinal cord injury, brain stem stroke, amyotrophic lateral sclerosis (ALS), and muscular dystrophies. Life-support technology (e.g., home ventilators) now enables even the most severely disabled people to survive for many years. Furthermore, it is now clear that even people who have little or no voluntary muscle control, who may be nearly 'locked-in' their bodies, unable to communicate in any way, can have lives that they consider enjoyable and productive if they can be given even the most basic means of communication and control.

The second element is the greater knowledge of the nature and functional correlates of the EEG and other measures of brain activity that has come from animal and human research. Along with this new understanding have come improved methods for recording these signals, in both the short-term and the long-term. This increased knowledge and improved technology are directing and enabling more sophisticated and productive BCI research.

The third element is the easy availability of powerful, inexpensive computer hardware that supports the complex real-time analyses of brain activity important for successful BCI operation. Until quite recently, much of the online signal processing used in current BCIs was impossible or extremely expensive.

The fourth element contributing to the rapid growth of BCI research is new appreciation of the brain's remarkable adaptive capacities, both in normal life and in reaction to trauma or disease. The growing recognition of these adaptive capacities generates enormous excitement and interest in the potential for using them to create novel interactions between the brain and computer-based devices, interactions that can substitute for or even augment the brain's normal neuromuscular interactions with its external and internal environments.

Definition of a BCI

A BCI creates a nonmuscular output channel for the brain. Instead of being executed through peripheral nerves and muscles, the user's wishes are conveyed by brain signals (such as those detected by an EEG), and these brain signals do not depend for their generation on neuromuscular activity. (Thus, for example, a device that uses visual-evoked potentials in the EEG to determine eye-gaze direction is not a true BCI because it relies on muscular control of eye position and simply uses the EEG as a measure of that position.)

Like other communication and control systems, a BCI establishes a real-time interaction between the user and the outside world. The user gets feedback on the results of the BCI's operation, and that feedback influences the user's intent and the brain signals that encode that intent. For example, if a person uses a BCI to control the movements of a robotic arm, the arm's position after each movement affects the person's intent for the succeeding movement and the brain signals that convey that intent. Thus, a system that only records and analyzes brain signals, without providing the outcome of that analysis to the user in a real-time interactive fashion, is not a BCI. Figure 1 shows the design and operation of any BCI.

Popular speculation and some scientific efforts have been based on the belief that BCIs are 'mind-reading' or 'wire-tapping' technology, devices that listen in on the brain, detect its intent, and then execute that intent. This is a misconception that ignores a central feature of the brain's interactions with the external world. The motor skills that accomplish a person's intent, whether it be to walk across a room, speak specific words, or play a particular piece on the

Figure 1 The basic design of any brain–computer interface (BCI) system. Signals reflecting brain activity are acquired from the scalp, from the cortical surface, or from within the brain and are analyzed to measure signal features (such as amplitudes of evoked potentials or electroencephalograph rhythms or firing rates of single neurons) that reflect the user's intent. These features are translated into commands that operate a device such as a word-processing program, a wheelchair, or a neuroprosthesis. Adapted from Wolpaw JR and Birbaumer N (2006) Brain–computer interfaces for communication and control. In: Selzer ME, Clarke S, Cohen LG, Duncan P, and Gage FH (eds.) *Textbook of Neural Repair and Rehabilitation; Neural Repair and Plasticity,* pp. 602–614. Cambridge: Cambridge University Press, with permission from Cambridge University Press.

piano, are mastered and maintained by initial and continuing 'adaptive changes' in brain function. In early development and throughout later life, central nervous system (CNS) neurons and synapses change continually to master new skills and to maintain those already mastered. This adaptive plasticity is responsible for basic skills such as walking and talking and for more specialized skills such as ballet, and it is guided by the results produced. Thus, as muscle strength, limb length, and body weight change with growth and aging, the CNS modifies its outputs so as to maintain its motor skills.

This requirement for initial and continuing adaptation exists whether the person's intent is carried out naturally, that is, by peripheral nerves and muscles, or through an artificial interface, a BCI, that uses brain signals instead of nerves and muscles. Successful BCI operation requires the effective interaction of two adaptive controllers: the user, who must generate brain signals that encode intent; and the BCI system, that must translate these signals into commands that accomplish the user's intent. Thus, BCI usage is essentially a skill that user and system work together to acquire and maintain. The user encodes intent in signal features that the BCI system can measure, and the system measures these features and translates them into device commands. This initial and continuing dependence on the mutual adaptation of user to system and system to user is a fundamental principle of BCI operation; its effective management is one of the principal challenges for BCI research and development.

Brain Signals That Could Be Used in a BCI

A variety of different methodologies can detect brain activity. These include methods for recording electrical or magnetic fields, functional magnetic resonance

imaging (fMRI), positron emission tomography (PET), and functional near-infrared (fNIR) imaging. However, magnetoencephalography, fMRI, and PET are not currently suited for everyday use due to their intricate technical demands, high expense, and/or limited real-time capabilities. Only electrical field recording (and possibly fNIR imaging) are likely to be of value for practical applications in the near future.

The electrical fields produced by brain activity can be recorded at the scalp (electroencephalographic activity (EEG)), at the cortical surface (electrocorticographic activity (ECoG)), or within the brain (local field potentials (LFPs)) or neuronal action potentials (spikes). Figure 2 shows these three recording alternatives. Each method has advantages and disadvantages. EEG recording is easy and noninvasive, but it has limited topographical resolution and frequency range and can be contaminated by electromyographic (EMG) activity from cranial muscles or electrooculographic (EOG) activity. ECoG has better topographical resolution and frequency range, but it requires implantation of electrode arrays on the cortical surface, which has been done as yet for only brief periods (a few days or weeks) in people. Intracortical recording, or recording within other brain areas, yields signals with the highest resolution, but it requires insertion of multielectrode arrays within brain tissue, and it faces as yet unresolved problems in reducing tissue damage and scarring and in achieving long-term recording stability.

Figure 2 Recording sites for electrophysiological signals used by brain–computer interface (BCI) systems. Electroencephalographic activity (EEG) is recorded by electrodes on the scalp. Electrocorticographic activity (ECoG) is recorded by electrodes on the cortical surface. Neuronal action potentials (spikes) or local field potentials (LFPs) are recorded by electrode arrays inserted into the cortex. Each recording method has advantages and disadvantages. Adapted from Wolpaw JR and Birbaumer N (2006) Brain–computer interfaces for communication and control. In: Selzer ME, Clarke S, Cohen LG, Duncan P, and Gage FH (eds.) *Textbook of Neural Repair and Rehabilitation; Neural Repair and Plasticity*, pp. 602–614. Cambridge, UK: Cambridge University Press, with permission from Cambridge University Press.

The ultimate usefulness of each of these methods will hinge on the range of communication and control applications it can support and on the extent to which its disadvantages can be overcome. The question of the relative value of noninvasive methods (i.e., EEG), moderately invasive methods (e.g., ECoG), and more-invasive methods (e.g., intracortical recording) remains unanswered. It is conceivable that practical, stable, and safe techniques for long-term recording within the brain will prove relatively easy to develop. On the other hand, the information transfer rates possible with intracortical methods may turn out to be no greater than those achievable with less-invasive methods (e.g., ECoG, or even EEG). It is quite likely that different recording methods will prove useful for different applications and for different individuals. Comprehensive evaluations of the characteristics and capacities of each recording method are needed.

Present-Day BCIs

Human BCI experience to date consists largely of noninvasive EEG-based research. A few short-term ECoG studies have been reported, and limited data are available from a few people with intracortical implants. Most intracortical BCI data come from animals, primarily monkeys. EEG-based BCI methods can certainly support simple applications and seem to be able to support more complex ones. Invasive methods may be able to support more complex applications, but the issues of risk and long-term performance are not yet resolved.

Three different kinds of EEG-based BCIs have been evaluated in people. They are distinguished by the particular EEG features they use to derive the user's intent. Figure 3(a) illustrates a P300-based BCI. It focuses on the P300 component of the event-related brain potential, which appears in the EEG over central areas about 300 ms after a salient, or attended stimulus. In most P300-based BCIs described to date the stimulus is visual. Typically, letters, numbers, and/or other possible choices are arranged in a matrix, and the rows and columns of the matrix flash in rapid succession. Only the row and column that contain the item that the user wants to select produce P300 potentials. By detecting these P300 potentials, the BCI system can determine the user's selection. This BCI method is able to support operation of a simple word-processing program that enables users to

Figure 3 Noninvasive EEG-based BCI methods that use EEG recorded from the scalp. (a) P300 evoked potential brain–computer interface (BCI). A matrix of possible selections is shown on a screen. Scalp electroencephalographic activity (EEG) is recorded over centroparietal cortex (EEG recording location P_Z) while these selections flash in succession. Only the selection desired by the user evokes a large P300 potential (i.e., a positive potential about 300 ms after the flash). r^2 is the coefficient of variation; a/d u are the analog to digital conversion units. (b) Sensorimotor rhythm BCI. Scalp EEG is recorded over sensorimotor cortex. Users control the amplitudes of one or more 8–12 Hz mu rhythms or 18–26 Hz beta rhythms to move a cursor to a desired target located somewhere on a computer screen. Frequency spectra (top) for top and bottom targets indicate that this user's control of vertical cursor movement is clearly focused in the mu-rhythm frequency band. Sample EEG traces (bottom) also show that the mu rhythm is prominent with the top target and minimal with the bottom target. Trained users can also control movement in two dimensions. Adapted from Kübler A, Kotchoubey B, Kaiser J, Wolpaw JR, and Birbaumer N (2001) Brain–computer communication: Unlocking the locked-in. *Psychological Bulletin* 127: 358–375, with permission from American Psychological Association.

communicate at rates up to several words per minute. Improvements in signal analysis may substantially increase its capacities.

Figure 3(b) illustrates a BCI based on sensorimotor rhythms. Sensorimotor rhythms are 8–12 Hz (mu) and 18–26 Hz (beta) oscillations in the EEG recorded over sensorimotor cortices. Normally, changes in mu and/or beta rhythm amplitudes accompany movement and sensation, and motor imagery as well. BCI studies show that people can learn to control mu or beta rhythm amplitudes in the absence of any movement or sensation and that they can use this control to move a cursor to select letters or icons on a screen or to operate a simple orthotic device. Both one- and two-dimensional control are achievable. Sensorimotor rhythm-based BCIs, like P300-based BCIs, can support basic word-processing or other simple functions. They might also support multidimensional control of the movements of a neuroprosthesis or a device such as a robotic arm.

A BCI can also use slow cortical potentials (SCPs) in the EEG, which last from 300 ms to several seconds. In normal brain function, negative SCPs accompany preparatory depolarization of the underlying cortical network, and positive SCPs are thought to reflect cortical disfacilitation or inhibition. With appropriate training, people can learn to control SCPs to produce positive or negative shifts. With this control, they can perform basic word-processing and other simple control tasks such as accessing the Internet.

Current BCIs depend mainly on visual stimuli and visual feedback. However, people who are severely disabled may lack the vision or eye movements needed to perceive visual stimuli, especially if the stimuli change rapidly. Thus, BCI systems that employ auditory rather than visual stimuli would also be valuable – and are under investigation.

Figure 4(a) illustrates a BCI that uses sensorimotor rhythms in ECoG recorded by electrode arrays on the cortical surface. ECoG signals are much higher in amplitude than are scalp-recorded EEG signals, they have much higher spatial and temporal resolution, and they are much less susceptible to contamination by EMG or EOG. ECoG encompasses not only mu and beta rhythms but also higher-frequency gamma (>30 Hz) rhythms, which are very small or entirely lacking in EEG. With appropriate interelectrode spacing, ECoG can resolve activity limited to a few square millimeters of cortical surface. To date, ECoG studies have been confined to short-term experiments in people temporarily implanted with electrode arrays prior to epilepsy surgery. These studies reveal sharply focused ECoG activity associated with movement and sensation and with motor imagery. Furthermore, with only a few minutes of training, people can learn to use motor imagery to control cursor movement.

The speed of this learning, which appears to be faster than that usually found with sensorimotor rhythms in scalp-recorded EEG, together with ECoG's high topographical resolution, wide spectral range, and freedom from contamination, suggests that ECoG-based BCIs might provide communication and control superior to that possible with EEG-based BCIs. Widespread clinical use of ECoG-based BCIs will require development of fully implanted systems (i.e., systems that use telemetry and thus do not have wires passing through the skin) and clear evidence that they provide safe and stable recording for years.

Figure 4(b) shows a multielectrode array for intracortical recording and the locations of its implantation in human motor cortex. Intracortical BCI studies conducted in monkeys and to a limited extent in humans have shown that single-neuron activity recorded by such arrays can be used to control movement of a cursor in one, two, or even three dimensions. It appears that LFPs, which can be recorded by the same electrode arrays and reflect nearby synaptic and neuronal activity, might provide similar control. In these intracortical single-neuron and LFP studies, the usual strategy has been to define the neuronal activity associated with standardized limb movements, then to apply this activity to simultaneously control comparable cursor movements, and finally to demonstrate that the neuronal activity alone can continue to control cursor movements in the absence of actual limb movements. As Figure 4(b) shows, the relationships between neuronal activity and cursor movements change over time. Ideally, neuronal activity adapts over sessions so as to improve cursor control. This adaptation, like the adaptations seen with EEG- and ECoG-based BCIs, illustrates the need for initial and continuing adaptation of system to user and user to system.

The major questions that must be answered prior to clinical use of intracortical BCIs include their long-term safety, the stability and persistence of their signals in the face of cortical tissue reactions to the implanted electrodes, the long-term usefulness of these signals, and to what extent their capabilities in actual practical applications (e.g., in neuroprosthesis control) significantly exceed those of less-invasive BCIs. The first two websites listed provide videos that illustrate that a noninvasive EEG-based BCI using sensorimotor rhythms can provide cursor control comparable in speed and accuracy to that achieved to date with intracortical methods.

Signal Processing

A BCI records brain signals and analyzes them to derive device commands. This signal processing has two parts. The first part is feature extraction, the measurement of those features of the signals that encode the user's intent. These features can be relatively simple measures such as the amplitudes or latencies of particular evoked potentials (e.g., P300), the amplitudes or frequencies of particular rhythms (e.g., sensorimotor rhythms), or the firing rates of individual cortical neurons, or they can be more complex measures such as spectral coherences or weighted combinations of simple measures. To provide effective BCI performance, the feature-extraction part of signal processing needs to focus on features that actually do encode the user's intent, and it needs to extract those features accurately.

The second part of BCI signal processing is a translation algorithm that translates these features into device commands. Features such as rhythm

Figure 4 Invasive brain–computer interface (BCI) methods. (a) Human electrocorticographic (ECoG) control of vertical cursor movement using specific motor imagery to move the cursor up and using rest (i.e., no imagery) to move it down. The electrodes used for online control are circled, and the spectral correlations of their ECoG activity with target location (i.e., top or bottom of screen) are displayed. Electrode arrays for Patients B, C, and D are green, blue, and red, respectively. The specific imagined actions used are indicated. The substantial levels of control achieved with different kinds of imagery are apparent. (The dashed lines indicate significance at the 0.01 level.) For Patients C and D, the solid and dotted r^2 spectra correspond to the sites indicated by the dotted and solid line locators, respectively. Reproduced from Leuthardt EC, Schalk G, Wolpaw JR, Ojemann JG, and Moran DW (2004) A brain–computer interface using electrocorticographic signals in humans. *Journal of Neural Engineering* 1: 63–71, with permission from IOP Publishing Limited. (b) Top left: Array

amplitudes or neuronal firing rates are translated into commands that specify outputs such as cursor movements, icon selection, or prosthesis operation. Translation algorithms can be simple (e.g., linear equations) or complex (e.g., neural networks, support vector machines).

A successful translation algorithm ensures that the user's range of control of the chosen features supports selection of the full range of device commands. Suppose, for example, that the feature is the amplitude of a 21–24 Hz beta rhythm in the EEG over left sensorimotor cortex, that the user can vary this feature over a range of 1–5 μV, and that the application is horizontal cursor movement. In this case, the translation algorithm must ensure that the 1–5 μV range permits the user to move the cursor to both the right and left edges of the screen and at a rate consistent with the rapidity and maximum duration of the user's beta control. In addition, the algorithm must accommodate spontaneous variations in the user's range of control (i.e., variations due to diurnal change, fatigue, or other factors). Finally, the translation algorithm should be able to adapt to at least accommodate, and at best encourage, improvements in the user's control. Thus, if the user's range of control improves from 1–5 to 1–8 μV, the translation algorithm should take advantage of this improvement in order to increase the speed and/or precision of cursor control.

The need for ongoing adaptation of the translation algorithm to accommodate spontaneous and other changes in the signal features reflects the continuing importance of system–user and user–system adaptation and has important implications. First, it means that new algorithms cannot be evaluated adequately by off-line analyses alone. They must also be evaluated online, so that the effects of their adaptive interactions with the user can be determined. This online evaluation should be long-term as well as short-term since important adaptive interactions often develop gradually. Second, the need for ongoing adaptation means that simpler algorithms, for which adaptation is typically easier and more effective, have an inherent advantage. Simple algorithms (e.g., linear equations) should be replaced by more complex alternatives (e.g., neural networks) only after online as well as off-line evaluations demonstrate that the more complex alternatives give superior long-term performance without continual and laborious recalibration procedures.

Potential Users

In their current early stage of development, BCIs are likely to be of significant practical value primarily for people with the most severe neuromuscular disabilities, people for whom conventional assistive communication technologies, all of which require some measure of consistent voluntary muscle control, are not satisfactory options. These include people with ALS who decide to accept artificial ventilation (rather than to die) as their disease advances, children and adults with severe cerebral palsy who do not have useful muscle control, patients with brain stem strokes who have only minimal eye movement control, individuals with severe muscular dystrophies or peripheral neuropathies, and possibly people with acute disorders associated with extensive paralysis (such as Landry-Guillain–Barré syndrome). People with slightly less severe disabilities, such as those with high-cervical spinal cord injuries, may also find BCI technology preferable to conventional assistive communication methods that co-opt their remaining voluntary muscle control (e.g., methods that depend on gaze direction or EMG of facial muscles). The extent to which future BCIs prove useful to those with much less-severe motor disabilities will depend on the speed and precision of the control the BCI systems can provide and on the reliability and convenience of their use.

People with disabilities of different kinds may differ in the BCI methods that are most useful to them. For some, the CNS deficits responsible for their disability may impair their control of certain brain signals and not others. For example, the motor cortex damage that can accompany ALS or the subcortical damage of severe cerebral palsy could conceivably impair generation or control of sensorimotor rhythms or single neuron activity. In these individuals, other brain signals (e.g., P300 potentials or neuronal activity from other brain areas) might be good alternatives.

of 100 microelectrodes chronically implanted in human motor cortex to record neuronal action potentials and local field potentials to control a cursor or other device. Top right: Position of array in human motor cortex. Reprinted by permission from Macmillan Publishers Ltd: *Nature,* Hochberg LR, Serruya MD, Friehs GM, et al. Neuronal ensemble control of prosthetic devices by a human with tetraplegia. 442: 164–171; copyright 2006. Bottom: Control of three-dimensional cursor movements by single neurons in motor cortex of a monkey. The left graph shows the improvement over daily training sessions of the average correlation (r^2) between the firing rate of a single cortical neuron and target direction. The right graph shows the resulting improvement in performance (assessed as the mean target radius required to maintain a 70% target hit rate). As the firing rates of the neurons that are controlling cursor movement become more strongly correlated with target direction, the size of the target can be reduced. Adapted from Taylor DM, Helms Tillery SI, and Schwartz AB (2003) Information conveyed through brain-control: Cursor versus robot. *IEEE Transactions on Neural Systems Rehabilitation and Engineering* 11: 195–199 (© 2003 IEEE), with permission from IEEE.

In this regard, it is encouraging that people severely disabled by ALS appear to retain the ability to control sensorimotor rhythms or single-neuron activity in sensorimotor cortex.

Apparently trivial and prosaic factors are likely to have substantial impact on the practical success of BCI applications. Factors such as the steps required for donning and doffing electrodes or for accessing a BCI application, or the user's appearance while operating the BCI, may greatly affect the numbers and characteristics of the people who adopt the system and the degree to which they actually use it in their daily lives.

Applications

BCIs have an extensive range of possible practical applications, from very simple to very complex. Simple BCI applications have already been demonstrated in the laboratory and in limited clinical use. They include systems for answering Yes/No questions, managing basic environmental control (e.g., lights, temperature), adjusting a television, or opening and closing a hand orthosis. Such simple systems can be configured for basic word-processing, sending e-mail, or accessing the Internet. For people who are totally paralyzed (i.e., locked-in), these simple BCI applications could make it possible to lead lives that are pleasant and even productive. Indeed, many recent studies indicate that, with good supportive care and the capacity for basic communication, severely paralyzed people can enjoy what they consider to be a reasonable quality of life and are hardly more likely to be depressed than are people without physical disabilities. Thus, simple BCI applications seem to have a significant future in their capacity to improve the daily lives of those who are most severely disabled. Indeed, a few severely disabled people are already using EEG-based BCI systems for important purposes in their daily lives.

More-complex BCI applications could control devices such as a motorized wheelchair, a robotic arm, or a neuroprosthesis that provides multidimensional movement to a paralyzed limb. Although present efforts focus on development of invasive BCI systems for such applications, noninvasive EEG-based BCIs also offer the possibility of such control. The eventual practical importance of such BCI applications will hinge on their capacities, practicality, and reliability, on their acceptance by specific kinds of users, and on the extent to which they have important advantages over conventional methodologies.

Establishment of the clinical value and practicality of BCI applications will require thorough evaluation to demonstrate their long-term reliability, to show that people actually use the applications, and to document that this usage has beneficial effects on factors such as mood, quality of life, and productivity. Particularly in the first stages of their development, it will frequently be necessary to configure applications that match each user's unique needs, desires, and physical and social environments. Although the cost of BCI equipment is relatively modest, current systems need substantial and continuing expert oversight, which is extremely expensive and now obtainable only from a few research labs. As a result, these systems are not available to most potential users. Thus, the widespread dissemination of BCIs will also depend on the degree to which the need for such ongoing technical support can be minimized. BCI systems must be easy to set up, easy to use, and easy to maintain if they are to have significant practical impact on improving the lives of people with severe disabilities.

Nature and Needs of BCI Research and Development

BCI research and development is a multidisciplinary effort. It requires neuroscience, engineering, applied mathematics, computer science, psychology, and rehabilitation. The need to select useful brain signals, to record them reliably, to analyze them appropriately in real-time, to control devices that provide functions valuable for those with severe disabilities, to manage the intricate short-term and long-term adaptive interactions between user and system, and to integrate BCI applications into the daily lives of their users means that the expertise and efforts of all these disciplines are essential for success. Thus, each BCI research group must incorporate all the essential disciplines, or groups with different expertise must collaborate closely. Collaborative studies are being facilitated by the widespread adoption of the general-purpose BCI software platform BCI2000, which can readily accommodate a wide variety of different signals, processing methods, applications, operating protocols, and hardware (see third website address). Productive collaborations have also been encouraged by recent meetings drawing BCI researchers from all relevant disciplines and from all over the world, by numerous symposia and collections of BCI research presentations at larger general meetings, and by publication of extensive sets of peer-reviewed BCI articles.

Brains of Primitive Chordates

J C Glover, University of Oslo, Oslo, Norway
B Fritzsch, Creighton University, Omaha, NE, USA

Introduction

Craniates (which include the sister taxa vertebrata and hyperotreti, or hagfishes) represent the most complex organisms in the chordate phylum, particularly with respect to the organization and function of the central nervous system. How brain complexity has arisen during evolution is one of the most fascinating questions facing modern science, and it speaks directly to the more philosophical question of what makes us human. Considerable interest has therefore been directed toward understanding the genetic and developmental underpinnings of nervous system organization in our more 'primitive' chordate relatives, in the search for the origins of the vertebrate brain in a common chordate ancestor. We describe some of the principal features of the central nervous systems of hemichordates, cephalochordates, and urochordates – taxa of increasing genetic relatedness to craniates. The central nervous systems of these taxa show a variety of forms, from a hardly specialized basiepithelial nerve plexus (hemichordates) to a few small ganglia with a tail nerve cord (urochordates), a swimming spinal cord with a barely recognizable cerebral vesicle (cephalochordates), and a fully developed brain and spinal cord (craniates). It is important to emphasize that although the term primitive may be construed as implying a lower rank in evolutionary sequence, we use it strictly with respect to extant brain complexity. Each of these groups has in fact existed for substantial periods of evolutionary time and represents highly adapted life-forms in their own right. We focus here on shared aspects of central nervous system structure and development that may relate to a common evolutionary origin but also indicate some of the specialized structural features that bear witness to the degree of divergence and range of derived characters that have arisen in the several hundred million years since these groups split from that origin.

Phylogenetic Relationships

Originally constructed solely through comparative analysis of morphological traits, phylogenetic trees are being increasingly tested and revised on the basis of gene sequence comparisons. Such analysis, although providing a more direct link to the evolutionary clock, is nevertheless hampered by differing rates of evolution, both among species and among genes, and a still largely deficient fossil record. Until recently, it was widely accepted, both on morphological and molecular grounds, that cephalochordates and craniates were sister taxons, with urochordates being more distant craniate relatives and with hemichordates being more closely related to echinoderms (Figure 1(a)). The molecular data only weakly supported a coherent chordate taxon, however, indicating that apparent morphological similarities among chordates are imposed on deep divisions among the extant deuterostome taxa. Recent analysis of a substantially larger number of genes has reversed the positions of cephalochordates and urochordates, promoting the latter to the most closely related craniate relatives (Figure 1(b)).

Comparative Appearance of Brains, Spinal Cords, and Nerves

Primitive Craniates (Cyclostomes)

The jawless cyclostomes, lampreys and hagfish, constitute a basic clade of craniates that shows the major features of brain organization also found in gnathostomes (jawed vertebrates). Externally, the brain of extant cyclostomes consists of a bilaterally symmetric rostral enlargement, the forebrain (telencephalon), each side of which is composed of an olfactory bulb and a cerebral hemisphere (Figure 2). Each hemisphere is connected to the single, bipartite diencephalon. The diencephalon gives rise to a number of neural appendages. Ventrolaterally are located the paired optic nerves leading to the lateral eyes. Dorsally lies a single enlargement, the habenula, that in lampreys, but not hagfish, has an attached pineal organ. Ventrally is located the pituitary gland. The central ventricle of the diencephalon is continuous with the ventricle in the midbrain, the hindbrain, and the central canal of the spinal cord, all of which are greatly reduced in hagfish. Lampreys have a dorsal central opening in the midbrain that is covered by a choroid plexus, a uniquely derived feature of lampreys not shared by other craniates. Lampreys, like gnathostomes, have an oculomotor nerve leaving the midbrain ventrally and a trochlear nerve exiting lateral to the cerebellum, neither of which do hagfish possess. Caudal to the small cerebellum in lampreys is the rhombencephalon (hindbrain) with a large choroid plexus covering the IVth ventricle. A small ventricle is also found in hagfish, but there is no trace of a

Figure 1 (a) Conventional scheme of phylogenetic relationships among chordates and related taxa. (b) A revised scheme based on more recent gene sequence analysis. Adapted from original image by Dr. Billie Swalla, University of Washington.

choroid plexus and the presence of a cerebellum has been questioned.

Lampreys have all the hindbrain nerves found in gnathostomes (trigeminal, abducens, facial, otic or stato-acoustic, glossopharyngeus, and vagus), with the possible exception of the hypoglossal nerve. The relative positions and fiber compositions of these nerves are very similar but not identical in cyclostomes and gnathostomes. For example, the abducens nerve root is almost integrated into the trigeminal nerve root in lampreys, whereas it is always a separate ventral nerve root at a more caudal level in gnathostomes. Moreover, gnathostomes have three distinct motor neuron populations in the brain stem, each innervating a different type of peripheral target: the somatic motor neurons that innervate somitomere-derived musculature, the branchial motor neurons that innervate branchial arch-derived musculature, and the visceral motor neurons that innervate neural crest-derived parasympathetic ganglia of the head and body. In contrast, cyclostomes as a group lack the somatic motor neurons of the hypoglossal nucleus and have no visceral motor neurons since no cranial parasympathetic ganglia are known to exist. However, the hindbrain of lampreys contains so-called branchiomotor neurons, the axons of which exit dorsally and innervate branchial arch-derived muscle. To emphasize differences between gnathostomes and cyclostomes, the hagfish hindbrain, while recognizable as such, is unusually shaped, which relates to differences in its internal organization. The organization of cranial nerves in hagfish, other than the apparent absence of the entire extraocular muscle-related nerves, shows a number of deviations from gnathostome vertebrates. Hagfish have three completely segregated parts of the trigeminal nerve, two otic (stato-acoustic) nerves, no recognizable vagal ganglion, and a facial nerve that exits dorsal to the otic nerves.

The spinal cord in craniates is a continuous extension of the neural tissue of the hindbrain. Adult cyclostomes have unusually shaped spinal cords that are dorsolaterally flattened. Lampreys, like gnathostomes, have separate dorsal and ventral roots, but unlike in gnathostomes, these do not converge to form mixed spinal nerves and are asymmetrically distributed between the left and right side. A similar but more pronounced asymmetry of spinal nerves is exhibited by cephalochordates and has been suggested to be primitive for chordates because an asymmetric pattern is also found in hagfish and some gnathostomes. In hagfish, as in gnathostomes, the dorsal and ventral nerve roots converge, except in

Saccoglossus cambrensis

Branchiostoma floridae

Ciona intestinalis

Oikopleura dioica

Myxine glutinosa

Figure 2 Continued

the tail region. It is believed that convergent dorsal and ventral roots is a derived feature of gnathostomes and that the superficial similarity of this feature in hagfish is independently derived. The fiber composition of spinal nerves is highly variable among cyclostomes and fits neither the cephalochordate nor the basal gnathostome composition. Consequently, their relationship to the nerves of cephalochordates and urochordates is problematic.

As in craniates, somatic motor neurons are distributed along the length of the spinal cord in cycolostomes and provide independent innervation of each segment of body musculature (**Figure 3**). Cyclostomes do not have autonomic ganglia and lack spinal visceral motor neurons that innervate such ganglia (**Figure 4**). It appears that autonomic ganglia arose with gnathostomes through the advent of migratory neural crest cells. This innovation has led to the formation in higher craniates of preganglionic parasympathetic motor neurons in the brain stem and the sacral part of the spinal cord and preganglionic sympathetic motor neurons in the thoracic and upper lumbar spinal cord (**Figure 4**).

Cyclostomes have dorsally located intramedullary sensory neurons (dorsal cells), which appear to be homologous to the Rohan–Beard cells of anamniote craniates, as well as sensory neurons in dorsal root ganglia. Dorsal root ganglia and proximal cranial ganglia are derived from migratory neural crest in craniates; in cyclostomes, spinal dorsal root ganglia are generated by neural crest, whereas cranial ganglia derive from placodes. In contrast to their craniate counterparts, the dorsal root ganglion cells in cyclostomes express modulatory neurotransmitters such as serotonin and neuropeptides and may therefore have more derived functions, although they do appear to transmit nociceptive signals in lampreys.

In many chordates, large neurons with descending axons have been identified in the rostral region of the neuraxis. Using cytological criteria, one can identify certain large reticulospinal neurons in the rhombencephalon of lampreys (the Müller and Mauthner cells) that have long descending axons that extend the length of the spinal cord. Similar neurons are found in hagfish, but Mauthner cells cannot be identified among them, and whether the other large cells are homologous to Müller cells is unclear.

Cephalochordates

The central nervous system of cephalochordates is a simple tube that does not show any obvious enlargement at the rostral pole comparable to the brain

Figure 2 A comparison of the basic anatomical structure of the hemichordate, cephalochordate, urochordate, and craniate central nervous systems. Enteropneust hemichordates (represented by *Saccoglossus cambrensis*) have an epidermal nerve network that shows condensations in certain areas. At the base of the proboscis is an anterior nerve ring (a.n. ring) that is next to the ciliary organ (cil.org.), which is adjacent to the oral opening (asterisk). The collar region has a collar nerve cord (coll.n.c.), an invaginated part of the epidermis with anterior and posterior neuropores (ant.np., post. np.) that lies dorsal to the buccal cavity. At the third body division, the metasome, the collar nerve cord becomes confluent with the dorsal nerve cord (d.cord) and, through the posterior nerve ring (p.n.ring), with the larger ventral cord. Neither true nerves nor major sensory organs are apparent in this simple epithelial nerve net. Cephalochordates (represented by an adult specimen of *Branchiostoma floridae*) have a hollow nerve cord that is fairly uniform in diameter throughout its length. There is a recognizable vesicular expansion at the anterior end, with a number of specialized appendages and neuron groups that provide indications of cephalic elaboration. Among these are Kölliker's pit (believed by some to be an olfactory organ), the pigmented cells of the single frontal eye, the infundibular organ (which gives rise to Reissner's fiber; Rf) and preinfundibular zone (possibly containing an organ of balance), and a dorsal column of putative photoreceptors called Joseph cells. The first nerve (n1) is ventral, and all other nerves are dorsal. Muscle segments (m) are located along the entire length of the nervous system. Urochordates have small nervous systems with a recognizable tripartite organization, consisting of a rostral ganglion (termed the cerebral ganglion in appendicularians and the sensory vesicle in ascidians), a caudal ganglion (termed the visceral ganglion in ascidians), and a caudal nerve cord. This organization is maintained throughout life in appendicularians (exemplified here by *Oikopleura dioica*), whereas ascidians (represented here by *Ciona intestinalis*) lose this organization at metamorphosis from larva to adult, in line with the transition from pelagic to sessile lifestyle. The rostral ganglion is intimately associated with a statocyst (s, containing an otolith) and in ascidian larvae also an ocellus. In appendicularians, there is also a ciliated funnel (cf), an outgrowth of the cerebral ganglion believed to be homologous to the pituitary gland. Several brain nerves (bn) connect the rostral ganglion to peripheral sensory and motor structures. The rostral ganglion is connected to the caudal ganglion by a nerve trunk (ncg) in appendicularians and by a cellular 'neck' region in ascidians. The nerve cord of ascidians is evidently nearly aneuronal, consisting predominantly of ependymal cells, whereas in appendicularians it contains neurons, including motor neurons. Craniates (shown is the hagfish, *Myxine*) have a brain that develops from invaginated ectoderm that becomes completely transformed into nervous tissue but remains confined within the former epithelial basement membrane. Major subdivisions that can be identified on the basis of external and internal features include (in anteroposterior order, right to left in the figure) the telencephalon (forebrain), diencephalon, mesencephalon (midbrain), and rhombencephalon (pons and medulla oblongata, or the hindbrain). Several distinct cranial nerves pass through the basement membrane to connect the brain with various sensory organs that provide chemical (olfaction and taste), mechanical (touch, proprioceptive, auditory, and vestibular), and visual (eyes) input. The brain integrates this input with information about internal states and uses this to generate motor output that is effected via motor neurons in the brain stem and spinal cord. The image of amphioxus is reproduced from Wicht H and Lacalli T (2005) The nervous system of amphioxus: Structure, development, and evolutionary significance. *Canadian Journal of Zoology* 83: 122–150. The image of *Saccoglossus Cambrensis* is reproduced from Bullock TH and Horridge GA (1965) *Structure and Function in the Nervous Systems of Invertebrates*. San Francisco, CA: W. H. Freeman. The image of *Myxine glutinosa* is reproduced from Nieuwenhuys R, Donlekaar HJT, and Nicholson C (1998) *The Central Nervous System of Invertebrates*. New York: Springer.

Figure 3 The distribution of motor neurons is shown from the dorsal aspect (hemichordates) or lateral aspect (others) as well as in transverse projections viewed in the caudal direction from the levels indicated by the dotted lines. Motor neurons in hemichordates are predominantly located in the caudal half of the collar cord, and their axons typically cross the basal membrane individually to reach muscle fibers. In ascidian urochordate larvae, all motor neurons are concentrated in the caudal ganglion and project caudally through the nerve cord to reach muscle fibers of the tail. In appendicularian urochordates, motor neurons are also present in the nerve cord and project directly to adjacent muscles. Cephalochordates have three types of motor neurons (only two are shown). One type is the somatic motor neuron that extends an axon along the spinal cord margin to innervate muscular processes that form synapses abutting the cord. The second type is the visceral motor neuron that projects through the dorsal root to innervate the pterygial muscle. The third type innervates muscle cells of the notochord at the ventral spinal cord margin. Lampreys have only somatic motor neurons in the spinal cord, whose axons project out through ventral roots, and in their hindbrain only dorsal exiting motor neurons, referred to as branchiomotor neurons because they innervate muscle derived from branchial arches. Lampreys also have three populations of ocular motor neurons in the midbrain/hindbrain region, some of which have the appearance of somatic motor neurons.

of craniates, hence the alternate name 'acrania' for this taxon. The hollow tube has a central canal that shows a vesicular enlargement at the anterior pole, into which the processes of frontal eye sensory cells extend. Like craniates, cephalochordates (as well as urochordates) have a unique structure that extends throughout the central canal, Reissner's fiber, which may provide a topological landmark for comparing different brain regions (Figure 5). Another structure of similar utility is the notochord, which shows a striking difference in its relationship to the brain in cephalochordates and craniates. In both taxa, the notochord lies subjacent to the entire length of the spinal cord. In craniates, it extends rostrally to end at the transition from hindbrain to midbrain, whereas in cephalochordates it extends beyond the rostral aspect of the neural tube. The notochord is known to have a major inductive influence on the developing brain and spinal cord of craniates through the release of diffusible signaling proteins. This influence and the resultant regional patterning is therefore likely to be shifted rostrally along the neuraxis of cephalochordates relative to craniates, potentially contributing to the acraniate nature of the cephalochordates.

Figure 4 Motor neurons and their projections are compared in craniates and cephalochordates. Two motor neuron types have been characterized in cephalochordates – the branchiomotor neurons, which innervate the pterygial muscle and exit through dorsal roots, and the somatic motor neurons, which do not exit the neural tube but rather form synapses with muscle processes at the lateral margin of the spinal cord. The lamprey brain stem has mainly branchiomotor neurons (BM) that project through dorsal roots. Whether the abducens is a somatic motor nucleus in lampreys as indicated (SM) is unclear because its motor neurons also project through a dorsal root. The lamprey spinal cord has only somatic motor neurons that exit through the ventral root. Mammals have evolved visceral motor neurons (VM) in the spinal cord that migrate into a distinct position and project to autonomic ganglia. In mammals, there is also the addition of visceral motor neurons in several cranial nerves that project to the parasympathetic ganglia. These visceral motor neurons can be regarded as special branchiomotor neurons.

Figure 5 In one proposal for the evolutionary origin of the forebrain, the flexural organ (FO) and the subcommisural organ (SCO) represent a split of a single original cell population, represented by the infundibular organ (IO) in cephalochordates, thereby intercalating a novel population (black line). If this is accepted, then the entire area between the SCO and FO of craniates could be viewed as a craniate neomorph, in which case the entire telencephalon and large areas of the thalamus of craniates would have no equivalent in cephalochordates.

The cranial and spinal nerves of cephalochordates are difficult to compare with those of craniates. First, they are distributed too far rostrally, leaving virtually no space for what is typically considered the brain. There are no true ventral roots in the sense of motor neuron axons leaving the spinal cord. Rather, the somatic muscles extend processes that contact the ventrolateral margin of the spinal cord where they appose synapses from central processes of motor neurons (Figures 3 and 4). Moreover, the notochord is composed of muscle fibers that similarly contact the ventral spinal cord where they receive synapses from ventromedial motor axons. Motor neurons are found throughout the spinal cord and as far rostral as the primary motor center between the second and third dorsal nerves. An additional set of motor neurons are the so-called visceral motor neurons. These are the most ventral neurons in the nervous system, situated virtually at the floor plate in the anterior portion of the nerve cord. The axons of these cells exit through the dorsal roots and supply the pterygeal muscle with cholinergic endings. There is in fact only one true ventral nerve, the first (most rostral) nerve. All other nerves are dorsal and become increasingly more caudal on the right than on the left side – an asymmetry that by far exceeds anything found in other chordates.

There are no dorsal root ganglia anywhere along the neuraxis of cephalochordates, in line with the apparent lack of a migratory neural crest population. Sensory projections arise from dorsally located intramedullary sensory neurons, similar to those found in cyclostomes. In addition, there is evidence for the presence of peripheral sensory neurons located in the epithelial lining of the buccal and atrial body cavities that project centripetal axons into the nerve cord. Paired sensory organs are conspicuously absent in cephalochordates. However, there is an unpaired frontal eye, putative balance and olfactory organs, and certain primordia of mechanosensors and chemosensors may be present among the numerous single or multicellular sensory organs. Among these are small encapsulated clusters of sensory cells located in branches of the first two brain nerves, the corpuscles of Quatrefages, believed to have a mechanosensory function.

Other features of the cephalochordate anterior neuraxis are the conspicuous lamellar body, believed to be

homologous to the vertebrate pineal gland but present only in larvae, the infundibular organ, whose name implies a proposed homology to the ventral diencephalic region, and the dorsally located Joseph cells, which are putative photoreceptors. Conspicuously pigmented individual ocelli are distributed along the length of the spinal cord. How these various features relate to the internal divisions of the craniate brain and spinal cord is unclear, leaving open the question of the existence of brain subdivisions, although gene expression studies have begun to shed some light on this issue.

In the rostral neuraxis of juvenile cephalochordates, two pairs of larger interneurons with descending axons have been identified and termed 'ventral giant cells of the primary motor center,' potentially homologous to the large reticulospinal neurons of cyclostomes. Another system of large neurons, the Rohde cells, are situated dorsally in the anterior region, starting at what is considered to be the transition from brain to spinal cord, and have descending axons in the spinal cord. A separate population of Rohde cells is located in the caudal spinal cord.

Urochordates

The urochordate subphylum includes the ascidians, the thaliaceans, and the appendicularians. Nearly all ascidians, some thaliaceans, and all appendicularians have a free-swimming larval stage with a notochord and a small central nervous system that appear homologous to the same structures in craniates. In contrast to the rather uniform appearance of the neuraxis of cephalochordates, the larval ascidian and larval and adult appendicularian central nervous systems are organized into an obvious tripartite structure (Figure 2). The three divisions are (1) a rostral ganglion (totaling approximately 215 cells in the ascidian *Ciona* and approximately 75 cells in the appendicularian *Oikopleura*), which contains sensory receptor structures, including an ocellus and/or an otolith, followed by (2) a caudal ganglion (containing approximately 45 cells in *Ciona* and approximately 25 neurons in *Oikopleura*), from which extends (3) a caudal nerve cord (containing approximately 65 cells, mostly ependymal, in *Ciona*, and approximately 30 neurons and 25 support cells in *Oikopleura*). In addition, the rostral and caudal ganglia are connected by a nerve trunk in appendicularians or a slender 'neck' region containing nerve cells in ascidians. Other urochordate taxa seem to exhibit primarily variations in size but not in structure. The ganglia of urochordates have the organization of an invertebrate ganglion, with cell bodies at the periphery and a neuropil in the center. Several nerves that vary considerably between species have been traced from adult ganglia, reaching up to 75 nerves in certain salps. These nerves appear to be mixed sensory and motor nerves and are asymmetric in several species, potentially related to the overall body asymmetry.

The organization of motor projections varies among urochordates. In ascidian larvae, all the motor neurons (three to five pairs in different species) are located in the caudal ganglion and project along the predominantly aneural nerve cord before exiting to innervate the peripheral muscle. In appendicularians, both the caudal ganglion and the nerve cord contain motor neurons, whose axons project laterally to the peripheral muscle either directly or after extending some distance in the cord.

Comparisons between urochordates and cephalochordates claim similarities in sensory organs within the central nervous system, in particular the infundibular sensory cells and otolith. The ciliated funnel, which extends to one side of the rostral ganglion, is believed to be homologous to the pituitary. However, the interpretation of homologies for most sensory cells and sensory organs outside the central nervous system is contended. Some adult urochordates have fairly complex eyes attached to the cerebral ganglion. There is a marked asymmetry in the organization of central and peripheral sensory structures.

No large neurons with descending axons that might be homologous to the large reticulospinal neurons of craniates have been described in urochordates, although there are some large cells within the rostral ganglion that could subserve a similar function.

Hemichordates

Hemichordates are not grouped within the chordates but share a number of chordate features, including a rudimentary notochord-like structure, the stomochord. Whether the simple nervous system of hemichordates should be referred to as a central nervous system is unclear. The overall organization is that of a basiepithelial plexus that shows regional concentrations in the three parts of the body, the protosome (the preoral proboscis), the mesosome (the postoral collar), and the metasome (or trunk, with rostral gill slits). The intraepithelial nerve plexus is well developed on the basement membrane but remains epithelial even in the invaginated collar region, which is hollow and opens through two neuropores (Figure 2). Concentrations of longitudinal strands of cells and fibers also exist on the trunk, where they form a dorsal and a larger ventral cord. The proboscis has a well-developed nerve plexus and numerous sensory cells. Except for the preoral ciliary organ with its abundance of sensory cells, there are no specialized sense organs. Concerning nerves, it appears that muscles are supplied by nerve fibers that cross the basement membrane singly and diffusely without forming obvious peripheral nerves.

Large neurons have been described in hemichordates, clustered in the caudal part of the collar cord and also scattered in more rostral and caudal areas. Some of these neurons have uncrossed or crossed axons that extend toward the ventrolateral longitudinal muscles and therefore may be motor neurons. Others have been compared to the Mauthner and Müller cells of craniates.

Molecular Patterning of the Neuraxis during Development

Despite their overall anatomical differences, the central nervous systems of the primitive chordates exhibit similarities to craniates with respect to the molecular mechanisms responsible for regional patterning during development, along both anteroposterior and dorsoventral axes. Shared by all chordates and the hemichordates is the expression of *otx* genes in the most rostral region of the central nervous system and the expression of *hox* genes starting more caudally; in all these taxa except cephalochordates, the *engrailed* gene (*en*) is expressed in the region between *otx* and *hox* genes, and in all save the hemichordates *pax* genes of the Pax-2/5/8 class are expressed in the very most rostral region (Figure 6). These elements alone provide support for proposed homologies between specific portions of the primitive chordate nervous

Figure 6 Gene expression patterns define regions along the anteroposterior axis. Several relationships are highly conserved, including the rostral expression of *pax2/5/8* and *otx* genes and a more caudal expression of *hox* and *en* (*engrailed*) genes. These gene expression patterns provide support for defining putative forebrain and hindbrain homologs in cephalochordates and urochordates. Intermediate gene expression patterns exhibit too many variants to support a clear homology with the midbrain and midbrain/hindbrain boundary (MHB), however.

systems and the brain subdivisions in craniates. On this basis, both urochordates and cephalochordates would appear to have homologs of the craniate forebrain, hindbrain, and spinal cord. Less compelling is the presence of a region homologous to the midbrain and the midbrain/hindbrain boundary (MHB), the latter of which is an important inductive organizer region in the craniate brain. Although certain genes that delineate the MHB in craniates, such as Pax2/5/8, are expressed in the general vicinity of the expected MHB location, the specific gene combination criteria that define the MHB in craniates are not met in any of the primitive chordates. This may mean that the definitive MHB and midbrain are later evolutionary elaborations of the neuraxis.

These genes, whose expression regionalizes the anteroposterior neuraxis (Figure 6), may be ancestrally related to the overall rostrocaudal patterning of the deuterostome body, and the degree of pattern conservation may reflect the fact that the neural tube evidently evolved only once in ancestral chordates. The presence of a similar anteroposterior pattern in the basiepithelial nerve plexus of hemichordates suggests that this anteroposterior regionalization predates the invagination of the neural tube from external ectoderm. A similar anteroposterior sequential pattern of some of the key genes in the insect nervous system lends support to this idea.

An alternative approach to deducing anteroposterior homologies between craniate and noncraniate nervous systems is to assess the location of specific neuron types known to bear a specific topographic relationship to given craniate brain subdivisions. Catecholaminergic neurons, which express the enzyme tyrosine hydroxylase (TH), provide a good example because these have very focal distributions within the craniate brain. In cephalochordates, TH- and catecholamine-positive neurons are found near the anterior end of the neural tube and near the first two dorsal nerves. This has been interpreted to indicate similarities with the di-, mes-, and rhombencephalic catecholaminergic neuron groups of craniates. TH-positive neurons are also present within the rostral ganglion of urochordates, providing support for a diencephalic or mesencephalic character there. Catecholamine-positive neuron populations have not been described in hemichordates.

Neural Crest, Placodes, and Their Derivatives

One of the fundamental evolutionary advances that characterizes craniates is the appearance of the neural crest and ectodermal placodes, from which are derived a large spectrum of peripheral structures and cell types, notably through the process of epithelial delamination that generates migratory mesenchyme. Restricting our focus to neural structures, the neural crest gives rise to all peripheral ganglia in the trunk, including sensory, autonomic, and enteric ganglia, and together with specific placodes, all of the cranial autonomic ganglia. It also gives rise to Schwann cells, which provide myelination of peripheral nerves. The placodes, which are local thickenings of the embryonic cranial ectoderm, invaginate to form sensory structures and associated neural epithelia and ganglia, in addition to contributing to some autonomic ganglia. The elaboration of sensory and motor function in the cranial region provided by the advent of neural crest and placodes clearly facilitated a more rapid acquisition of the predatory behavioral repertoire exhibited by craniates.

The substantial divergence in peripheral sensory and motor structures and limitations in the embryonic data have made the search for neural crest and placode precursors in noncraniates a difficult field. In hagfish, neural crest and placodes are clearly present at embryonic stages, but there is little direct evidence that they generate migratory cell populations, possibly limiting the scope and spatial range of the derivatives they can produce. Definitive migratory neural crest appears to be lacking in cephalochordates and urochordates. In particular, neural crest-specific genes do not appear to be expressed in the lateral margins of the neural tubes of these taxa as they are in craniates. Nevertheless, there are small populations of migratory neural cells in both taxa that have been proposed to have an evolutionary relationship to the neural crest. Possible placode-like structures have been identified both in amphioxus and in urochordates, and the expression of some placode-specific genes in these structures strengthens the argument that they may represent the early origins of certain craniate placodes. The first brain nerves of appendicularians, for example, express a gene profile and possess cell types consistent with a homology to the craniate olfactory placode, and similar evidence provides support for a homology between the appendicularian ciliary funnel and the adenohypophysis. In amphioxus, Hatschek's pit has also been proposed as an adenohypophyseal homolog, but here the gene expression data are weaker. A number of other small peripheral sensory structures in appendicularians express placode-specific genes, but their relationship to craniate placodes is less clear. It has been suggested that specific mechanoreceptors may represent precursors of the lateral line placode derivatives. Beyond these proposals, the evidence for placodal homologies is currently weak, and even the placodal nature of these best documented cases is still controversial.

Brainstem and Cranial Nerves

Introduction

The history of cranial nerve classification dates back to the twelfth century, and distinction of the 12 pairs of cranial nerves is associated with the publication by Soemmering in 1778. In that time, the great epoch-making explorations were achieved in the field of comparative neuroanatomy, and the recognition of gradually increasing organismal complexity in the more advanced vertebrate phyla led to the conclusion that new levels in complexity arose by differentiation of existing structures in evolution. This view was the Kopftheorie ('head theory') of JW Goethe in 1790, who stated that the cranium was composed of modified vertebrae. Consequently, new structures in the head and neck region were homologized with structures in the trunk accordingly, and the homologization of spinal nerves with nerves of the brain stem produced a number of contradictions and a peculiar terminology.

In our present endeavor we want to consider the following characteristics of motor neuron pools innervating different structures: the specific functions performed by the target muscles of motor neurons, the morphology of individual neurons constituting the neuron pool, and the genetic profile of neurons in that pool. This complex approach reveals a number of minor details which help make a distinction among motor neurons classified in a common group, but which control different muscles with a variety of actions. In taking this approach, problems sharply emerge in assessing transitions between different species of vertebrae when a new function appears and the smooth transition between classes is missing, or extinct. For example, some fishes have neither a tongue nor a hypoglossal nerve, but their 'evolutionary neighbors,' the amphibians, possess a beautiful tongue with a rather sophisticated innervation. Or consider the capacity of mammals to grind and chew food, which depends on the evolution of a 'chewing organ' innervated by a group of motor neurons; this feature does not exist in nonmammalian vertebrates. Another example would be the auditory muscles and their innervation; the course of their evolution is still an exciting problem, not only of neurobiology but of evolution as well.

We think that with our method of assessing the characteristics of motor neuron pools innervating different structures we can demonstrate the beautiful parallelism in the evolution of the peripheral target and the central neuronal structure. We can show, from literary data, differences in the genetic profiles of motor neurons controlling different actions; by pursuing this line of studies, we may eventually find the genetic background in transition from one class to the next during the course of evolution. In order to demonstrate the differences in organization of cranial nerve nuclei of different species, we have to start with the organization of motor neurons in the spinal cord. We try to group the motor neurons according to the specification they control.

Efferent System of the Spinal Cord

Function, Position, and Form

According to the action performed by muscle groups in the trunk region, we can distinguish motor neurons that innervate epaxial muscles, hypaxial muscles, limb muscles, and others (Figure 1). Epaxial motor neurons innervate muscles that originate from, and are attached to, the axial skeleton. They occupy the ventromedial part of the ventral horn and their fusiform perikaryon emits a strong lateral and medial richly arborizing dendritic tree. The medial dendrites cross the midline and reach the contralateral lateral white column. The position of motor neurons and the bilateral expanding dendritic arbor receiving inputs on both sides provide an excellent model for the sinuous movements of the spine.

Hypaxial motor neurons innervate muscles that surround body cavities. These motor neurons are found in the lateral part of the ventral horn. Two dendrite stems originate in the irregular perikaryon. The lateral dendrite arborizes in the lateral white column, and the medial abuts on the midline and arborizes mainly in the gray matter. The hypaxial muscles probably contribute to the sinuous movements of the trunk.

Unlike the two former groups, neurons that innervate limb muscles are confined exclusively at the level of limb segments of the spinal cord, and only these neurons receive monosynaptic innervation form the dorsal roots. Their perikarya cluster in the enlarged dorsolateral part of the ventral horn. Of the three dendrites, a laterally oriented branch expands in the lateral white column. A dorsal branch extends toward the dorsal root and receives the bulk of dorsal root fibers. The third branch is directed medially and terminates on the midline. The presence of these neurons is an absolute prerequisite for the control of coordinated limb movements.

Figure 1 Camera lucida drawings from cobalt-stained specimens, showing cross sections of the brain stem and the spinal cord. Numerals refer to cranial nerve motor nuclei. In the mesencephalon (top section), an oculomotor nucleus with crossing axon is shown on the left side. The nucleus of the accessory nerve nucleus is pushed up into the lower medulla in order to save space. In the spinal cord (bottom section), a limb muscle (l), an epaxial muscle (e), and a hypaxial muscle (h) neuron are shown. Szekely G and Matez C (2004) Cranial nerves – a new perspective and classification. In Adelman G and Smith BH (eds.) The Encyclopedia of Neuroscience, 3rd edn. Oxford: Elsevier.

Figure 2 Schematic drawing, color-coded to indicate the genetic profile of the different spinal motor neurons (the gene-related color code is shown on the bottom): yellow, motor neurons with crossing dendrite innervating epaxial limb muscles; black, motor neurons innervating hypaxial muscles; red, the lateral subgroup of motor neurons innervating limb muscles; green, the medial subgroup of motor neurons innervating limb muscles; blue, sympathetic visceromotor neurons. Szekely G and Matez C (2004) Cranial nerves – a new perspective and classification. In Adelman G and Smith BH (eds.) The Encyclopedia of Neuroscience, 3rd edn. Oxford: Elsevier.

In the thoracic section of the spinal cord a group of small neurons forms a continuous column, and the neuronal axons continue their route to the sympathetic ganglia. In the sacral section of the spinal cord another group of small neurons can be found at the dorsal aspect of the ventral horn; these neurons supply the perineal muscles. In mammalian vertebrates there is a group of motor neurons filling up the ventral horn at the midcervical level of the spinal cord. These motor neurons, by their longitudinal dendritic expansion, innervate the diaphragm.

Genetic Profile

Differentiation of progenitor neuroblasts is achieved through the actions of a cascade of transcription factors. In the ventral part of the medullary tube, cells expressing *Pax6* homeobox genes respond to a graded signaling activity of the Sonic hedgehog (Shh) protein and acquire a distinct 'ventral' identity, and begin to express numbers of the LIM homeodomain (HD) family of transcription factors (Figure 2). Progenitors with Lim3 (Lhx3) transcription factor acquire a motor neuron fate by the expression of the NMR2 HDs, and the transient expression of HB9 HD determines the motor neuron fate. Progenitors which leave the cell cycle earliest give rise to the so-called primary motor neurons. They form the medial motor column of type 1 neurons and innervate the epaxial muscles. Longitudinal differentiation of the medullary tube is controlled by the *Hox* homeobox gene family, expressed by the paraxial mesoderm. The Hoxc8 HD identifies the branchial segments, and the *retinaldehyde dehydrogenase 2* (*RALDH2*) gene (current nomenclature, *aldehyde dehydrogenase 1 family, member A2; ALDH1A2*) is the genetic marker of neurons to form the type 3 motor neuron which innervates limb muscles. Following establishment with the periphery, distinct pools are defined by the expression of *PEA3* and *ER81* genes, members of the *ETT* homeobox family. Neurons expressing the corresponding HD proteins encoded by *PEA3* and *ER81* innervate muscles that derive respectively, from the posterior and anterior part of the limb bud. There are no data for the differentiation of type 2 neurons innervating hypaxial muscles.

In the intermediate zone of the medullary tube, the expression of the Phox HD protein marks the identity

of the sympathetic visceromotor neurons at thoracic levels. The genetic history of the sacral parasympathetic neuron group is not known. Unfortunately, motor neurons that are present only in mammals and innervate the diaphragm have not been investigated.

Efferent System of the Brain Stem

Traditionally, two discontinuous motor neuron columns containing the nuclei of cranial nerves are discerned in the brain stem: the somatomotor column, containing hypoglossal (12th), abducens (6th), trochlear (4th), and oculomotor (3rd) nuclei, and the specific visceromotor column, containing accessory (11th), vagus (10th), glossopharyngeal (9th), facial (7th), and trigeminal (5th) motor nuclei (Figure 3). In the forthcoming description, we call these columns the dorsomedial column and the ventrolateral motor column, respectively. This terminology also indicates the positions of the columns in the cross section of the brain stem. Whereas the dorsomedial column is very conservative, disclosing virtually no changes in phylogenesis, the ventrolateral column greatly differs in the nonmammalian and mammalian brain stems. In addition, some satellite neurons and vegetative parasympathetic motor neurons are among the efferent neurons of the brain stem. We describe the cranial nerve motor nuclei according to their function.

Figure 3 Median-sagittal section of the brain stem, showing the position of cranial nerve motor nuclei in the rat. Some findings obtained from the lizard brain are also incorporated in the scheme. Numbers refer to the corresponding nuclei and nerves. The accessory abducens nucleus is colored light blue; the broken line demarcates the site of the Edinger–Westphal nucleus, and dots with curved-line tails indicate the probable sites of preganglionic neurons of the ciliary ganglion. Similar dots and lines represent the scattered preganglionic parasympathetic neurons in the lateral visceromotor area of the medulla. Small rings in front of the m7th nucleus and ventral to the m5th nucleus represent the neurons of the auditory muscles. A section of the facial root, which would cover these neurons, is removed from this site. In the caudal part of the nucleus ambiguus, a big oval spot represents a neuron which sends the axon through the caudalmost rootlet of the vagus nerve. This rootlet is 'captured' by the ascending root of the accessory nerve, and vagal and accessory fibers travel together for a short while. Where the two nerves (10th and 11th) transiently fuse, all ambiguus fibers join the common trunk of the vagus. A disk is cut out of the nucleus ambiguus in order to reveal the course of the axon. The cerebellum is not shown. dvc, dorsal visceral column of the medulla; Iq, lamina quadrigemia; IV, fourth ventricle. Szekely G and Matez C (2004) Cranial nerves – a new perspective and classification. In Adelman G and Smith BH (eds.) The Encyclopedia of Neuroscience, 3rd edn. Oxford: Elsevier.

Dorsomedial Column

Movement of the tongue: The hypoglossal nucleus (12th nucleus) The motor neurons have spindle-shaped perikarya which emit a lateral and medial dendrite stem (Figure 1). The medial dendrite extends into the contralateral side; the axon exits next to the midline on the ventral surface of the medulla. This general shape can be found in the frog, lizard, and rat and is reminiscent of the medially positioned motor neurons innervating epaxial muscles in the spinal cord. As shown in Figure 4, the genetic profiles of the two types of neurons are also similar.

Coordinated movements of the eyeball (6th, 4th, and 3rd nuclei) The eyeball is moved by the same six nuclei in all of the vertebrate phyla, showing negligible variation from fish to apes. In most vertebrates

Figure 4 Schematic drawing of the brain stem, showing the genetic profile of the motor nuclei of cranial nerves. Shaded gray areas with decreasing color intensity indicate the approximate extent and position of the respective nuclei labeled with numbers. The darkest gray areas next to the midline indicate the dorsomedial column of the medulla; the next grade of shading is the dorsal visceromotor nucleus, followed by the accessory abducens nucleus; the next is the branchiomotor column, and the two lightest gray areas indicate the main trigeminus and facialis nuclei. Solid circles in the gray areas represent motor neurons. Narrow, dotted-line oval shapes indicate ventral axon exit areas. The gene-related color code is shown on the right. Szekely G and Matez C (2004) Cranial nerves – a new perspective and classification. In Adelman G and Smith BH (eds.) The Encyclopedia of Neuroscience, 3rd edn. Oxford: Elsevier.

there is an additional group of retractor muscles, which are innervated by the accessory abducens nucleus and withdraw the eye into the socket. The abducens nerve originates in two nuclei (Figures 1 and 3). The main nucleus, which innervates the lateral rectus muscle, lies in line with the 12th nucleus. The general shape of the neurons resembles the hypoglossal neurons but there are no crossing dendrites. The axons exit close to the midline on ventral surface. The accessory nucleus (a6) lies lateral and caudal to the main 6th nucleus in lateral reticular formation. The polygonal perikarya give origin to a lateral broomlike and a dorsal fanlike dendritic arborization; the axon arises from the dorsal part of neuron, runs about the main 6th nucleus, and joins the 6th root.

The 4th and 3rd nuclei form a continuous column in the mesencephalic tegmentum (Figure 3). Their dendrites arborize in a fanlike manner (Figure 1). There is a very precise musculotopic organization within this column of neurons. Axons of the rostral part of the column originate in ventral part of the neurons and exit at the ventral surface of the mesencephalon. In the caudal pole of the 3rd nucleus, axons originate in the dorsal part of the neuron, follow a curved course, cross to the other side, and join the contralateral 3rd root. They innervate the medial rectus muscle. Axons in the 4th nucleus also originate in the dorsal aspect of the neurons, follow a curious dorsalward route, and appear on the contralateral side of the dorsal surface of the mesencephalon. These fibers innervate the superior oblique muscle. Note that these two muscles co-contract with the contralateral lateral rectus muscles in a lateral gaze.

Genetic profile The morphology and genetic profile of the six main neurons and the 12th neuron closely resemble each other, but both of these parameters differ in the a6 neurons (Figure 4). Although the course of the axon suggests a later migration of the a6 nucleus from the main 6th nucleus, the differences in morphology and genetic profile do not support a common origin of the two kinds of abducens neurons. In fat, the neurons differentiate in separate loci in the medulla. The retractor muscles and their nerves are absent from Chiroptera (bats) and apes.

After leaving the cell cycle, neurons of the 4th and 3rd nuclei take a different route by expressing the *Phox2a* gene. The Isl2 HD protein is thought to induce the secretion of a protein that guides the outgrowing axon in the ventral direction. One would expect another factor which controls the decussation of axons in the caudal part of the column of the 3rd and 4th nuclei, and even drives one group of axons to the dorsal side of the mesencephalon. The possible candidate responsible for the navigation of the trochlear axons is the Fgf8 protein.

Ventrolateral (Branchiomotor) Column

As shown in Figure 1, the general features of the morphology of motor neurons can be summarized in the following manner: the dendritic arbor displays a dorsoventral orientation, and the ventral array arborizes in a broomlike manner, whereas the dorsal array expands like a fan. The course of the axon is very characteristic: it originates in dorsal aspect of the neuron, takes a dorsomedial course, then turns back, sometimes sharply, as a hairpin, and, passing the ventral aspect of the nucleus of origin, exits in the ventrolateral sulcus of the medulla. Disregarding size differences, this description applies to all motor neurons, including the parasympathetic visceromotor neurons; therefore, this form is regarded as the basic representation of motor neurons in this column.

Control of head movements: The accessory (11th) nucleus Although the alleged precursors of this nerve indicate that it is only an accessory branch of the vagus–glossopharyngeal complex in fishes, the nucleus and the nerve comprise a fully independent structure, innervating a variety of different muscles associated with the skull in different species. The nucleus is at the medullospinal transition level (Figures 1 and 3). The scattered neurons do not form a compact nucleus, but they can be easily recognized by their relatively large size and characteristic form. In mammals, the thin column of the accessory neurons is evident as far as the 6th cervical spinal cord segments.

Deglution and phonation: The nucleus ambiguus (9th and 10th nuclei) The nucleus ambiguus is the common nucleus of the glossopharyngeus and vagus nerve. Its name originates from the difficulty in identifying the location of the components, which are quite variable in different species. We have to deal separately with a central structure controlling phonation. As is well known, laryngeal sound can be produced only by mammals (bird songs are generated in the syrinx, innervated by the 12th nerve). Only the mammalian larynx is provided with sophisticated set of muscles; the nonmammalian larynx possesses an insignificant constrictor muscle. This difference is reflected in the structure of the 10th nucleus (Figures 1 and 3). In submammalian species, the nucleus ambiguus emerges in the reticular formation and terminates almost unnoticed. In mammals, neurons in the caudal part of the nucleus can be easily distinguished by the fact that they grow bigger than

adjacent neurons of reticular formation. Their axons form the most caudal rootlets of the 10th nerve, they transiently fuse with rostralmost rootlets of the 11th nerve, and then separate again and form the recurrent laryngeal nerve. They innervate all laryngeal muscles except one: the cricothyroid muscle. This muscle is supplied from rostral part of the 10th nucleus, which innervates the pharyngeal constrictor muscles. Considering its position and the source of innervation, the cricothyroid muscle is not a real laryngeal muscle. Laryngeal vocalization is therefore a new acquisition in phylogenesis.

Control of jaw movements: The nonmammalian (accessory) facial (7th) and trigeminal (5th) nuclei The spectacular phylogenetic difference between nonmammals and mammals is prominent in the region of the head – the primary mandible joint undergoes very profound transformation during phylogenesis; unfortunately, we have no data about possible transitional forms and can therefore describe only the beginning process and end result. The primary mandible joint acts as the hinge of a two-armed lever. The structural restriction permits only opening and closing the mouth. The participating muscles are the adductor mandible and depressor mandible. The first derives from the primordial constrictor muscle at the level of the first branchial arch, and is innervated by the mandibular branch of the 5th nerve. At the level of second branchial arch, the constrictor splits into a deep and superficial sheet. The deep sheet gives rise to the depressor mandibulae and the sphincter colli. The facial nerve innervates both muscles.

Neurons of the 5th and 7th nerves form a common group in some animals and are separated in others (Figures 1 and 3). The caudal part of the common nucleus is composed of a morphologically homogeneous population of neurons that innervate the opener muscle. The rostral part of the nucleus is more voluminous, containing more neurons; their dendritic arborization does not present as regularly as do the characteristic morphological features of branchiomotor neurons, as can be seen in the facial nucleus.

Control of mastication and facial expression: The mammalian (main) trigeminal (5th) and facial (7th) nuclei The mammalian 5th and 7th nuclei contain two types of neurons (Figure 1). One type is represented by the accessory a5 and a7 neuron types – neurons that innervate the depressor mandibulae in nonmammalian vertebrates. These neurons have preserved their original form, the dendritic arborization pattern, and their course of axons, but only the most rostral neurons form a conglomerate; many of them are scattered along a ventrolateral line between the well-defined neuron groups of the mammalian 5th and 7th nuclei (Figure 3). The rostralmost of these neurons send their axons via the trigeminal motor root; the axons of neurons in the caudal part of this line of neurons join the facial nerve and they innervate the suprahyoid muscles.

The secondary mandibular joint began to evolve probably with the appearance of carnivorous mammal-like reptiles. It has been conventionally assumed that the muscles derive from muscle mass that gives rise to the adductor mandibulae in lower vertebrates, but it has now been observed that the radical remodeling that occurs in mammals makes impossible the homologization of individual mammalian masticatory muscles to the derivatives of the primordial adductor muscle mass. Parallel to the transformation of the joints, the teeth are fastened via gomphosis in the alveoli of the upper and lower jaw. The complex arrangements of the muscles and their new type of innervation have rendered it possible to grind and masticate food. Joints, muscles, and nerve are novel acquisition, in evolution.

Muscles of facial expression are also mammalian attributes. Their evolutionary course is not known. In the old literature, the constrictor colli is regarded as the primordium of the facial muscles. this is improbable, because the constrictor is innervated by accessory (a7) motor neurons. Large, polygonal neurons of the facial muscles form a well-defined nucleus in the ventrolateral column. The axons originate in the ventral aspect of the perikaryon; after a short run they turn dorsal, and at the lateral aspect of the 6th nucleus they form a whirl-like structure. This tangle of fibers extends rostrally and dives down to the exit site, forming the enigmatic genu of the facial nerve. The facial muscles and nerve can also be regarded as novel structures.

Satellite neurons to the facial–trigeminal nuclear complex In the frog, there is a muscle sheet, the orbital muscle, which separates the orbit from the snout cavity. It is innervated by a group of neurons in the upper pole of the 5th nucleus, and the axons reach the muscle by way of the ophthalmic and maxillary nerves. In the mammalian brain stem a loosely arranged group of small neurons can be found ventral to the 5th and 7th nuclei (Figure 3). Their axons join either the 5th nerve (musculus tensor tympani) or the 7th nerve (musculus stapedius). These tensor tympani and stapedius muscles probably evolved together with the transformation of the mandibular joint.

Vegetative parasympathetic column A group of small cells form a continuous column lateral to the

dorsomedial nuclei from the caudal end of the 7th nucleus till the rostral part of spinal cord. This group of cells is the dorsal nucleus of vagus (Figure 3). Axons emerging from the dorsal aspect of the small perikarya run in the direction of longitudinal medial fascicle, then after sharp turn they join the roots of the 7th, 8th, and 9th nerves. At the level of the ambiguus nucleus, there are a number of middle-sized neurons scattered in lateral part of the reticular formation. Their axons take a similar course before joining the 9th and 10th nerve roots. This group of neurons is called the medullary vegetative column.

Genetic Profile

The basic difference between the dorsomedial and ventrolateral column is that the *Pax6* gene interprets the induction of the Shh HD protein in the first column, whereas we find the Nkx2 homeobox family in the second column (Figure 4). The Phox2 protein determines the route of axons, and a subsequent HB9 effect defines their motor neuron identity. The LIM HD family is represented by the Isl1 HD. It is interesting that the axons of all branchiomotor and visceromotor neurons take the characteristic hairpin loop course and exit dorsolaterally. This may suggest that the initial differentiation of the two classes of neurons controlled by the *Nkx2.2* and *Phox2b* genes determines this axonal route as well. Regarding the most variable morphology and function controlled by the branchiomotor column, one would expect some genetic differences in the backgrounds of these morphological and functional variations.

Unfortunately, there are no data about the 'new' neurons in the class of branchiomotor neurons. It would be especially interesting to follow the phylogenetic appearance of the main trigeminal nucleus and the transformation of the primary mandibular joint, and how it is associated with the development of the middle ear, its muscles, and their innervation. The same consideration applies to the 'new' facial nucleus, which is different in its structure from the other motor nuclei, and to the muscles of facial expression, which are also different from other skeletal muscles.

In summary, the foregoing samples present a number of motor neuron types that can be classified on the basis of morphological characteristics. Well-defined functions can be assigned to major classes in a number of cases. The capacity to perform some of these functions is determined in early embryonic life. The *RALDH2* (*ALDH1A2*) gene distinguishes motor neurons in the lateral part of the ventral horn, and the variously expressed Lim proteins continue to subdivide this pool of neurons. The *Hox* homeobox genes identify the limb segments of the spinal cord, and presumably trigger the sequence of gene expression that determines the 'limb' fate of motor neurons, which are alone capable of moving the limb in a coordinated manner. HDs of the *ETT* homeobox family supposedly guide motor fibers to the appropriate muscle group. The instructive contribution of the somatodendritic morphology to the neural implementation of patterned movements (e.g., limb, jaw) verifies the interest in their differentiation and raises the question of the extent to which this differentiation is controlled by genetic and epigenetic mechanisms. Recently, the instrumental role of dendritic geometry was emphasized in the organization of neuronal interactions. In this context, motor neurons that can be identified in the embryo provide excellent material for the study of the development of neural morphology, and they may help answer questions concerning the role of genetic and epigenetic factors in the shaping of neural organization.

Afferent System of the Brain Stem

Sensory fibers are carried only by the branchial cranial nerves (Figure 5). The trigeminal nerve subserves the exteroceptive innervation of most of the head. Its sensory nuclei constitute a long column that continues into the dorsal horn of the spinal cord. This is called the general somatic afferent column in the

Figure 5 Cranial nerve sensory nuclei are shown in the same outline of the brain stem as in Figure 3. For a better orientation, the motor nuclei are indicated with thin lines. lq, lamina quadrigemia; mes5, the mesencephalic sensory nucleus of the 5th nerve; IV, fourth ventricle; pr5, the principal sensory nucleus of the 5th nerve; nts5, the nucleus of the spinal tract of the 5th nerve; sol, the solitary tract and nuclear complex; v-c, the vestibulocochlear complex. classic scheme. However, this nerve supplies the mucous membranes of the mouth, tongue, and nasal cavity, and the pulp of the teeth; this is a general viscerosensory function in the classic scheme. Furthermore, from its mesencephalic nucleus, this nerve provides the proprioceptive innervation to masticatory muscles (which belong to the specific visceromotor group), to eye muscles (which are innervated by another type of motor nuclei), and to the periodontal connective tissue. In many animals, the snout and the whiskers function as real sense organs. They are also innervated by the trigeminal nerve, with specific thalamic and cortical representation. These fibers should be classified in a common group with the 8th nerve, which is the sensory nerve of another sense organ in the hindbrain region, and should be referred to as specific somatosensory fibers. Thus the trigeminal nerve contains all possible types of sensory fibers. The classic scheme breaks down in the trigeminal sensory field as well.

Sensory fibers of the 7th, 9th, and 10th nerves terminate in a general visceral afferent column and in a specific visceral afferent column, according to the classic scheme. The general visceral afferent column corresponds to the solitary tract and its nuclear complex (**Figure 5**). The specific visceral column, the alleged center of gustatory sensation, supposedly lies medial to the solitary complex. Modern tracing techniques have failed to detect this specific visceral afferent center, and the area medial to the solitary complex seems to be involved in vestibulocerebellar connections. Specific and general visceral sensations, therefore, converge onto a common center. There is also an extensive interchange of fibers between the trigeminal and solitary sensory nuclei in the frog, lizard, and rat; this suggests that interoceptive and exteroceptive impulses are jointly processed in the trigeminal and solitary nuclear complexes. The two kinds of afferent impulses are mixed to an unknown extent in these centers. The most lateral part of the hindbrain harbors sense organ nuclei for hearing and equilibration, and for the lateral line organ in aquatic vertebrates.

Brainstem Control of Eye Movements

Saccadic Eye Movements and Fixation

Saccades are rapid, steplike shifts of the orientation of the eyes that serve to reposition the line of sight on a new object of interest. They are among the most rapid and precisely controlled form of motor behavior in animals with foveal or heightened central visual acuity. Because visual acuity is depressed during saccades, the neural circuits that control these eye movements have evolved to generate extremely high rotational velocities (up to $800^\circ\,s^{-1}$ or more in primates) and accurate terminations that place the fovea on or near the new target of interest. These characteristics of saccades produce movements of short duration (e.g., 50–100 ms) in which duration is a fixed function of saccade amplitude. Once a saccadic movement ends, an active fixation system is engaged that prevents further movement of the eyes for a short period of time as the visual system inspects the newly acquired target. The saccadic system, therefore, operates in a discontinuous fashion, alternating between periods of fixation and high-speed movement. Saccades that overshoot or undershoot the target, that drift onto the target, or that occur with degraded speeds or drifts in eye position between saccades are sensitive indicators of pathology in the saccadic and fixation control system. Neurologists have used such measures of ocular motility as indicators of saccadic system malfunction and as indicators of the probable location of lesions in the brain that produced the malfunctions.

Organization of Brain Stem Circuits Involved in Saccades

The precision with which saccadic eye movements are controlled suggests that feedback about the ongoing eye movement is used to control the trajectory and endpoint of these movements. However, visual feedback from the retina is too slow to affect the movement accuracy during saccades due to their very short duration. A major advance in understanding the saccadic system was provided by neurophysiological studies that showed that saccades are not ballistically guided but, indeed, are controlled by feedback during the movement. This feedback is derived, not from the visual system but, instead, from an efference copy of the neural commands controlling the motor output. Because this source of feedback is derived from the motor system output, it has extremely short latency and can thus control the accuracy of saccades during the movement in almost real time. The ability of the saccadic system to use efference signals to control saccadic accuracy stems from one of its unusual characteristics when compared to other motor systems. The load moved by the system is the eyeball and other orbital tissues. This load is nearly invariant over all sizes and directions of movement, and saccades are simple rotations about a single, relatively fixed point. In addition, proprioceptive feedback signals from stretch receptors in the extraocular muscles do not directly control saccades, but these signals may be involved in longer-term adaptive control of eye movements. Neural control signals directly from receptors in the eye muscles to oculomotor neurons, which is called afferent feedback, is much more ubiquitous in other skeletal motor systems. Proprioceptive input from the eye muscles may also be used to calibrate the efferent copy during development.

The concept that saccades are controlled by neural feedback signals originating from the motor (efferent) output has led to the general model of saccadic system organization shown in Figure 1(a). This model is a simple, one-dimensional representation of the negative feedback system that produces horizontal rotations of the eyes. Signal development and processing are represented with single input/output operators that summarize the neural mechanisms involved. Descending control signals from sources outside the brain stem provide the desired goal of the saccade. This signal is indicated as E_d in Figure 1(a). The new eye position or goal signal originates from the cerebral cortex, cerebellum, and superior colliculus (SC). Although the SC is anatomically part of the brain stem, its operation is not discussed here, except to note that it forms part of the distributed input to the brain stem circuits generating eye-movement control. The spatial frame of reference of E_d and how it is coded are still a matter of discussion among investigators of the saccadic system. Frame of reference means whether the desired rotation of the eyes is specified in retinotopic or spatial coordinates. Methods of coding means whether E_d is generated by a topographically organized activation of a population of neurons (place coding) or by a frequency code in which the rate of neural discharge codes the desired goal or saccadic end point (rate coding). Studies of the cortical and collicular sources of E_d suggest that this input signal is retinotopically coded by a distributed place-coded ensemble of activity. The cerebellar

Figure 1 Schematic view of the brain stem organization of (a) the saccadic system and (b) the smooth pursuit system. Black circles, rectangles, and pathways indicate excitatory operations. Red circles and pathways indicate inhibitory operations. Arrowheads indicate the direction of control signal flow. In (a), the efferent control of saccade trajectory is generated by the lower feedback pathway. The green dotted-line box is the saccadic burst generator. The dashed horizontal line indicates that the system is divided into a push/pull fashion for left/right directed horizontal saccades or into up/down vertical saccades. In (b), the afferent control of smooth pursuit eye movements is accomplished by the generation of a retinal slip signal, the motion difference signal between the moving target and the moving eye and attached sensor (the retina). The system operates continuously to minimize retinal slip. The green dotted-line box is the pursuit generator. *C*, comparator; *E*, eye position; $\dot{E}$, eye velocity; E_d, desired shift in eye position; $\Delta E(t)$, current eye displacement during a saccade; EBN, excitatory burst neuron; IBN, inhibitory burst neuron; *me*(*t*), dynamic motor error signal; MN, motor neurons; NI, neural integrator; OM plant, orbital mechanical system; OPN, omnipause neurons; PD, pursuit drive neurons; RNI, resettable neural integrator; *rs*(*t*), dynamic retinal slip signal; S/p cells, saccade/pursuit neurons; $\dot{T}$, target velocity; Tonic dr, tonic drive.

contribution to E_d may be a mixed rate/place-coded signal. The distributed input from the SC connects to the brain stem burst generator (the green dashed box in Figure 1(a)), whose cells are rate-coded. Thus, a spatial-to-temporal transform must occur at this level of the system. However, the SC connects to burst-generator cells with a pattern of variable synaptic strengths (weights). Those inputs from the rostral SC discharge for small saccades and connect to the burst-generator cells with small weights, whereas those from the caudal SC discharge for large saccades and connect with large weights. This arrangement may produce the spatial-to-temporal transform required in the saccadic system, in which the same ensemble input from the rostral or caudal SC produces a smaller or larger rate of discharge in burst-generator cells for smaller or larger saccades, respectively.

The Neural Comparator

The efferent feedback signal coding the current displacement of the eyes (with respect to their starting position) during a saccade is subtracted from the desired goal (E_d) of the movement to generate a dynamic motor error signal (*me*(*t*)). In Figure 1(a), this computational step is symbolized with standard linear system operators as a lumped subtractive operator or comparator (*C*). The use of this linear system operator or comparator suggests that neurons carrying a discharge coding eye displacement ($\Delta E(t)$) inhibit a single group of neurons that also receive an excitatory input coding the desired goal. The resulting output of the group of neurons is the motor error signal. It is now clear that the actual operation of this part of the system is much more complicated and that the comparator merely serves as a short-hand symbol

to represent the theoretical operations that the saccadic system must perform to insure the accuracy of the saccadic endpoint through feedback control. In the first place, the descending input to the comparator is a distributed signal representing the goal with a spatial population code, not a rate-coded signal. Furthermore, saccades are actually three-dimensional rotations of the eye; however, attempts to extend the model shown in Figure 1(a) to three-dimensional rotations (by adding a second circuit that represents vertical movements) have not been successful because of the kinematic laws governing three-dimension rotations. The results of these complications means that a literal rate-coded motor error signal may not exist in any one group of brain stem neurons but that the driving signal representing error may instead be a highly distributed signal having both place and rate coding. Nevertheless, the system depicted in Figure 1(a) remains a viable way of framing the discussion of the neurophysiology and connectivity of the various types of brain stem neurons that control saccades.

Saccadic Burst Generator

The saccadic burst generator (SBG) is a brain stem circuit consisting of anatomically separated groups of neurons with different firing characteristics that collectively control saccade direction and amplitude. Because the orbital mechanical system (OM plant) is heavily dominated by viscous forces, the muscle forces that generate saccades must provide a large pulse of force to the rotating eyeball for the duration of the movement. The high-velocity ocular rotations reached during saccades amplifies the need for the large pulse of muscle force, and the essence of saccadic control is to remove this pulse of force just before the eyes reach the desired saccadic goal (i.e., when $me(t) = 0$). This pulse of force is generated by a burst of motor neuron activity in the agonist muscles that leads to saccade movement onset and lasts for the duration of the saccade. The motor neuron activity supplying the antagonist muscles shows the reciprocal pattern of activity – a complete inhibition of discharge during the saccade. This reciprocally organized burst/pause of motor neuron activity during saccades is generated by the output of the SBG. The reciprocal nature of the functional organization of the SBG, which involves ipsilateral excitatory pathways and inhibitory pathways that cross the midline of the brain stem is simplified in Figure 1(a) with the use of the solid green lines into a single group of motor neurons.

The SBG consists of burst neurons and omnipause neurons (OPNs). The former are further differentiated into excitatory burst neurons (EBNs) and inhibitory burst neurons (IBNs). Anatomically, EBNs are located in two regions, the paramedian pontine reticular formation (PPRF), just rostral to the abducens nucleus (AN), and a region of the mesencephalic reticular formation called the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF). The IBNs are located in the medullary reticular formation just caudal to the AN and are intermixed with EBNs in the riMLF. The caudal groups of burst neurons are responsible for the horizontal component of saccades, whereas the rostral burst neurons subserve the vertical component of saccades. Both EBNs and IBNs produce a high-frequency burst of activity that that slightly leads (by ~10 ms) the onset of saccades, and this burst of activity ends before saccade offset. The discharge rate of the burst neurons is related nonlinearly to instantaneous saccadic velocity through a saturating exponential function. The more caudal group of EBNs project monosynaptically to the ipsilateral AN, whereas the caudal IBNs project across the midline to the opposite AN. This pattern of projections ensures the reciprocally organized discharge of ANs for horizontal saccades; it is indicated by the green solid lines in Figure 1(a). The intermixed rostral EBNS and IBNs project to the oculomotor and trochlear nuclei. The timing of the burst in burst neurons determines the timing and duration of the burst or pause in motor neuron discharge through their direct connections to the motor neurons (green arrows). As their name implies, burst neurons do not discharge during fixation.

The other functionally distinct group of neurons in the SBG is the OPNs. These cells are located in thin bilaterally placed nuclei located on the midline of the brain stem, just rostral to the AN. They discharge tonically at a high constant rate (~100 sps) during fixation, but they pause completely before and during saccades in all directions. The OPNs project monosynaptically to and inhibit all the groups of burst neurons, both EBNs and IBNs. The high discharge rate of OPNs and their inhibitory connections to burst neurons silences these latter neurons during fixation, thus preventing unwanted saccades. Earlier studies suggested that the OPNs precisely gated the timing of the burst in EBNs and IBNs, a control function which would determine saccade amplitude. More recent studies showed that the resumption of discharge in OPNs near the saccade end may not be precise enough to terminate the burst in EBNs and IBNs by itself. These studies suggested, instead, that other neurons, perhaps IBNs, may play a role in the endpoint control of saccades.

Intracelluar studies in OPNs during saccades show that the pause in OPN discharge is caused by

a pulselike hyperpolarization of the OPN membrane just before saccade onset that rapidly silences their spike discharge. Following this transient sharp hyperpolarization of the OPNs, the trajectory of the membrane hyperpolarization closely parallels the dynamic shape of the ongoing saccadic eye velocity. These observations suggest that OPNs receive two signals during saccades: a short presaccadic inhibitory input, called the trigger, that silences them and a more prolonged inhibitory input, called the latch, that holds off OPN discharge for the duration of the saccade. The trigger signal initiates saccades by turning off OPNs and, thus, disinhibiting burst neurons, whereas the latch signal maintains the pause in the OPNs for the duration of the saccade. Microelectrode recordings have not yet identified the cell groups or the locations of the hypothesized trigger and latch neurons. Finally, because OPNs are active when the eyes are fixed between saccades, there must be an input tonic drive signal to these cells. Alternatively, the spontaneous discharge of OPNs could be an endogenous property of this type of cell. Most likely, the tonic discharge of OPNs stems from an exogenous input because the high-frequency discharge in these cells ceases when monkeys become less alert.

The Neural Integrator

During fixation, oculomotor neurons discharge at a steady rate proportional to eye position (e.g., AN motor neurons increase their discharge as a function of the abducted position of the innervated eye). The neural circuit that generates this eye position signal in motor neurons is called the neural integrator (NI). The input signal to the integrator comes from the EBNs, neurons which discharge with a signal proportional to eye velocity during saccades. The function of the integrator is to integrate the eye velocity signal from EBNs, in a mathematical sense, to provide an appropriate eye-position signal to the motor neurons. The eye-position signal in motor neurons generates muscle force to hold the eye steady during fixation against elastic restoring forces in the orbit that would otherwise return the eye to the straight-ahead position between saccades. The NI is located in several brain stem nuclei, including the vestibular nuclei and the nucleus prepositus hypoglossi, but circuits through the cerebellum also contribute to its operation.

The Resettable NI

The feedback pathway to the comparator consists of a highly distributed set of pathways that include connections from the burst neurons to the SC and the cerebellum. Because both the latter structures also contribute to the feed-forward signal, E_d, it is clear that the saccadic control system is not a standard negative feedback system that directly computes motor error as depicted in Figure 1(a). Instead, this schematic serves as an organizing concept to guide and clarify anatomical and neurophysiological data and to emphasize that saccades are not generated as ballistic movements but are controlled by internal feedback. Overall, the signal generated by the feedback pathways is a dynamically changing representation of current eye placement (change in eye position), not eye position, which is the output of the NI. This is schematically depicted in Figure 1(a) by the inclusion of a separate resettable NI in the feedback pathway, which generates an eye displacement signal. Studies have shown the time constant for the reset of this NI must be extremely short. The cells and pathways that contribute to the generation of the eye displacement signal have not been determined. Furthermore, eye velocity signals from efference copy may also contribute to the overall feedback pathways.

Smooth Pursuit Eye Movements

The brain stem mechanisms that control smooth pursuit eye movements have not been specified with the clarity that has emerged for saccades. The control of pursuit movements is fundamentally different from saccades because they continue over a lengthy time course that allows the feedback of afferent signals from the retina to contribute to the control of the movement. Furthermore, the early phases of pursuit tracking of a target that suddenly starts to move are open loop (not controlled by feedback at all). The neural elements located near the pursuit system output involve the cerebellum and the vestibular nuclei, but also involve some of the same brain stem elements that were traditionally assigned exclusively to the saccadic system. Figure 1(b) shows the brain stem organization of the pursuit system.

Target Motion Inputs and the Formation of Retinal Slip Signals

The cortical signals specifying target motion ($\dot{T}$) are directed through the pontine nuclei and the nucleus reticularis tegmenti pontus, both brain stem structures. The colliculus also contributes to these distributed inputs, although its signals may specify a position motor error, not a motion signal. The same structures contribute to the formation of a retinal slip (*rs*) signal, which is the error signal driving steady-state smooth tracking eye movements. Slip signals are derived from information about target motion and the feedback of the physical motion of the eye ($\dot{E}$) (because the sensor, the retina, is attached to the moving eye). Just as is the case for the saccadic

system, these observations mean that the pursuit system is not actually a standard negative feedback system and that the signal comparator shown in Figure 1(b) is actually a highly distributed operation involving many brain structures.

The Pursuit Generator

The pursuit system is subject to the mathematical laws of feedback control even if the feedback is highly distributed among many brain structures. There is a long delay (on the order of 100 ms) in the pathways that generate the slip signals and the forward pathways in the pursuit generator. This delay and the high gain present in the forward pathways means that this feedback-controlled system would be hopelessly unstable without compensatory signal processing pathways. Eye velocity would oscillate with growing excursions about the actual velocity of the intended target. Although small, damped oscillations are often observed in the transient pursuit response to a suddenly moving target, the steady-state eye velocity response after a few hundred milliseconds is very stable and closely matches target velocity. This requires that the pursuit generator contain mechanisms that overcome the potential delay-caused instability. These mechanisms may include the use of internal (efferent) feedback about eye velocity (as in the saccadic system), the use of anticipation and other cognitive signals derived from raw target motion signals, and the use of slip acceleration signals in the feedback pathways. Many of these hypothesized higher-level signals involve cortical and cerebellar processing, but the brain stem may also make a contribution to their generation. This contribution is shown schematically in Figure 1(b) as the box labeled slip processing.

Brain Stem Elements in the Pursuit System

The same NI used in the saccadic system to generate steady eye position may be shared by the pursuit system. However, some studies suggest that these NI circuits may be partially separated in the brain stem. The burst neurons, the EBNs and IBNs in the SBG, do not participate in pursuit eye movements.

It was originally assumed that OPNs also did not participate in pursuit movements, but recently it has been determined that OPNs do participate in pursuit movements. Instead of being fully on during fixation and completely off during eye movements (as they are for saccades), OPNs modulate their discharge downward during pursuit and then resume normal levels of activity at the end of the pursuit movement. Because OPNs project inhibition monosynaptically to both the rostral and caudal groups of burst neurons, the downward modulation in OPN discharge significantly lowers the ongoing level of inhibition in these burst neurons at the onset of pursuit. However, they do not begin to discharge because they do not have an error signal present as they do at the onset of saccades (see Figure 1(a)). That the lowered level of OPN discharge present during pursuit movements contributes functionally to the generation of higher pursuit eye velocity has been shown with electrical microstimulation of OPNs. A train of stimulation pulses delivered to the OPNs during ongoing steady-state pursuit turns the OPNs back on fully, which produces an immediate reduction in the pursuit velocity that lasts for the duration of the stimulation train. During stimulation, pursuit velocity did not fall to zero, indicating that OPN modulation only acts as a gain control on pursuit, not as an on/off switch as it does for saccades.

The observation that OPNs are not fully turned off at pursuit onset but, instead, are more gradually turned down in a fashion that resembles increasing eye velocity, suggests that during pursuit no inhibitory trigger signal exists in the pursuit system. In the saccadic system, this signal to OPNs serves to completely and sharply turn off these cells at saccade onset.

Saccade/Pursuit Neurons

Saccade/pursuit neurons (S/p cells) are found near and sometimes intermixed with EBNs. These cells have weaker bursts during saccades than EBNs and produce a low level of discharge that is sustained for the duration of the pursuit. Some also show a gradual buildup of discharge before the onset of both saccades and pursuit, in contrast to EBNs, which show an abrupt initiation of high-frequency discharge just before saccade onset. In this feature, they resemble long-lead saccadic burst neurons that are found scattered throughout both the pontine and mesencephalic reticular formation.

The trajectory of the discharge modulation in S/p cells for pursuit movements roughly parallels the increasing eye velocity during pursuit initiation. Thus, S/p cells have a discharge during pursuit that is the mirror image of that of OPNs. To explain this relationship, Figure 1(b) suggests that S/p cells inhibit OPNs and are the source that turns down, but does not totally silence, OPN discharge during pursuit. OPNs, in turn, inhibit both saccadic burst cells and pursuit driving cells (PDs), the latter found in the vestibular nuclei and the cerebellum. Thus, S/p cells have many of the same functional connections as the latch neurons of the saccadic system and may be shared by the two systems.

This brief summary of the brain stem circuits involved in pursuit movements suggests that many

of the same types of neurons are shared by the pursuit and saccadic systems. This claim is supported by other studies that show that some input signals to the brain stem from the rostral SC specify only that a position motor error exists. Whether this error signal generates a saccade, a pursuit movement, or a combination of both is determined by decision processes at the level of the cerebellum and brain stem.

Introduction

Breathing, the process of moving air through the mouth, nose, and airways and into and out of the lung, is an essential behavior for life. Breathing plays a critical role in several fundamental domains of mammalian nervous system function, including regulatory, volitional, and emotional domains.

Volition

Breathing is a highly automated behavior but with significant voluntary control. At least for short periods, we can alter our breathing by holding our breath or by consciously breathing faster or slower. The precise control of expiratory airflow over the vocal folds underlies phonation, including speech, in which both cognitive and emotional mental processes are integrated in a complex motor pattern.

Emotion

Many emotional behaviors, such as laughing, sighing, and crying, involve stereotyped breathing movements. These are evoked independently of volitional movements and use neural pathways of an emotional motor system that are located more laterally in the brain stem than those effecting voluntary breathing movements. Extensive lesions in the ventromedial pons result in a locked-in syndrome in which patients are quadriplegic and speechless but regulatory breathing movements appear normal because the essential neural circuits, located more caudally in the medulla and spinal cord, are typically unaffected. Their breathing is not altered by acknowledged requests to hold their breath or breathe faster, but breathing patterns can show a marked change in response to a (funny) joke, consistent with the stereotyped 'laughing' breathing pattern, that is, episodic and prolonged expiratory efforts. Breathing disturbances can accompany mental states with strong emotional components, such as during panic attacks. In patients with the genetic disorder Rett's syndrome, pronounced disturbances in breathing occur during stress, and these disturbances are thought to be of cortical origin.

Regulation

The most essential role of the respiratory control system is to maintain homeostasis, regulating breathing to optimize oxygen and carbon dioxide exchange. Breathing is sometimes erroneously referred to as an 'autonomic' function, that is, a regulatory act mediated by smooth muscle and glands. Although airway caliber can be modulated by airway smooth muscle, the essential role of skeletal muscles in the respiratory pump excludes breathing from this categorization. Aerobic metabolism consumes O_2 and produces CO_2. In the lung, these gases are exchanged by passive diffusion at the alveolar–capillary interface, which in humans has a surface area of $\sim 70\,m^2$. To move O_2 in and CO_2 out, the lung expands and contracts, driven by skeletal muscles of the respiratory pump. The critical central circuitry for the regulatory control of breathing is in the brain stem and spinal cord. Consequently, decerebration rostral to the pons results in a normal breathing rhythm capable of responding to many homeostatic challenges. Also included in the regulatory component are neural circuits underlying the processing of peripheral chemosensory and mechanosensory signals relevant to breathing, as well as reflexes that protect the airways and lung, including cough, sneeze, sigh, and gag.

Automatic breathing in mammals is both stable and labile (Table 1). As metabolism increases or decreases, ventilation must change accordingly. As one goes from rest to mild exercise, O_2 consumption can easily triple. Because there is only a modest reservoir of O_2 in the blood (about 4 min worth at rest), ventilation must change rapidly and accurately.

In healthy humans at rest, normal breathing during wakefulness and quiet sleep (referred to as eupnea) is characterized by alternating inspiratory and expiratory airflow at about 12–15 breaths per minute. Mammals are unique among vertebrates in having a diaphragm, an upward facing dome-shaped sheet of muscle separating the thoracic and abdominal viscera. In an adult, modest contraction of the diaphragm ($\sim$1.5 cm downward deflection) with a patent airway expands the lung by $\sim$500 ml. Expiration at rest does not require active effort in humans, as the elasticity of an inflated lung and expanded ribcage cause a recoil back to their resting volume. This end-expiratory volume is referred to as the functional residual capacity of the lung. The precise rhythmic muscle activation pattern for breathing is optimized to minimize energy expenditure ($<5\%$ of total body

Table 1 Breathing is both robust and labile

metabolism at rest, increasing to 10% during heavy exercise), as breathing is an essentially continuous behavior throughout life. Over an evolutionary timescale, inefficiencies represent survival disadvantages, and on a shorter timescale, inefficiencies due to disease or injury lead to serious breathing discomfort, or breathlessness (dyspnea). Dyspnea is an essential signal, providing feedback that breathing is somehow compromised and that changes in behavior may be warranted.

Acute changes in breathing pattern underlie important reflexes. Cough, a large inspiration followed by a strong expiratory effort initially against a closed, then open, glottis, produces a high-velocity, turbulent expiratory airflow that moves mucus and foreign objects away from the lung, up the airways, and toward the mouth. Gag is a powerful coordinated reflex aimed at dislodging objects occluding the airways. Sneeze represents a rapid expiratory effort preceded by a large inspiration. Sigh is a very large inspiratory effort that can reinflate portions of the lung that have collapsed due to pulmonary disease such as pneumonia; sighs can also be induced by certain emotional states, and the relationship between the mechanisms of reflex and emotional sighs is unknown.

Breathing is an automatic function and, as such, is one of the few behaviors that can be studied *in vivo* in intact awake, anesthetized, or decerebrate animals. It may also be examined in highly reduced *in vitro* preparations, typically from neonatal rodents. Such preparations have allowed a broad range of investigations that at present support an in-depth understanding of the basic neural mechanisms that underlie breathing in mammals: (1) the basic rhythm is generated in the brain stem, (2) the rhythm is transformed into a pattern of motorneuronal activity by premotor circuits and motor neurons in the medulla and spinal cord, and (3) the rhythm and pattern are modulated by various afferents: Sources within the brain stem include 'central chemoreceptors,' raphe serotonergic and various brain stem noradrenergic and dopaminergic neurons, and the rostral pons. Peripheral sources, such as chemoreceptors in the carotid bodies and mechanoreceptors of the lung and respiratory muscles, also modulate breathing.

Most recently, studies of respiratory rhythm and pattern generation have been dominated by studies using highly reduced *in vitro* and *in situ* preparations that generate a rhythmic respiratory-related motor pattern. Key early discoveries have included the following: (1) Respiratory rhythm persists in thin (250–700 μm) transverse brain stem slices that encompass the preBötzinger complex (preBötC). (2) Rhythm persists in these preparations after attenuation of postsynaptic inhibition, suggesting the possibility that network interactions are not necessary for respiratory rhythm generation.

One, Perhaps Two, Oscillators for Generation of Respiratory Rhythm

One key medullary structure for breathing is the preBötC of the ventral respiratory column. Based on several observations, most investigators agree that the preBötC contains microcircuits critical for rhythm generation: (1) Medullary slices containing the preBötC generate a respiratory-related rhythm (one must be careful here and elsewhere in recognizing that behavior observed *in vitro* often differs distinctly from respiratory behaviors in intact mammals for multiple reasons, including absence of peripheral and many central inputs, lower temperature, and hypo- or hyperoxygenation of the bathing medium in the *in vitro* chamber). (2) Moderate lesions selectively targeting preBötC neurons that express the neurokinin-1 receptor in intact adult rats (unanesthetized and forebrain intact) induce a disturbed breathing pattern during sleep; with more extensive lesions, ataxic breathing occurs during wakefulness, with apneas (complete cessation of breathing) during sleep. (3) Neonatal mice lacking the transcription factor *MafB* show a marked reduction in preBötC neurons accompanied by markedly abnormal breathing patterns. (4) Juvenile rats with a transection of the brain stem just rostral to the preBötC continue to generate rhythmic inspiratory-dominated breathing patterns expressed in the spinal motor output to pump muscles.

A second proposed site for rhythm generation is the ventral parafacial respiratory group (given its proximity to the retrotrapezoid nucleus (RTN), and because of the as yet to be determined distinction between these two groups of neurons, this region may be referred to as the RTN/pFRG). Another

Figure 1 Respiratory regions in the lateral rhombencephalon. Expiratory and inspiratory oscillators (parafacial respiratory group (pFRG) and pre-Bötzinger complex (preBötC), respectively) are part of an essentially continuous column of respiratory-related neurons in the lateral rhombencephalon (see (a)–(e) and (g)). While the pFRG is well documented in the neonatal and adolescent rat brain, its exact location has yet to be directly determined in the adult. Hence, retrogradely labeled cells in (b) are tentatively identified as the pFRG(?). Relative to respiration, this lateral pontomedullary column is usually subdivided along its length into compartments based on distinct roles of the component neurons relative to rhythm and pattern generation (in (h), respiratory compartments are color-coded while nearby landmark brain stem regions are coded gray). The posterior part of the rostral part of ventral respiratory group (rVRG) and the caudal part of ventral respiratory group (cVRG) are characterized by inspiratory and expiratory bulbospinal premotor neurons, respectively, while the preBötC and anterior part of the rVRG contain inspiratory interneurons. The BötC contains mainly inhibitory expiratory interneurons with a subpopulation also projecting to the spinal cord. The pFRG consists of 'preinspiratory' interneurons neurons regulating expiratory motor output. The retrotrapezoid nucleus (RTN) originally designated all the neurons beneath the facial nucleus that project to the respiratory column in ventrolateral medulla. However, it has been suggested more recently that this term might be usefully limited to a group of nonphasic chemosensory neurons located at the caudal pole of the facial nucleus. Sections (a)–(e) are darkfield images of tranverse sections from an adult rat brain in which retrograde neuronal labeling of respiratory-related neurons is depicted in red after a tracer injection in the rostral part of the ventral respiratory group (rVRG in (e)). The approximate levels of sections (a)–(e) are shown by the arrows in (g). Sections (g) and (h) are schematic sagittal sections of the rat brain stem depicting retrograde labeling in the lateral brain stem after a tracer injection in the preBötC (g) and the division of this cell column into functionally distinct respiratory-related compartments (h). Cutting planes *x* and *y* in (g) indicate levels at which more-rostral brain stem removal does not interfere with expiratory motor output (plane *x*) or eliminates expiratory motor output (plane *y*). In (h), the correspondence of adult rhombencephalic regions to their origins in embryonic rhombomeres (r) is indicated by the labeled red arc and radial dashed dividing lines. The dividing line between rhombomeres 4–5 and rhombomere 6 has been displaced to include the facial nucleus (7) within r4–5. In the mammalian embryo, facial motor neurons originate in r4–5, then migrate dorsally, caudally, and ventrally to rhombomere 6. (f) A transverse section representative of neonatal brain stem slices encompassing the preBötC that are used for *in vitro* recording of neurons in the preBötC that fire in phase with continuous integrated inspiratory-like activity (∫12n) on the hypoglossal nerve (12n). The brain stem location of the slice shown in (f) is indicated by the red bar in (h). 5n, trigeminal nerve; 7, facial nucleus; 7n, facial nerve; 12n, hypoglossal nerve; A5, A5 noradrenergic neurons; AmbC, nucleus Ambiguus, compact part; BötC, Bötzinger complex; Itr, intertrigeminal nucleus; KF, Kölliker-Fuse nucleus; LPBr, lateral parabrachial area; LRt, lateral reticular nucleus; Mo5, motor nucleus of the trigeminal nerve; pFRG, parafacial respiratory group; preBötC, preBötzinger complex; PN, basilar pontine nuclei; scp, superior cerebellar peduncle; SO, superior olive; VLPons, ventrolateral pons. collection of neurons related to rhythmogenesis in the respiratory network is located just adjacent to the ventral surface of the facial nucleus. Some RTN/pFRG neurons project to the respiratory circuits of the ventrolateral medulla. RTN/pFRG neurons were initially investigated concerning their possible function as central chemosensors owing to their close proximity to proposed chemosensitive sites on the ventral surface of the medulla. Neurons in this general region, and especially those located laterally in the RTN, also contribute to rhythm generation, at least under some conditions. Key observations include the following: (1) A cluster of rhythmically active neurons is concentrated in the RTN/pFRG in *en bloc* preparations. When isolated from the preBötC by intramedullary transection in these preparations, a block of medullary tissue containing the RTN/pFRG can continue to generate a rhythm. (2) Inspiratory activity in slices which contain the preBötC but not the RTN/pFRG slow down continuously when exposed to μ-opiate agonists, whereas in *en bloc* preparations containing both structures, inspiratory activity slows discontinuously ('quantal slowing'; Figure 1). *In vivo*, opiates induce quantal slowing of inspiratory activity, which would be expected if RTN/pFRG neurons play some role in generating or influencing the underlying inspiratory rhythm, but expiratory activity remains unaffected (Figure 1). These latter observations suggest that the preBötC and RTN/pFN both have the intrinsic capacity to generate a respiratory rhythm but that they are normally entrained to produce a single respiratory rhythm. However, under some conditions, such as opiate receptor activation *in vitro*, the coupling is weakened and the RTN/pFRG is unencumbered and produces a predominantly expiratory-related motor rhythm reflecting its intrinsic oscillatory properties.

Thus, while many structures can modulate respiratory pattern, the working hypothesis of many in the field is that there are (at least) two coupled oscillators, the preBötC and the RTN/pFRG. An additional hypothesis is that inspiratory rhythm is generated by the preBötC (Figure 2) and active expiration by the RTN/pFRG.

The neural circuitry for breathing in mammals is the end result of an evolutionary lineage of rhythmic movements essential for gas exchange in vertebrate lung whose origins are closely related to the development of gas exchange in the gills of fish and the transformation of the swim bladder into the lung. Comparative analyses of breathing in nonmammalian vertebrate species, including reptiles and amphibians, are consequently of interest in understanding the origin of the oscillator(s) for terrestrial breathing. Tadpoles have two distinct breathing patterns (buccal and lung) that can act separately or in ensemble; in the latter case, they are phase-locked. It is interesting that the lung rhythm is opiate sensitive, whereas the buccal rhythm is not. Wilson and colleagues have speculated that these oscillators are homologs of the preBötC and the RTN/pFRG, respectively. An interesting distinction of mammalian breathing is that it is primarily driven by the diaphragm, a powerful inspiratory muscle not present in nonmammalian vertebrates. The relative role of the two oscillators (Figure 3) may differ between mammals and nonmammals since the power stroke for breathing is primarily inspiratory and diaphragm driven in mammals, whereas in most reptiles and amphibians, the power stroke is dominated more by expiratory effort.

While we do not understand why any respiratory oscillator would be opiate sensitive (or insensitive), this property clearly has consequences at birth, when there is a significant surge of maternally derived opiates in the newborn mammal. Such an opiate surge would depress the opiate-sensitive preBötC, revealing

Figure 3 Summary of gross organization of respiratory rhythmogenesis in the brain stem of mammals. In this view, two oscillators are differentially affected by various inputs, such as opiates and lung inflation/deflation. The more rostral oscillator is located in the region of the retrotrapezoid nucleus/parafacial respiratory group (RTN/pFRG) and appears to drive active expiratory (E) activity (and may not be rhythmic at rest in many mammals when there is little or no active expiration), and the more caudal oscillator is located in the pre-Bötzinger complex (preBötC) and appears to drive inspiratory (I) activity. SP-SAP lesion of preBötC neurokinin-1 receptor (NK1R) neurons disrupts breathing. Transection between the two oscillators disrupts expiratory motor outflow although inspiratory activity continues unabated. Lung inflation enhances the activity of the expiratory oscillator and depresses the inspiratory oscillator, which serves ultimately to reduce lung volume, whereas lung deflation has the opposite effect on the inspiratory and expiratory oscillators. It is further speculated that the mechanism of rhythmogenesis in the preBötC involves a group pacemaker. What is unresolved in this model is why lesions of the preBötC NK1R neurons in adult rats disrupt rhythm and render breathing ineffective. From Feldman and Del Negro, *Nature Reviews Neuroscience*, 2006.

activity in the opiate-insensitive RTN-vpRFG, which then functions as what Champagnat and colleagues have suggested is an 'antiapnea center.'

While breathing is a continuous movement in mammals over the timescale of minutes, it can be interrupted by such transient behaviors as speech, emesis, defecation, or breath holding. Moreover, during sleep or unconsciousness, breathing can stop for brief periods, and such sleep apneas are common even in otherwise healthy humans. The preBötC may play a role in apneas in which the rhythm of breathing is interrupted (central sleep apneas). Thus, focal lesions specifically targeting a small subset of preBötC neurons (those expressing the neurokinin-1 receptor; NK1R) lead to significant disruption of, or even pathological, breathing in adult mice (**Figure 4**). Destruction of <50% of preBötC NK1R neurons does not appear to markedly affect the breathing pattern. At ~50% destruction, breathing during sleep is disturbed, exhibiting a marked increase in apneas. At ~80% destruction, a normal rhythmic breathing pattern is no longer seen even during wakefulness, and sleep invariably induces prolonged apneas that cease only on awakening in the form of abrupt arousal.

Serious disruption of breathing during sleep, including central apneas, is seen in at least three human neurodegenerative diseases: Parkinson's disease (PD), multiple systems atrophy (MSA), and amyotrophic lateral sclerosis (ALS). In the human ventrolateral brain stem, there is a marked decrease in NK1R neurons, presumably including those in the preBötC, in individuals who died at late stages of PD and MSA. A similar loss might be expected in individuals at the late stages of ALS, who often suffer from central sleep apneas. Recurring apneas, each inducing a period of brain hypoxia, could initiate a vicious cycle that accelerates the loss of preBötC neurons, leading to further and more profound breathing disruptions and ultimately death by asphyxia or from an apnea-induced heart attack or stroke.

Cellular and Network Bases for Generation of Respiratory Rhythm

The simplest explanation for the principal mechanism underlying generation of respiratory rhythm is autonomous bursting (pacemaking) in a subset of neurons, presumably in the preBötC and/or RTN/pFRG. The persuasive, but now debated, evidence in this case came from recordings of medullary slices that contain the preBötC and generate an inspiratory rhythm. That this rhythm continues after blockade of postsynaptic inhibition led directly to the hypothesis that pacemaker neurons generate the respiratory rhythm.

Figure 4 Lesions of the pre-Bötzinger complex (preBötC) significantly disturb breathing pattern in an adult unrestrained, unanesthetized rat. SP-SAP was injected bilaterally into the preBötC, which eventually killed more than 80% of preBötC neurokinin-1 receptor neurons on (or shortly after) postinjection day 10. Under control conditions, breathing is continuous throughout the sleep–wake (W) cycle, as determined from electroencephalogram and neck electromyogram (EMG) signals (not shown). However, on day 8, breathing pattern is normal except during rapid eye movement (REM) sleep, when apnea develops and ventilation is restored only on waking; this cycle repeats. I_{amp}, inspiratory amplitude; DIA_{EMG}, integrated diaphragmatic EMG; NREM, non-REM. From McKay LC, Janczewski WA, and Feldman JL (2005) Sleep-disordered breathing following targeted ablation of preBötzinger complex. *Nature Neuroscience* 8: 1142–1144.

Based solely on *in vitro* studies in neonatal rodents (Figure 5), neurons with bursting-pacemaker properties represent a subpopulation (5–25%) of preBötC neurons. There are two types of preBötC pacemaker neurons. One type, present at birth, is voltage dependent and driven by a persistent Na conductance (I_{NaP}). The second type appears to be extraordinarily sparse before postnatal day 7 in rodents and is dependent on Ca^{2+} and/or a Ca^{2+}-activated nonspecific cation current (I_{CAN}).

While the pacemaker hypothesis is intuitively appealing, there is no evidence to show that pacemaker activity is essential for respiratory rhythm generation at this time. In fact, there are data suggesting that such activity is not essential, at least *in vitro*. Thus, rhythm persists in brain stem slices after blocking the key pacemaker currents in the two populations of preBötC neurons that support pacemaker activity. While an obligatory role of pacemaker activity is disputed, there is a critical role in rhythmogenesis for intrinsic I_{NaP} and I_{CAN} currents that appear to be present in all preBötC neurons, pacemaker or otherwise, and contribute to burst generation in the context of amplifying inspiratory-related synaptic input.

Regardless of the cellular properties that underlie rhythm generation, network properties undoubtedly contribute in important ways. As mentioned above, rhythmogenesis appears unaffected unless >50% of preBötC NK1R neurons are destroyed. Unfortunately, very little is known in detail about the local connectivity

Figure 5 Group-pacemaker hypothesis of respiratory rhythm generation. The membrane potential of a rhythm-generating neuron is shown (V_M) with network activity, represented by XII motor output. Images at the bottom depict neuronal activity at different stages of the cycle. **A** is the refractory state following inspiration in which activity-dependent outward currents depress membrane potential and excitatory synapses in the network are inactive. During epoch **B**, the most excitable neurons recover from postburst hyperpolarization and begin to spike at low rate. In **C**, these highly excitable cells begin to synaptically activate other neurons, leading to aggregation of network activity, itself due to recurrent synaptic excitation – a positive-feedback process. The inspiratory burst ensues in **D** once a critical number of cells in the network are activated by recurrent excitation. In this final step, synaptic inputs recruit burst-generating intrinsic currents such as calcium-activated nonspecific cationic current and persistent sodium current, which give rise to large inspiratory burst potentials with high-frequency spike activity. Inspiratory bursts terminate due to intrinsic properties of cells that can reverse the positive feedback process, including Ca-dependent K currents and electrogenic pumps, which are recruited by cationic influx during inspiration. From Feldman and Del Negro, *Nature Reviews Neuroscience*, 2006.

of the preBötC or of RTN/pFRG neurons and scarcely more about their brain stem interconnections.

Cellular and Network Basis of Burst Pattern Formation

Once the respiratory timing has been established by the process of respiratory rhythm generation, the oscillating neuronal activity must be distributed appropriately to the different respiratory muscles to generate rhythmic and coordinated breaths. Little is known about the details of burst pattern formation, but activity from the preBötC is relayed to premotor neurons and interneurons of the ventral respiratory column. These premotor neurons relay information to respiratory motor neurons with inspiratory and expiratory activity, including motor outputs to the respiratory pump muscles and muscles regulating upper airway resistance. Sensory information and modulatory inputs are integrated at each step in this translation of respiratory rhythm into the detailed motor output to each respiratory muscle. Although apneas of central origin most likely arise from abnormalities in the process of rhythm generation, obstructive apneas and other forms of motor dyscoordination represent abnormalities in burst pattern formation.

Summary

Breathing in mammals consists of thoracic and upper airway movements that move gas into and out of the lungs for respiratory homeostasis. Breathing adjusts to changing physiological demands such as exercise yet also accommodates episodic behaviors like coughing and emesis. The underlying respiratory rhythm most likely originates in the preBötC and may also involve the RTN/pFRG, which is hypothesized to be critical for active expiration. Rhythms in preBötC neurons depend on excitatory network interactions as well as intrinsic membrane properties.

Broca's Area: Evolution

W D Hopkins, Yerkes National Primate Research Center, Atlanta, GA, USA

© 2009 Elsevier Ltd. All rights reserved.

In 1861, Paul Broca described the speech and linguistic production deficits of a patient named 'Tan Tan.' Upon death, Broca obtained the postmortem brain and described a large lesion in the left inferior frontal gyrus (IFG). From his subsequent clinical observations, Broca concluded that the left inferior frontal lobe was important for linguistic functions in humans. Thirteen years later, Wernicke described his famous cases which constituted patients with lesions in the posterior portion of the left temporal lobe. Wernicke's patients had deficits in speech and linguistic comprehension. Since the time of Broca and Wernicke, these two brain regions have received an enormous amount of scientific attention and empirical investigation. Behavioral as well as neurophysiolocal imaging technologies have consistently implicated these two regions in higher order linguistic, cognitive, as well as motor functions in the human brain. In terms of morphology, there is also evidence of a left hemisphere bias in humans, although this remains somewhat debated. For example, using standard region-of-interest approaches to measuring Broca's area, left hemisphere asymmetries have been reported in the pars operculum and pars triangularis, but some voxel-based analyses from magnetic resonance imaging (MRI) have failed to reveal consistent evidence of leftward asymmetries within the inferior frontal region.

Almost since the earliest observations of Broca, there has been parallel interest in whether animals, and particularly our closest living relative the great apes, possess similar lateralized cortical systems that might serve as antecedent conditions to the emergence of language and speech in modern humans. Scientific interest in whether apes and other nonhuman primates exhibited neuroanatomical asymmetries was undoubtedly influenced and stimulated by the behavioral demonstrations of sophisticated cognitive abilities such as self-recognition, symbol acquisition, and tool use in nonhuman primates, particularly in great apes. However, until recently, it has been widely held that only humans exhibit brain asymmetries at the population level; however, this conclusion was largely based on very little data in great apes and relatively simple and descriptive studies in other primate species involving few numbers of subjects. With the advent of modern imaging technologies as well as an increasing interest in preserving and examining postmortem brains, the question of whether apes and other nonhuman primates exhibit population-level asymmetries has become increasingly evident.

This article describes and summarizes the comparative evidence of Broca's area neuroanatomy and function in nonhuman primates. Integrating these findings may provide important clues to the evolution of brain asymmetry and functions as it potentially relates to the evolution of cognitive and behavioral functions in primates, including humans.

Morphology and Cytoarchitectonics

Broca's area is composed of Brodmann's area 44 and 45, and these cell types have been described in a variety of nonhuman primate species. The most commonly studied genera has been *Macaca*, and this has included cytoarchitectonic and histological studies of areas 44 and 45. In macaques, area 44 and 45 cells have been identified in regions surrounding the inferior arcuate sulcus, inferior principal dimple, and sulcus principalis, although there is debate about the characterization of the ventrolateral region of the macaque brain. Specifically, previous studies had not adopted the same cytoarchitectonic criteria as that employed in human brain and therefore some confusion has arisen over the exact region and function of cells within this morphological region. However, it has been shown that the cytoarchitecture and granular structure of areas 44, 45, and 6 are significantly different in the macaque brain. Specifically, within area 45, there are unusually large neurons in layer III compared to layer V. Second, area 45 has a well-developed granular area, whereas it is rudimentary and irregular in area 44 and absent in agranular area 6V. Thus, within the ventrolateral region of the frontal lobe of the macaque, there are distinct layering patterns reflective of areas 6, 44, and 45, respectively.

With respect to chimpanzees and orangutans, early studies initially mapped areas 44 and 45 in the chimpanzee brain. According to Von Bonin, predominantly area 44 cells were found in the IFG in the region lying between the precentral inferior sulcus (PCI) and the fronto-orbital (FO) sulcus. In contrast, area 45 cells were found in the frontal cortex, just dorsal to the superior tip of the FO sulcus. Sherwood and colleagues performed a similar cytoarchitectonic analysis of the IFG of chimpanzees and found a somewhat different pattern of results from those of Von Bonin and colleagues. According to Sherwood and colleagues, both area 44 and area 45 cells, as well as

area 6 (primary motor cortex), can be found in regions corresponding to the IFG originally described by Von Bonin. Moreover, Sherwood and colleagues argue that there are considerable individual differences in the sulci making up the inferior frontal region, and the presence of inconsistent structural landmarks makes mapping the cellular to the morphological regions difficult. Inconsistencies between the cytoarchitectonic and sulcal border of regions 44 and 45 have similarly been claimed in postmortem human brains.

Lateralization of Broca's Area

As noted previously, clinical and experimental data clearly suggest that the left inferior frontal cortex is involved in speech production, although other motor systems, such as the basal ganglia and cerebellum, play a role in language production. With respect to morphology, data from humans have largely shown that inferior frontal cortex is larger in the left compared to the right hemisphere. For example, measuring brain asymmetries from MRI, both the pars operculum and the pars triangularis have been reported to be larger in the left compared to the right hemisphere, particularly among right-handed individuals. Less clear from the extant data in humans is the evidence of mircrostructural asymmetries (or cellular asymmetries). In one study, postmortem measurements of the cytoarchitecture of Brodmann's regions 44 and 45 in ten individuals showed a leftward asymmetry for area 44 but not area 45. Moreover, cytoarchitectonic borders of areas 44 and 45 did not strongly coincide with sulcal contours used to define the regions. In a follow-up study, in a sample of 34 brains ranging in age from 3.5 months to 75 years of age, evidence of asymmetries in Broca's area was reported but for Brodmann's area 45, not area 44, as in the original report. Using a different approach, others have reported that there are significantly more acetylcholinesterase-rich neurons located in layer III within Brodmann's area 45 in the left compared to the right hemisphere in a sample of six human brains. In none of the postmortem studies were handedness data on the subjects available.

With respect to the comparative data on asymmetries in the frontal lobe, there are few studies in monkeys and most have directly measured sulci form postmortem brain or endocasts. For example, Falk and colleagues examined asymmetries of 11 sulci in the frontal lobe in a sample of 403 macaque endocasts. Population-level rightward asymmetries were found for the length of the rectus and lateral orbital frontal sulcus. A significant leftward asymmetry was found for the length of the central sulcus. Falk and colleagues also reported a right frontal petalia asymmetry in the macaques, results consistent with findings in great apes. In summary, although there is evidence of population-level asymmetries in macaque brains, asymmetries in regions or sulci demarking Broca's area have not been reported.

In great apes, the bank of tissue lying between FO and PCI was measured from MRIs in a sample of 27 great apes, including 20 chimpanzees, five bonobos, and two gorillas (**Figure 1**). For the measurement of the IFG, MRI scans were aligned in the sagittal plane and cut into 1 mm slices. Consecutive parasagittal slices were traced from the lateral surface of the IFG to the most medial slice immediately preceding the insula. The IFG was defined as the portion of cortical surface bounded by the FO and the PCI sulci. Both FO and PCI could be clearly seen in parasagittal (1 mm thick) MRI slices. Overall, a significant leftward asymmetry was found for the IFG of the great apes.

MRI scans have been obtained in 49 more chimpanzees and the addition of these specimens has confirmed the previous observations of a left hemisphere asymmetry in the frontal operculum of chimpanzees (**Figure 2**). A comparison of asymmetry values between the original sample and the subsequent 49 individuals found no significant differences between them. If the frontal operculum is divided into lateral and medial portions, the leftward asymmetry is particularly robust for the medial compared to the lateral portion of this region (**Figure 2**).

Some have suggested that there is too much variability in IFG sulci, particularly in the PCI which comprise the landmarks of the frontal operculum in great apes, to obtain a reliable assessment of asymmetry in this region. Although variability is observed in the sulci comprising the frontal operculum of apes, others have argued that consistent criteria can be applied to this region to obtain reliable measurements. Specifically, the majority of cases of PCI bifurcation observed in the sample of chimpanzee brains follow a typical pattern in which the posterior ramus of the bifurcation (1) terminated at a more dorsal level than the anterior one and (2) tended to run more horizontally than the anterior ramus, which in turn ran more vertically and parallel to the central sulcus. Notably, Sherwood and colleagues gave a similar account for this usual pattern of PCI bifurcation in their cadaver specimens. Thus, most instances of PCI bifurcation do not present any serious ambiguity as to determining the posterior boundary of the pars opercularis. Because (1) PCI is usually seen as running vertically and roughly parallel to the central sulcus in the common sulcal pattern of the IFG of great apes and (2) in many instances it is likely that the posterior ramus of

a b

Figure 1 (a) The frontal operculum or inferior frontal gyrus (IFG) of a chimpanzee brain. The tissue lies between the precentral inferior sulcus (PCI) and fronto-orbital (FO) sulcus as defined by Cantalupo and Hopkins. (b) Mean asymmetry quotients (± SE) for the overall region of the IFG as well as divided into the lateral and medial portions of the gyrus. Asymmetry quotients (AQ) values are derived following the formula $AQ = (R - L)/((R + L) \times 0.5))$, where R and L refer to the summed area measures for the left and right cerebral hemispheres, respectively.

a b

Figure 2 (a) Chimpanzee manually gesturing toward a human when begging for food. (b) Mean asymmetry quotients (±SE) for three brain regions measured in chimpanzees, including the inferior frontal gyrus (IFG), planum temporale (PT), and motor–hand area of the precentral gyrus (KNOB). Chimpanzees that prefer to gesture with their right hand have a more leftward asymmetry in the IFG compared to chimpanzees who do not prefer to use the right hand. No significant differences in PT and KNOB are found for right- and non-right-handed chimpanzees.

a PCI bifurcation is, in fact, the subcentral anterior sulcus joining PCI, one can consistently adopt the criterion of choosing the anterior ramus of a PCI bifurcation as the posterior boundary for the pars opercularis. In fact, this criterion was consistently employed in previous reports. Lastly, individual differences in bifurcation patterns of FO are less frequent than in PCI; thus, my colleagues and I measured FO from MRI scans in the left and right cerebral hemispheres in a sample of 66 chimpanzees. A significant leftward asymmetry was found for FO, and asymmetries in the length of FO positively correlated with asymmetries in the entire region of the IFG ($r = 0.588$, $df = 67$, $p < 0.01$), suggesting that FO is a good estimate of lateralization in the inferior frontal region.

In summary, leftward morphological asymmetries, whether quantified for the tissue lying between PCI

and FO or by measuring the length of FO on successive 1 mm slices, are present in chimpanzees. The extent to which the morphological regions map to individual differences in cytoarchitectonics remains unknown but clearly warrants further investigation.

Potential Evolutionary and Functional Correlates of Broca's Area in Primates

The implication of Broca's area in speech and language functions in humans has theoretically stimulated a significant amount of work on the role of the homologous regions to Broca's in nonhuman primates. Inherent in many of these arguments is the question of whether human speech evolved directly from neural substrates associated with the production of vocalizations in closely related species or whether language and speech evolved from an earlier, manual gestural system of communication. Discussing different evolutionary theories of language evolution is beyond the scope of this article, but none of the existing data on the function of Broca's area in nonhuman primates strongly support any one theory or another; however, there are at least some data hinting at the function of Broca's area.

The homolog to Broca's area in monkeys does not appear to have any role in the production of species-specific vocalizations because lesions to this region do not disrupt either the frequency or the structure of sound production. Indeed, many have argued that the production of vocalizations by nonhuman primates is not under cortical control. However, a single cell recording study in macaques showed that stimulation of area 44 neurons from the frontal lobe simultaneously induced both digit and oral–facial movements. Similarly, early research performed in chimpanzees and recent work in macaques has shown that stimulation of the ventral portion of the motor cortex, including regions within the IFG, induces orofacial movements as well as movement of the larynx. Thus, the inferior frontal region, particularly area 44, seems to be involved in orofacial movements, movements of the larynx, and possibly hand or digit movements.

Rather than focusing on orofacial movement and its potential link to language and speech evolution, a substantial body of work has accumulated during the past 10 years on the role of the inferior frontal regions, notably area F5 in the macaque, in the perception and action of motor movements. Notably, so-called mirror neurons have been identified in area F5 in macaques (as well as other regions). Single cell recording studies in monkeys have shown that mirror neurons located in F5 respond when monkeys execute a grasping action or perceive another animal (or human) engaging in the same grasping action. In humans, a number of functional imaging studies have implicated Broca's area in production and recognition of simple grasping movements, orofacial movements, and imitation of gestures and mimed actions. It has been hypothesized that mirror neurons may have played a vital role in the evolution of brain systems underlying language and speech. Rather than focusing entirely on direct selection for motor systems associated with speech, it has been argued that the presence of mirror neurons in F5 (macaques) or Broca's area (humans) provides a neural substrate for the emergence of necessary cognitive links between recognition and production of complex motor actions, including social learning and imitation.

In chimpanzees, studies have examined the association between asymmetries in the inferior frontal region and lateralization in hand use for manual gestures compared to hand use for noncommunicative actions. Specifically, in a sample of 56 chimpanzees, asymmetries in the IFG were compared in subjects classified as right- or non-right-handed for manual gestures, and right-handed apes had a significantly greater leftward asymmetry than non-right-handed individuals. When the handedness of the same sample of chimpanzees was characterized for a noncommunicative motor action, simple reaching, no significant differences in asymmetry values for the IFG were found. Thus, differences in the asymmetry quotient scores of the IFG were specific to hand use for manual gestures.

Conclusions

Based on cellular anatomy, regions homologous to Broca's area are evident in apes and more distantly related primate species. In humans and great apes, the inferior frontal lobe is lateralized, with a significant majority of subjects exhibiting a left hemisphere asymmetry. It is unclear whether more distantly related primates show asymmetries in the frontal operculum, particularly in regions homologous to areas 44 and 45, but this should be investigated further. With the development of quantification of cytoarchitectonic regions using gray-level indices, the question of asymmetry in macaques and apes seems feasible. In addition, there are few studies in humans and virtually none in nonhuman primates examining whether asymmetries at the cellular level correlate with either morphological asymmetries in the same regions or behavioral asymmetries. Similarly, this issue also warrants further investigation, not just on asymmetries in the inferior frontal region but also in other parts of the cortex. The comparative data further suggest that asymmetries in the IFG of chimpanzees are associated with variation in hand use for gestural communication. In principle, these

data support theories proposing that lateralization for human speech evolved from an earlier, extant gestural communication system present in early hominids. Although possible, the results do not rule out other theoretical explanations for left hemisphere lateralization in human speech and other motor functions (i.e., handedness). Moreover, certainly other functional asymmetries could be linked to these regions. For example, there is evidence of population-level orofacial asymmetries in marmosets, rhesus monkeys, and chimpanzees, and perhaps these asymmetries might be associated with frontal operculum asymmetries. Lastly, additional studies are needed on neural connectivity between Broca's area and other cortical regions of the brain. The multimodal function of Broca's area seen in humans clearly implies connectivity between many other neural regions involved in multiple functions. It may be that differences in connectivity between Broca's and other brain regions account for the complexity in structure and function of this brain region in closely and more distantly related primates, including humans.

Brodmann's Areas

E G Jones, University of California, Davis, CA, USA

© 2009 Published by Elsevier Ltd.

This article is reproduced from the previous edition © 2004, Elsevier B.V.

The concept of the cortical area or cortical field has its origins in comparative cytoarchitectonic studies of the cerebral cortex made in the first decade of the twentieth century by a number of anatomists, particularly Bolton, Lewis, Campbell, Brodmann, C Vogt, and O Vogt. Among these names, that of Brodmann is perhaps the best remembered since the numbers he assigned to the cortical fields he identified have entered into the common vocabulary of cortical anatomy and physiology. The numbers simply indicate the order in which Brodmann studied them (Figure 1).

Cytoarchitectonics, and myeloarchitectonics, the complementary technique that followed it, have as their basis the recognition that different regions of the cerebral cortex have reproducible differences in cell and fiber layering and packing density. Architectonics is the art of determining where the boundaries fall between different areas. The early impetus to this type of study came first from phrenology, then from demonstrations of the electrical excitability of the motor cortex, and from the recognition of the dependence of vision on posterior regions of the cerebral cortex. The identification of cytoarchitectonic areas and their borders thus became a search for areas of the cerebral cortex with distinct functions. The visual, motor, and somatic sensory areas were the first identified and later auditory, associational, and many further subdivisions of the original areas have been described. In the human brain Brodmann recognized nearly 50 areas, Campbell less than 20, C Vogt and O Vogt more than 200. Progressively fewer were found in the cortices of lower mammals, though Brodmann argued that the sensory and motor areas could be identified in all. At the moment, most neuroscientists would probably agree that Brodmann's divisions come somewhere near what seems reasonable, though after a period of the converse, the trend now appears to be going in the direction of a finer and finer parcellation, akin to that of the Vogts, as functional subdivisions are recognized within areas by new techniques and as imaging studies reveal new functional localizations. Brodmann's numbered fields have been given names in other nomenclatural schemes, and individual areas in modern experimental studies have sometimes been given specific names, but in general there is a remarkable correspondence between schemes. Where new fields have been described, they commonly represent further parcellations of larger regions of cortex identified as single fields by Brodmann.

The persistence of the architectonic field concept and its resurgence after the attacks on it of the 1950s and 1960s, stem from the facts that structural variation can be seen across the cortex and that many of these structural variations can be correlated with distinct patterns of input–output connections, with distinct physiological properties, and often with definable aspects of sensation, perception, cognition, and motor control.

A modern definition of a cortical field would probably encompass the following points: (1) It is an area of singular cellular and fiber architecture often with boundaries that are particularly sharp and recognizable even by the inexperienced eye. The border between areas 17 and 18 in the visual cortex is probably the most clear-cut. Borders between other areas are not always so sharp and one area may appear to give place to another over a gradient of architectonic change. This may represent a truly blurred border or be imposed by stretching of the cortex in the floor of a sulcus or on the crown of a gyrus and then present a trap for the unwary who may see a distinct field where one does not exist. (2) It is an area that receives afferent fibers from the major population of cells in a defined relay nucleus of the thalamus. This input stops abruptly at an architectonic border and often serves to demonstrate the position of a sharp border when architectonics alone suggests a gradient of change. There appears to be no overlap between inputs from different specific thalamic nuclei to adjacent fields. Fibers arising from so-called nonspecific thalamic nuclei and from subsidiary populations of cells in a relay nucleus, however, often disregard these borders. (3) It receives a set of corticocortical and commissural axons from a limited, defined, and constant set of other cortical areas. These tend to respect the same boundaries delimited by architectonics and by the distribution of thalamic afferents. (4) It gives rise to a constant set of output connections to a limited and constant set of cortical and subcortical targets, including returning fibers to those thalamic nuclei (specific and nonspecific) from which it receives inputs. (5) A topographic map of a receptive periphery such as the visual field, auditory space, the body surface, or of the body's musculature can be detected in certain cortical fields by evoked potential or microelectrode mapping or by electrical stimulation

Figure 1 Brodmann's map of the areas in the human cerebral cortex. (Top) lateral view; (bottom) medial view. From Brodmann K (1910) Feinere Anatomie des Grosshirns. In: Lewandowsky M (ed.) *Handbuch der Neurologie, Vol. 1: Allgemeinere Neurologie*, pp. 206–307. Berlin: Springer.

of the field. In association with these maps, the neurons in the field may display physiological properties that distinguish them from those in other fields. Aggregation of subpopulations of cells with different functional properties can occur in a field and sometimes, as in some of the visually related areas, these aggregations may have definable anatomical characteristics. These characteristics may then serve as a basis for further subdividing the cortical field. (6) Deactivation of a field by ablation, cooling, or injection of drugs may lead to loss of a particular sensory or motor function or of other behaviors. (7) The field may show a characteristic pattern of histochemical or immunocytochemical staining different from that of its neighbors. The so-called chemoarchitectonic borders defined in this manner commonly coincide with those defined by cell and fiber staining.

Obviously, not every cortical field can be demonstrated to meet all these criteria, primarily because of

the difficulty in eliciting physiological responses in many of them or in defining the nature of a deficit resulting from their deactivation. Similarly, arguments invariably ensue about the sharpness of certain architectonic borders and about whether particular architectonic changes indicate the existence of new fields or simply variation within a field, a variation perhaps resulting from a local concentration of cells projecting to the same site or with a particular physiological property. The connectional basis of the cortical field, especially that defined by connections with a particular principal thalamic nucleus, probably remains the most reliable anatomical guide for deciding when a region of cortex should be called a cortical area or field independent of its neighbors and for determining its boundaries. It is to be hoped that eventually molecular-genetic markers will be discovered that determine this reproducible parcellation of the cerebral cortex on the basis of structural and functional properties.

CADASIL (Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy)

A Joutel, INSERM U740, Paris, France

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Arteries are specified into different calibers and types of vessels to perform different functions. Schematically, the major arteries of the trunk are elastic arteries of large diameter and low resistance that provide the resilience these arteries need to absorb the hemodynamic stress of cardiac systole, and to release this energy in the form of sustained blood pressure during diastole. Conversely, distal arteries are muscular arteries of small diameter and high resistance that are critically important for the development of resting vascular tone, preventing peripheral vascular collapse, and for local regulation of blood flow, particularly in the brain. Pathological changes of distal arteries in the brain produce small deep infarcts or hemorrhages and widespread white-matter changes. Cerebral small-artery diseases are recognized as being the origin of a major proportion of abnormal conditions. They are responsible for 20–30% of all strokes and are the leading cause of vascular dementia. The molecular and cellular bases of small-artery diseases of the brain are poorly understood, although three major risk factors have been identified, including aging, arterial hypertension, and diabetes. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a recently identified autosomal dominant small-artery disease, caused by mutations in the Notch 3 receptor. The fact that CADASIL is a prototypical small-artery disease renders it a paradigm for studying the pathobiology of related diseases. In this article, the core findings on CADASIL and the Notch 3 signaling pathway are reviewed.

CADASIL

The story of this disease began back in the early 1990s, with the clinical, neuropathological, and molecular characterization of a large affected French pedigree. Since then, CADASIL has been diagnosed in several hundred pedigrees worldwide and now emerges as the most common form of hereditary stroke and vascular dementia. The onset of symptoms can occur from ages 25 to >60 years, but most commonly begins during the fourth to fifth decade. Notably, the disease manifests irrespective of vascular risk factors. Affected patients exhibit a variety of symptoms, including transient ischemic attacks and strokes (85%), cognitive deficits (60%), migraine with aura (30%), psychiatric disorders (30%), and epilepsy (up to 10%). The overall course of the disease is highly variable but gradually leads to cognitive decline, dementia, and premature death of the patient about 15–20 years after clinical onset. On magnetic resonance imaging (MRI) of the brain, there is evidence of widespread white-matter hyperintensities on T_2-weighted images, subcortical lacunar infarctions on T_1-weighted images, and old cerebral microhemorrhages on T_2*-weighted images or gradient-echo images. Virtually no therapies are available to modulate the progression of the disease.

On neuropathological examination, CADASIL brains show a diffuse myelin loss and multiple, small, deep infarcts located within the basal ganglia, the deep white matter, and the brain stem. The underlying vascular lesion is a unique nonatherosclerotic, nonamyloid arteriopathy involving primarily the small penetrating brain arteries. The arteriopathy is characterized by prominent alterations of vascular smooth muscle cells, which ultimately degenerate, and the thickening of arterial walls by the accumulation of various extracellular matrix components. The defining pathological hallmark is the deposit of granular osmiophilic material (GOM), of yet uncertain composition, within the basement membrane of smooth muscle cells. Similar arterial changes, particularly GOM deposits, are detected in the small arteries of many other organs, indicating that CADASIL is actually a systemic arteriopathy, although the symptoms are restricted to the central nervous system (Figure 1).

The mutated gene was identified through a positional cloning approach. The CADASIL locus was first mapped to the short arm of chromosome 19 by linkage analysis in a large affected family. Analysis of additional families revealed that CADASIL is a genetically homogeneous disorder. The critical region was narrowed to an 800 kb interval by identification of cross-over events in these families. CADASIL patients were shown to exhibit deleterious mutations in the *Notch3* gene contained within this critical interval. These mutations were absent in control individuals and cosegregated with the disease phenotype in affected families, demonstrating that *Notch3* is the causative gene of CADASIL.

The Notch 3 Receptor

Structure of Notch 3

NOTCH3 belongs to the *NOTCH* gene family, which encodes evolutionarily conserved single-pass

Figure 1 The characteristic arterial lesions in CADASIL patients. Section of a brain artery from a control individual (a) and an elderly CADASIL patient (b) (hematoxylin and eosin staining). The CADASIL patient's artery exhibits prominent thickening of the vessel wall, with accumulation of eosinophilic material, and disappearance of smooth muscle cells. Electron micrograph (right) of a CADASIL brain artery shows degeneration of smooth muscle cells and numerous deposits of granular osmiophilic material (arrows) located within the basement membrane of smooth muscle cells. Scale bar 30 μm = (a, b). Micrograph courtesy of MM Ruchoux.

transmembrane receptors. The family includes the *Drosophila melanogaster Notch* gene and four mammalian *Notch* genes (*Notch1–4*). Notch receptors share a common structural organization: a large extracellular domain containing a characteristic tandem array of 29–36 epidermal growth factor-like repeats (EGFRs) and three cysteine-rich Notch/Lin12 repeats, followed by a short transmembrane domain and an intracellular domain containing the RAM domain, six ankyrin repeats flanked by two nuclear localization signals. Notch 3 receptor is a 2321-amino-acid-long protein; it contains all typical Notch motifs – namely, an extracellular domain with 34 EGFRs. Notch 3, as the other Notch receptors, is synthesized as a precursor protein which is cleaved (S1) in two during the transport to the cell surface, forming a large ~210 kDa ectodomain ($Notch^{ECD}$) and a ~97 kDa membrane-tethered intracellular domain ($Notch^{TMIC}$). These products remain associated at the cell surface as a heterodimer through noncovalent dependent interactions (Figure 2).

Figure 2 Schematic diagram of Notch signaling in mammals, showing S1, S2, and S3 cleavage steps and the RBP-Jκ proteins (see text for discussion). HDAc, histone deacetylase; CoR, corepressor.

Functional Role of Notch 3 in the Vessel

The Notch signaling pathway plays a central role in the development and maturation of most vertebrate organs, with pleiotropic effects depending on dose and context. In most cases Notch signaling blocks differentiation toward a primary differentiation fate in a cell and instead directs the cell to a second, alternative differentiation program or forces the cell to remain in an undifferentiated state. In addition to the classical role of 'gatekeeper against differentiation,' recent studies demonstrated that Notch signaling may also be instructive – that is, Notch signaling can actively promote a particular cell fate.

Analysis of the Notch 3 expression pattern in late embryos and adult tissues provided the first insight into its role. Examination of sections of various organs, including the brain, heart, skeletal muscle, lung, kidney, urinary bladder, and intestine, using *in situ* hybridization and immunohistochemistry, revealed that Notch 3 is predominantly expressed in blood vessels, with a preferential expression in arteries. Within the arteries, expression of Notch 3 is confined to smooth muscle cells, being absent in endothelial cells and adventitial fibroblasts. Notably, Notch 3 expression in not detected in the media (muscular wall) of large, elastic arteries. Moreover, Notch 3 is not expressed in visceral smooth muscle cells.

Careful analysis of mice completely lacking *Notch3* (*Notch3*$^{-/-}$) established a critical role for Notch 3 in the structural and functional integrity of small arteries, particularly of brain arteries. *Notch3* null mice are viable and fertile, demonstrating that the *Notch3* gene is not essential for embryonic development or fertility in mice. Adult *Notch3*$^{-/-}$ mice show no overt phenotype. However, upon detailed analysis, *Notch3*$^{-/-}$ mice were found to exhibit marked arterial defects affecting the distal arteries, but, remarkably, sparing the large elastic arteries. Mutant arteries are enlarged, with a thinner muscular coat and prominent alterations in the shape and size of smooth muscle cells. At the functional level, arterial myogenic responses are strongly impaired. In arteries of the cerebral circulation, myogenic responses underlie the autoregulation of cerebral blood flow (i.e., the maintenance of constant blood flow during variations in systemic blood pressure). Specifically, in response to angiotensin II or phenylephrine injections, *Notch3*$^{-/-}$ mice show normal arterial blood pressure elevations but strongly impaired cerebral blood flow (CBF) autoregulation: the slight increase in CBF elicited by acute induced hypertension in wild-type mice is greatly exacerbated in *Notch3*$^{-/-}$ mice.

Further investigations established that Notch 3 cell autonomously regulates the arterial differentiation and postnatal maturation of vascular smooth muscle cells. Specifically, in *Notch3* null mice, the postnatal maturation stage of smooth muscle cells, that lends arterial vessels their final shape, is deficient, and there is strong evidence that smooth muscle cells in mutant arteries lack an arterial fate and are converted to a venous fate. Remarkably, endothelial cells in mutant arteries retain an arterial fate. Until recently, it was thought that the genetic program specifying artery and vein identity was restricted to the endothelial cells. The current findings indicate that arteries are genetically distinct from veins also at the level of smooth muscle cells. Moreover, the signaling pathways controlling arterial identity of these two vascular cell types are regulated independently. Finally, while it has been shown that arterial specification of endothelial cells is required during early embryonic vascular development, to maintain boundaries between arteries and veins, these data indicate that arterial differentiation of smooth muscle cells is required to ensure integrity of the structure and function of small arteries in the adult (Figure 3).

How *Notch3* expression regulates the postnatal arterial maturation and differentiation of smooth muscle cells is not fully understood. *In vitro* studies suggest a direct effect of Notch 3 on the actin cytoskeletal dynamics of smooth muscle cells. Cultured smooth muscle cells expressing a constitutively active Notch 3 receptor exhibit dramatic cell shape changes, with a triangular or polygonal shape and very few cytoplasmic expansions and protrusions as compared to control cells. Moreover, smooth muscle cells expressing the constitutively active Notch 3 receptor show prominent actin stress fibers, an increased steady-state level of polymerized actin, and higher resistance to actin-depolymerizing drugs.

The Notch 3 Signaling Pathway

Activation of Notch receptors is triggered by interactions with ligands of the Delta/Jagged family expressed on juxtaposing cells. Ligand binding to Notch proteins triggers a tumor necrosis factor-α converting enzyme/disintegrin metalloproteinase (TACE/ADAM)-mediated cleavage (S2) within the extracellular juxtamembranous region, followed by a presenilin/γ-secretase-dependent proteolytic (S3) release of the Notch intracellular domain (NICD) from the membrane. NICD translocates to the nucleus and forms a transcriptional activation complex with a DNA-binding protein termed CBF1/RBP-Jκ, which regulates the transcription of target genes by displacement of corepressors and simultaneous recruitment of coactivators. A fairly limited number of Notch/RBP-Jκ target genes have been identified, and among these are the *Hes* and *Hrt* gene families that comprise in the mouse six and four members, respectively. *In situ* hybridization and real-time reverse transcriptase–polymerase chain reaction (RT-PCR) analysis showed that the expression level of these genes was unaltered in arteries of *Notch3*$^{-/-}$ mice, strongly suggesting that *Notch3* effects in arteries are not mediated by these genes. Thus the Notch 3 direct target genes in small vessels remain to be identified.

CADASIL: A Disordered Notch 3 Signaling Pathway?

Mutation Spectrum

Mutational analysis in a very large number of CADASIL families has revealed several key features. First, all mutations are located within the 23 exons that encode for the 34 EGFRs. Second, the mutations are strongly clustered within EGFR2–EGFR5, repeats that have no recognized specific function. Third, the mutations are highly stereotyped: the vast majority are missense mutations and a very few are splice site mutations or small in-frame deletions, but remarkably, all of the mutations lead to an odd number of cysteine residues. These data provided the basis for setting up a robust and reliable diagnostic test of CADASIL.

Figure 3 Continued

Accumulation of Aggregated Notch 3^{ECD} Protein

The highly stereotyped nature of pathogenic mutations detected in CADASIL patients suggest that an aberrant homo- or heterodimerization of Notch 3, due to abnormal disulfide bridging, may be involved in the pathogenesis of this condition. In tissues from CADASIL patients, immunohistochemical and biochemical studies show an abnormal accumulation of aggregated Notch 3 protein within the brain vessels as well as in the vessels of many other organs (e.g., kidney, skeletal muscle, skin). Importantly, there is a selective accumulation of the ectodomain of Notch 3 (Notch 3^{ECD}) without any accumulation of the Notch 3^{TMIC}. Immunoelectron microscopy revealed that Notch 3^{ECD} accumulates at the plasma membrane of smooth muscle cells. However, whether Notch 3^{ECD} is a component of GOM is a matter of debate. Amounts of Notch 3 transcripts are essentially identical in both CADASIL and control individuals, indicating that Notch 3 accumulation is unlikely to result from an increased synthesis of Notch 3 mRNA but rather from an impaired clearance of the protein.

Notch 3 and GOM aggregates are pathological hallmarks of CADASIL; early in the pathogenesis, they can be detected in the blood vessels before the appearance of clinical symptoms and brain MRI abnormalities. However, the question remains as to how they participate in the pathogenic process. The notion that ultrastructural alterations of smooth muscle cells can be detected prior to GOM and Notch 3^{ECD} deposits in CADASIL patients (or mouse models recapitulating the CADASIL arterial lesions) suggests that the deposits are an outcome rather than a primary causative event in the CADASIL pathogenic process (Figure 4).

Impact of CADASIL Mutations on Notch 3 Receptor Activity

The fact that all CADASIL mutations result in an odd number of cysteine residues within a given EGFR has suggested that CADASIL disease is associated with a gain-of-function activity of mutant protein. Gain-of-function mutations in principle include (1) hypermorphic mutations which elevate gene activity, (2) dominant-negative mutations which reduce wild-type gene activity, and (3) neomorphic mutations in which mutant protein has additional activity. However, it remains possible that CADASIL mutations are hypomorphic mutations that lower activity of the receptor, since there is ample evidence that Notch function is sensitive to gene dosage. Additionally, loss of *Notch3* in the mouse results in smooth muscle cell alterations, although they do not appear to phenocopy those seen in human CADASIL patients.

Effects of CADASIL mutations on Notch 3 signaling have been investigated in cultured cells. Contrasting with the highly stereotyped nature of the mutations, these *in vitro* studies failed to reveal an underlying common mechanism. On the one hand, a number of mutations, including those located in the mutational hot spot region (EGFR2–EGFR5), appear to retain the ability to activate RBP-Jκ in response to Delta/Jagged binding, although some mutations exhibit impaired maturation and decreased cell surface expression of the receptor. On the other hand, a few mutations have been identified within EGFR10–EGFR11, a domain required for ligand binding. *In vitro*, these mutations show strongly reduced signaling activity. Interpretation of these data is complicated by the fact that these experiments do not mimic the effect of *Notch3* mutations in human arteries, since mutant Notch 3 is vastly overexpressed, and, importantly, Notch 3^{ECD} accumulation at the smooth muscle cell plasma membrane, which could titrate the ligand and inhibit the normal pathway, is not recapitulated in these assays. Additionally, wild-type Notch 3 expressed in cultured cells may have confounded the interpretation of the data. Moreover, only the response to membrane-bound ligands of the Delta/Jagged families was investigated, and additional ligands have been now identified.

Conclusion and Future Prospects

CADASIL, an inherited small-vessel disease, emerges as the most prevalent heritable condition leading to stroke and vascular dementia. The causative gene encodes a transmembrane receptor, Notch 3, primarily expressed in smooth muscle cells of small arteries.

Figure 3 Specific arterial defects in *Notch3*$^{-/-}$ mice. (a, b) Semithin sections of the middle cerebral artery from *Notch3*$^{+/+}$ and *Notch3*$^{-/-}$ mice; the mutant artery is enlarged, with a flattened elastica lamina. (c, d) α-Smooth muscle actin immunostaining on wild-type and *Notch3*$^{-/-}$ arteries, showing that, in the mutant artery, smooth muscle cells are present but have an abnormally thin profile. (e, f) Electron micrographs of *Notch3*$^{+/+}$ and *Notch3*$^{-/-}$ arteries show the marked alteration in the shape and size of smooth muscle cells in the *Notch3*$^{-/-}$ artery. (g, h) Semithin sections of a wild-type and mutant aorta show no defect in the *Notch3*$^{-/-}$ sample. (i, j) *Notch3*$^{+/+}$ and *Notch3*$^{-/-}$ mice, heterozygous for the arterial smooth muscle-specific *SM22α-lacZ* transgene, were assayed for smooth muscle cell arterial identity. X-Gal staining is restricted to arterial smooth muscle cells in the *Notch3*$^{+/+}$ sample and is markedly reduced in the *Notch3*$^{-/-}$ artery, indicating a defective arterial fate of smooth muscle cells. a, artery; v, vein. Scale bars = 45 μm (a, b), 34 μm (c, d), 8 μm (e), 14 μm (f), 34 μm (g, h), 85 μm (i, j).

Figure 4 Notch 3^{ECD} ($N3^{ECD}$) abnormally accumulates at the plasma membrane of smooth muscle cells in CADASIL patients. (a) Protein extracts prepared from CADASIL and control human brains and from of a control human artery were immunoblotted with the anti-Notch 3^{IC} monoclonal antibody 5G7 (bottom) and the anti-Notch 3^{ECD} 5E1 monoclonal antibody (top). The 210-kDa Notch 3^{ECD} and the 97-kDa Notch 3^{TMIC} ($N3^{TMIC}$) are detected in the control artery but not in the control brain, owing to the very low expression level of Notch 3 and to its expression being restricted to smooth muscle cells. In the CADASIL brain, there is a prominent accumulation of the Notch 3^{ECD} fragment, but no accumulation of the 97-kDa Notch 3^{TMIC} fragment. (b, c) Brain paraffin sections from a control individual (b) and a CADASIL patient (c) were immunolabeled with the anti-Notch 3^{ECD} monoclonal antibody 1E4. In the control brain, Notch 3 antibody labels the arterial wall, with a weak and homogeneous staining. By contrast, the CADASIL brain artery exhibits a characteristic strong and granular staining. Scale bar = 85 μm. (d) CADASIL brain sample was processed for immunoelectron microsocopy analysis using the 1E4 anti-Notch 3^{ECD} antibody. Numerous granular osmiophilic material deposits (large arrow) are observed within the basal lamina (square), other granular osmiophilic material deposits spread far away, within the vessel wall (star). Notch 3 immunolabeling (black dots) is clustered at the cell surface of smooth muscle cells, closely arranged around the granular osmiophilic material. ec, endothelial cell; Lu, lumen) (ultrathin section stained with uranyl acetate and lead citrate; ×20 000).

Recent data document a critical role for Notch 3 in the elaboration and maintenance of small arteries. However, whether CADASIL arises from an alteration of the Notch 3 signaling pathway remains a fundamental yet unresolved issue. Notch 3 signaling components are attractive candidates for their involvement in other small-vessel diseases and as potential therapeutic targets in small-vessel diseases.

Cadherins and Synapse Organization

S-H Lee and L F Reichardt, University of California at San Francisco, San Francisco, CA, USA

Introduction

Cadherins constitute a large superfamily of cell-to-cell adhesion molecules defined by the presence of multiple copies of a unique domain termed the cadherin motif in their extracellular domains. Cadherins mediate the formation of many types of cell–cell junctions, including adherens junctions and desmosomes in epithelia, adherens junctions and complexus adherens in endothelia, intercalated disks in cardiac myocytes, and synaptic junctions between axons and their target cells. The vast majority of the cadherins are transmembrane proteins with functionally important interactions mediated by both extracellular and cytoplasmic domains. Some cadherins also have functionally significant *cis* interactions that control their oligomerization and the strength of cell-to-cell adhesion.

Most of the more than 80 mammalian cadherins are expressed in the nervous system and many have been shown to be present at synapses and in some instances to regulate synapse development or function. Synapses are formed through a series of reciprocal inductive events in which contact between axons and their targets (muscle at the neuromuscular junction and dendrites in the central nervous system (CNS)) is followed by assembly of pre- and postsynaptic constituents. Many cadherin members function in synapse formation and plasticity (Table 1).

The classical cadherins were identified initially as Ca^{2+}-dependent cell adhesion molecules that mediated primarily homophilic adhesion. One of the cadherin's motifs present in a cadherin contain hydrophobic residues including one or two tryptophan residues mediating interactions with the same cadherin present on other cells. Gene sequence analysis has enlarged the cadherin superfamily membership, which can be subdivided into several subfamilies based on homology, structure, and function. The classical cadherins have been divided into type I and type II subfamilies, distinguished by the presence of conserved amino acid residues in the most N-terminal cadherin motif which results in differences in the structures of their interaction interfaces. All classical cadherins in vertebrates are single-pass transmembrane proteins that contain five tandem repeats of the cadherin motif in their extracellular domains and a conserved cytoplasmic domain that mediates through linker proteins named catenins association with the F-actin cytoskeleton. Invertebrates contain similar cadherins that also mediate interactions through the catenins with the F-actin cytoskeleton but have different numbers of extracellular cadherin motifs. The desmosomal cadherins, the desmogleins and desmocollins, constitute a distinct family of cadherins that mediate through their cytoplasmic domains interactions through the plakophilins and desmoplakins with intermediate filament networks. Because they are not found at synapses, they are not discussed further in this article. Additional cadherin subgroups include the seven-pass transmembrane or Flamingo cadherins, and the protocadherins. In addition, there are a number of proteins containing the cadherin motif that do not fit into these subfamilies, including the receptor tyrosine kinase c-ret, Fat, Ksp-cadherin, and LI-cadherin. c-ret is stimulated by the GDNF family of neurotrophic factors and is not discussed further in this article. Atypical glycosyl phosphatidylinositol-linked cadherin, T-cadherin, is expressed in neurons and regulates neurite outgrowth.

Classical Cadherins

Each member of the classical cadherins mediates primarily homophilic interactions with the same cadherin on neighboring cells. Of particular interest, several members have been shown to be associated with networks of interconnected neurons within the brain and to be present at synapses, suggesting a role in establishing specific synaptic connections. Type I cadherins, such as N-, E-, P-, and R-cadherins, and many different members of type II cadherins, such as MN-cadherin and cadherin-6, -8, and -11, are observed at the synapses.

At synapses, cadherins are typically found in puncta adherens-like structures within or surrounding synapses, suggesting they play a role in organizing synaptic membrane domains similar to their roles in organizing adherens junctions and surrounding membrane domains in epithelial cells. In epithelial cells, cadherins typically collaborate to form adherens junctions with a subfamily of the immunoglobulin superfamily, named nectins. Nectins promote cell adhesion but exhibit strongest interactions with related, but not identical, family members. In contrast to epithelia, synapses are not symmetric and it is not clear how cadherins functioning alone can ensure that axons form synapses with dendrites as opposed to other axons. Work has demonstrated that differential transport of different nectins to axonal versus dendritic

Table 1 The synaptic phenotypes upon perturbation and suggested function of main cadherin components

Class	*Molecules*	*System*	*Mechanism of inhibition and synaptic phenotypes*	*Function*
Classical cadherin	N-cadherin	Chick optic tectum *in vivo*	Ab inhibition: overshooting of retinal axons that fail to stop in normal target layers	Target recognition
		Thalamic slice culture	Ab inhibition: overshooting of thalamic afferent beyond layer IV to the pial surface	Target recognition
		Drosophila visual system	Genetic mutation: disruption of target selection by R1–R8 cell axons in the lamina and medulla	Target recognition
		Cultured hippocampal neurons	Dominant negative inhibition: longer dendritic protrusions; smaller spine head width; decreased presynaptic puncta; inhibition of late-phase LTP	Synaptic maturation
	Cadherin-11	Mouse hippocampus	Genetic mutation: increased LTP in CA1 region; altered fear- and anxiety-related responses	Synaptic plasticity
	β-Catenin	Hippocampal pyramidal neurons *in vivo* and *in vitro*	Genetic mutation: disruption in the localization of synaptic vesicles and synaptic transmission	Maturation of synapse
		Cultured hippocampal neurons	Phosphorylation mutant (Y654F): increased spine β-catenin levels; increased PSD size and mEPSC frequency	Synaptic plasticity?
	αN-catenin	Cultured hippocampal neurons	Genetic mutation: increased dendritic spine length and decreased spine stability Overexpression: increased spine density and stabilization of spines	Maturation of synapse
	p120 catenin	Hippocampal pyramidal neurons *in vivo* and *in vitro*	Genetic mutation: reduced dendritic spine and synapse densities *in vivo* and *in vitro*; misregulated Rho family GTPase activity	Maturation of synapse
	δ-Catenin	Hippocampal pyramidal neurons *in vivo*	Genetic mutation: cognitive defect; impaired short-term and long-term plasticity	Maturation of synapse; synaptic plasticity
Protocadherin	Protocadherin-γ	Mouse spinal cord	Genetic mutation: decreased spinal cord synapse density, reduced synaptic current amplitude, sensorimotor defect	Induction or maturation of synapse
Seven-pass transmembrane cadherin	Flamingo	*Drosophila* visual system	Genetic mutation: inappropriate target selection by R1–R6 cell axons in the lamina; disruption of local pattern of synaptic terminals in the medulla	Target recognition

compartments promotes the preferential interactions observed by axons with dendrites. In this manner, the nectins may help ensure that only appropriate synaptic contacts are formed or stabilized within the CNS. Mutations of several cadherin genes or perturbation of cadherin function impair normal synapse development and function in vertebrates and invertebrates.

Cadherins appear to play roles in several stages of synapse development. Synaptic adhesion molecules, including the cadherins, are important in directing the localization and specificity of interactions between presynaptic axons with postsynaptic targets. In many instances, cadherins are required for this target selection process. In the *Xenopus* retina, for example, impairment of N-cadherin function slows axon growth, thereby preventing axons from reaching their normal targets in the optic tectum (**Figure 1**). In elegant experiments analyzing the pattern of synaptic connections formed by photoreceptor axons in *Drosophila*, N-cadherin appears to mediate homophilic and attractive interactions between the growth cones of photoreceptors and their targets that precede

Figure 1 Importance of cadherin complex in synapse development. Examples of synaptic phenotypes resulting from perturbations of cadherin and catenin functions are shown. (a, a′) N-cadherin regulates lamina-specific connectivity in the brain. Injection of N-cadherin monoclonal antibody-producing hybridoma into chick optic tectum results in extension of some retinal axons past their normal target in laminae B and D in the optic tectum *in vivo*. Retinal axons were visualized by DiI injection. (b, b′) In *Drosophila* N-cadherin is required for R cell axon target connectivity. In cadherin mutant animals, the normal projection patterning by R1–R6 axons is disrupted and R cell growth cones fail to extend to their normal targets. DiI was injected into single ommatidia. (c, c′) β-Catenin plays a role in synaptic vesicle localization and presynaptic assembly. Deletion of β-catenin results in a reduction of vesicle number per synapse in the stratum radiatum of the CA1 hippocampus. (d, d′) p120catenin regulates dendritic spine development *in vivo*. Pyramidal neurons from the CA1 hippocampus which lacks p120 catenin exhibit reduced spine number compare to control neurons. Pyramidal neurons were visualized by Golgi staining. (e, e′) N-cadherin regulates dendritic spine morphogenesis of hippocampal pyramidal neurons. Neurons expressing cN390Δ, an N-cadherin mutant which lacks its extracellular domain, form immature and elongated filopodial-like spines and spines with bifurcated heads. Cells were stained with F-actin (green). Transfected cells are labeled in red. synaptic partner selection. Inhibition of N-cadherin function disrupts laminar-specific connectivity in chick optic tectum and results in overshooting of thalamic afferents beyond layer IV to as far as the pial surface in cortical–thalamic slice cultures. Cadherins are also required for synapse maturation. For presynaptic maturation, active zone proteins and synaptic vesicles are concentrated at synaptic contacts. During CNS development, presynaptic compartments are known to be assembled from preassembled packets of active zone proteins, synaptic vesicles, and associated synaptic proteins, and they are trapped at the sites of cell–cell contacts. The N-cadherin complex plays an important role in localizing synaptic vesicles at nascent synapses *in vitro*. In the CNS, many excitatory synapses are made onto dendritic spines, actin filament-based protrusions. N-cadherin-mediated contact stabilization and modulation of the actin cytoskeleton through interacting signaling molecules are essential for proper spine maturation *in vitro*. Finally, cadherins have a role in synaptic efficacy *in vivo*. The deletion of *cadherin-11* alters mouse behavior and synaptic plasticity. Taken together, these results indicate that cadherins have roles in synaptic development, specificity, and function. It seems almost certain that mutations in the many additional genes encoding classical cadherins will also prove to have interesting synaptic and

behavioral phenotypes, especially when mutations are combined to reduce functional redundancy. The large number of neuronally expressed classic cadherins complicates studies on their neural functions because of the potential for compensation.

In considering the roles of cadherins in directing synaptic development and function, it is important to consider the proteins that are associated with cadherins (Figure 2). Through these proteins, cadherin ligation regulates several distinct signaling pathways which impinge on neuronal development and synapse development and function. Two major classes of proteins associate directly with the classic cadherins: members of the β-catenin (β-catenin and plakoglobin) and p120catenin (p120ctn) (p120ctn, δ-catenin, p0071, and armadillo repeat protein deleted in velocardio-facial syndrome (ARVCF)) families. Members of each family contain a central domain consisting of several armadillo (arm) repeats and flanking N- and C-terminal domains. The cadherin cytoplasmic domains bind to the arm repeats of these proteins.

β-Catenin controls cell adhesion and cytoskeletal organization through interactions with α-catenin and with Rho family GTPase regulators, such as

Figure 2 Protein constituents and interactions in cadherin adhesion complexes. Classical cadherins interact with catenins. Both cadherins and catenins also interact with diverse additional proteins, thereby regulating many intracellular signaling pathways. Reported interacting partners of cadherin, β-catenin, α-catenin, p120 catenin, and δ-catenin are listed. The proteins which have been shown to interact with cadherin components in the synapse are shown in blue. Cadherin signaling regulates the actin cytoskeleton through p120-catenin family-mediated regulation of Rho family GTPases and cortactin. Through association with cadherins mediated through β-catenin, α-catenin provides a physical link to actin-binding proteins and the F-actin cytoskeleton.

Ras-GAP-like protein with IQ motifs (IQGAP) and Rho GAP involved in the β-catenin-*N*-cadherin and NMDA receptor signaling (RICS). Some of these interactions are known to be competitive with cadherin binding. In addition, the presence of β-catenin is required for activation of the classical wingless-type MMTV integration site (Wnt) signaling pathway, and the role of β-catenin in this pathway is mediated through interactions with transcription factors such as the T-cell factor (TCFs), negative regulators such as ICAT (inhibitor of β-catenin and TCF), and regulators of protein stability such as adenomatosis polyposis coli (APC), axin, and glycogen synthetase kinase 3-β (GSK3β). Phosphorylation of cadherins and β-catenin regulates their interactions, functions, and turnover, and many protein kinases and phosphatases have been shown to control the stability of the cadherin–β-catenin complex following extracellular stimuli. In the synapse, for example, neural activity induces dephosphorylation and redistribution of β-catenin into spines, where it interacts with cadherins to influence synaptic size and strength. Brain-derived neurotropic/factor (BDNF) has been shown to regulate tyrosine phosphorylation and interaction of β-catenin with cadherin, thereby modulating synaptic vesicle localization and synapse density *in vitro*. Within cadherin-centered junctions, a major role of β-catenin is to provide a link from cadherins to α-catenin, which in turn promotes interactions with the F-actin cytoskeleton. The presence of β-catenin and α-catenin is required to promote strong adhesion between cells. The association between these two catenins is mediated through the N-terminal region of β-catenin, a domain containing multiple serine/threonine phosphorylation sites that regulate separately the association with α-catenin and β-catenin degradation. Dendritic spines on αN-catenin-deficient neurons are unstable and highly mobile. Loss of αN-catenin reduces the stability and size of synaptic contacts, possibly by disruption of the cadherin–F-actin linkage or perturbation of cadherin-mediated regulation of F-actin organization.

β-Catenin and most p120ctn family proteins include C-terminal post synaptic density-disc large-Z01 protein (PDZ) domain interaction motifs. Through these, cadherins can associate indirectly with the PDZ domain-containing scaffold proteins know to be crucial for synapse organization. The β-catenin C-terminus binds the Cask-Mint-Veli complex, the neuronal isoform of MAGI (MAGUKS (membrane-associated guanylate kinases) with inverted domain structure), S-SCAM (synaptic scaffold molecule), and additional PDZ domain-containing proteins, some of which modulate β-catenin's transcriptional functions. Through its C-terminus, β-catenin functions as a scaffold that promotes localization of the Cask-Mint-Veli complex and synaptic vesicles to synapses. β-Catenin has also been shown to promote dendrite growth and arborization through pathways independent of Wnt signaling. Through its interaction with MAGI-1b, β-catenin has been shown in nonneuronal cells to recruit the phosphatase phosphatase and tensin homlog (PTEN) to adhesion sites where it promotes their stability through localized suppression of Src-induced invasiveness in cancer cells. Src suppression is likely to promote adhesion site stability through control of Rho family guanine nucleotide exchange factors (GEFs) and possibly Rho family effectors such as myosin II. Through these interactions, PTEN may also regulate synapse stability. Another MAGUK family member which interacts with β-catenin, lp-dlg/KIAA0583, provides a potential alternative link through vinexin and vinculin to the F-actin cytoskeleton. Finally, there are poorly understood intramolecular interactions between the N- and C-terminal and arm domains in β-catenin that regulate the interactions of these domains with other proteins.

β-Catenin is also an essential intermediate in the classical signaling pathway activated by Wnt proteins, but largely separate pools of β-catenin appear to be involved in its cadherin-associated and Wnt pathway-mediated functions. Wnt signaling results in stabilization of β-catenin and then it interacts with TCF family and other transcription factors to regulate gene expression. As a result of its essential role in this major Wnt signaling pathway, β-catenin has many additional roles within the nervous system, including regulation of neuroepithelial precursor proliferation, forebrain patterning, and sensory neuron specification. Wnt7a/Dishevelled-1 signaling promotes presynaptic assembly and neurotransmitter release in mossy fiber–granular cell synapse in the cerebellum, but it is not clear whether this is mediated by β-catenin-dependent canonical or noncanonical signaling pathway. Finally, plakoglobin, which is primarily expressed in epithelia, is a homologue of β-catenin that functions similarly in promoting cell–cell adhesion. However, plakoglobin cannot replace β-catenin in the Wnt signaling pathway. Interest in plakoglobin has increased due to the observation that it is enriched in some synapses.

Members of the p120ctn family interact with the membrane-proximal portion of the cytoplasmic domains of the classical cadherins. All members of this protein family have ten putative arm repeats with high sequence identity (more than 45%) among members and flanking N- and C-terminal polypeptides with less homology. Except for p120ctn, these proteins include PDZ domain interaction motifs at their C-terminals capable of interacting with several PDZ proteins, including synaptic scaffold proteins.

p120ctn and δ-catenin are strongly expressed in the nervous system. Mice lacking δ-catenin are viable but have many behavioral deficits that have been attributed to perturbations of synaptic function. In the hippocampus of mutant animals, short-term plasticity, as assessed by paired-pulse facilitation, is impaired, whereas long-term plasticity, as assessed by measurements of long-term potentiation, is elevated following high-frequency stimulation but reduced following low-frequency stimulation. Long-term depression is also impaired at hippocampal synapses in these animals. The absence of p120ctn results in early mouse embryo lethality. Mice in which p120ctn is eliminated solely in the forebrain are viable and have severely perturbed neuronal morphologies. In particular, the dendrites of neurons form with few spines and the density of synapses is severely reduced. This phenotype can be recapitulated in cell culture and rescue experiments indicate that p120ctn enhances spine density through inhibition of Rho activation while it promotes spine maturation through interactions with cadherins, acting either upstream or downstream of the cadherins.

p120ctn family members have been shown to regulate cadherin turnover, intracellular signaling, and cytoskeletal organization in several cell types. First, the presence of p120ctn family members is important for stabilizing cadherins on the cell surface *in vitro* and *in vivo*. In their absence, cadherins are transported normally to the surface but are rapidly endocytosed and degraded. p120ctn family members also play important roles in the signaling functions of adherent junctions. Cadherin-mediated adhesive junctions recruit and activate numerous signaling proteins, including PI3 kinase, Rac, Rho, and Arp2/3. The p120ctn family members promote assembly of these signaling centers through recruitment of the tyrosine kinases Fer, Fyn, and Yes and phosphatases including SHP-1, PTP-μ, and DEP-1 and have been shown to substrates of several kinases including receptor tyrosine kinases and Src family kinases. In the nervous system, δ-catenin also interacts with neurotransmitter receptors such as mGluR1a and NR2A and also PDZ-containing scaffold proteins such as S-SCAM. p120ctn family members regulate actin filament organization through regulation of Rho GTPases, with p120ctn promoting activation of Rac and inhibition of Rho following cell adhesion. The C-terminal region of δ-catenin also interacts in a phosphorylation-dependent manner with cortactin, an activator of the Arp2/3 complex, thereby providing a second pathway for regulation of the F-actin cytoskeleton. In addition, p120ctn family members also interact with the microtubule network directly as well as indirectly through kinesin.

Somewhat analogously to the involvement of β-catenin in Wnt signaling, the arm repeats of p120ctn associate with the transcriptional repressor Kaiso and thereby control expression of Wnt11 and *Xenopus* morphogenesis. Finally, deletion of p120ctn from keratinocytes results in elevated Rho activity, which in turn promotes activation of nuclear factor kappa B (NF-κB) and a proinflammatory cascade. Deletion in acinar epithelial cells prevents normal gland development and results in delamination of epithelial cells, almost certainly as a consequence of decreased surface E-cadherin and/or NF-κB.

In summary, the classical cadherins have been shown to regulate synapse formation, function, and plasticity. Many of the functions of the cadherins are controlled through binding to two families of catenins, which in turn control cadherin complex signaling, association with the cytoskeleton, and association with molecules important in synaptic function, including transmitter receptors and synaptic vesicles. In the future, it will be important to understand how these interactions are regulated by signaling pathways activated through activity and neurotransmitter receptors because these seem likely to control alterations in synaptic efficiency, in part, through regulation of synaptic cell adhesion molecule function.

Seven-Pass (Flamingo-like) Transmembrane Cadherins

The prototypic member of the seven-pass transmembrane cadherin family, Flamingo, was identified as a protein that mediates interactions between epithelial cells that control planar cell polarity. In the planar cell polarity pathway, Flamingo acts through modulation of Wnt/frizzled signaling. Flamingo has nine cadherin repeats, two laminin G domains, five epidermal growth factor (EGF)-like domains, and seven transmembrane domains and has been shown to promote cell aggregation *in vitro*. Cadherin, EGF-like, LAG-like, seven pass receptor (Celsr)1, Celsr2, and Celsr3 are the mammalian orthologs of Flamingo and are expressed in brain and epithelial cells, exhibiting distinct expression patterns.

Flamingo has several actions that influence early steps in neuronal differentiation that precede synapse formation. First, in *Drosophila* sensory neurons, it acts autonomously to promote axon growth and prevent premature axon branching. In addition, Flamingo controls the timing and length of dorsal dendrites of these neurons. Interestingly, it functions to delay their initiation and thereby limit their extent of growth. Flamingo is expressed on both the axons and the dendrites of these neurons and some of the mutants that affect its function also affect its

localization, suggesting that proper localization is required for its function. It has been suggested that Flamingo engages in both homophilic and heterophilic interactions, the latter with unknown ligands, to control the extent and patterning of dendrite growth. Flamingo is also expressed in the *Drosophila* visual system, where its presence is required for normal targeting of R1–R6 photoreceptor axons to appropriate cartridges in the lamina and of R8 axons in the medulla. Flamingo is expressed on the surfaces of these growth cones during their invasion of the brain. Intriguingly, other genes known to be required in the planar cell polarity pathway are not required for normal target selection by *Drosophila* photoreceptor axons, so Flamingo appears to be acting through a distinct pathway to regulate axon guidance. However, the genetic pathway through which *Celsr3* controls axon tract development in mouse brain development seems likely to involve the planar cell polarity pathway because mice mutants in Celsr3 and frizzled (Fzd)-3, a member of the Frizzled family, have similar phenotypes.

Protocadherins

Protocadherins constitute a very large family of proteins containing up to seven cadherin-like motifs that are distinct from those present in classical cadherins, a single transmembrane domain, and distinct cytoplasmic domains. In mammals, many of these proteins are highly expressed in the nervous system, where several have been localized to synapses. Their expression patterns in the brain frequently correlate with functional CNS subdivisions, and it has been proposed that they have important roles in establishing and maintaining synaptic specificity. Four clusters (α, β, γ, and δ) of genes encoding these proteins have been identified. Products of the protocadherin-α cluster are also named the CNRs (cadherin-like neuronal receptors). In the α, β, and γ clusters, single exons, each of which is coupled to a separate promoter, encode the variable extracellular domains. In the α and γ clusters, the mRNA product derived from each exon is spliced to an exon encoding the transmembrane and cytoplasmic domain, resulting in expression of several distinct extracellular domains, each fused to a constant cytoplasmic domain. β Cluster expressed transcripts contain variable extracellular domains together with a transmembrane and cytoplasmic domain. They lack the shared, constant exon which is observed in the α and γ clusters. Genes in the fourth cluster, the δ-protocadherin genes, are distributed on different chromosomes and exhibit similar alternative splicing patterns to those observed in the α and γ clusters.

Studies have shown that, in addition to biallelic expression, there is monoallelic but combinatorial expression of variable exons of the protocadherin-α and -γ cluster in single Purkinje cells – that is, only one of the two chromosomes can be used as a template for transcription of a single variable exon, but more than one variable exon can be expressed within a single neuron. In principle, this is a powerful mechanism to generate neuronal diversity and identity. In contrast to the classical cadherins, however, there is comparatively little evidence that these proteins function through homophilic adhesion. Some reports suggest that they may interact with each other, recognize arginine-glycine-aspartic acid (RGD)-binding β_1 integrins, and interact with reelin. It has also been suggested that protocadherins control homophilic binding by classical cadherins. There is little information on the cytoplasmic signaling pathways regulated by the protocadherins. Fyn is reported to interact with CNR cytoplasmic domain. Pcdh18 has been shown to associate with Dab1, which has been shown to mediate reeling signaling upon phosphorylation by an Src family kinase such as Fyn.

Members of the α- and γ-protocadherin proteins have been localized to synapses and have been proposed to control synapse formation, specificity, or maintenance. Analysis of mice in which the entire protocadherin-γ had been deleted found that it resulted in early lethality with specific loss through apoptosis of interneurons in the spinal cord. In addition, the spinal cords of these animals had a lower density of synapses. Analysis of this mutant in a *Bax* gene mutant background, which prevents apoptosis, revealed a striking deficit in the density of both excitatory and inhibitory synapses. Synaptic function was also compromised in neurons cultured from these animals. The results provide direct evidence that this family of protocadherins promotes synaptic development and/or maturation. Currently, there is no evidence that they control synaptic specificity, but future studies on this and other protocadherins seem likely to be informative. Mechanisms through which these proteins control synapse development remain mysterious.

Fat-Related and Other Members of Cadherin Superfamily

The Fat cadherins are single-transmembrane pass proteins that typically contain in their extracellular domains 34 tandemly arrayed cadherin repeats, plus in the membrane proximal region one or two laminin A subunit G domains and several EGF motifs. Involvement of Fat cadherins in synapse formation or function is purely speculative. There are two and four Fat cadherin genes in *Drosophila* and mice,

respectively. Mouse Fat2 mediates homophilic binding and is detected solely in cerebellar granule cells, where it is localized to the axons of these cells, the parallel fibers. Its expression level is elevated during the time period of synapse formation by these cells and remains high at later times. Its localization suggests that it helps organize the parallel fibers, which form synapses primarily on the dendritic spines of Purkinje cells. Fat3 expression is more broadly expressed in the embryonic CNS, including the spinal cord, but there is no information on its CNS functions.

Cadherin 23 is a novel single-pass transmembrane cadherin with 27 extracellular tandemly organized cadherin repeats that is expressed in both hair cells in the inner ear and photoreceptors in the retina. Cadherin 23 is a component of the tip link in hair cell stereocilia and forms a complex with each of the other proteins whose genes are mutated in Usher syndrome, a syndrome that results in deafness and blindness resulting from stereoclia disorganization. Through a C-terminal PDZ interaction motif, cadherin 23 has been shown to associate with the PDZ domain-containing scaffold protein harmonin. Harmonin is an F-actin bundling protein that also associates protocadherin-15, myosin VIIa, and a scaffold protein called Sans which contains several ankyrin repeats plus a sterile alpha-motif (SAM) domain. In addition, several transmembrane proteins, including usherin (a putative cell adhesion molecule), Usher's Syndrome type 2B (USH2B; a putative ion cotransporter), the very large G-protein-coupled receptor USH2C, and the four-pass transmembrane protein clarin, also associate with this complex. Mutations in each of the genes encoding these proteins also result in characteristic forms of Usher syndrome. In addition to their roles in organization of stereocilia, several of these proteins are expressed at photoreceptor synapses, suggesting that they have additional functions at these synapses.

The cytoplasmic domain of mammalian Fat1 has been shown to bind Ena/Vasp proteins and to regulate actin dynamics at cell–cell contacts. In *Drosophila*, the absence of Fat, but not of Fat-like, results in hyperproliferation of cells in imaginal disks. Fat is also involved in regulation of planar cell polarity, where it appears to modulate the strength of Wnt-Frizzled signaling, although the mechanisms through which it interacts with the planar polarity pathway are not understood. It seems likely that future studies will reveal diverse functions for these proteins, including roles at the synapse, but currently these are not clear.

Conclusion

This article summarized the current knowledge on the regulation and function of cadherin superfamily proteins known to be expressed at synapses or involved in synapse formation. Many of the mechanistic studies have been performed in nonneuronal cell types and it will be fascinating to determine whether these mechanisms govern their synaptic functions. Future studies are also expected to reveal the functions of individual genes and proteins in different types of synapse at different stages in their development.

Cajal's Place in the History of Neuroscience

J DeFelipe, Instituto Cajal (CSIC), Madrid, Spain

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Santiago Ramón y Cajal was born on 1 May 1852, in Petilla de Aragón (Figure 1), a small village in Navarra (Northern Spain), and he died on 17 October 1934, in Madrid. He studied medicine at the Faculty of Medicine in Zaragoza and was professor of anatomy and histology at the universities of Valencia, Barcelona, and Madrid (Figure 2). He was also the director of the Laboratorio de Investigaciones Biológicas (Biological Research Laboratory) for more than 20 years, a facility later to be incorporated into a research institute that was inaugurated in 1932 and, through the kindness of His Majesty Alfonso XIII, was named the Instituto Cajal.

Cajal published almost 300 articles and several books of great importance (see later) and he received numerous awards and distinctions (Figure 3); among these were some of the most prestigious awards of his time, including the Moscow Award (1900) and the Helmholtz Gold Medal (1905); he also received the Nobel Prize for Physiology or Medicine (1906), which he shared with Camillo Golgi (1843–1926). He was also an important figure in the development of science and culture in Spain. For example, he not only published several nonscientific books (e.g., 1905; *Cuentos de Vacaciones*, Madrid: Fortanet) but he also founded the journals *Revista Trimestral de Histología Normal y Patológica* in 1888 and *Revista Trimestral Micrográfica* in 1896 (later called *Trabajos del Laboratorio de Investigaciones Biológicas de la Universidad de Madrid*). He was also a pioneer in the development of color photography (1912; *La Fotografía de los Colores. Fundamentos Científicos y Reglas Prácticas*, Madrid: Moya) and served as the director of several institutions, the most important being the Junta para la Ampliación de Estudios, founded in 1907. This institution was created with the idea of promoting science, culture, and education in Spain, and Cajal was its first president. During the Spanish civil war the activities of the Junta practically ceased, all its centers and laboratories were closed, and many of its members went into exile. In 1939, Franco's new regime converted the centers and laboratories of the Junta into the Consejo Superior de Investigaciones Científicas, currently one of the most important Spanish scientific research institutions.

The emergence of Cajal's work in the field of neuroscience produced a dramatic change in the course of neuroscience history. However, his scientific career did not experience an easy beginning, as, unlike most scientists of his era, he was not introduced to the field under the direction of an acknowledged researcher; Cajal became a prominent neurohistologist essentially on his own. Also, in contrast to many other great researchers, Cajal did not make a single, unique great discovery, but instead made numerous diverse and important contributions to our understanding of the entire structure and function of the nervous system. His observations regarding degeneration and regeneration, together with his ideas about the development and plasticity of the nervous system, not only had a deep influence on the scientists of his time, but they also constitute a virtually inexhaustible source of inspiration at present. This is thanks to Cajal's correct interpretation of the microscopic images obtained first with Golgi's 'reazione nera' (black reaction) impregnation technique, and later, the other methods that he developed.

It is clear today that our knowledge of the nervous system is certainly the result of the collective work of a large number of scientists. Nevertheless, the research of Cajal contributed more than that of anybody else in creating the scientific atmosphere necessary for the birth of modern neuroscience. The genius of Cajal resided in his extraordinary capacity of observation and his interpretation of the microscopic images; he was able to extract from these images the fundamental features of neuron and glial morphology. This talent was coupled to his ability to produce schemes summarizing his observations and to show the possible functional implications of the neuronal circuits based on connections by contacts ('neuron doctrine'), later called synapses. Indeed, all scientists of Cajal's era had the same microscopes and produced similar histological preparations, but it was Cajal who clearly saw details that were unnoticed by others or that were erroneously interpreted. An interesting example is Cajal's discovery of the dendritic spines using the Golgi method, in 1888 (see later). These were elements that he considered fundamental to the nervous system, while others, like Golgi, considered them to be mere histological artifacts.

Summary of the Scientific Career of Cajal

Cajal's career can be divided into three major phases. The first of these began in 1877 with the completion

Figure 1 Photographs taken in 2001 of the village of Petilla de Aragón and the house where Cajal was born.

Figure 2 Portrait of Cajal and his collaborator Juan Bartual Moret at Cajal's laboratory in Valencia (around 1885). Copyright by Herederos de Santiago Ramón y Cajal.

of his doctoral thesis, 'Patogenia de la Inflamación,' and extended until 1887 when he was introduced to Golgi's method of impregnation. During this period he published various histological and microbiological studies (some of which were signed with the pseudonym Dr. Bacteria) that were generally of relatively little significance.

In the second phase of his career (1887–1903) Cajal's research was very productive, and it was the period in which he exploited the Golgi method to describe almost every part of the nervous system in detail. During this period of his life he was to formulate important theories, the most popular being the neuron doctrine and the law of dynamic polarization of the neuron. The histological descriptions were so accurate that his classic book summarizing these studies, *Textura del Sistema Nervioso del Hombre y de los Vertebrados*, is still a title of reference in many neuroscience laboratories. Indeed, if each cell type that Cajal discovered was given his name, there would be so many types of Cajal cells that it would make neuroscientist's life impractical. Cajal also published several classic articles during the first few years of this second phase, including La rétine des vertébrés (1892; *La Cellule* 9: 121–133), La fine structure des centres nerveux (1894; *Proceedings of the Royal Society of London* 55: 444–468), and his masterworks on the human cerebral cortex. Furthermore, Cajal discovered and named the axonal growth cone ('cono de crecimiento') and devised the hypothesis of chemotaxis or chemotactism, later to be called neurotropism. At present, these early contributions represent two of the most exciting fields of research in neuronal development. In addition, Cajal made important contributions to general pathology, and to cancer research in particular. These contributions are evident in the articles he published and especially in his book *Manual de Anatomía Patológica General*, the first edition of which appeared in 1890

Figure 3 A plaque and some medals that Cajal received in recognition of his studies. The images of the medals were kindly supplied by Dr. Pere Berbel.

(Barcelona: Imprenta de la Casa Provincial de Caridad) and that he updated in successive editions until the end of his career.

In the third phase of Cajal's career, which began in 1903 and ended with his death in 1934, he experimented with a new technique, the reduced silver nitrate method. This period was devoted mainly to research into degeneration and regeneration in the nervous system. He published numerous articles on this subject that were of great relevance and that were summarized in another classic book, *Estudios sobre la Degeneración y Regeneración del Sistema Nervioso*. During this phase, Cajal also published important papers on the structure of the retina and optic centers of invertebrates, and the classic review article on the neuron theory, 'Neuronismo o reticularismo.' Therefore, rather than attempting to present here an exhaustive review of the work and influence of Cajal in neuroscience, the focus instead is on some of Cajal's first studies with the Golgi method, which represent the starting point of

the birth of modern neuroscience. In particular, two theories are discussed: the neuron doctrine and the law of dynamic polarization of neurons.

Cajal and the Golgi Method: The Neuron Doctrine and the Commencement of a New Era in Neuroscience

Before the studies of Golgi and Cajal, very little was known about the microanatomy and functioning of the nervous system, mainly because there were no histological techniques available to visualize an entire neuron (cell body, dendrites, and axon), or to follow the course of the axons up to its terminal arbor (Figure 4). Thus, it was not possible to address the critical issue of neuronal connectivity. At that time, the most common view regarding the organization of the nervous system was the reticular theory, developed principally by Joseph von Gerlach (1820–96). von Gerlach was considered to be the father of this theory, which states that the nervous system consists of a diffuse network that is formed by the anastomosing branches of the nerve cell processes (dendrites and axons), the cell somata principally playing a role in nourishment.

The structure and functioning of the nervous system truly began to be understood when Cajal started to try to unravel its organization using the Golgi method. Without this method, Cajal would probably have passed into the history of neuroscience as just another of many good scientists but one whose work was of no exceptional relevance. However, as we will see, in the end it is likely that without Cajal neuroscience would have suffered an important delay in its development. Accordingly, the Nobel Prize that Cajal and Golgi shared in 1906 is absolutely justified. Certainly, Cajal's studies on degeneration and regeneration were also of extraordinary importance and they were performed with a different method, reduced silver staining (see later). Furthermore, he used a variety of other methods to reveal a number of important findings. Nevertheless, the intellectual skeleton necessary for the interpretation of the new experiments and techniques was constructed thanks to the ideas he obtained from his studies with the Golgi method. However, Golgi was not the only scientist responsible

Figure 4 Pages from a nineteenth-century text; the right-hand page depicts morphological types of nerve cells. When Cajal was studying for his doctorate and attended the doctoral course of normal and pathological histology in 1877, one of the principal texts used was the *Tratado de Histología Normal y Patológica* (*Treatise of Normal and Pathological Histology*) by Aureliano Maestre de San Juan, professor of histology at the Faculty of Medicine in Madrid. The description of the structure of the nervous system was rather simple in these early publications. For example, Cajal would have read the following description regarding the morphological types of nerve cells in the *Tratado de Histología*: "The nerve cell may or may not present prolongations of its protoplasm, and from that come their division in 1°., apolar, that is to say, without any protoplasmic prolongation . . .; and 2°., others [nerve cells] that show a variable number of prolongations."

for the success of Cajal in his scientific career. There were also another three scientists who were fundamental to the development of his career: Aureliano Maestre de San Juan (1828–90), and, more particularly, Luis Simarro (1851–1921) and Albrecht Kölliker (1817–1905). While it was Maestre who introduced Cajal to the world of the microscope, Simarro introduced him to the Golgi method. In contrast, Kölliker 'discovered' Cajal, which was fundamental in disseminating Cajal's observations, concepts, and theories throughout the scientific community.

Interestingly, when Golgi examined the silver-impregnated preparations, he concluded that the reticular theory enunciated by Gerlach was wrong, since Golgi thought that dendrites ended freely and that only the axons and their collaterals were seen to anastomose. Therefore, he suggested that the nervous system consisted of a "rete nervosa diffusa" (diffuse nervous network), an idea that he supported even during his Nobel Prize lecture. It was in this scientific atmosphere that Simarro first showed Cajal a Golgi-impregnated preparation in 1887. Beautifully retained even in the translations of several of Cajal's writings is the historical moment when Cajal discovered the properties of the Golgi method (see Figures 5 and 6):

> In summary, a method was necessary to selectively stain an element, or at most a small number of elements, that would appear to be isolated among the remaining invisible elements. Could the dream of such a technique truly become reality, in which the microscope becomes a scalpel and histology a fine [tool for] anatomical dissection? A piece of nervous tissue was left hardening for several days in Müller's pure liquid [potassium dichromate] or in a mixture of this [fixative] with osmic acid. Whether it was the distraction of the histologist or the curiosity of the scientist, the tissue was then immersed in a bath of silver nitrate. The appearance of gleaming needles with shimmering gold reflections soon attracted the attention. The tissue was cut, and the sections were dehydrated, cleared, and then examined [with the microscope]. What an unexpected spectacle! On the perfectly translucent yellow background sparse black filaments appeared that were smooth and thin or thorny and thick, as well as black triangular, stellate or fusiform bodies! One would have thought that they were designs in Chinese ink on transparent Japanese paper. The eye was disconcerted, accustomed as it was to the inextricable network [observed] in the sections stained with carmine and hematoxylin where the indecision of the mind has to be reinforced by its capacity to criticize and interpret. Here everything was simple, clear and unconfused. It was no longer necessary to interpret [microscopically] the findings to verify that the cell has multiple branches covered with 'frost,' embracing an amazingly large space with their undulations. A slender fibre that originated from the cell, elongated over enormous distances and suddenly opened out in a spray of innumerable sprouting fibres. A corpuscle confined to the surface of a ventricle where it sends out a shaft, which is branched at the surface of the [brain], and other cells [appeared] like comatulids or phalangidas. The amazed eye could not be removed from this contemplation. The dream technique is a reality! The metallic impregnation has unexpectedly achieved this fine dissection. This is the method of Golgi! [...] whose clear and decisive images enables us to cast off the famous net of Gerlach, [as well as] of the [dendritic] arms of Valentin and Wagner, and of so many other fanciful hypothesis. (Cajal Histologic du systéme nerveux del'homme et des vertébrés)

Figure 5 First illustration by Cajal from a Golgi-impregnated preparation of the nervous system. Cajal provided the caption: "Vertical section of a cerebellar convolution of a hen. Impregnation by the Golgi method. A, represents the molecular zone, B, designates the granular layer and C, the white matter." From Cajal SR (1888) Estructura de los centros nerviosos de las aves. *Revista Trimestral de Histolología Normal y Patológica* 1: 1–10. Copyright by Herederos de Santiago Ramón y Cajal.

Figure 6 Cajal's drawing of Golgi-impregnated neuroglial cells. The figure caption provided by Cajal stated: "Neuroglia of the superficial layers of the cerebrum: child of two months. Golgi Method. *A*, *B*, *[C]*, *D*, neuroglial cells of the plexiform layer; *E*, *F*, [*G*, *H*, *K*], *R*, neuroglial cells of the second and third layers; *V*, blood vessel; *I*, *J*, neuroglial cells with vascular [pedicles]." This figure was reproduced as figure 697 in the book *Textura del Sistema Nervioso del Hombre y de los Vertebrados*. Copyright by Herederos de Santiago Ramón y Cajal.

Cajal's typical vivid writing style and enthusiasm, appreciated here, were especially represented in the French translation of the *Textura*. (Note: The comatulids of which Cajal wrote are marine crinoid invertebrates such as sea lilies and feather stars. Phalangidas (or opiliones), also known as water harvestmen, are arachnids that superficially resemble true spiders but have small, oval-shaped bodies and long legs. In the preceding extract, Cajal is probably referring to some neuroglial cells that, when stained with the Golgi method, have a morphology resembling that of these invertebrates; see Figure 6).

Cajal was captivated by this marvelous staining and immediately started to use it to analyze practically the entire nervous system in several species. One year later after the meeting with Simarro, Cajal had published his first important article based on results obtained with this method in the avian cerebellum (Figure 5). In this study, entitled 'Estructura de los centros nerviosos de las aves,' published in 1888, Cajal made two great contributions. First, he described for the first time the existence of dendritic spines (which he also named), structures that currently generate particular interest, as they are highly plastic, and the main postsynaptic site of excitatory synapses in the cerebral cortex. Second, Cajal confirmed Golgi's conclusion that dendrites end freely, but in contrast to Golgi, Cajal added the critical conclusion that this also applies to axons and their branches:

> We have carried out detailed studies to investigate the course and connections of the nerve fibers in the cerebral and cerebellar convolutions of the human, monkey, dog, etc. We have not been able to see an anastomosis between the ramifications of two different nervous prolongations, nor between the filaments emanating from the same expansion of Deiters [axons]. While the fibers are interlaced in a very complicated manner, engendering an intricate and dense plexus, they never form a net [...] it could be said that each [nerve cell] is an absolutely autonomous physiological canton [unit]. (Cajal, translation – *Revista Trimestral de Histolología Normal y Patológica* 1, 1888)

Cajal and the Neuron Doctrine

During the next few years, Cajal provided many examples from throughout the nervous system to support his observation that dendrites and axons end freely (Figure 7). Indeed, the early studies that Cajal performed with the Golgi method were so decisive that they represented the main core of the review published in 1891 in the journal *Deutsche Medizinische Wochenschrift* (vol. 17) by Wilhelm von Waldeyer-Hartz (1836–1921). In this article, the term 'neuron' was introduced to denominate the nerve cells, and the so-called neuron doctrine become popular. By the end of the nineteenth century this theory was the most accepted theory to explain the organization of the nervous system, in which the neuron was considered as the anatomical, physiological, genetic, and metabolic unit of the nervous system. However, there were some notable exceptions, since in addition to the reticular ideas of Golgi, some prestigious researchers, such as Stephen von Apáthy (1863–1922), Hans Held (1866–1942), and Albert Bethe (1872–1954), were ardent supporters of the reticular theory. In particular, Bethe started to publish several influential experimental papers in 1901 on the regeneration of peripheral nerve fibers. In these writings he claimed that axons that had separated from their trophic centers were capable of autoregeneration, supporting the polygenetic theory of axon growth and regeneration claimed by earlier physiologists and pathologists. This theory states that the regenerated axons could result from the fusion of numerous axon segments due to the differentiation and transformation of the ensheathing cells of the old nerve fibers, a theory not compatible with the neuron doctrine. This was one of the main reasons why Cajal started another major project to study degeneration and regeneration in the nervous system. In this study, he mainly used the reduced silver nitrate method, a new technique that he had developed in 1903, which enabled him to examine the regenerated axons in greater detail than was possible with any other staining technique available at that time. From the beginning of these studies, it was clear to Cajal that the new fibers, which appeared in the peripheral stump of a cut nerve, originated from the sprouting of axons of the central stump, and with this the neuron doctrine once again became

Figure 7 Cajal's drawing to explain the differences between the 'neuron theory' and the 'reticular theory.' The figure caption provided by Cajal stated: "Scheme to compare the concept of Golgi regarding the sensory–motor connections of the spinal cord (I) with the result of my investigations (II). *A*, anterior roots; *B*, posterior roots; *a*, collateral of a motor root; *b*, cells with short axon which, according to Golgi, would intervene in the formation of the network; *c*, diffuse interstitial network; *d*, our long collaterals in contact with the motor cells; *e*, short collaterals." This figure was reproduced as figure 9 in *Recuerdos de mi Vida*. Copyright by Herederos de Santiago Ramón y Cajal.

Figure 8 Portrait of Sherrington included in the 1947 edition of his book, *The Integrative Action of the Nervous System*.

widely accepted. The many, fundamental contributions of Cajal to the neuron doctrine were summarized by himself in several articles and books, and especially in the article 'Neuronismo o reticularismo,' published in 1933.

Nevertheless, in spite of the wealth of experimental data (physiological and Wallerian secondary degeneration studies) and histological observations supporting the neuron doctrine, the crucial observation that there was a physical separation between the neurons took a long time to emerge, since the limited resolving power of light microscopy impaired making this distinction. Thus, the neuron doctrine was generally accepted but with certain doubts and exceptions up to the middle of the twentieth century. This situation was beautifully summarized by Charles Sherrington (1857–1952) in his classic book, *The Integrative Action of the Nervous System* (see Figure 8). Sherrington, who in 1897 introduced the term 'synapse' for the hypothetical one-way contact between axon terminals and somata or dendrites, wrote the following with regard to this subject in 1947:

> As to the existence or non-existence of a surface of separation or membrane between neurone and neurone, that is a structural question on which histology might be competent to give valuable information. In certain cases, especially in Invertebrata, observation (Apáthy, Bethe, etc.) indicates that many nerve-cells are actually continuous one with another. It is noteworthy that in several of these cases the irreversibility of direction of conduction which is characteristic of spinal reflex-arcs is not demonstrable [...]. But in the neurone-chains on the gray-centred system of vertebrates, histology on the whole furnishes evidence that a surface of separation does exist between neurone and neurone. [...] It seems therefore likely that the nexus between neurone and neurone in the reflex-arc, at least in the spinal arc of the vertebrate, involves a surface of separation between neurone and neurone; and this as a transverse membrane across the conductor must be an important element in intercellular conduction. [...] In view, therefore, of the probable importance physiologically of this mode of nexus between neurone and neurone it is convenient to have a term for it. The term introduced has been *synapse*. (Foster and Sherrington, *The Integrative Action of the Nervous System*, 1897)

To resolve this structural question posed by Sherrington, the advent of electron microscopy in the 1950s was necessary to confirm that there is a separation between the pre- and postsynaptic elements of approximately 10–20 nm, the so-called synaptic cleft.

Law of Dynamic Polarization of Nerve Cells

Obviously, it is not the same to think that nerve currents flow through a continuous rather than a discontinuous network of neuronal processes. Thus, the new ideas about connections between neurons led to novel theories on the relationship between neuronal circuits and brain function. Cajal wrote in the

Textura: "The cell bodies [dendrites and axons], terminate freely but nevertheless, the flow of currents is not impeded in such an infinitely interrupted, fragmented nervous system. How can such currents flow? There can be only one answer, by contact, in much the same way that electric current crosses a splice between two wires."

An important consequence of the neuron doctrine was Cajal's theory of the law of dynamic polarization of nerve cells. At that time, the direction of impulse activity within the neurons remained a puzzling question to researchers, as nicely expounded by Cajal in 1917 in his autobiography *Recuerdos de mi Vida*: "In what direction does the nervous impulse travel within the neuron? Does it spread in all directions, like sound or light, or does it pass constantly in one direction like water in the watermill?"

It was commonly thought that dendrites played a nourishing role, whereas axons transmitted nervous impulses in a cellulifugal direction (a generalization based mostly on the cellulifugal conduction in the axons of the spinal motor neurons). However, there was no general consensus or a clear idea about the role of dendrites in the processing of information. In 1889, Cajal thought that at least in certain cases it was clear that the dendrites play a role in the reception of currents, and 2 years later, he tried to generalize this idea with the Law of Dynamic Polarization. This law was based on the direction followed by the impulses in regions of the nervous system where, through their activity, it was apparently clear what anatomical routes the impulses followed, such as in the visual and olfactory systems (**Figure 9**): "If in such inquiry, the [dendritic] arborization is always shown as a *receptor* apparatus and the [axonal arborization] as an apparatus for the *application* of the [impulses], by analogy we would have attained a rule to judge the direction of the currents in the [nerve cells within the central nervous system]."

Cajal proposed that neurons could be divided into three functionally distinct regions: a receptor apparatus (formed by the dendrites and soma), an emission apparatus (the axon), and a distribution apparatus (terminal axonal arborization). Later he realized that the soma does not always intervene in the conduction of the impulses and that, sometimes, impulse activity goes directly from the dendrites to the axon (**Figure 10**). Thus, the Law of Dynamic Polarization was changed

Figure 9 Cajal's scheme showing the current flow in the visual and olfactory systems. The figure caption provided by Cajal stated: "*Fig. 1*. Scheme of cellular connections of the olfactory mucosa, olfactory bulb, tractus, and olfactory lobe of the cerebrum. The arrows indicate the direction of the currents. *A*, olfactory bulb; *B*, mucosa; *C*, olfactory lobe. *a, b, c, d*. to the Theory of Axipetal Polarization: "The soma and dendrites display axipetal conduction, whereby they transmit the nervous waves towards the axon. Conversely, the axon or cylinder-axis has somatofugal or dendrifugal conduction, propagating the impulses received by the soma or dendrites towards the terminal axonal arborizations. [...]. This formula can be applied universally without exception, both in the vertebrates and invertebrates."

These studies of Cajal had a deep impact on researchers at that time, and his observations and theories were essentially confirmed. However, the introduction and development of electron microscopy, together with the appearance of new techniques to study the nervous system at the anatomical, physiological, and molecular level, have shown over the years that there are many exceptions that challenge the neuron doctrine and the Law of Dynamic (or Axipetal) Polarization. For example, axons have been found to form synapses with other axons (axo-axonal synapses), and presynaptic elements are not necessarily axonal but they can be dendrites or somata. Thus, a variety of synaptic relationships have been observed, including dendro-dendritic, somato-somatic, somato-dendritic, dendro-somatic, dendro-axonic, and somato-axonic synapses. Furthermore, neurons are not only connected by point-to-point chemical synapses, but they may also be coupled electrically, while the direction of transmission may be bidirectional through gap junctions. The plasma membranes of adjacent neurons at the gap junctions are separated by a gap of about 2 nm, but they contain small channels that connect the cytoplasm of the adjoining neurons. These channels permit the diffusion of small molecules and the flow of electric current. Moreover, the transmitter released at synaptic or nonsynaptic sites may diffuse a certain distance and act on other synaptic contacts, or on extrasynaptic receptors. Finally, neuroglial cells are not only key components of the nervous system for their numerous structural, metabolic, and protective functions, but it has been shown that astrocytes are involved in information processing through bidirectional signaling between these cells and neurons. These different features represent further complexities in the system, making it even more difficult to establish the information flow and wiring of neural circuits. Nevertheless,

axo-dendritic synapses are by far the most common type of synaptic contact (followed by axo-somatic synapses). Other types of synaptic contacts are not found in all regions of the nervous system, and when they are present, they are usually established only between certain types of neurons. Therefore, we agree with the conclusion of Gordon Shepherd that the idea of the nerve cell as an independent cellular unit, with an overall polarization to mediate its input–output functions, continues to be one of the foundations on which our concepts of nervous function are based.

Coming back to Cajal, if some of the recent discoveries mentioned herein had been made in his time, it would probably not have been a surprise to him. In fact, he had indeed described the existence of anastomosis in certain instances, which he sometimes called interprotoplasmic or internervous bridges. However, Cajal was convinced that the vast majority of connections between neurons involved "contact or contiguity." In his article 'Neuronismo o reticularismo,' once again Cajal was ahead of his time when he drew the following conclusion:

> We are neither exclusive nor dogmatic. We are proud of retaining a mental flexibility that is not embarrassed by the need to rectify. Thus exceptions may arise to the neuronal discontinuity that is so evident in innumerable examples. We ourselves have reported [some cases of anastomosis] [...]. For this reason, we have pointed out, and we insist in this, when dealing with the morphology and connections of neurons, we must abide by the law of the greatest numbers, that is to rigorously statistical criteria. (Cajal, *Archivos de Neurobiología* 13, 1933)

Calcitonin Gene-Related Peptide (CGRP) and Receptors

W Ma, J-G Chabot, and R Quirion, McGill University, Montreal, QC, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Calcitonin gene-related peptide (CGRP) was discovered in the early 1980s as a gene product of the alternative splicing of the calcitonin gene. It is an important member of the CGRP family, which also includes amylin, adrenomedullin (AM), intermedin, and the calcitonin receptor-stimulating peptide (Figure 1). The broad distribution of CGRP in both central and peripheral nervous systems (CNS and PNS) suggests its extensive biological effects, including the modulation of the senses and autonomic functions, vasodilation, cardiovascular protection, muscular motility, learning and memory, pain and inflammation, as well as the regulation of water and food intake. CGRP exerts its biological effects by acting on specific CGRP receptors. The CGRP1 receptor belongs to the type II or B family of the G-protein-coupled receptor (GPCR) superfamily. The CGRP receptor is rather unique compared to other GPCRs. In addition to sharing a seven-transmembrane domain protein known as calcitonin receptor-like receptor (CLR) with AM receptors (AM1 and AM2), CGRP and AM receptors require other accessory proteins to be functional. These accessory proteins include the receptor-activity-modifying proteins (RAMPs), which determine receptor specificity, and the receptor complement protein (RCP), which facilitates signal transduction coupling. This article reviews the anatomical distribution of CGRP and its receptors, as well as some of its biological functions.

Discovery of CGRP

CGRP is composed of 37 amino acids and was discovered by a molecular biological approach in 1982 by Amara and coworkers. Alternative RNA splicing is an important means to increase proteomic complexity in eukaryotic organisms. Through this process, the majority of human premessenger RNAs (mRNAs) generate more than one mRNA, which often leads to the production of multiple polypeptides from a single gene. Tissue-specific alternative RNA processing plays an important role in regulating gene expression. The human calcitonin/CGRP gene is a good example of such regulation. The mRNA encoding CGRP was identified as a result of alternative splicing of RNA transcripts from the calcitonin gene. This gene is predominantly expressed in two tissues, thyroid C cells and a subset of primary sensory neurons.

The isolation and sequence analysis of the calcitonin genomic DNA and calcitonin/CGRP complementary DNA (cDNA) demonstrated that both CGRP and calcitonin mRNAs are generated by differential processing from a single genomic locus. The calcitonin/CGRP gene consists of six exons (Figure 2). The calcitonin/CGRP pre-mRNA is alternatively spliced in a tissue-specific manner, leading to the production of calcitonin mRNA containing exons 1–4 in thyroid C cells and CGRP mRNA containing exons 1–3, 5, and 6 in neurons.

The possible existence of other gene products related to CGRP was investigated by screening the library of chimeric plasmids containing inserts complementary to mRNAs from rat medullary thyroid carcinomas with a clone of CGRPα cDNA probe. The analysis resulted in the identification of a novel mRNA, called CGRPβ, which is closely related to CGRPα mRNA. The CGRPβ gene does not contain sequences corresponding to the calcitonin-coding sequences of the calcitonin/CGRPα gene. Thus, only CGRPβ can be derived from this second gene. Human CGRPβ gene was identified in 1985 by Steenbergh and collaborators and differs from human CGRPα by three amino acids. CGRP is a highly conserved peptide between mammalian species, with 26 homologous amino acids. Figure 3 depicts the primary structures of CGRP and related peptides.

In general, the transcripts for CGRPα and CGRPβ have a similar distribution in CNS and PNS. However, some evidence suggests that they can be differentially distributed and regulated in certain tissues, such as primary sensory neurons and intrinsic enteric neurons, suggesting selective regulation of these CGRP genes. The expression of the calcitonin/CGRP gene is regulated by glucocorticoids and cyclic adenosine monophosphate. Alternative RNA splicing is subject to complex control, often involving multiple sequence elements and protein factors. Studies to date have identified a large number of *cis*-acting regulatory elements located in the exons and introns as well as *trans*-acting factors to regulate alternative RNA splicing. Studies on alternative splicing factors have indicated that they are often RNA binding proteins capable of binding to specific *cis*-acting RNA elements, thus affecting RNA processing choice through interactions with the basal splicing or polyadenylation machinery. For example, it has been shown that

TIAR, a recently characterized splicing regulator which is related to TLA, plays a role in regulating the calcitonin/CGRP gene.

Neuroanatomical Localization

CGRP is broadly distributed in the nervous system of both vertebrates and invertebrates. The distribution of CGRP mRNA and CGRP-like immunoreactivity (CGRP-IR) has been reported in the CNS and PNS of various species, including humans. In Table 1, the distribution of CGRP mRNA, CGRP-IR, and CGRP receptor binding sites in the rat CNS and PNS is illustrated, Figures 4 and 5 depict CGRP-IR projections and CGRP receptor binding sites, respectively, in the rat brain.

Figure 1 Diagram depicting members of the calcitonin and calcitonin gene-related peptide (CGRP) family: CGRP, amylin, adrenomedullin, intermedin, and calcitonin receptor-stimulating peptide.

CGRP mRNA-Containing Neurons

Using *in situ* hybridization histochemistry, the distribution of CGRP mRNA was examined in the rat CNS (Table 1). Generally, the highest densities of CGRP mRNA-expressing neurons are mainly seen in the lateral hypothalamic area, various thalamic nuclei, brain stem cranial motor neurons, lateral superior olivary nucleus, parabrachial nuclei, and the majority of α-motor neurons of the spinal cord, with about 50% of neurons in the cranial trigeminal and dorsal root ganglia expressing CGRP.

Moderate levels of CGRP mRNA-positive neurons are observed in the medial division of the bed nucleus of the stria terminalis, the nucleus of the lateral olfactory tract, various hypothalamic and thalamic nuclei, the nucleus of the lateral lemniscus, the reticular paragigantocellular nucleus, the cuneate nucleus, and various hypoglossal nuclei.

Figure 2 Model of tissue-specific neuropeptide production from the calcitonin gene. Alternative RNA processing pathways generate calcitonin or calcitonin gene-related peptide (CGRP) in a tissue-specific manner. mRNA, messenger RNA; aa, amino acid; Poly A, polyadenosinc. In: Quirion R, Bjorklund A, and Hökfelt T (eds.) *Peptide Receptors, Part I*, pp. 301–374. Amsterdam: Elsevier.

Figure 3 Amino acid sequence of CGRP and related peptides. Amino acids in common with human CGRPα are indicated by -. Spaces inserted to allow for sequence comparison are indicated by *. Adapted from Jacques D, Dumont Y, van Rossum D, et al. (2000) Calcitonin gene-related peptide (CGRP), amylin and adrenomedullin: Anatomical localization and biological functions in the mammalian and human brains. In: Quirion R, Bjorklund A, and Hökfelt T (eds.) *Peptide Receptors, Part I*, pp. 301–374. Amsterdam: Elsevier.

Low levels of CGRP mRNA-expressing neurons are seen in the lateral division of the bed nucleus of the stria terminalis, the dorsal hippocampus, various hypothalamic and thalamic nuclei, the mesencephalic cuneiform nucleus, and the pontine and medullary reticular nuclei.

CGRP-IR Neurons and Axons

Through immunohistochemistry, the distribution of CGRP-IR in the rat CNS has been described in detail. In accordance with the distribution of CGRP mRNA, CGRP-IR neurons and axons are widely but unevenly distributed in the rat brain. As shown in Table 1, high amounts of CGRP-IR neurons are seen in various parabrachial nuclei and the Kölliker-Fuse nucleus. Moderate levels of CGRP-IR neurons are observed in various amygdaloid, hypothalamic, and thalamic nuclei, cranial and spinal motor neurons, and the lateral superior olive. Low levels of CGRP-IR neurons are observed in the primary olfactory cortex, bed nucleus of the stria terminalis, various hypothalamic and thalamic nuclei, arcuate nucleus, central periaqueductal gray, cuneiform nucleus, tegmental nuclei, inferior colliculus, lemniscus nuclei, pontine nuclei, central gray of the pons, cuneate nucleus, nucleus of Roller, and raphe obscurus nucleus.

High levels of CGRP-IR axons are seen in various hypothalamic nuclei, including the medial preoptic area, periventricular area, dorsomedial nucleus, medial eminence, and medial forebrain bundle area, as well as the superficial layers of the trigeminal dorsal horn. Moderate levels of CGRP-IR axons are found in various thalamic nuclei, septal nuclei, bed nucleus of the stria terminalis, central amygdaloid nucleus, striatum, periaqueductal central gray, medial geniculate body, parabigeminal nucleus, lateral lemniscus, interpeduncular nucleus, parabrachial nucleus, superior olive, cochleal nucleus, nucleus of the solitary tract, and vestibular nuclei. Low levels of CGRP-IR axons were noted in the olfactory bulb, medial prefrontal cortex, most neocortical areas, and anterior pituitary.

High densities of CGRP-IR axons are also found in laminae I and II of the spinal dorsal horn. CGRP-containing axons constitute about 30% of primary afferent axons of the Lissauer's tract, the major input to superficial laminae of the dorsal horn. More than 80% of spinal afferent neurons supplying visceral structures including urogenital and upper gastrointestinal tracts as well as blood vessels are CGRP expressing. Low densities of CGRP-IR axons are seen in deeper layers of the dorsal horn as well as in the ventral horn and areas surrounding the central canal.

CGRP Receptor Binding Sites

CGRP receptor binding sites are discretely distributed in the CNS of various species, including rat and human. As shown in Table 1 and Figure 5, high densities of CGRP binding sites are seen in the olfactory

observed in the Darkschewitsch nucleus, oculomotor and trochlear nuclei, dorsal raphe nucleus, interfascicular nucleus, parabrachial nucleus, Purkinje cell layer of cerebellum, and deeper cerebellar nuclei. Low levels of binding sites were seen in lamina II and the ventral horn.

Recent Progress in CGRP Receptor Research

Early on, based on the differential biological activities of various CGRP analogs, CGRP receptors have been classified into the CGRP1 and CGRP2 subtypes. Pharmacologically, these two subtypes have been described based on properties of the antagonist CGRP8–37 and the agonist (Cys(ACM^{2,7}))CGRP. Structure-activity studies of CGRP analogs showed that the C- and N-terminal regions of the peptide interact independently with their receptors. While C-terminal peptides such as CGRP8–37 behave as preferential CGRP1 receptor antagonists, N-terminal peptides such as CGRP1–12 act as weak agonists. Structural modifications of CGRP28–37 have yielded micromolar to nanomolar affinity ligands. The CGRP1 subtype has been cloned, and it is a complex macromolecular structure (see below), but the existence of molecularly distinct CGRP2 receptors is yet to be confirmed.

A GPCR belonging to the secretin receptor family (B family of GPCR) has been described and is known as CLR. As shown in Figure 6, CLR is not a functional receptor by itself and requires accessory proteins to function. These proteins are known as RCP which couple CLR to signaling pathways and RAMP, a single membrane-spanning protein, which acts as a chaperone protein and confers pharmacological specificity to CLR. This complex behaves as a CGRP1 receptor if CLR is associated with RAMP1, while AM receptors (AM1 and AM2) are generated by the association of CLR with RAMP2 and RAMP3,

Figure 6 Receptor model for calcitonin gene-related peptide (CGRP) and adrenomedullin (AM). CGRP1, AM1, and AM2 share the calcitonin receptor-like receptor (CLR), a G-protein-coupled seven transmembrane domain. Three receptor activity-modifying proteins (RAMPs) are single transmembrane domain protein and determine the pharmacological specificity of the receptor. The receptor complement protein (RCP) is suggested to play a role in the coupling of the receptor to its subsequent signal transduction pathway via adenylate cyclase (AC), leading to increased production of cAMP. A functional receptor is optimally composed of CLR, RAMP, and RCP, with RAMP1 in CGRP and RAMP2 and 3 in AM1 and AM2, respectively. Adapted from Brain SD and Grant AD (2004) Vascular actions of calcitonin gene-related peptide and adrenomedullin. *Physiological Reviews* 84: 903–934.

respectively. Recently, the second intracellular loop of CLR was shown to provide the molecular determinants for signal transduction and cell surface expression. Human, rat, and porcine CLRs have been cloned and characterized. Currently, a major focus is on the identification of potent and specific nonpeptide antagonists for this receptor in order to establish its physiological and pathophysiological roles. BIBN4096BS is the current prototype, and this molecule has been reported to be effective in the treatment of migraine in a clinical trial.

RCP-like immunoreactivity has been examined in the rat CNS and PNS. Its distribution is broad, closely matching with that of CGRP-IR and CGRP binding sites. Cells expressing CLR and RAMP1, 2, and 3 have recently been shown to be present in the dorsal root ganglia (DRG) and superficial dorsal horn of the rat spinal cord.

CLR knockout mice were recently generated using homologous recombination. Similar to AM knockout mice, homozygous CLR knockout mice exhibited severe cardiovascular defects and died at the embryonic stage, suggesting that CLR is a key protein involved in normal embryonic development.

Biological Activities

The wide distribution of CGRP-IR and receptors suggests a broad involvement in various brain functions and more specifically in sensory, motor, and integrative systems. The main CGRP pathways are described in the following sections and summarized in Figure 4.

CGRP and Olfaction

As mentioned before, high levels of CGRP-IR axons and CGRP receptor binding sites are distributed in the olfactory system, suggesting that CGRP may play a role in olfaction. When applied to cultured mouse olfactory bulbs, CGRP was shown to increase the number of tyrosine hydroxylase/dopamine-expressing neurons *in vitro*. It is still unclear if CGRP is directly involved in the differentiation of dopaminergic olfactory bulb neurons, since CGRP was hardly detectable within most olfactory neurons during development. CGRP-containing axons in the olfactory epithelium were also shown to exhibit a region-specific distribution, with some CGRP-IR axons penetrating through the epithelium to reach the lumen of the nasal cavity. CGRP could either be transported from afferent axons or synthesized locally.

CGRP and Audition

CGRP-containing neurons and axons are observed in audition-related regions such as the superior olive nucleus, medial geniculate body, and lateral lemniscus, suggesting a role for CGRP in the processing of auditory information, although no direct functional data are yet available.

CGRP-containing neurons in the superior olive nucleus were shown to project axons to the ipsilateral cochlea, known to amplify and sharpen mechanical responses to sound. These axons were found to terminate in the inner spinal bundle underneath the inner hair cells and to form synaptic contacts with afferent terminals on these cells. These synapses are in turn controlled and/or regulated by efferents containing neuroactive substances. A cholinergic/CGRP vestibular efferent system could feedback on primary sensory axons and receptor hair cells in the cochlea, but it is not yet clear whether CGRP and acetylcholine are functionally interacting to induce such effects.

CGRP and Vision

CGRP-containing neurons are present throughout the parabigeminal nucleus, which projects essentially to the superior colliculus. The presence of high densities of CGRP binding sites in the superior colliculus and its lower levels in the lateral geniculate nucleus suggests a role for CGRP in the visual system. CGRP-containing cells were also found in the accessory optic system of adult rats, suggesting that CGRP may play a neuromodulatory role in vision and eye movements. CGRP, present in rat corneal nerves, is derived from sensory, sympathetic, and parasympathetic origins. A role for CGRP in vision certainly deserves further investigation.

CGRP and Taste/Feeding

CGRP is expressed in various neurons associated with taste, including sensory axonal endings in taste buds, as well as in central projections of these fibers terminating in the rostral part of the nucleus of the solitary tract. CGRP was also shown to be expressed in the relay system originating from the parabrachial nucleus and projecting to thalamic nuclei. Moreover, most motor neurons of the hypoglossal nucleus are CGRP expressing. Similar to CGRP-IR, CGRP binding sites are noted in the multisynaptic gustatory pathway, including the nucleus of the solitary tract, parabrachial nucleus, central amygdaloid nucleus, ventromedial posterior nucleus of the thalamus, and insular cortex. The presence of both CGRP and CGRP binding sites in olfactory and gustatory systems suggests that CGRP may have a key role in taste and ingestive behaviors.

A role for CGRP in taste and feeding is also supported by functional data. For example, intracerebroventricular (icv) administration of CGRP decreases food intake, and its receptors in the forebrain may mediate the anorexic effect. Lesion of the lateral portion of the parabrachial area, which contains numerous CGRP-positive neurons, induces hyperphagia and obesity whereas its stimulation causes hyperglycemia. Moreover, icv injection of CGRP also suppresses gastric secretion, which is influenced by the lateral and ventromedial regions of the hypothalamus and the central amygdaloid nucleus, two areas enriched with CGRP-IR. CGRP is also present in capsaicin-sensitive primary afferents, supporting its role in hyperemic and acid response. Hence, CGRP is likely to be a significant player in taste and feeding behaviors.

CGRP and Learning Behavior

Abundant CGRP-containing axons and a few CGRP-positive neurons are present in the caudate-putamen and a few CGRP-containing neurons in the thalamus project to various central amygdaloid subnuclei. Most of CGRP-containing axons in the central amygdaloid subnuclei originate from the parabrachial nucleus of the pons. It has been suggested that the overlap between acoustic and somesthetic inputs in the posterior thalamus, and the projection from this region to the amygdala and the striatum, is the anatomical substrate for the formation of learned associations between acoustic stimuli and pain. Bilateral destruction of the medial geniculate nucleus or of the amygdala and striatum prevents changes in autonomic activity and behaviors elicited by acoustic conditioned stimuli. CGRP has also been shown to be involved in the facilitation of learning and memory tasks. The effect of CGRP on learning could be blocked by pretreatment with either a serotonergic, β-adrenergic, or opiate receptor antagonist, suggesting that CGRP modulates several systems that are involved in learning behaviors. CGRP was also shown to attenuate learning impairments induced by MK-801 via a sigma receptor-related mechanism. Finally, CGRP may act as a neurotransmitter in the expression of fear in aversive learning tests, and CGRP released within the amygdala is likely to be involved in auditory fear conditioning.

CGRP and Autonomic Functions

Abundant CGRP-containing neurons are present in the parabrachial nucleus, an important relay center for processing autonomic function-related information, including cardiovascular, respiratory, and sleep regulatory processes. CGRP-containing neurons in the parabrachial nucleus project to a variety of forebrain structures, including the central nucleus of the amygdala and bed nucleus of the stria terminalis. In line with its anatomical distribution, microinjections of CGRP into the central nucleus of the amygdala have elicited increases in arterial blood pressure and heart rate in the rat. After exposure to stressful conditions, the majority of CGRP-containing neurons in the central nucleus of the amygdala exhibited fos immunoreactivity, suggesting that

projection pathways from the parabrachial nucleus to this nucleus and to the medial preoptic area are activated by stress.

CGRP-containing neurons in the parabrachial nucleus and in the caudal and intermediate part of the nucleus of the solitary tract also project to various areas, including the lateral hypothalamus, central nucleus of the amygdala, caudal parts of the caudate-putamen, globus pallidus, lateral septal nucleus, and bed nucleus of the stria terminalis, as well as to layer III of the agranular insular and perirhinal cortices. Accordingly, CGRP may be involved in the relay of visceral sensory information to these autonomic function-related regions. In addition, CGRP contained in both visceral afferent and efferent axons innervate the heart and branchial muscles in the pharynx, providing support to the findings that CGRP modulates a variety of autonomic functions.

CGRP and Motor Neurons, Development and Functions

Virtually all motor pools contain CGRP-IR motor neurons. CGRP is present in both embryonic and adult motor neurons. CGRP may play an active role in the formation of a functional synapse at the neuromuscular junction. CGRP receptor binding sites are also present in myotubes in culture and skeletal muscle membrane preparations. The possible effects of CGRP on striated muscle are (1) inducing increased levels of surface acetylcholine receptors in cultured chick myotubes by enhancing the rate of synthesis and insertion of new receptors into the plasma membrane, (2) increasing the rate of desensitization of nicotinic receptors by reducing acetylcholine-activated channel opening frequency, (3) regulating the phosphorylation of nicotinic acetylcholine receptors in rat myotubes, and (4) inhibiting insulin-stimulated synthesis of glycogen while stimulating glycolysis in mammalian skeletal muscles.

CGRP modulates the biochemical, physiological, and metabolic properties of skeletal muscles through the activation of specific CGRP receptors. Several trophic factors have been shown to regulate the content of CGRP in motor neurons. For example, CGRP-IR is upregulated in mouse motor endplates in which nerve terminal sprouting was induced by the exogenous application of ciliary neurotrophic factor. In addition, basic fibroblast growth factor (bFGF), insulin-like growth factor 1 (IGF-1), and IGF-2 were shown to have important regulatory effects on the expression of CGRPα in rat motor neurons. CGRP levels in motor neurons may also be influenced by axotomy. For example, sciatic nerve section or facial nerve crushing in rat induces a transient increase in CGRP (mRNA and protein) in axotomized motor neurons. Blockade of axonal flow also increases the expression of CGRPα mRNA in motor neurons. CGRP levels in motor neurons are sensitive to supraspinal inputs since thoracic spinal cord transection resulted in decreased levels of CGRP in motor neurons. It is interesting to note that lower CGRP levels were observed in motor neurons of Wobbler mice, a model for amyotrophic lateral sclerosis and infantile spinal muscular atrophy.

CGRP and Sensory Neurons

CGRP-containing cells constitute 40–50% of DRG and trigeminal ganglion neurons. CGRP-containing primary afferents terminate in the superficial layers of the dorsal horn or the trigeminal nucleus. While CGRP-positive cells mainly belong to unmyelinated C and thinly myelinated Aσ axons, only 10–15% of CGRP-containing cells are identified as Aα/β axons. CGRP is frequently shown to coexist with other peptides in primary sensory afferents, including substance P, cholecystokinin, and dynorphin.

The localization of CGRP in small DRG neurons as well as in axonal terminals in the pain-related area of the dorsal horn suggests that CGRP may participate in nociceptive transmission. CGRP is one of the best examples of a neuromodulator that could exert rather limited effects by itself and yet significantly potentiates the nociceptive effects of other substances, such as substance P. For example, CGRP has been shown to inhibit the degradation of substance P and to facilitate the release of both substance P and excitatory amino acids from primary sensory afferents. Intrathecal administration of CGRP was shown to facilitate spinal nociceptive response and to produce a slower onset but prolonged excitation of nociceptive dorsal horn neurons *in vivo*. *In vitro* studies also showed that CGRP can produce a slow depolarization by a direct action on nociceptive dorsal horn neurons.

It has recently been shown that strain dependence of CGRP expression results in variable responses to noxious heat, which could be abolished by peripheral injection of CGRP, blockade of cutaneous and spinal CGRP receptors, or long-term inactivation of CGRP with a CGRP-binding Spiegelmer. Linkage mapping has shown that variable behavioral pain responses were due to differential expression of the *Calca* gene that encodes for CGRPα.

Chronic exposure to opioids such as morphine is shown to result in a marked decrease in its antinociceptive effects, physical dependence, and parallel increases in CGRP content in DRG neurons. Antagonists such as CGRP8–37 and BIBN4096BS are able to prevent or reverse the development of morphine

tolerance and physical dependence, suggesting their potential usefulness in the maintenance of the antinociceptive properties of morphine and derivatives.

It is also well known that CGRP expression in primary sensory neurons is modulated by nerve growth factor, which is required for the survival of CGRP-expressing cells during development and needed for the maintenance of the phenotype during adulthood. Most CGRP-containing nociceptors also co-express transient receptor potential vanilloid receptor 1, a nonselective Ca^{2+} channel which can be activated by pungent capsaicin, heat, and prion. Neonatal capsaicin treatment is able to eliminate almost all CGRP-containing DRG neurons, while capsaicin is able only to deplete CGRP in these cells in adulthood. CGRP is upregulated in DRG neurons during inflammation while downregulated in injured DRG neurons following nerve injury. CGRP also plays an important role in the pathogenesis of migraine and cluster headache. Most interesting, the CGRP antagonist BIBN4096BS has been shown to be effective to treat migraine in a recent clinical trial.

CGRP Effects on Inflammation

CGRP-IR is broadly expressed within the cardiovascular system, consisting of a dense peripheral sensory network innervating the arteries, veins, and heart of various species, including human. CGRP receptor binding sites are also present in the heart and blood vessels. CGRP is one of the most potent vasorelaxing substances known thus far. CGRP-induced vasorelaxation is mediated via CGRP1 receptors, coupled to Gsα protein. CGRP-induced vasodilation is possibly mediated through both nitric oxide- and endothelium-independent and dependent pathways.

Inflammation can be categorized as immunogenic and neurogenic. Immunogenic inflammation is mediated by the activation of specific immune cells, whereas neurogenic inflammation is mediated directly by the activation of nociceptive and thermal-sensitive endings in various tissues. CGRP is actively involved in both immunogenic and neurogenic inflammation. During neurogenic inflammation, tissue damage is able to activate nociceptive axonal endings to cause CGRP-containing nociceptors to release CGRP into inflamed tissues. Released CGRP can, in turn, potentiate the local effects of inflammatory agents including histamine, leukotriene, bradykinin, and substance P, essentially through its vasodilating properties. CGRP can also modulate responsiveness of immune cells such as T-helper cells, B cells, neutrophils, and macrophages. CGRP was recently shown to be produced in lymphocytes and monocytes, as well as in invading macrophages in inflamed areas, and is involved in the production of some proinflammatory chemokines such as monocyte chemoattractant protein 1 and cytokines such as interleukin-1β, tumor necrosis factor-α, and interleukin-6. Hence, CGRP contributes to the inflammatory processes by promoting vasodilation and modulating the activity of various types of immune cells. Therefore, developing more-selective and -potent nonpeptide CGRP receptor antagonists will have clinical significance in the treatment of neurogenic and/or immunogenic inflammation-related diseases such as diabetes, asthma, migraine, nerve injury-associated neuropathic pain, and rheumatoid arthritis.

CGRPα Knockout Mice

Homozygous CGRPα knockout mice with normal calcitonin expression were obtained through target disruption of exon 5 of the calcitonin/CGRPα gene or by the introduction of a stop codon upstream of the CGRPα encoding sequence in exon 5. These two lines of knockout mice were viable and fertile and did not display obvious abnormalities. Calcitonin/CGRPα double knockout mice also developed normally, without obvious defects, but the number of viable fetuses in uterus of homozygous mothers was reduced compared to heterozygous knockout or wild-type mothers.

In CGRPα knockout mice derived from an introduced translational stop codon in exon 5, the cardiovascular system is apparently not affected. But in CGRPα knockout mice generated by targeted disruption of exon 5, mean arterial pressure, heart rate, peripheral vascular resistance, and sympathetic nervous activity are elevated. In calcitonin/CGRPα double-knockout mice, the systemic and mean arterial pressure are also increased. It is clear that the generation of CGRPα-β double-knockout mice is required since CGRPβ is normally expressed in CGRPα knockout mice and could hence have a compensatory effect.

The contribution of CGRPα in pain perception was also examined in CGRPα knockout mice with the selectively disrupted exon 5 of the calcitonin gene, and in calcitonin/CGRPα double knockout mice. Acute pain sensation in CGRPα knockout mice was not affected, but these mice exhibited reduced edema formation and nociception to chemical pain associated with inflammation. Calcitonin/CGRPα double-knockout mice also did not display abnormality in acute pain sensation. Unlike normal mice, these double-knockout mice exhibited no secondary hyperalgesia after arthritic inflammation. These observations suggest that endogenous CGRPα is involved in the production and transmission of pain associated with both neurogenic and arthritic inflammation.

Conclusion and Perspectives

CGRP is widely distributed in both CNS and PNS and possesses a wide variety of biological effects. Although our understanding of CGRP receptors has progressed over the past decade, limited information is available on molecular characteristics and topography of possible subtypes. The fact that receptor recognition is dependent on the level of expression of associated RAMPs adds another level of complexity. Hence, a clear understanding of the role of the various RAMPs in CGRP receptor pharmacology and signaling is required in order to make significant progress on the role of CGRP, related peptides, and their receptors in various diseases.

Calcium Regulation

In the course of evolution, calcium has become a fundamental component of intracellular signaling; Ca^{2+}-mediated signaling is present in almost all eukaryotic organisms. The signaling properties of calcium originate from the dynamic characteristics of the mineral: cytoplasmic concentrations of free Ca^{2+} can change very rapidly from the resting levels of 50–100 nM to the millimolar range, and can return to baseline very quickly, too. In other words, Ca^{2+} signaling depends on transient changes of intracellular free Ca^{2+} concentration. Evolution has chosen calcium as a major intracellular signaling messenger, and it also selected a set of mechanisms that tightly control intracellular Ca^{2+} concentration.

Under resting conditions, intracellular Ca^{2+} concentration is very low, 50–100 nM, while extracellular concentration is in the millimolar range (2.5 mM). There is therefore a 10 000-fold difference in Ca^{2+} concentration across the plasma membrane and endo(sarco)plasmic reticulum. The energy contained in this gradient allows rapid influx of Ca^{2+} once the 'gates/channels' open. Maintaining such a steep Ca^{2+} gradient also requires high energy expenditure and depends on the coordinated functions of pumps/transporters located in the plasma membrane and various subcellular organelles, and on a number of Ca^{2+}-binding proteins (Figure 1).

Plasma Membrane Regulation of Ca^{2+} Levels

Plasma membrane Ca^{2+} pump and exchanger Low intracellular Ca^{2+} concentration is achieved in part by the activation of various proteins in different subcellular locations. At the plasma membrane level, two systems are involved in the extrusion of Ca^{2+}: a low-affinity, high-capacity, and electrochemically driven Na^+/Ca^{2+} exchanger (NCX), and a high-affinity, low-capacity Ca^{2+}-ATPase. The plasma membrane Ca^{2+}-ATPase (PMCA) has a $K_d < 0.5\,\mu M$ and is assumed to play a dominant role in cells when cytosolic concentration is around 0.1–0.2 μM, while the exchanger ($K_d \sim 10$–$15\,\mu M$) functions best when Ca^{2+} concentration rises to 1–10 μM. PMCA is activated by acidic phospholipids, with the mono- and bis-phosphorylated derivatives of phosphatidylinositol being the most effective ones. PMCA is also regulated by calmodulin and other Ca^{2+}-activated enzymes. For instance, calpain truncation of its C-terminal domain makes the pump constitutively active, while phosphorylation by protein kinase A (PKA) and protein kinase C (PKC) increases its Ca^{2+} affinity. In humans, four different isoforms of PMCA, which are products of more than 26 transcripts of four genes, have been identified. While PMCA1 and PMCA4 are ubiquitously distributed, PMCA2 and PMCA3 are mainly found in brain. Interestingly, expression levels of PMCA are regulated by Ca^{2+}.

While PMCA is the dominant Ca^{2+} ejector at the plasma membrane of nonexcitable cells, the NCX plays a fundamental role in excitable tissues. The capacity of the plasma membrane Na^+/Ca^{2+} exchanger to pump calcium is 10 times greater than that of PMCA. Unlike PMCA, the NCX is not an enzyme; it is a transporter mediating the import of three Na^+ ions for the extrusion of one Ca^{2+}. The extrusion of Ca^{2+} against its large electrochemical gradient depends on the energy of the Na^+ gradient generated by the Na^+ pump. Depending on the thermodynamic values of Ca^{2+} and Na^+ and on the membrane potential, the direction of the NCX-mediated transport of Na^+ and Ca^{2+} can be reversed – that is, Ca^{2+} may enter cells in exchange for extruded Na^+. The activity of NCX is also regulated by intracellular pH, ATP levels, other ions, and redox agents. In addition, phsophorylation of NCX by PKA and PKC has been shown to increase its activity. To date, three different genes encoding three NCX isoforms (NCX1–NCX3) have been cloned in mammals. The distribution of these NCX isoforms has also been analyzed: NCX1 is expressed in most tissues, including brain and heart, while NCX2 and NCX3 are mainly detected in neuronal and skeletal muscle tissues. Analyses of messenger RNA and protein levels have revealed that all three isoforms of NCX are highly expressed in most central nervous system (CNS) structures, although in some brain areas they are differentially expressed. Interestingly, the NCX1 isoform exists at both pre- and postsynaptic sites.

Plasma membrane Ca^{2+} channels Besides pumps and exchangers, the plasma membrane also contains Ca^{2+} channels. Ca^{2+} channels are transmembrane proteins that function as a 'gate.' These gates are generally closed in resting cells, but when the gates open, Ca^{2+} rapidly flows into the cytoplasm down its electrochemical gradient. There are three types of Ca^{2+}

Figure 1 Schematic representation of the major mechanisms involved in Ca^{2+} regulation and signaling, illustrating the various mechanisms involved in Ca^{2+} influx, transport, extrusion, and storage present in various cellular compartments. Also illustrated are several mechanisms involved in Ca^{2+} signaling, including phosphorylation processes, gene regulation, and protein degradation. As discussed in the text, age-related alterations in several of these mechanisms have been identified and could be responsible for age-related decline in cognitive function and increased susceptibility to diseases and insults. AC, adenylate cyclase; CaM, calmodulin; CaMKK, CaMKII, CaMKIV, calmodulin-dependent protein kinases; cAMP, cyclic adenosine monophosphate; CREB, cyclic adenosine monophosphate (cAMP) response element-binding protein; ER, endoplasmic reticulum; Erk1/2, extracellular signal-related kinase 1/2; InsP3, inositol triphosphate; M, mitochondrion; MEK, mitogen-activated protein extracellular kinase; NCX, Na^+/Ca^{2+} exchanger; PKA, protein kinase A; PLC, phospholipase C; PMCA, plasma membrane Ca^{2+}-ATPase; PYK2, proline-rich tyrosine kinase 2; RSK1-3, ribosomal S6 kinases 1–3; RTK, receptor tyrosine kinase; SERCA, sarco(endo)plasmic reticulum Ca^{2+}-ATPase; SOS, son of sevenless exchange factor.

channels, defined by the mechanisms controlling their opening and closing: (1) voltage-operated channels (VOCs), the function of which depends on membrane potential, (2) receptor-operated channels (ROCs) that are gated by binding of ligands to their receptors, and (3) store-operated channels (SOCs) that are controlled by Ca^{2+} levels in the endoplasmic reticulum (ER). VOCs are the best characterized Ca^{2+} channels and have high Ca^{2+} selectivity. VOCs are widely distributed, not only in excitable tissues, but also in non-excitable tissues. At the single-channel level, these channels are subdivided into L, N, P, Q, R, and T types based on their physiological and pharmacological characteristics. Recent molecular work reveals that, structurally, VOCs are large complexes consisting of either four or five subunits that are encoded by five separated genes ($\alpha 1$, $\alpha 2$, β, γ, and δ); a1, the product of the $\alpha 1$ gene is the largest and can form a channel, while the other subunits are regulators.

A number of Ca^{2+} channels belong to the ROC family, including both ionotropic and metabotropic glutamate receptor families. According to their ligand selectivity, ionotropic glutamate receptors are further divided into α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-, *N*-methyl-D-aspartate (NMDA)-, and kainic acid (KA)-type receptors. Metabotropic glutamate receptors are receptors coupled with G-proteins. Genes encoding all glutamate receptors have been cloned and their structures and functions have been characterized. Among these receptors, NMDA receptors have the highest Ca^{2+} permeability. Interestingly, activation of NMDA receptors also depends on membrane potential, which means that Ca^{2+} flux through this receptor channel is also voltage gated. Traditionally, AMPA receptors are considered Ca^{2+} impermeable. Following the cloning of this family of receptors, it became clear that Ca^{2+} impermeability was due to the presence of one of the

subunits, GluR2. In rare cases in which AMPA receptor complexes do not contain this subunit, they are Ca^{2+} permeable. Activation of ROCs is also subjected to regulation by proteins kinases and proteases.

SOCs have been best studied in neuroendocrine cells, in which depletion of hormones and Ca^{2+} induces activation of SOCs. SOCs have also been found in other cell types, including mast cells, basophils, and neurons. However, their physiological and pharmacological properties, molecular structures, and regulation are still largely unknown.

The ER

The ER is the best characterized Ca^{2+} signaling organelle. It has large Ca^{2+} buffering capacity and functions as the main intracellular Ca^{2+} storage compartment. The ER Ca^{2+} buffering and storage properties originate from the concerted action of a number of proteins. Ca^{2+} uptake into the ER lumen results from the activation of Ca^{2+} pumps, belonging to the sarco(endo)plasmic reticulum Ca^{2+}-ATPase (SERCA) family. Release of Ca^{2+} from the ER is controlled by inositol triphosphate (InsP3)-gated channels and ryanodine receptors (RyRs), also know as Ca^{2+}-gated Ca^{2+} channels. Ca^{2+}-binding proteins, such as calsequestrin and calreticulin, also contribute to Ca^{2+} storage in the ER. Ca^{2+} concentration in the ER has been estimated to be in the millimolar range, which generates a large electrochemical gradient for Ca^{2+} across the ER membrane. RyRs are generally activated by Ca^{2+} influx at the plasma membrane, induced by depolarization or binding of ligands to ROCs. InsP3-gated channels, also know as InsP3 receptors, are activated by the binding of InsP3. InsP3 is a product of phospholipase C (PLC)-mediated hydrolysis of the membrane phospholipids, phosphatidylinositol 4,5-bisphosphate (PtdInsP2), generally as a result of activation of G-protein-coupled receptors in the membrane. In addition, InsP3 receptors are regulated by Ca^{2+}, ATP, and phosphorylation by PKA. The positive feedback stimulation of RyRs and InsP3 receptors by Ca^{2+} leads to a regenerative opening of the release channels and contributes to the formation and propagation of Ca^{2+} waves.

Mitochondria and Ca^{2+} Regulation

In addition to the ER, mitochondria also contribute to Ca^{2+} homeostasis in the cytoplasm; this function of mitochondria becomes more important in nerve terminals in the presence of high levels of electrical activity. In particular, increasing evidence indicates that mitochondria limit the rise in intracellular calcium concentration ($[Ca^{2+}]_i$) that occurs during periods of intense activity. This function might be particularly critical under conditions of reduced energy supply (ischemia, hypoglycemia) or following injury, as well as during aging. Alternatively, it has been proposed that Ca^{2+} uptake by mitochondria serves to adjust the concentration of free Ca^{2+} inside the mitochondria, which in turn controls the rate of energy metabolism by regulating the activity of a number of Ca^{2+}-dependent intramitochondrial enzymes. Another critical role of the mitochondria in apoptotic cell death has been identified: the mitochondrial permeability transition pore (mPTP) is a complex of proteins in the mitochondrial membrane that is activated by a number of factors, and in particular by calcium when its concentration reaches a certain threshold inside the mitochondria. Following opening of the mPTP, several factors, including apoptotic-inducing factor and cytochrome *c*, are released from the mitochondria and initiate apoptotic cell death.

Ca^{2+} Signal Transduction

Ca^{2+} signaling is so ubiquitous that it is involved in almost every single function of a living cell. In neurons, Ca^{2+} signaling controls neurogenesis, neuronal differentiation, axonal growth, dendritic maturation, and synaptic plasticity. Ca^{2+} also contributes critically to neuronal death under various conditions. At the molecular level, Ca^{2+} signaling regulates transcription and posttranscriptional modifications of mRNA, translation and posttranslational regulation of proteins, and protein phosphorylation and degradation. Among the diverse properties of Ca^{2+} signaling, one feature that needs to be emphasized is the so-called coupling function. Ca^{2+} signaling couples extracellular signals (neurotransmitters, growth factors, cytokines, etc.) to intracellular responses (enzymatic reactions, gene expression, cytoskeleton rearrangement, release of neurotransmitters, etc.).

Ca^{2+} and Transcription Regulation

Ca^{2+} signaling control of gene expression has been known for over a decade. In the CNS, Ca^{2+}-dependent transcriptional regulation is involved in dendritic morphogenesis, path finding, and activity-dependent synaptic modifications leading to adaptive properties of brain function. The best characterized signaling pathway that conveys Ca^{2+} signals to gene regulation is the calmodulin and Ca^{2+}/calmodulin-dependent protein kinase (CaMK) system (Figure 1). Elevated Ca^{2+} levels, resulting from the activation of channels located on plasma membrane or from Ca^{2+} released from ER, activate CaMKs indirectly via binding to calmodulin.

CaMKs, especially CaMKIV and CaMKII, then phosphorylate a transcription factor, the cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB), at residue Ser133, which is critical for factor activation. Recent work has shown that nuclear Ca^{2+} can also increase transcriptional activity by recruiting a coactivator, the CREB-binding protein (CBP). Interestingly, phosphorylation of CREB depends on the entry of Ca^{2+}: Ca^{2+} influx through L-type voltage-gated Ca^{2+} channels (VGCCs) leads to sustained CREB Ser133 phosphorylation, while Ca^{2+} entry through NMDA receptors triggers only transient phosphorylation of CREB at Ser133, at least in cultured embryonic neurons. The transcriptional activity of CREB is also regulated by other Ca^{2+}-dependent signaling pathways, such as activation of PKA and the Ras/mitogen-activated protein kinase (MAPK) pathway. In fact, CREB was first reported as a transcriptional factor that responded to elevation of cellular cAMP levels induced by activation of PKA. Activation of CREB through the Ras/MAPK pathway involves the recruitment of nuclear RSK kinases (including RSK2) that phosphorylate CREB at Ser133. Brain-derived neurotrophic factor (BDNF) plays critical roles in development and synaptic plasticity by regulating CREB in an activity-dependent manner. In addition to protein kinases, protein phosphatases such as calcineurin also contribute to Ca^{2+}-induced gene regulation. Finally, Ca^{2+} can also influence gene expression by directly binding to transcriptional factors.

Ca^{2+}-Mediated Regulation of Protein Phosphorylation and Dephosphorylation

Protein phosphorylation is an enzymatic reaction that modifies either serine/threonine or tyrosine residues. Numerous Ser/Thr-type protein kinases and one Ser/Thr protein phosphatase are regulated by Ca^{2+}. In general, Ca^{2+} regulates these kinases indirectly by binding to calmodulin, with the exception of PKC, in which case Ca^{2+} and phospholipids combine to regulate the activity of this kinase. Interestingly, CaMKII is abundantly present in essentially all neuronal compartments. While CaMKIV plays a predominant role in CREB phosphorylation and gene regulation, CaMKII is enriched in postsynaptic densities and is critically involved in synaptic function and plasticity. CaMKII is also subject to modulation by autophosphorylation at Thr286, a process that has been proposed to participate in hippocampal CA1 region long-term potentiation (LTP) and in hippocampus-dependent behaviors such as spatial learning and memory. CaMKII phosphorylates a large number of synaptic proteins, including AMPA and NMDA receptors. Recent work suggests that CaMKII enhances synaptic function by phosphorylation of AMPA receptor GluR1 subunits at Ser831 and by promoting insertion of new receptors into synapses. Other kinases, such as PKA and PKC, have also been implicated in synaptic plasticity. In a recent study, Sacktor and colleagues showed that an inhibitor of an atypical PKC isoform (PKCζ) not only reversed LTP maintenance but also erased existing memories.

Ca^{2+}-Dependent Protein Degradation

Proteins are generally degraded by proteases in the cytosol or in specialized organelles, such as lysosomes. A large number of proteases are under the regulation of Ca^{2+}-dependent signaling cascades. Among these, Ca^{2+}-dependent proteases (calpains) and caspases are the best characterized. A few studies have also reported that the ubiquitin–proteasome system is under the regulation of Ca^{2+}, although the reported results were not conclusive. Calpains, a 16-member family of proteases, have attracted tremendous interest due to their diverse roles under physiological as well as pathological conditions. Structurally, calpains are heterodimers composed of a large catalytic subunit and a small subunit. The function of the small subunit is still not clear. The crystal structure of this subunit reveals the existence of Ca^{2+} binding motifs, the binding ability of which has been experimentally confirmed. The large subunit varies in different calpain isoforms. The most common forms of calpains are μ-calpain, activated *in vitro* by micromolar calcium concentrations, and m-calpain, activated at millimolar calcium concentrations. The unique property that distinguishes calpain from other proteases is that it does not completely degrade its substrates into inactive fragments; instead, it produces a partial proteolysis that generally changes the function of the proteins. To date more than 100 proteins have been characterized as calpain substrates. These proteins belong to several classes of proteins, including transcription factors, structural proteins, receptors or channels, protein kinases and phosphatases, and other proteases. The variety of calpain substrates further stresses the diversity of functions in which this family of proteases is implicated. In the CNS, calpain has been implicated in cell migration, axonal growth, synaptic plasticity, and, most importantly, neurodegeneration. In addition to Ca^{2+}, calpain activity is regulated by multiple factors, including phosphorylation and association with membrane phospholipids and with DNA. There is also a highly selective endogenous calpain inhibitor, calpastatin. Calpastatin is a ubiquitously expressed protein of 110 kDa. Interestingly, binding of calpain to its inhibitor is also Ca^{2+} dependent.

Ca^{2+} Regulation and Signal Transduction in Aged Brains

The 'calcium hypothesis of aging,' proposed by Zaven Khachaturian and Gibson and Peterson more than 20 years ago, postulated that a slow disruption of Ca^{2+} homeostasis accompanied the aging process and was responsible for many of the pathological consequences of aging. The words that Khachaturian wrote then, "it is clear that any significant and long lasting change in the normal functioning of Ca^{2+} transport systems, pumps, buffers or storage systems that help maintain the homeostasis could influence the delicate balance of Ca^{2+} concentration in the cytosol, with serious consequences," are still echoed today in most studies of Ca^{2+} regulation and aging. The initial idea that basal Ca^{2+} concentration was increased in aged cells, and in particular in neurons, has been largely disproved. The current consensus is that the major difference between neurons from young and old animals consists in the rate of $[Ca^{2+}]_i$ recovery following stimulation-induced increase in intracellular Ca^{2+} level. The lack of changes in basal Ca^{2+} concentrations indicates that none of the mechanisms involved in setting this level is significantly altered with aging, and in particular, that the metabolic activity of aged neurons is sufficiently normal to provide the energy required for establishing this set point. On the other hand, the slower recovery of Ca^{2+} following increased Ca^{2+} influx suggests that one or several processes that are engaged following a rapid increase in Ca^{2+} concentrations are altered with aging. Among these, it has been clearly demonstrated that the activity of the plasma membrane Ca^{2+}-ATPase is decreased with aging. One of the hypotheses proposed to account for such decrease is a modification of Ca^{2+}-ATPase regulation by calmodulin, possibly due to increased oxidation of this regulatory protein, as well as a large decrease in the levels of calmodulin. Activity of the SERCA is also decreased with aging, resulting in changes in endoplasmic Ca^{2+} homeostasis. However, it is worth mentioning that age-related changes in SERCA are quite mild, in contrast to what is observed under pathological conditions, in which changes in SERCA play a more important role. On the other hand, no age-related changes in the Na^+/Ca^{2+} exchanger have been reported in neurons. A hallmark of aged neurons is an increase in the number of L-type voltage-gated calcium channels. As will be discussed in the following section, this effect has important functional consequences for normal synaptic physiology and for synaptic plasticity.

As discussed earlier, an important regulator of Ca^{2+} homeostasis consists in the pool of mitochondria. Numerous morphological studies have indicated that while the number of mitochondria might decrease with aging, their size increases. Functionally, aged mitochondria also exhibit chronic depolarization, which could be due to a decreased activity of the electron transport chain. Such decreased activity of the electron transport chain and the resulting membrane depolarization might account for the reported decrease in Ca^{2+} uptake by aged mitochondria. More importantly, alterations in mitochondria with aging result in their decreased effectiveness to respond to any increase in energy demand occurring during periods of increased neuronal activity. Similarly, any fluctuations in the supply of energy substrates or in oxygen will have important consequences for the formation of ATP and consequently for the functions of the multiple ATP-dependent enzymes involved in Ca^{2+} homeostasis. The consensus that is therefore emerging is that alterations in Ca^{2+} homeostasis with aging result from relatively subtle changes in some elements contributing to Ca^{2+} regulation, together with alterations in the metabolic status of the cells due to increased mitochondrial dysfunction.

Functional Consequences of Age-Related Changes in Ca^{2+} Signaling

As previously mentioned, Ca^{2+} is an important signaling molecule, and any alteration in Ca^{2+} homeostasis will have profound functional consequences at all levels of neuronal function, and this is one of the reasons involved in formulating the 'calcium hypothesis of aging.' One of the immediate consequences of the increased number of L-type voltage-gated calcium channels is the increase in the afterhyperpolarization that follows action potentials due to increased activity of Ca^{2+}-dependent potassium channels. This phenomenon has been well described by many groups and is responsible for the decreased excitability found in aged neurons and, more importantly, for decreased synaptic plasticity, in particular in LTP, as it makes summation of depolarization more difficult and therefore decreases the activation of NMDA receptors, a critical step in LTP induction. Interestingly, blockade of the L-type channels or of some of the Ca^{2+}-activated potassium channels reestablishes normal LTP and learning in aged animals.

Another consequence of the alterations in Ca^{2+} homeostasis is that Ca^{2+} signals following intense neuronal activity are elevated and prolonged, thus producing excessive activation of all of the targets and signaling pathways normally activated by intracellular Ca^{2+}. One of the pathways activated by Ca^{2+} leads to regulation of gene expression, and it has

recently been shown that aging is associated with much wider changes in gene expression than initially thought. In particular, expression of pathways related to inflammation, mitochondrial function, oxidative stress responses, and synaptic plasticity is significantly increased in aged animals. Interestingly, calpain activation has also been shown to be increased in several brain regions and cellular locations in aging, as increased levels of calpain-mediated spectrin degradation products are present in cerebral cortex and cerebellum from aged brains. Furthermore, activated calpain 1 has also been found in white matter and in activated microglia in aged monkeys. Considering the numerous cross-talks between protein phosphorylation and protein degradation, it is apparent that alterations in Ca^{2+} regulation will have complex effects on the extent and duration of changes in protein phosphorylation, susceptibility to protease degradation, and, ultimately, functional modifications. Another critical factor, mentioned previously, relates to the age-related increase in oxidized proteins due to increased formation of reactive oxygen species. In the case of calmodulin, this results in its decreased ability to stimulate PMCA and other calmodulin-dependent enzymes.

Conclusions

All the data accumulated since the original formulation of the 'calcium hypothesis of aging' have led to revision of the details of the hypothesis while maintaining and strengthening its overall validity. It is now clear that multiple factors participating in Ca^{2+} regulation and signaling are altered during aging and contribute to alterations in Ca^{2+} homeostasis and signaling functions. Some of these processes have been directly linked to age-related cognitive decline, while others have been shown to be involved in increased neuronal vulnerability to age-related diseases and insults. While we do know much more about the mechanisms involved in Ca^{2+} homeostasis and signaling and their alterations in aging, we are far from being able to propose solutions that would readily counteract these changes and provide the long-sought élixir de jouvence.

Calcium Channel and Calcium-Activated Potassium Channel Coupling

N V Marrion, University of Bristol, Bristol, UK

© 2009 Elsevier Ltd. All rights reserved.

Activation of calcium (Ca^{2+})-activated potassium (K^+) channels by influx of Ca^{2+} ions through voltage-dependent Ca^{2+} channels is critical for regulating cell excitability in many cell types. The activation of Ca^{2+}-dependent K^+ channels can hasten the repolarization of an action potential or modulate the frequency of action potential firing. In early years, it was of paramount importance to identify the subtype of Ca^{2+}-activated channel and resolve the physiological role of its activation. The origin of intracellular Ca^{2+} was of little significance, and it was generally assumed that all possible sources of Ca^{2+} entry were involved and that Ca^{2+}-activated channels simply responded to global changes of intracellular Ca^{2+}. In recent years, the pharmacology of blockers of Ca^{2+} channels has improved dramatically, permitting some investigation into the identity of voltage-dependent Ca^{2+} channels that mediate the entry of Ca^{2+} to cause activation of Ca^{2+}-activated K^+ channels. There is now considerable interest in whether there is selective pairing of Ca^{2+} and Ca^{2+}-activated channels.

Regulating Membrane Excitability by Activation of Ca^{2+}-Activated Potassium Channels

Activation of Ca^{2+}-activated potassium channels results in membrane hyperpolarization that is crucial in regulating action potential duration and firing frequency. For example, activation of large conductance Ca^{2+}-activated potassium (BK, $K_{Ca}1.1$) channels hastens the repolarization of the action potential in hippocampal pyramidal neurons and underlies generation of the fast afterhyperpolarization (AHP) that controls the frequency of action potential firing at the onset of a burst. In contrast, a train of action potentials in hippocampal CA1 pyramidal neurons is terminated by an AHP that displays two main time components. The AHP results, at least in part, from activation of small conductance Ca^{2+}-activated potassium (SK, $K_{Ca}2$) channels. AHPs can be broadly classified into two groups – those that are sensitive to the bee venom toxin apamin and those that are not. Most examples of AHPs in excitable cells are apamin sensitive, with only a small number of cell types (e. g., cortical and hippocampal pyramidal cells) exhibiting apamin-insensitive slow AHPs.

BK ($K_{Ca}1.1$) channels are activated by the concerted action of membrane depolarization and a rise of intracellular Ca^{2+}, with the concentration of Ca^{2+} required to open a BK channel being less at depolarized levels. In general, BK channels are considered to exhibit a low affinity for Ca^{2+} binding, requiring submembrane concentrations of Ca^{2+} in excess of $1\,\mu M$. In contrast, activation of SK ($K_{Ca}2$) channels is voltage independent and the channels display a higher affinity for Ca^{2+} binding, being activated by submicromolar concentrations of intracellular Ca^{2+}. The different sensitivities of BK and SK channels to intracellular Ca^{2+} have obvious implications for where the Ca^{2+}-activated channel may be located relative to the source of Ca^{2+}. In general, the concentration of intracellular Ca^{2+} required to activate either BK or SK channels has not been observed during their activation. This suggests that neither BK nor SK channels are responding to global changes of intracellular Ca^{2+} and that a local submembrane rise of Ca^{2+} is more likely to be responsible for the activation of both of these channels. The opening of a voltage-gated Ca^{2+} channel will provide a submembrane microdomain of raised Ca^{2+} that will last for several hundred microseconds. The concentration of Ca^{2+} reached in the microdomain will be dependent on the amount of Ca^{2+} that enters during a single Ca^{2+} opening, which will depend on the channel conductance and amount of time that it is open. Because the Ca^{2+} concentration will decrease exponentially with distance from the microdomain core, Ca^{2+}-activated channels can be placed at particular distances from the Ca^{2+} channel to experience the appropriate concentration of Ca^{2+}. The lower sensitivity of BK channels to Ca^{2+} compared with SK channels strongly suggests that BK channels reside very close to or possibly in direct contact with voltage-gated Ca^{2+} channels. In contrast, it is likely that SK channels are located at some distance from Ca^{2+} channels (Figure 1) because they require less Ca^{2+} to be activated.

The pharmacology of voltage-dependent Ca^{2+} channels has improved in recent years, with compounds available to distinguish between native T-, L-, N-, P/Q-, and R-type calcium channels. In most cases, functional coupling has been inferred from the effects of block of a Ca^{2+} channel subtype on the

Figure 1 Schematic representation of possible locations of voltage-dependent Ca^{2+} channels and the Ca^{2+}-activated BK and SK channels. The combination of measured Ca^{2+} sensitivities of BK and SK channels and experimental data suggests that a clear difference of relative locations of these Ca^{2+}-activated K^+ channels to Ca^{2+} channels exists.

activation of a Ca^{2+}-activated potential or membrane current. These types of data fail to distinguish between functional coupling resulting from a specific interaction between channel subtypes and that arising because channels share the same subcellular location.

Pharmacological Determination of Ca^{2+} Channel Subtypes Underlying Activation of Ca^{2+}-Dependent Hyperpolarizations in Central Neurons

Identity of the Ca^{2+} Channel Subtype Activating Apamin-Sensitive AHPs

The cloning of SK channel subunits revealed three subtypes termed K_{Ca}2.1–2.3. Apamin-sensitive AHPs are likely derived from either K_{Ca}2.2 or -2.3 channel subunits. Although each cloned subunit displays characteristic sensitivity to the bee venom toxin, most brain slice experiments have used a concentration of apamin (>10 nM) that is too high to permit discrimination of the identity of the apamin-sensitive SK channel. Most of this work has been performed using current clamp recording from central neurons and the effect of Ca^{2+} channel subtype-specific blockers on Ca^{2+}-dependent hyperpolarizations has been assessed, with most examples of apamin-sensitive AHPs decaying with a time constant of approximately 70–100 ms.

Coupling of Ca^{2+} Channel Subtypes to Activation of Apamin-Sensitive AHPs

Ca_V1.2 and -1.3 L-type Ca^{2+} channels Both Ca_V1.2 and -1.3 L-type Ca^{2+} channels are blocked by dihydropyridine antagonists. There are two examples of apamin-sensitive AHPs with slow decay reported to result from Ca^{2+} entry through L-type Ca^{2+} channels. The example reported from gonadotropin-releasing hormone neurons was shown to be generated from Ca^{2+} entry through L-, N-, Q-, and R-type Ca^{2+} channels.

Ca_V2.2 N-type Ca^{2+} channels N-type Ca^{2+} channels are blocked selectively by ω-conotoxin GVIA. It has been observed that a large component of the apamin-sensitive AHP found in both nucleus basalis cholinergic neurons and subthalamic nucleus neurons is sensitive to the conotoxin.

Ca_V3 T-type Ca^{2+} channels A minor contribution of Ca^{2+} entry through T-type Ca^{2+} channels underlies generation of an apamin-sensitive AHP in nucleus basalis cholinergic neurons. In contrast, activation of the apamin-sensitive AHP in dopaminergic midbrain neurons is selectively coupled to T-type Ca^{2+} channels.

Ca_V2.1 P/Q-type Ca^{2+} channels P- and Q-type Ca^{2+} channels are both derived from the Ca_V2.1 subunit but differ in their apparent sensitivity to the toxin ω-agatoxin IVA. P-type Ca^{2+} currents are blocked by low concentrations of ω-agatoxin IVA ($IC_{50} = 1$–3 nM), whereas Q-type currents require higher concentrations ($IC_{50} = 90$ nM). In contrast, both P- and Q-type (and N-type) channels are blocked by ω-conotoxin MVIIC. In practice, it is difficult to distinguish between P- and Q-type currents using this pharmacology. However, the apamin-sensitive AHP in neocortical neurons is blocked by approximately 20% by 25 nM ω-agatoxin IVA. This suggests that Ca^{2+} entry through P-type channels activates approximately 20% of this AHP. It appears that a component of Q-type current may also contribute to the generation of the apamin-sensitive AHP in neocortical neurons because addition of ω-conotoxin MVIIC after ω-agatoxin IVA blocked another 20% of the AHP. In contrast, ω-conotoxin GVIA alone had no effect. A similar incomplete block by ω-conotoxin MVIIC of an apamin-sensitive AHP is observed in cerebellar Purkinje cells.

It is clear that there is not a common pairing between the Ca^{2+}-activated SK and Ca^{2+} channel to generate apamin-sensitive AHPs in different neurons. In addition, there are several examples of the apamin-sensitive AHP being generated from Ca^{2+} entry through

multiple Ca^{2+} channel subtypes. Clearly, there are two interpretations of these data. It is possible that the apamin-sensitive SK channel is associated with a number of different Ca^{2+} channel subtypes in those neurons. This seems unlikely and it probably suggests that apamin-sensitive SK channels are not functionally coupled to Ca^{2+} entry through a particular Ca^{2+} channel subtype. The current underlying the apamin-sensitive AHP is rapid in onset and decays with an exponential time course that is similar to that of the SK channel following the rise of intracellular Ca^{2+} from uncoupled sources.

Identity of the Ca^{2+} Channel Subtypes Activating Apamin-Insensitive AHPs

An apamin-insensitive AHP is seen in a small number of cell types, such as hippocampal and cortical pyramidal neurons. It exhibits a very unusual time course when present, displaying both a slow rise (peaking approximately 0.5–1 s after the end of the action potential train) and decay phase (exponential decay of time constant of 1.5–3 s). There has been considerable discussion regarding the mechanism(s) underlying this unusual time course, with hypotheses ranging from a large distance separating Ca^{2+} and Ca^{2+}-activated channel to a slowly activating Ca^{2+}-activated potassium channel or delayed facilitation of coupled L-type Ca^{2+} channels dictating the time course. Each proposal has its merits, but all are hindered by the fact that the identity of the Ca^{2+}-activated potassium channel that underlies the slow apamin-insensitive AHP is unknown.

Coupling of Ca^{2+} Channel Subtypes to Activation of Apamin-Insensitive AHPs

$Ca_V1.2$ and -1.3 L-type Ca^{2+} channels Dihydropyridine L-type Ca^{2+}channel antagonists significantly block the slow apamin-insensitive AHP in hippocampal pyramidal neurons. This is shown in Figure 2, in which the selective effects of the L-type channel antagonists are seen together with the lack of effect of blockers of other Ca^{2+} channel subtypes. The block of the slow AHP in hippocampal CA1 neurons in a slice preparation by the dihydropyridine L-type Ca^{2+} channel antagonist was incomplete (Figure 2), but the degree of block was very similar to the partial sensitivity to these channel antagonists observed for cloned $Ca_V1.3$ L-type current. These data suggest that L-type Ca^{2+} channels are functionally coupled to activation of the Ca^{2+}-dependent potassium channel that underlies the slow apamin-insensitive AHP and that the L-type channel is $Ca_V1.3$.

$Ca_V2.2$ N- and $Ca_V2.1$ P/Q-type Ca^{2+} channels The apamin-insensitive AHP in neocortical pyramidal neurons was blocked completely by the combination of ω-conotoxin GVIA and ω-agatoxin IVA,

Figure 2 Selective coupling of Ca^{2+} channel subtype activation and generation of I_{sAHP}. (a) I_{sAHP} following a step depolarization to +10 mV (100 ms duration) from a holding potential of −50 mV in the absence and presence of isradipine (10 μM; gray trace). The slow current was partially blocked by the L-type Ca^{2+} channel blocker. (b–d) No effects on I_{sAHP} were observed for toxin blockers for N- and P/Q-type (ω-conotoxin MVIIC; 5 μM), T-type (SFTX-3.3; 3 μM), or R-type (SNX-482; 3 μM) Ca^{2+} channel subtypes.

with each blocker inhibiting approximately 50% of the AHP.

The different proposals concerning the origin of the slow time course of the apamin-insensitive AHP all imply that a single Ca^{2+} channel subtype is responsible for its activation. Different Ca^{2+} channels exhibit various subcellular locations. If a large distance separated Ca^{2+} and Ca^{2+}-activated channel or the AHP was generated by a slowly activating Ca^{2+}-activated potassium channel, it would be expected that the time course of the AHP would change if one Ca^{2+} channel subtype was blocked. No change in time course was reported when Ca^{2+}entry was through one of the two Ca^{2+} channel subtypes that generated the AHP in neocortical neurons. Therefore, it is difficult to reconcile these data with any proposed mechanism of what may underlie the slow time course of this AHP.

Pharmacological Determination of Ca^{2+} Channel Subtypes Underlying Activation of BK ($K_{Ca}1.1$) Channels in Central Neurons

Activation of BK channels hastens action potential repolarization and underlies generation of the fast AHP in some central neurons, such as hippocampal and cortical pyramidal neurons. Therefore, the relationship between Ca^{2+} and BK channels is based mostly on measurement of these parameters.

$Ca_V2.2$ N-type Ca^{2+} Channels

Action potential duration is prolonged in hippocampal slice CA1 neurons after block of N-type Ca^{2+} channels (Figure 3). This effect was selective for N-type Ca^{2+} channels, with no effect of L-type Ca^{2+} channel antagonists. Pharmacological block of either channel subtype has effects on synaptic release of glutamate in the hippocampus, which is in accord with N-type Ca^{2+} and BK channels being present on synaptic terminals.

$Ca_V1.2/1.3$ L- and $Ca_V2.2$ N-type Ca^{2+} Channels

Ca^{2+} entry through both L- and N-type Ca^{2+} channels underlies the activation of BK channel current in voltage-clamped acutely dissociated neocortical pyramidal neurons. In addition, it has been demonstrated that block of BK channels prolongs action potential repolarization. However, an effect of Ca^{2+} channel blockers on action potential duration has not been observed. Some suggestion of selectivity has been reported, with Ca^{2+} entry through N-type channels activating a transient BK channel current, whereas L-type Ca^{2+} channel activation generates both inactivating and sustained BK channel currents.

$Ca_V2.1$ P/Q-type Ca^{2+} Channels

A loose coupling between P/Q-type Ca^{2+} and BK channels has been reported for cerebellar Purkinje cells. BK channel activation was only observed after

Figure 3 Selective block of N-type Ca^{2+} channels prolongs action potential duration. (a) An action potential train of five spikes in a CA1 pyramidal neuron from a hippocampal slice evoked by a 200 ms depolarizing current injection. The asterisk indicates the fast AHP. (b) Example action potentials illustrating the slowing of action potential repolarization and block of the fast AHP after addition of the BK channel blocker charybdotoxin (10 nM). (c) Block of N-type Ca^{2+} channels by ω-conotoxin GVIA (1 μM) slowed the lower half of action potential repolarization and abolished the fast AHP, like that observed with direct block of BK channels by charybdotoxin.

increasing single Ca^{2+} channel current through P/Q-type channels by increasing extracellular Ca^{2+}. Interestingly, although this coupling suggests distance between Ca^{2+} and BK channels, the effect was selective for P/Q-type channels.

Direct Measurements of Channel Association in Brain

All the presented examples rely on the effect of Ca^{2+} channel blockers on the Ca^{2+}-dependent hyperpolarizations (or outward current) that are attributable to activation of the Ca^{2+}-activated channels, BK ($K_{Ca}1.1$) and SK ($K_{Ca}2$). As mentioned previously, this approach fails to distinguish between coupling arising because of a common subcellular location and that arising from a specific interaction between channel subtypes. A number of studies have attempted to identify the direct association of channel subtypes. These studies have used a range of electrophysiological and biochemical techniques to resolve specific interactions between Ca^{2+} and Ca^{2+}-activated channels.

Ca^{2+} Channels and SK ($K_{Ca}2$) Channels

Single channel recordings from acutely dissociated hippocampal CA1 pyramidal neurons showed a selective coupling between Ca^{2+} and Ca^{2+}-activated channels, with L-type Ca^{2+} channels selectively activating SK channels. This coupling exhibited a delay between the closing of the L-type channel and the opening of the SK channel. This delay and estimated open probability of the SK channel opening suggested that the SK channel experienced approximately 1 μM Ca^{2+} during activation. This in turn suggested that a distance of 50–150 nm separated the channel subtypes. Therefore, it would not be expected that the two channel subtypes be directly associated, but it is more likely that they are assembled within a complex that forms a bridge between the two channels. Interestingly, this has been reported in cardiac cells, in which $Ca_V1.3$ L-type Ca^{2+} and $K_{Ca}2.2$ channels are associated by a common interaction with the actin-binding protein α-actinin 2.

Unfortunately, there are few immunovisualization data available to confirm a co-localization of Ca^{2+} and SK channels in brain. For example, the proposed functional coupling between P/Q-type Ca^{2+} channels and an apamin-sensitive SK channel in neocortical neurons is not borne out by immunohistochemical localization data. $Ca_V2.1$ P/Q-type channels are located in the dendrites of layer V, whereas the only apamin-sensitive SK channel present ($K_{Ca}2.2$ (SK2)) is in the soma of layer V neurons. In contrast, $Ca_V2.1$ and $K_{Ca}2.3$ (SK3) channel subunits have been shown to be on mossy fiber terminals innervating hippocampal CA3 pyramidal neurons, although no functional data are available to confirm functional coupling between the two channel subtypes. The identity of the SK channel underlying the slow AHP in hippocampal and cortical neurons is unknown. However, the only candidate in the past has been the $K_{Ca}2.1$ or SK1 channel. Co-localization of $Ca_V1.3$ L-type and $K_{Ca}2.1$ (SK1) channels has been observed in the soma and proximal dendrites of hippocampal neurons. This co-localization at the light level is consistent with the pharmacological block of L-type Ca^{2+} channels inhibiting the slow AHP in hippocampal neurons.

Ca^{2+} Channels and BK ($K_{Ca}1.1$) Channels

There is reasonable correlation between examples of functional coupling of particular Ca^{2+} channel subtypes to the activation of BK channels and immunolocalization of channel subunits.

$Ca_V2.2$ N-type Ca^{2+} channels and BK channels A direct functional coupling between N-type Ca^{2+} and BK channels was observed using single channel recording from acutely dissociated hippocampal CA1 pyramidal neurons. This coupling is supported by immunohistochemical data that show that N-type Ca^{2+} channels and BK channels are both predominantly located in the dendrites of CA1 hippocampal neurons. Immunovisualization of both N-type and BK channels in cortex has shown both channels to be present in outer neocortical layers II and III.

$Ca_V1.2$ and -1.3 L-type Ca^{2+} channels and BK channels There are few immunohistochemical data to suggest that L-type and BK channels reside in the same subcellular compartment within the hippocampus. However, both $Ca_V1.2$ and BK channels are present in all cortical layers, which supports the pharmacological data from neocortical cells of a functional coupling of L-type Ca^{2+} and BK channels. The confirmation of identical subcellular locations for each channel subtype is unavailable.

$Ca_V2.1$ P/Q-type Ca^{2+} channels and BK channels There is no evidence that the reported loose functional coupling between these two channel subtypes is reflected in channel co-localization at the light level, with BK channels shown to be present in the soma of cerebellar Purkinje cells and the $Ca_V2.1$ (P/Q-type) subunit on terminals. However, both channel subtypes are present on terminals within the cerebellum, which supports the finding that both channel types affect transmitter release.

Biochemical determination from rat brain of interaction between channel subunits has shown that $Ca_V1.2$, -1.3, -2.1, and -2.2 subunits can all be immunoprecipitated with $K_{Ca}1.1$ (BK) channels. This undoubtedly supports the reported examples of functional coupling. This type of data indicates that Ca^{2+} and BK channels are closely associated but falls short of demonstrating that the interactions are direct. However, experiments using the intracellular application of the fast Ca^{2+} chelator BAPTA have indicated that $Ca_V2.2$ and $K_{Ca}1.1$ channels are within 30 nm of each other. Considering that the diameter of an α subunit of a voltage-dependent potassium channel (Kv1.2) has been estimated from crystallization data to be approximately 10 nm, it is likely that Ca^{2+} and BK channels directly associate through their α subunits. This makes mechanistic sense, with rapid coupling between these channels underlying the repolarization of the hippocampal action potential.

Conclusion

In the approximately 20 years since the discovery of the slow AHP in hippocampal neurons, our understanding of the relationship between Ca^{2+} entry and the activation of Ca^{2+}-activated potassium channels has become more sophisticated. No longer do we assume that any subcellular location of Ca^{2+} entry is sufficient for the activation of either BK or SK channels. This is entirely consistent with the cytotoxic effect of accumulating a high concentration of intracellular Ca^{2+}. Now, we can consider that localized Ca^{2+} entry has its effect within nano- or microdomains and is buffered or extruded before the cell's bulk experiences a significant accumulation of the divalent ion. The obvious extension to the acceptance of co-localized Ca^{2+} and Ca^{2+}-activated channels is whether the association can be regulated in space and time. If the subcellular location of co-localized channels were to change, the integration of action potentials between the soma and dendrites would be affected. Both soma and dendrites of central neurons possess a complement of Ca^{2+} and Ca^{2+}-activated potassium channels that control firing patterns. This could substantially change if the subcellular co-localization were to be regulated. Finally, it seems likely that the number of co-localized channels can be regulated over time or with the onset of disease states. The amplitude of the slow AHP increases with age, which correlates with a deficit in learning a simple associative task. L-type Ca^{2+} channels increase in number with age, and the increase in the slow AHP likely results from an increased association of L-type and SK channels. It is possible that targeting of co-localization of L-type Ca^{2+} and SK channels to reduce the age-evoked increase in the slow AHP would produce improvements in cognition that may be beneficial in certain disease states that exhibit symptoms of dementia.

Ca^{2+} Channels in Excitation–Response Coupling

Voltage-gated calcium channels (Ca^{2+} channels) are members of a superfamily of voltage-gated ion channels which also includes sodium and potassium channels (Na^+ and K^+ channels, respectively). Expressed in a wide variety of cell types, Ca^{2+} channels transduce changes in membrane potential (depolarization) to increased intracellular [Ca^{2+}], which in turn triggers diverse cell biological processes, including secretion, contraction, migration, proliferation, and transcription. Such 'excitation–response coupling' is exemplified by the link between presynaptic depolarization and the triggering of neurotransmitter release, the main topic of this article. Voltage-gated Ca^{2+} channels offer many advantages for excitation–response coupling. The opening of a voltage-gated Ca^{2+} channel is a powerful mechanism for delivering the second messenger (Ca^{2+}) very quickly. There is no lack of Ca^{2+} in the external milieu, and membrane transport mechanisms operate to keep cytosolic Ca^{2+} low, providing an approximately 10 000-fold concentration gradient for supporting a large net influx. Because basal levels of free Ca^{2+} concentration are low (typically 10^{-7} M), influx can cause a rapid and large percentage change in intracellular Ca^{2+}. Unlike Ca^{2+} channels in membranes that surround intracellular Ca^{2+} stores, Ca^{2+} channels in the plasma membrane have direct access to the transmembrane voltage, a global indicator of cellular activity. A rapid, voltage-dependent closing of the channel allows for dissipation of the message by diffusion and strong, rapid local buffering thereby achieving spatiotemporally precise signaling.

To capitalize on all of these advantages, Ca^{2+} channels must satisfy a number of structural and biochemical requirements. First, they should be highly voltage dependent, making them quick to both open and close in response to changes in membrane potential (e.g., action potentials and excitatory postsynaptic potentials). Second, they must be highly permeable to Ca^{2+} but not to other ions, such as Na^+ or K^+. Calcium channels must also be properly localized near the relevant targets of Ca^{2+} regulation, allowing for local increases in Ca^{2+} concentration. Finally, they must be subject to modulation and diverse enough to allow particular classes of calcium channels to be selectively regulated. All of these requirements seem to have been fulfilled by the Ca^{2+} channels found in excitable cells in general and those in nerve terminals in particular. Given the wide range of downstream effects mediated by Ca^{2+} entry, it is perhaps not surprising that a rich diversity of Ca^{2+} channels has evolved, with individual channel types specialized for, but not exclusively limited to, specific biological roles.

Steps in Coupling Excitation to Neurotransmitter Release

Excitation–secretion coupling at typical glutamatergic nerve terminals can be described by the following steps (Figure 1, top):

1. Action potential in axon leads to electrotonic depolarization of axonal bouton.
2. Depolarization causes opening of Na^+ channels and action potential in bouton.
3. Action potential depolarization causes opening of voltage-gated Ca^{2+} channels.
4. K channels open, repolarizing voltage and increasing the driving force for Ca^{2+} to pass through Ca^{2+} channels.
5. Ca^{2+} rises sharply in a microdomain around the mouth of the Ca^{2+} channels.
6. Ca^{2+} binds to Ca^{2+} sensor for vesicle fusion, synaptotagmin triggering vesicle to fuse to surface membrane.
7. Fusion pore opens, providing passage between one or more vesicles containing the neurotransmitter glutamate and the synaptic cleft.
8. Neurotransmitter (e.g., glutamate) passes through fusion pore and diffuses in the cleft.
9. Neurotransmitter binds to multiple sites on postsynaptic receptors (e.g., AMPA receptors), causing their channels to open.
10. Excitatory postsynaptic current ensues.

This provides a general cell physiological framework for understanding the role of specific types of Ca^{2+} channels. The process of neurosecretion relies on two distinct cycles – the classical Hodgkin cycle for nerve excitation (Figure 1, bottom left) and the Heuser–Reese cycle for the clathrin-mediated retrieval of vesicle membrane components (Figure 1, bottom right). Opening of gates in the Hodgkin cycle controls Ca^{2+} entry via Ca^{2+} channels, which in turn regulates vesicle priming and fusion and possibly endocytosis as well.

Figure 1 (Top) Schematic showing steps in the process of chemical synaptic transmission, exemplified by an excitatory synapse with postsynaptic receptors for the fast neurotransmitter glutamate. (Bottom) Ca^{2+} forms the link between the classical Hodgkin cycle of excitability and the synaptic vesicle cycle of the kind envisioned by Heuser and Reese. Discovery of Multiple Ca^{2+} Channel Types

Ca^{2+} channel types were initially classified according to their voltage threshold for activation through the work of Susumu Hagiwara and others. High-voltage-activated (HVA) channels require strong depolarization, whereas low-voltage-activated (LVA) channels activate with relatively little change in membrane potential. This distinction was reinforced by the finding of Armstrong and colleagues that LVA channels deactivate (shut off) much more slowly with hyperpolarization than HVA channels. Beginning in 1985 and for approximately the next 10 years, understanding of the multiple types of Ca^{2+} channels was significantly advanced by analysis of their biophysical, pharmacological, and molecular properties in combination. It is now generally agreed that the HVA channels most important for mammalian neurotransmission (N-, P/Q-, R-type) are different from the HVA channels that dominate excitation–contraction or excitation–transcription coupling (L-type) or the LVA channels that help govern pacemaker activity (T-type).

The presynaptic Ca^{2+} channels are exemplified by N-type channels, first discovered in recordings from cell bodies of sensory neurons and later found to support neurotransmitter release from sympathetic neurons or cholinergic nerve terminals in the ciliary ganglion. P/Q- and R-type channels were discovered later and also contribute to varying degrees to neurotransmission at various central nervous system (CNS) synapses, including large and relatively accessible synapses discussed later. P/Q-, N-, and R-type channels are generated by pore-forming subunits known as $Ca_V2.1$, $Ca_V2.2$, and $Ca_V2.3$, respectively; each is

the specific target of a blocking toxin (ω-AgaIVA, ω-CTx-GVIA, and SNX-482, respectively). Auxiliary subunits (α_2-δ and β) contribute to proper cellular trafficking and function of the pore-forming α_1 subunits.

The single-letter terminology for Ca^{2+} channel types (L-, N-, and T-type) reflects initial distinctions based on patch clamp recordings of unitary channel activity. The observed pattern of unitary channel properties – their slope conductances and activation and inactivation properties – did not fit neatly into the LVA/HVA categorization of Hagiwara. Closer examination of whole cell and single channel recordings made it clear that three channel types could be distinguished, then called T-type (LVA) and N- and L-type (both HVA). The L-type channels were so named because they had a large unitary conductance to Ba^{2+} and supported a long-lasting Ba^{2+} current (different properties were found with Ca^{2+} as the charge carrier, but the Ba^{2+} currents provided the most distinctive channel profiles). Importantly, the L-type channel activity was similar to that found in heart cells and could be distinguished by a profound enhancement with the dihydropyridine drug Bay K8644. The T-type channels generated tiny unitary Ba^{2+} currents, gave rise to a transient average current, showed characteristically slow deactivation following sudden repolarization, and were also found in heart cells. Finally, the N-type channels were largely specific to neurons, had an intermediate conductance to Ba^{2+}, and although they required negative holding potentials to be available for opening, they were activated at high voltages, indicating that they were neither T- nor L-type. The diverse nature of the Ca^{2+} channel, advanced on the basis of patch clamp recordings, has received ample corroboration from molecular biology. Sequence analysis has confirmed and extended the original tripartite classification (Figure 2). The identification of N-type channels presaged the discovery of the Ca_V2 subfamily of α_1 subunits, now known to be critical for neurotransmission.

Further experiments in the early 1990s resulted in the identification of two additional members of the subfamily exemplified by N-type channels. Llinás and colleagues discovered a noninactivating, dihydropyridine-insensitive current in the cell bodies of cerebellar Purkinje neurons, henceforth called P-type. Others demonstrated that P-type channels were exquisitely sensitive to the funnel web spider toxin peptides (e.g., ω-Aga-IVA). Cerebellar granule displayed a prominently inactivating current with somewhat different properties, labeled Q-type. Multiple lines of evidence obtained with antibodies, antisense techniques, and gene knockout have firmly established that P- and Q-type currents both arise from the same pore-forming subunit, now known as $Ca_V2.1$ or α_{1A}. For example, both current types are completely eliminated in cerebellar Purkinje and granule neurons of α_{1A}−/−mice. The original distinctions between the P and Q components have been mostly accounted for by splice variation in the α_{1A} gene, hence the currently accepted terminology of 'P/Q-type' channel.

The actions and specificity of available toxins and pharmacological compounds are sufficient to allow a separation of current components based primarily on pharmacology. A combination of nimodipine (L-type-specific), ω-conotoxin-GVIA (N-type-specific), and ω-Aga-IVA (P/Q-type-specific) can be used to tease apart the various Ca^{2+} current types in cerebellar granule neurons. Application of inhibitors

Figure 2 Agreement between channel biophysics studied by patch clamping neurons and molecular cloning of α_1 subunits in tripartite Ca^{2+} channel classification. (Left) Distinctions between three types of Ca^{2+} channels based on recordings of unitary channel activity. N-type channel activity was separated from L- or T-type activity on the basis of its requirement for strongly negative holding potential (HP) and strongly depolarized test potential (TP), as well as its unresponsiveness to dihydropyridines such as Bay K8644 (not shown). (Right) Ensuing molecular cloning revealed three major subfamilies of pore-forming α_1 subunit.

of the three known channel types revealed a fourth component with kinetic and pharmacological properties distinct from L-, N-, and P/Q-type channels. Because this residual current was resistant to the known inhibitors, it was tentatively named R-type. This current showed unique properties, including very rapid decay and an unusual sensitivity to block by Ni^{2+}. Various approaches indicate that R-type current is supported by channels encoded by $Ca_V2.3$. In several neuronal systems, R-type current can be blocked by a specific inhibitor – a spider toxin peptide known as SNX-482.

In General, Multiple Types of Ca^{2+} Channels Contribute to Central Nervous System Neurotransmission

Ca^{2+} channels from the Ca_V2 subfamily are the primary types responsible for excitation–secretion coupling at fast excitatory and inhibitory synapses in the brain. At most of these CNS synapses, the neurotransmitter release is accomplished through synergistic actions of more than one type of channel, most prominently P/Q- and N-type channels. This seems to be the case for typical, approximately 1 μm CNS nerve terminals as well as large presynaptic structures (e.g., the calyx of Held of the auditory brain stem and the mossy fiber synapse of the hippocampus). R-type channels also participate in triggering exocytosis in those instances in which its potential contribution has been carefully explored. Thus, all three members of the Ca_V2 subfamily may play a significant role in fast central neurotransmission. The biophysical properties of these channels (e.g., their rapid activation upon strong depolarization and brisk deactivation following repolarization) are well suited to responding to typical presynaptic action potentials, which reach strongly positive overshoots but have a brief duration on the order of 1 ms.

Intimate Relationship between Ca^{2+} Entry and Neurotransmitter Release

Only Ca^{2+} Channels Close to the Release Machinery Matter

As Ca^{2+} enters, it can act rapidly because only Ca^{2+} elevation near the Ca^{2+} channels is required, rather than a change in the bulk cytoplasm. This is because the Ca^{2+} sensors that trigger vesicle release are strategically located within a 'microdomain' near the Ca^{2+} channels. The first support for this concept came from work on the giant synapse of the squid and indicated that Ca^{2+} could rise to 200 μM in the microdomain. An important advance occurred with the development of structural methods, including electron tomography, that helped localize the intramembranous particles thought to be Ca^{2+} channels. At the neuromuscular junction, it has been estimated that vesicles are positioned within 20 nm of the Ca^{2+} channels – close enough that the vesicles may even hinder the diffusion of Ca^{2+} away from the channel.

Transmitter Release is Triggered by Ca^{2+} Entry, whereas Depolarization *per se* Exerts No Direct Effect

The effects of a rise in presynaptic Ca^{2+} and membrane depolarization have been dissected apart by using light-induced release of caged Ca^{2+} to drive vesicle fusion. In these circumstances, strong depolarizations comparable to presynaptic action potentials failed to increase synaptic responses. This excludes the idea that neurotransmission is jointly dependent on both $[Ca^{2+}]$ and presynaptic membrane potential, although it remains possible that presynaptic membrane voltage can have important modulatory effects, for example, on signaling by G-proteins.

The Ca^{2+} Sensor for Rapid Vesicle Release Is Synaptotagmin

There is substantial evidence that the Ca^{2+} sensor for fast neurotransmission is a Ca^{2+}-binding protein known generically as synaptotagmin. Various isotypes of synaptotagmin, most generally synaptotagmin 1 but also synaptotagmins 2 and 9, can act as a trigger for rapid transmission, as indicated by experiments using knockout mice. There are two main theories about how synaptotagmin works: by unleashing the SNARE machinery by removal of a tonic inhibitory brake or by adding a fusion-promoting influence, derived from Ca^{2+}/syt 1 binding to membrane phospholipids, to that already provided by preformed SNARE complexes.

Transmitter Release is Related to Ca^{2+} Entry by a Steep Power-Law Function

In a classical study on the frog neuromuscular junction, Dodge and Rahamimoff showed that neurotransmitter release was a steep function of external Ca^{2+} concentration and, by extension, Ca^{2+} influx. Later investigators extended the analysis to direct measurements of presynaptic Ca^{2+} currents, and cytosolic Ca^{2+} changes, converging on the idea that the Ca^{2+} sensor for secretion behaves as if it were cooperatively activated by the binding of four or five Ca^{2+} ions. The basis of this cooperativity remains unclear. Synaptotagmin has five Ca^{2+} binding sites, suggesting that the cooperative properties of single synaptotagmin molecules might be sufficient to

account for the Ca^{2+} cooperativity of release. Consistent with this, mutations in synaptotagmin that affect Ca^{2+} binding reduce this cooperativity. However, additional factors might influence the observed Ca^{2+} cooperativity. Vesicles contain several synaptotagmin molecules, possibly working together to produce release; cooperativity might be influenced by other molecules and the combined effects of multiple SNARE complexes.

Multiple Ca^{2+} Channels (and Channel Types) Provide Input to a Common Ca^{2+} Sensor

Pharmacological studies are consistent with regard to a scenario in which a mixed population of Ca^{2+} channels coexist at single release sites and contribute jointly to the local Ca^{2+} transient that operates on the Ca^{2+} sensor to trigger vesicular fusion. The convergence of Ca^{2+} delivered by different types of channels can be manifested as synergism or redundancy, depending on the experimental conditions (Figure 3). With normal action potentials as the stimulus, block of either P/Q- or N-type (but not L-type) Ca^{2+} channels can cause a significant diminution of transmitter release (Figure 3(a)). In the illustrated example, the percentage inhibition of neurotransmission for block of P/Q-type channels (~90%) and for block of N-type channels (~40%) totals more than 100%. This makes sense because both Ca^{2+} channel types contribute to Ca^{2+} influx at individual release sites and thus provide additive fluxes to take advantage of the steep power law for neurotransmission. Another way to establish that both channel types coexist at individual release sites is to examine the consequences of a depolarization imposed by application of K^+-rich solution, a much stronger stimulus for channel activation than a single action potential. In this case, both types of channels must be blocked to appreciably inhibit transmission (Figure 3(b)). The explanation for this redundancy is simple: Provided that the depolarizing stimulus is strong and sustained, Ca^{2+} influx

Figure 3 Differing perspectives on transmitter release and the role of N- and P/Q-type Ca^{2+} channels. (a) Contributions of various Ca^{2+} channels at CNS synapses when the stimulus for Ca^{2+} is a single action potential. Shown are the proportions of synaptic currents remaining after blockade of P/Q-type channels (ω-Aga-IVA present), with N-type channels blocked (ω-CgTx present), or with L-type channels blocked (nicardipine). Reproduced from Takahashi T and Momiyama A (1993) Different types of calcium channels mediate central synaptic transmission. *Nature* 366: 156–158, with permission. (b) Effect of blockade of P/Q- or N-type channels, individually or in combination, on dopamine release from rat striatal synaptosomes. Note that with strong depolarization (external potassium concentration >100 mM), both kinds of channels must be blocked in order to strongly inhibit neurosecretion. Circles, no channel inhibition; triangles, N-type channels blocked; upside down triangles, P/Q-type channels blocked; diamonds, both N- and P/Q-type channels blocked. Reproduced from Turner TJ, Adams ME, and Dunlap K (1993) Multiple Ca^{2+} channel types coexist to regulate synaptosomal neurotransmitter release. *Proceedings of the National Academy of Sciences of the United States of America* 90(20): 9518–9522, with permission.

through either type of channel is sufficient to drive secretion, and the other type can be regarded as 'spare channels.' The synergistic or redundant actions of multiple channel types can be observed in the same experiment (Figure 4). The switch between cooperative and redundant behavior can be accomplished simply by prolongation of presynaptic action potentials with the K^+ channel blocker 4-aminopyridine. Prolongation of the action potential causes more activation of each type of Ca^{2+} channel, favoring its self-sufficiency.

Exceptions to Generalizations about Multiple Ca^{2+} Channel Types

The detailed composition of Ca^{2+} channel subtypes that mediate transmission can vary widely among individual nerve terminals.

Not always Multiple Channel Types

Although neurosecretion is supported by more than one type of channel at most CNS synapses, at some synapses transmission may be heavily dominated by a single channel type. Examples include some preparations historically important for discovery of basic principles of neurotransmission such as mammalian neuromuscular junction and squid giant synapse, in which P- or P/Q-type channels are overwhelmingly prevalent. At some hippocampal inhibitory synapses, GABA release is mediated entirely by P/Q-type or by N-type Ca^{2+} channels. Neurotransmission at sympathetic neuron–effector junctions is governed almost completely by N-type channels. Differences in the reliance on various Ca_V2 family members take on additional significance when synaptic circuits are the target of pharmacological and possibly therapeutic intervention. For example, in the dorsal horn of the spinal cord, the main component in the circuitry of pain transmission/modulation, inhibitory synaptic transmission is dominated by P/Q-type Ca^{2+} channels; in contrast, N-type channels are more closely associated with glutamate release from the peptidergic primary sensory neurons that convey nociceptive information to the dorsal horn.

Not always Ca_V2 Channels

It is generally believed that Ca^{2+} channels of the Ca_V2 class are specialized to support transmitter release. This is true, but it is worth pointing out that in some cases, Ca_V1 and even Ca_V3 channels can also participate. For example, ribbon synapses in the retina and cochlea rely on $Ca_V1.3$ channels to trigger transmitter

Figure 4 Concerted or redundant actions of P/Q- and N-type channels, depending on strength of depolarizing stimulus. (a) Dependence of synaptic transmission on N-type Ca^{2+} channels changes markedly upon prolongation of the presynaptic action potential with 4-AP. Control graph (open circles) shows approximately 50% inhibition of basal transmission by ω-CTx-GVIA. In 4-AP (solid circles), the effect of N-type channel blockade is barely evident. (b) 4-AP also reduces the degree of inhibition produced by P/Q-type channel inhibition with ω-Aga-IVA. (c) Example of an experiment in which simultaneous blockade of N-type and P/Q-type Ca^{2+} channels with ω-CTx-GVIA and ω-Aga-IVA abolished transmission completely, even in the presence of 4-AP. (d) Schematic representation of a release site surrounded by multiple types of Ca^{2+} channels. (a–c) Reproduced from Wheeler DB, Randall A, and Tsien RW (1996) Changes in action potential duration alter reliance of excitatory synaptic transmission on multiple types of Ca^{2+} channels in rat hippocampus. *Journal of Neuroscience* 16: 2226–2237, with permission. (d) Reproduced from Cao Y, Piedras-Rentería ES, Smith GB, Chen G, Harata NC, and Tsien RW (2004) Presynaptic Ca^{2+} channels compete for channel type-preferring slots in altered neurotransmission arising from Ca^{2+} channelopathy. *Neuron* 43: 387–400.

release. Furthermore, Ca_V2 channels can perform important neuronal functions distinct from excitation–secretion coupling, such as excitation–transcription coupling.

Not always the Same Type of Ca^{2+} Channel throughout Development

At some synapses, N-type channels develop early but are gradually supplanted by late-blooming P/Q-type channels. Mammalian development might be echoing a phylogenetic progression seen at the neuromuscular junction, where lizards and frogs use L- and N-type channels, respectively, but mammals deploy P/Q-type channels.

What Are Multiple Ca^{2+} Channels Good for?

Why are there different kinds of presynaptic Ca channels? Almost certainly it is not because of evolutionary pressure for different biophysical properties. Indeed, basic features such as extremely high Ca^{2+} selectivity, high open channel flux rate, and steeply voltage-dependent channel gating are very similar for P/Q-, N-, and R-type currents. In all cases, selectivity and permeation are conferred by a pore that is continually occupied by at least one Ca^{2+} ion, which prevents more abundant Na^+ ions from rushing through. Despite overall similarities, there are substantial differences in channel regulation, and this is likely to be the main reason for channel diversity (Table 1). For example, P/Q- and N-type channels appear to differ in their susceptibility to modulation by G-proteins. N-type channels show a greater degree of modulation. On the other hand, P/Q-type channels are more susceptible to progressive increases with use, a phenomenon known as Ca^{2+} channel facilitation. Because of the steep power-law relationship between Ca^{2+} entry and secretion, even small increases in P/Q Ca^{2+} entry can have a profound effect on the strength of transmission. The presynaptic Ca^{2+} channels constitute a key convergence point for regulation of neurosecretion, either by neurohumoral modulation or by activity-dependent regulation. Much is known about the structural motifs in α_1 subunits that support various forms of regulation, for example, by G-proteins and protein kinases.

Table 1 Differences between P/Q- and N-type channels with regard to their properties and contributions to synaptic transmission

	P/Q-type channels	*N-type channels*
Specific blocker	ω-AgaIVA	ω-CTx-GVIA, ω-CTx-MVIIA = *Prialt*
Genetic diseases	Migraine, ataxia, epilepsy	No channelopathies found
Development	Late blooming	Early prominence
Voltage gating	Similar	Similar
Modulation by G-protein-coupled receptors	Weaker	Stronger
Facilitation by repeated stimuli	Stronger	Weaker if at all

Calcium Channels

W A Catterall, University of Washington, Seattle, WA, USA

Introduction

Voltage-gated calcium channels mediate calcium influx in response to membrane depolarization and regulate intracellular processes such as contraction, secretion, neurotransmission, and gene expression in many different cell types. Their activity is essential to couple electrical signals in the cell surface to physiological events in cells. This article describes their biochemical, molecular, and genetic properties; physiological roles; and pharmacological significance.

Calcium Currents in Excitable Cells

Ionic currents conducted by calcium ions in different cell types have diverse physiological roles and pharmacological properties, and an alphabetical nomenclature has evolved for the distinct classes of calcium currents (Table 1). L-type calcium currents typically require a strong depolarization for activation, have slow voltage-dependent inactivation, and are blocked by the organic L-type calcium channel antagonists, including dihydropyridines, phenylalkylamines, and benzothiazepines. They are the main calcium currents in muscle and endocrine cells, where they initiate contraction and secretion, respectively. L-type currents are prominent in neurons, in which they are important for integration of synaptic inputs in dendrites, regulation of many intracellular events, and initiation of excitation–transcription coupling, which regulates expression of many neural genes. L-type calcium currents also trigger synaptic transmission in specialized ribbon synapses in photoreceptors in the retina and hair cells in the cochlea.

N-type, P/Q-type, and R-type calcium currents also require strong depolarization for activation. They are relatively unaffected by L-type calcium channel antagonist drugs but are blocked by specific polypeptide toxins from snail and spider venoms (Table 1). They are expressed primarily in neurons, in which they initiate neurotransmission at most fast synapses and also mediate calcium entry into cell bodies and dendrites.

T-type calcium currents are activated by weak depolarization and are transient due to rapid voltage-dependent inactivation. They are resistant to both organic antagonists and most snake and spider toxins used to define the N- and P/Q-type calcium currents (Table 1). They are expressed in a wide variety of cell types, in which they are involved in shaping the action potential and controlling patterns of repetitive firing. They have particularly prominent roles in repetitively firing cells such as the pacemaker cells in the sinoatrial node of the heart and the relay neurons in the thalamus that control sleep and wakefulness by rhythmic firing of action potentials.

Calcium Channel Subunits

The calcium channels that have been characterized biochemically are complex proteins composed of four or five distinct subunits, which are encoded by multiple genes (Figure 1). The α_1 subunit of 190–250 kDa is the largest subunit, and it incorporates the conduction pore, the voltage sensors and gating apparatus, and most of the known sites of channel regulation by second messengers, drugs, and toxins. The α_1 subunit is composed of approximately 2000 amino acid residues organized in four homologous domains (I–IV) with six transmembrane segments (S1–S6) in each. The S1–S4 segments serve as the voltage sensor module, whereas transmembrane segments S5 and S6 in each domain and the P loop between them form the pore module.

The α_1 subunits are associated with four distinct auxiliary subunits encoded by three different genes (Figure 1). The intracellular β subunit is a hydrophilic protein of 50–65 kDa. The transmembrane disulfide-linked $\alpha_2\delta$ subunit complex is encoded by a single gene, but the resulting pre-polypeptide is posttranslationally cleaved and disulfide bonded to yield the mature covalently linked α_2 and δ subunits. A transmembrane γ subunit having four transmembrane segments is a component of skeletal muscle calcium channels, and related subunits are expressed in heart and brain. Although these auxiliary subunits modulate the functional properties of the calcium channel complex, the pharmacological and electrophysiological diversity of calcium channels arises primarily from the existence of multiple α_1 subunits.

Calcium Channel Genes

Calcium channel α_1 subunits are encoded by 10 distinct genes in mammals. These calcium channels are named using the chemical symbol of the principal permeating ion (Ca), with the principal physiological regulator (voltage) indicated as a subscript (Ca_v). The numerical identifier corresponds to the Ca_v channel α_1 subunit gene subfamily (1 to 3) and the order of discovery of the α_1 subunit within that subfamily (1 through n).

Table 1 Physiological function and pharmacology of calcium channels

Channel	*Current*	*Localization*	*Specific antagonists*	*Cellular functions*
$Ca_v1.1$	L	Skeletal muscle, transverse tubules	Dihydropyridines, phenylalkylamines, benzothiazepines	Excitation–contraction coupling
$Ca_v1.2$	L	Cardiac myocytes; smooth muscle myocytes; endocrine cells; neuronal cell bodies and proximal dendrites	Dihydropyridines, phenylalkylamines, benzothiazepines	Excitation–contraction coupling, hormone release, regulation of transcription, synaptic integration
$Ca_v1.3$	L	Endocrine cells, neuronal cell bodies and dendrites, cardiac atrial myocytes and pacemaker cells, cochlear hair cells	Dihydropyridines, phenylalkylamines, benzothiazepines	Hormone release, regulation of transcription, cardiac pacemaking, synaptic integration hearing – neurotransmitter release from ribbon synapses in auditory hair cells
$Ca_v1.4$	L	Retinal rod and bipolar cells, lymphocytes	Not established	Neurotransmitter release from ribbon synapses in photoreceptors
$Ca_v2.1$	P/Q	Nerve terminals and dendrites, neuroendocrine cells	ω-Agatoxin IVA	Neurotransmitter release, dendritic Ca^{2+} transients, hormone release
$Ca_v2.2$	N	Nerve terminals and dendrites, neuroendocrine cells	ω-CTx-GVIA	Neurotransmitter release, dendritic Ca^{2+} transients, hormone release
$Ca_v2.3$	R	Neuronal cell bodies and dendrites	SNX-482	Repetitive firing, dendritic calcium transients
$Ca_v3.1$	T	Neuronal cell bodies and dendrites, cardiac and smooth muscle myocytes	None	Pacemaking, repetitive firing
$Ca_v3.2$	T	Neuronal cell bodies and dendrites, cardiac and smooth muscle myocytes	None	Pacemaking, repetitive firing
$Ca_v3.3$	T	Neuronal cell bodies and dendrites	None	Pacemaking, repetitive firing

Figure 1 Subunit structure of Ca_v1 channels. The subunit composition and structure of calcium channels purified from skeletal muscle are illustrated. Predicted helices are depicted as cylinders. The lengths of lines correspond approximately to the lengths of the polypeptide segments represented. Pore forming module, green; S4 voltage sensor, yellow.

The Ca_v1 subfamily ($Ca_v1.1$–$Ca_v1.4$) mediates L-type Ca^{2+} currents (Table 1). The Ca_v2 subfamily ($Ca_v2.1$–$Ca_v2.3$) mediates P/Q-type, N-type, and R-type Ca^{2+} currents, respectively (Table 1). The Ca_v3 subfamily ($Ca_v3.1$–$Ca_v3.3$) mediates T-type Ca^{2+} currents. The complete amino acid sequences of these α_1 subunits are more than 70% identical within a subfamily but less than 40% identical among the three subfamilies. Division of calcium channels into these three subfamilies is phylogenetically ancient because representatives of each are found in the *Caenorhabditis elegans* genome. Consequently, the genes for the different α_1 subunits have become widely dispersed in the genome and even the most closely related members of the family are not clustered on single chromosomes in mammals.

Each of the auxiliary subunits of calcium channels is encoded by a small gene family. Four genes encode $\alpha_2\delta$ subunits, four genes encode β subunits, and eight genes encode γ subunits. The specificity of assembly of calcium channel auxiliary subunits with the principal, pore-forming α_1 subunits is not fully determined. However, in neurons, it appears that multiple subtypes of auxiliary subunits can assemble successfully with α_1 subunits. Therefore, it is likely that control of expression and localization of the principal and auxiliary subunits determines the subunit partners present in calcium channel complexes. Although the $Ca_v\gamma_1$ subunit is associated specifically with skeletal muscle $Ca_v1.1$ channels, other $Ca_v\gamma$ subunits interact with other calcium channels, glutamate receptors, and possibly other membrane signaling proteins. Thus, the γ subunits discovered as components of calcium channels apparently have a more widespread role in assembly and cell surface expression of other membrane signaling proteins.

Calcium Channel Structure and Function

Intensive studies of the structure and function of the related pore-forming subunits of sodium, calcium, and potassium channels have led to identification of their principal functional domains. Each domain of the principal α_1 subunits consists of six transmembrane α helices (S1–S6) and a membrane-associated P loop between S5 and S6. The S4 segments of each homologous domain serve as the voltage sensors for activation, moving outward and rotating under the influence of the electric field and initiating a conformational change that opens the pore. The transmembrane pore is formed in the midst of a square array of the four homologous domains. The S5 and S6 segments and the membrane-associated P loop between them form the pore lining of the voltage-gated ion channels. The narrow external pore is lined by the P loop, which contains a glutamate residue in each domain that is required for calcium selectivity. Remarkably, substitution of only three amino acid residues in the pore loops between the S5 and S6 segments in domains II–IV of sodium channels is sufficient to confer Ca^{2+} selectivity. The inner pore is lined by the S6 segments, which form the receptor sites for the pore-blocking calcium antagonist drugs specific for L-type calcium channels. All Ca^{2+} channels share these general structural features, but the amino acid residues that confer high affinity for the organic Ca^{2+} antagonists used in therapy of cardiovascular diseases are present only in the Ca_v1 family of Ca^{2+} channels, which conduct L-type Ca^{2+} currents.

The auxiliary subunits of calcium channels have an important influence on their function. $Ca_v\beta$ subunits greatly enhance cell surface expression of α_1 subunits and shift the kinetics and voltage dependence of activation and inactivation. Most $Ca_v\beta$ subunits accelerate activation and inactivation and shift the voltage dependence of gating to more negative membrane potentials, but the $Ca_v\beta_{2a}$ subunit has the opposite effect in most cases. The $\alpha_2\delta$ subunits also enhance cell surface expression of α_1 subunits, but they have smaller and less-consistent effects on the kinetics and voltage dependence of gating. The γ subunits do not increase cell surface expression of Ca_V channels, and in some cases they reduce it substantially. The functional role of these subunits of calcium channels is the least well defined.

Three-Dimensional Structure of Calcium Channels

The three-dimensional structure of calcium channels is unknown, but it is expected to resemble the structures of the closely related voltage-gated sodium and potassium channels. Low-resolution structural models have been developed from image reconstruction analysis of $Ca_v1.1$ channels purified from skeletal muscle membranes, and some of the structural features have been associated with the α_1 and $\alpha_2\delta$ subunits (**Figure 2(a)**). Further high-resolution structural analysis will be required to confirm these initial structural models.

The three-dimensional structure of the $Ca_v\beta$ subunits has been determined at high resolution by X-ray crystallography (**Figure 2(b)**). These subunits contain conserved SH3 and guanylate kinase domains like the MAGUK family of scaffolding proteins. These two domains are arrayed side by side in the $Ca_v\beta$ subunit (**Figure 2(b)**). The $Ca_v\beta$ subunits bind to a single site in the α_1 subunits (the α interaction domain (AID)), which is located in the first half of the intracellular loop connecting domains I and II. AID forms an α helix that is bound tightly to a groove in the guanylate kinase domain of the $Ca_v\beta$ subunit. This tight, multipoint binding interaction likely sustains the association between calcium channel α_1 and β subunits throughout the lifetime of the calcium channel complex at the cell surface membrane. MAGUK proteins often bind more than one protein partner, so $Ca_v\beta$ subunits may also interact with other intracellular proteins.

Physiological Roles of Calcium Channels

Calcium channels have two distinct classes of functional roles: They contribute to electrical events during action potential generation and conduction at the cell surface, and they conduct calcium into the cell to initiate many intracellular events.

Figure 2 Three-dimensional architecture of calcium channels. (a) Illustration of the skeletal muscle $Ca_v1.1$ channel based on cryo-electron microscopy. This drawing assumes pseudo-fourfold symmetry of the α_1 subunit. The view shows the extracellular side with the α_2 subunit. The α_1, γ, and δ subunits are embedded into the lipid membrane (not shown), which separates the extracellular α_2 subunit from the cytosol. α_2 is anchored via the disulfide-linked δ subunit within the α_1 subunit. The proposed model allows for a tight interaction between α_1 and δ as well as between α_1 and γ. (b) Structure of the $Ca_v\beta$ complex with the α interaction domain (AID). Coordinates are for the $Ca_v\beta_2$a–$Ca_v1.2$ AID complex, with SH3 (green) and NK (blue) domains indicated. V1–V3 show the locations of the three variable domains that are absent from the structure. AID (red) binds to a deep groove in the NK domain. AID residues tyrosine, tryptophan, and isoleucine are shown as CPK. The remaining residues are shown as lines.

Depolarization of neurons by calcium ions entering through voltage-gated calcium channels helps to shape the action potential and has an important role in determining the frequency of firing of action potentials. Depolarization of neurons by activation of sodium channels during the action potential activates Ca_v1 and Ca_v2 channels, and the further depolarization caused by calcium current flowing inward through them broadens the action potential in dendrites, cell bodies, and nerve terminals and modulates the shape of the repolarizing phase of the action potential. Ca_v3 channels conduct T-type calcium currents that activate in the same potential range or even more negatively than sodium channels and thereby influence the threshold and frequency of firing of neurons. These calcium channels are prominent in repetitively firing cells, in which they are activated following repolarization from one action potential and boost the membrane potential to the threshold for activating sodium channels and firing the next action potential. This function of Ca_v3 channels is important in the thalamus, in which repetitive firing of neurons is required for determining sleep and wakefulness, as well as controlling other aspects of cortical function.

In addition to their role in electrical signaling, calcium channels are also the key transducers of electrical signals. They convert depolarization of the cell surface membrane into an intracellular transient of calcium, which serves as a second messenger to initiate many physiological events. In neurons, three of the key physiological events initiated by calcium channels are synaptic integration, synaptic transmission, and gene regulation. All three subfamilies of calcium channels participate in calcium signaling in dendrites and cell bodies and in the integration of synaptic signals. In contrast, Ca_v1 and Ca_v2 channels are specialized for gene regulation and synaptic transmission, respectively.

Calcium entering neurons through Ca_v1 channels is particularly effective in activating expression of neuronal genes in response to electrical activity, in comparison to calcium entering through other permeability pathways. The molecular basis for this preferential effect of Ca_v1 channels on gene expression is not known, but one idea is that proteins bound to the Ca_v1 channels, or even the C-terminus of the Ca_v1 channels, serve as a calcium-regulated molecular signal to control gene expression.

Calcium entering through Ca_v2 channels is primarily responsible for initiating synaptic transmission at fast synapses. $Ca_v2.2$ channels, which conduct N-type calcium current, are most important at synapses formed by neurons of the peripheral nervous system. In contrast, $Ca_v2.1$ channels, which conduct P/Q-type calcium currents, are most important at synapses formed by neurons of the central nervous system. Both $Ca_v2.2$ and $Ca_v2.3$ channels also have a significant role in initiating transmitter release at central synapses. In some cases, including a subset of inhibitory interneurons of the hippocampus, $Ca_v2.2$ channels are predominant in neurotransmitter release. On the other hand, $Ca_v2.3$ channels seem to always play a secondary role at central synapses compared to $Ca_v2.1$ and/or $Ca_v2.2$ channels.

The molecular basis for the prominent role of Ca_v2 channels in neurotransmission is not completely understood, but one factor is their direct interactions with the neurotransmitter release machinery in calcium channel signaling complexes.

Calcium Channel Signaling Complexes

Calcium entering neurons through calcium channels forms a transient microdomain of high calcium concentration. Intracellular proteins that must bind calcium to initiate essential physiological processes must be located near calcium channels in order to receive the calcium signal. In many cases, this close localization is achieved by direct interaction with the intracellular domains of calcium channels, which serve as signal transduction platforms for cytosolic calcium signaling. Similarly, proteins that regulate calcium channels in response to second messenger signaling are also often directly associated with calcium channels.

Ca_v1 channels are regulated by cAMP-dependent protein phosphorylation, initiated by neurotransmitters and hormones acting at many G-protein-coupled receptors. Regulation of these channels by local cAMP concentrations is achieved by binding of cAMP-dependent protein kinase to A-kinase anchoring proteins (AKAPs) that in turn bind directly to calcium channels. AKAP15 binds directly to Ca_v1 channels and tethers protein kinase A (PKA) to the channels through a modified leucine zipper interaction with a site in the C-terminal domain (Figure 3(a)). The C-terminal domain is proteolytically processed (Figure 3(a)), and the distal C-terminal domain containing the site of interaction of AKAP15 and PKA remains bound to the channel and regulates its function. Calcium/calmodulin-dependent protein kinase II binds directly to the proximal C-terminal domain of $Ca_v1.2$ channels and regulates channel function (Figure 3(a)). These direct interactions position the kinases near the sites of phosphorylation that regulate channel activity and thereby enhance speed and specificity of channel regulation.

Ca_v2 channels bind a wide range of signaling proteins (Figure 3(b)). The SNARE proteins involved in docking and release of neurotransmitters bind to a synaptic protein interaction ('synprint') site in the intracellular loop connecting domains II and III. This interaction is important to position docked synaptic vesicles near the source of entering calcium in order to ensure rapid and efficient release of neurotransmitters. Moreover, this interaction regulates calcium channel activity so that channels with nearby docked synaptic vesicles are more likely to open in response to membrane depolarization. Ca_v2 channels also bind G-protein β_γ subunits that inhibit channel activation in response to neurotransmitters, which build up in the synaptic cleft and bind to G-protein-coupled receptors located in presynaptic nerve terminals. Multiple sites of interaction of G-protein β_γ subunits have been identified, with the intracellular loop connecting domains I and II providing a primary point of channel regulation (Figure 3(b)). Ca_v2 channels bind calmodulin and related neurospecific calcium sensor proteins to a site in the C-terminal domain. These proteins mediate short-term facilitation and inactivation of calcium channel activity, and these regulatory effects in turn contribute to short-term facilitation and depression of synaptic transmission during trains of repetitive action potentials. The C-terminal domain of Ca_v2 channels also binds calcium/calmodulin-dependent protein kinase II, which positions this key enzyme to receive calcium signals in nerve terminals and regulate nearby presynaptic proteins by phosphorylation.

Calcium Channel Molecular Pharmacology

The pharmacology of the three subfamilies of calcium channels is quite different, and it relates directly to their distinct physiological roles. The Ca_v1 channels are the molecular targets of the organic calcium channel blockers used widely in the therapy of cardiovascular diseases. These drugs are thought to act at three separate, but allosterically coupled, receptor sites (Table 1). Phenylalkylamines are intracellular pore blockers, which are thought to enter the pore from the cytoplasmic side of the channel and block it. Their receptor site is formed by amino acid residues in the S6 segments in domains III and IV, in close analogy to the local anesthetic receptor site on sodium channels (Figure 4). Dihydropyridines can be channel activators or inhibitors and therefore are thought to act allosterically to shift the channel toward the open or closed state, rather than by occluding the pore. Their receptor site includes amino acid residues in the S6 segments of domains III and IV and the S5 segment of domain III. The dihydropyridine receptor site is closely apposed to the phenylalkylamine receptor site and shares some common amino acid residues (Figure 4). Diltiazem and related benzothiazepines are thought to bind to a third receptor site, but the amino acid residues that are required for their binding overlap extensively with those required for phenylalkylamine binding.

The Ca_v2 subfamily of calcium channels is relatively insensitive to dihydropyridines and other organic calcium channel blockers, but these calcium channels are specifically blocked with high affinity by peptide toxins from spiders and marine snails (Table 1). The $Ca_v2.1$

(b) The presynaptic calcium channel signaling complex. A presynaptic calcium channel α_1 subunit is illustrated as a transmembrane folding diagram as in **Figure 1**. Sites of interaction of SNARE proteins (the synprint site), $G\beta\gamma$ subunits, protein kinase C (PKC), calmodulin, and neuronal calcium-binding proteins (CBD), and calcium/calmodulin-dependent protein kinase II are illustrated.

channels are blocked specifically by ω-agatoxin IVA from funnel web spider venom. The $Ca_v2.2$ channels are blocked specifically by ω-conotoxin GVIA and related cone snail toxins. The $Ca_v2.3$ channels are blocked specifically by the synthetic peptide toxin SNX-482 derived from tarantula venom. These peptide toxins are potent blockers of synaptic transmission because of their specific effects on the Ca_v2 family of calcium channels. Block of $Ca_v2.2$ channels by a synthetic analog of a conotoxin, ziconitide, provides relief from chronic pain in animal models and in humans, and a new generation of organic calcium channel blockers with specificity for $Ca_v2.2$ channels is being evaluated in clinical trials.

The Ca_v3 subfamily of calcium channels is insensitive to both the dihydropyridines that block Ca_v1 channels and the spider and cone snail toxins that block the Ca_v2 channels. There are no widely used pharmacological agents that block T-type calcium currents specifically with high affinity. The organic calcium channel blocker mibefradil is somewhat selective for T-type versus L-type calcium currents (three- to fivefold). High concentrations of ethosuximide block T-type calcium currents specifically, and this effect of the drug may be responsible for its effectiveness in treatment of absence seizures. The peptide kurtoxin inhibits the activation gating of $Ca_v3.1$ and $Ca_v3.2$ channels. Development of more

Figure 4 Receptor site for calcium channel blocking drugs. (Left) A phenylalkylamine positioned in the inner area. The high-affinity phenylalkylamine calcium channel blocker desmethoxyverapamil is illustrated in its bound position in a ribbon model of the inner pore, without the side chains of the amino acids so that the position of the drug molecule can be seen. (Right) The phenylalkylamine receptor site. Binding of desmethoxyverapamil (D888) in the half-folded conformation inside of the pore and the interface crevice between domains III and IV is illustrated. The central amine interacts directly with the carboxylate of the side chain of Glu1118 of the selectivity filter, thereby blocking permeation.

specific and high-affinity blockers of the Ca_v3 subfamily of calcium channels would be useful for more detailed analysis of their physiological roles and potentially for therapy of pain, epilepsy, sleep disorders, and cardiac arrhythmias.

Calcium Channelopathies

Mutations in calcium channels cause multiple inherited disorders in humans. Mutations of skeletal muscle $Ca_v1.1$ channels cause hypokalemic periodic paralysis, which is characterized by flaccid paralysis of voluntary muscles correlated with low serum potassium concentration. Mutations in the $Ca_v1.2$ channels cause Timothy syndrome. This multifaceted disorder includes cardiac arrhythmia, developmental abnormalities, and an autism-like mental retardation. Mutations in $Ca_v1.4$ channels, which are highly expressed in the retina, cause stationary night blindness. Mutations in $Ca_v2.1$ channels cause spinocerebellar ataxia and familial hemiplegic migraine. The mutations in these different disorders all cause important changes in the functional properties of calcium channels, but the precise relationships between changes in the physiological functions of calcium channels and the pathophysiology of these inherited diseases is unresolved and is a very active area of research.

Calcium Channels and SNARE Proteins

Z-H Sheng and A G M Leenders, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

Ca^{2+}-triggered synaptic vesicle (SV) exocytosis depends on the assembly of the basic fusion machinery, the soluble *N*-ethylmaleimide-sensitive factor attachment protein (SNAP) receptor (SNARE) complex, in which the vesicle-associated v-SNARE protein synaptobrevin (VAMP) interacts with two plasma target membrane-associated SNARE (t-SNARE) proteins, SNAP-25 and syntaxin-1, to form a stable heterotrimeric SNARE complex. Maturation into a release-ready SV requires synaptotagmin I, an integral Ca^{2+}-binding protein of the synaptic vesicle membrane, which provides the Ca^{2+}-dependent regulation of the fusion machinery. Calcium influx into the presynaptic terminal triggers the calcium sensor of the fusion machinery, upon which the SNARE complex binding progresses from a *trans* to a *cis* state, resulting in the fusion of apposing membranes and the release of neurotransmitter.

Neurotransmitter release is initiated within 200 μs after the arrival of the action potential and critically depends on Ca^{2+} influx through high-voltage Ca^{2+} channels. Given that synaptic vesicle exocytosis is a highly Ca^{2+}-regulated process and that the intracellular Ca^{2+} concentration falls off steeply as a function of the distance away from the Ca^{2+} channels, the brief rise in the Ca^{2+} concentration to the level necessary for exocytosis is thought to occur only in close proximity to the presynaptic Ca^{2+} channels. Thus, the tight, spatially localized rise in intracellular Ca^{2+} and the subsequent activation of synaptic vesicle fusion are likely achieved by the direct physical link between the Ca^{2+} channels and the synaptic vesicle release machinery.

Ca^{2+} channels are multisubunit complexes, composed of a major pore-forming transmembrane subunit $\alpha1$ and smaller auxiliary subunits that include β and disulfide-linked $\alpha2\delta$ subunits. Of the many types of voltage-gated Ca^{2+} channels (Ca_v1, Ca_v2, and Ca_v3) expressed in neurons, members of the Ca_v2 family, in particular $Ca_v2.1$ (P/Q-type) and $Ca_v2.2$ (N-type) channels, are the predominant subtypes supporting neurotransmitter release in central synapses. New evidence has emerged indicating that both of these subtypes interact directly with SNARE proteins through a region on the intracellular loop connecting domains II–III of the $\alpha1$ subunit; this region is called the synaptic protein interaction site, or, for short, the synprint site. The stability of these interactions is critically dependent on the intracellular Ca^{2+} concentration, protein kinase C (PKC), and Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) phosphorylation of the synprint site, thus allowing the channel–SNARE complexes to be dynamically regulated in response to Ca^{2+} influx and activation of signal transduction pathways. Disruption of these interactions in presynaptic neurons impairs synaptic transmission by reducing the amplitude of excitatory postsynaptic potentials (EPSPs) and the sensitivity of neurotransmitter release to external Ca^{2+}. Studies support the hypothesis that the synprint site tethers the readily releasable pool of SVs and the release machinery near presynaptic Ca^{2+} channels for effective fast exocytosis. In addition to this functional role in the anterograde process of synaptic transmission, SNARE proteins also retrogradely modulate the voltage dependence of steady-state inactivation on Ca_v2 channels, thus providing a feedback mechanism for fine-tuning Ca^{2+} influx and, hence, synaptic transmission.

The SNARE Protein Interaction Site on Presynaptic Ca_v2 Channels

About a decade ago, immunocytochemical studies in neurons indicated that both N- and P/Q-type Ca_v2 channels are densely localized with syntaxin-1 at presynaptic nerve terminals and are crucial components in neuronal excitation–secretion coupling. Furthermore, these channels can be isolated as a complex with SNARE proteins from brain homogenates, suggesting that both types of Ca_v2 channels are part of the synaptic vesicle fusion complexes. These initial findings triggered an intensive investigation into what molecular determinant allows these channels to bind SNARE proteins and how this physical interaction regulates synaptic transmission and channel function.

The direct interaction between the presynaptic Ca^{2+} channel and syntaxin-1A was first described in 1994 by Sheng and colleagues based on *in vitro* biochemical analysis of the recombinant SNARE proteins associated with fusion proteins expressing various cytoplasmic loops of the N-type $Ca_v2.2$ channel. The SNARE proteins syntaxin-1A and SNAP-25, but not VAMP2, specifically interact with an amino acid sequence extending from residues 718 to 963 within the cytoplasmic loop between domains II and III (LII–LIII) of the N-type Ca^{2+} channel $\alpha1B$ subunit, the synprint site (Figure 1(a)). The synprint peptide specifically

Figure 1 Structural model of the $Ca_v2.2$ synprint domain. (a) The synprint site of the $Ca_v2.2$ channels. The α1 subunit is composed of four homologous transmembrane domains, which are formed by six membrane-spanning helices and connected by large cytoplasmic loops. The domain II–III loop contains the synprint site, which binds syntaxin-1, SNAP-25, cysteine string protein (CSP), and synaptotagmin I. (b) Working model of the interaction between the $Ca_v2.2$ synprint with syntaxin-1A (SYN1A). Based on a Chou–Fasman secondary structural prediction algorithm, an ~80-amino-acid-long bundle with high probability of forming a helical domain is depicted extending from IIS6 into the II–III loop . This helical segment is interrupted by a short random coil that precedes a second α helix containing the first binding site (B1; yellow box). Following this helical segment, a coil domain with collagen-like sequence homology (amino acids 823–848; hatched oval) is adjacent to the second binding site (B2; yellow box). Red balls mark the arginine- and histidine-rich clusters, which may serve as membrane surface interaction sites. The synprint B1 and B2 segments provide potential binding contact sites for the C-terminal coiled-coil (H3) of syntaxin-1 in a closed conformation (white arrows). (b) Adapted from Yokoyama C, Myers SJ, Fu J, *et al.* (2005) Mechanism of SNARE protein binding and regulation of Ca_v2 channels by phosphorylation of the synprint protein interaction site. *Molecular and Cellular Neuroscience* 28: 1–17, with permission from Elsevier.

interferes with the co-immunoprecipitation of native N-type Ca^{2+} channels with syntaxin-1, indicating that this binding site is required for the stable interaction of these two proteins. This interaction was shown to be Ca^{2+} dependent, with maximal binding at 20 μM Ca^{2+} and reduced binding at resting Ca^{2+} concentrations and at concentrations above 50 μM. Although the physiological significance of this biphasic Ca^{2+}-dependent interaction is not clear, reduced binding affinity at high Ca^{2+} levels may imply that there is a sequential step in the dissociation of syntaxin-1A and SNAP-25 from the channels, in order for fusion to proceed.

A recent study by Yokoyama and colleagues defined the molecular determinants of syntaxin-1A and SNAP-25 binding in the synprint site more precisely. Two different peptide segments of $Ca_v2.2$, amino acids 773–786, and 872–901, are independently required to bind syntaxin-1A and SNAP-25 to each half of the synprint site. Based on structural analysis using the Basic Local Alignment Search Tool for proteins (BLAST-P), the two halves of the synprint site are separated by a linker sequence that contains a collagen-like strand with a number of proline and glycine residues (Figure 1(b)). This motif is predicted to form an extended and flexible linker which connects the two SNARE-binding segments. Furthermore, the synprint sequence exhibits a high charge density, with a charged residue found, on average, every 2.5 amino acids. This hydrophilic structure of the synprint site allows for facile interactions with the hydrophilic surface of the amphipathic α helices of SNARE proteins. In addition, repeated arginine/histidine-rich sequences in the synprint site may provide contacts with phospholipids in the plasma membrane or in the docked synaptic vesicles, thus mediating a structural tethering of synaptic vesicles near presynaptic $Ca_v2.2$ channels.

$Ca_v2.1$ (P/Q-type) channels also contain a synprint site in their LII–LIII intracellular loop. However, unlike the N-type, two isoforms of the α1A subunit of $Ca_v2.1$ channels, BI and rbA, exhibit different patterns of interaction with synaptic proteins and different Ca^{2+} dependencies. While the BI isoform interacts with syntaxin-1A and SNAP-25 independent of Ca^{2+} concentration, the rbA isoform interacts with SNAP-25 but not with syntaxin-1. Given that these Ca^{2+} channels are differentially distributed in the synapses of the central nervous system, the observed differences in the interactions between the channels and the SNARE proteins may reflect subtle variations in the efficacy of the initiation of transmitter release by Ca^{2+}

influx through these different channels, and may confer specialized regulatory properties that contribute to synaptic modulation. The synprint site is considered unique to vertebrate $Ca_v2.1$ (P/Q-type) and $Ca_v2.2$ (N-type) channels, as other Ca^{2+} channel subtypes, such as $Ca_v1.2$ (L-type, for neuroendocrine secretion) and $Ca_v2.3$ (R-type, for synaptic transmission), lack the classical synprint site in the corresponding regions. However, the functional interaction of both $Ca_v1.2$ and $Ca_v2.3$ channels with SNARE proteins is observed, possibly controlled by a mechanism that does not involve the synprint site.

Both $Ca_v2.1$ and $Ca_v2.2$ channels interact with the C-terminus of syntaxin-1A (amino acids 181–288), suggesting that Ca^{2+} channels bind to syntaxin-1A at a C-terminal site near the intracellular surface of the plasma membrane (**Figure 1(b)**). In addition, a recent study suggests that the N-terminal sequence (amino acids 1–69) of syntaxin-1A is also able to bind synprint *in vitro*.

Besides the SNARE proteins syntaxin-1A and SNAP-25, one other abundant synaptic vesicle protein, synaptotagmin, has been shown to directly interact with the synprint site of both N- and P/Q-type channels. Synaptotagmins are a family of Ca^{2+}-binding proteins containing two homologous C2 domains, the importance of which in exocytosis has been well established both genetically and biochemically. Synprint directly binds to synaptotagmin-I through the same region in the C2B domain required for synaptotagmin oligomerization and for adapter protein (AP-2) binding. Within this region, two adjacent lysine residues (K326 and K327) are critical for synaptotagmin oligomerization and AP-2 and synprint binding. Moreover, syntaxin interacts exclusively with either synprint or synaptotagmin in a Ca^{2+}-dependent manner, such that at low Ca^{2+} concentration syntaxin-1 binds synprint, whereas at higher concentrations (>30 μM) its association with synaptotagmin increases, thus providing a potential biochemical correlate for the sequence of events occurring at the synprint site of presynaptic Ca^{2+} channels during synaptic vesicle exocytosis. Collectively, these studies provide a molecular basis for a physical link of the neuronal N-type and P/Q-type Ca^{2+} channels with the synaptic vesicle fusion machinery, enabling tight structural and functional coupling of Ca^{2+} entry sites and neurotransmitter release sites.

The Synprint Site Is Important for Efficient Release of Neurotransmitter

When the action potential invades the nerve terminal, the Ca^{2+} influx through presynaptic Ca^{2+} channels rapidly elevates the Ca^{2+} concentration to 200–300 μM in microdomains of approximately 0.3 μm^2 at presynaptic terminal. This transient Ca^{2+} influx triggers synaptic vesicle exocytosis through binding to the Ca^{2+} sensor of the release machinery. Since diffusion and sequestration rapidly decrease the Ca^{2+} concentration, the Ca^{2+} concentration at the nerve terminal falls off steeply as a function of the distance from the Ca^{2+} entry sites. A physical anchoring of the release machinery to the source of the Ca^{2+} influx would be an attractive model for the docked synaptic vesicles to be spatially localized within the Ca^{2+} microdomains. Thus, whether binding of the SNARE proteins to the synprint site contributes to the efficiency of neurotransmitter release has been the subject of considerable investigation.

The first functional study by Mochida and coworkers demonstrated that injection of the synprint peptides into presynaptic superior cervical ganglion neurons (SCGNs) in culture significantly depressed the excitatory postsynaptic response, presumably by competitive uncoupling of the endogenous Ca^{2+} channels–SNARE interaction. In this case, rapid synchronous synaptic transmission is inhibited, while late asynchronous release and paired-pulse facilitation are increased, consistent with the hypothesis that synaptic vesicles are shifted from a pool for synchronous release to a pool not optimally primed or positioned for synchronous release. This study indicates that in addition to mediating Ca^{2+} entry, the N-type Ca^{2+} channels may have an effect on the transmitter release via its interaction with the SNARE proteins. This study also supports the notion that a tight physical interaction between the presynaptic Ca^{2+} channels and the release apparatus is required for rapid, synchronous neurotransmitter release.

To determine whether the inhibition of neurotransmitter release by the synprint peptides is due to the displacement of the docked vesicles from the N-type Ca^{2+} channels, Rettig and colleagues used *Xenopus* nerve muscle co-cultures, in which synaptic transmission is mainly dependent on the N-type Ca^{2+} channels. Injection of the synprint peptides into embryonic *Xenopus* spinal neurons shifted the Ca^{2+} dependence of release to a higher external concentration, even though Ca^{2+} influx was not altered. Transmitter release was reduced by approximately 50% when cells were stimulated in an extracellular solution containing physiological Ca^{2+} concentration. High external Ca^{2+} concentration rescued this inhibition, implying that the Ca^{2+} channels are not optimally located for efficient release, or are detached from release sites following the addition of the synprint peptides.

To determine whether the synprint deletion mutant could support vesicle fusion in secretory cells, Harkins and colleagues transiently expressed the wild-type or

the synprint-deleted mutant of $Ca_v2.2$ channels in mouse pheochromocytoma (MPC) 9/3L, a cell line containing the release machinery but lacking the voltage-dependent Ca^{2+} channels. When compared with the cells expressing the wild-type channels, expression of the mutant channel in the cells significantly reduces both total secretion and the rate of secretion as determined by capacitance measurements, although Ca^{2+} currents are similar regardless of whether synprint is deleted. A similar study by Mochida and colleagues showed that the deletion of the synprint site on the $Ca_v2.1$ P/Q-type channel results in a 50% reduction in release in cultured SCG neurons. This effect is correlated with a reduced localization of the exogenously expressed channels to presynaptic terminals. Transfer of the synprint sequence from $Ca_v2.1$ to $Ca_v1.2$ channels, which conduct L-type Ca^{2+} currents and are ineffective in supporting synaptic transmission, is sufficient to initiate synaptic transmission. These results consistently support the notion that the synprint site is necessary for the efficient functional coupling of Ca^{2+} influx through the $Ca_v2.1$ and $Ca_v2.2$ channels and vesicle exocytosis (Figure 2).

Given that t-SNARE proteins are widely distributed in neurons, including the dendrites and soma, the interaction between the synprint site and the t-SNARE proteins is likely a permissive event for presynaptic localization of the Ca^{2+} channels. Additional primary targeting signals required for nerve terminal localization of presynaptic Ca^{2+} channels remain to be identified. A recent study suggested that the adapter proteins Mint and CASK play a critical role in the targeting of N-type Ca^{2+} channels via a direct interaction with the C-terminal tail of the channels (Figure 1(a)).

While the synprint–SNAREs interaction critically affects the efficiency of neurotransmitter release in vertebrate neurons, recent evidence suggests that this interaction might not be absolutely required for synaptic vesicle exocytosis. First, invertebrate Ca^{2+} channels, representative of the Ca_v2 channels, lack a synprint site, although these channels participate in synaptic transmission. Second, splice variants of the human N-type channels lacking the synprint region have been identified. As originally noted by Zamponi, these findings raise the question as to how these

Figure 2 The proposed inhibitory role of the synprint peptide on the efficiency of neurotransmitter release. (a) The physical and functional coupling of presynaptic Ca_v2 channels and synaptic vesicle fusion machinery. As the intracellular Ca^{2+} concentration falls off steeply as a function of distance away from the Ca^{2+} entry sites, fast exocytosis likely occurs only in proximity to the Ca^{2+} channels. Thus, binding of the SNARE proteins to the synprint site contributes to the efficiency of neurotransmitter release. (b) The synprint peptide (gray chevrons) competitively uncouples the physical link between the Ca^{2+} channels and the SNARE proteins. This decreases the efficiency by shifting Ca^{2+} dependence to higher values. Rapid, synchronous synaptic transmission is inhibited, while late, asynchronous release and paired-pulse facilitation are increased, consistent with the hypothesis that synaptic vesicles are shifted from a pool primed for synchronous release near the Ca^{2+} entry sites to a pool not optimally primed or positioned for synchronous release.

channels couple to the synaptic vesicle fusion machinery. In addition, the deletion of the synprint site on both $Ca_v2.1$ and $Ca_v2.2$ channels did not completely abolish synaptic transmission and vesicle exocytosis. Therefore, further investigation is necessary to determine whether synprint serves as a primary binding site for the SNARE proteins or just as a SNARE anchoring domain to maintain the structural integrity of the fusion complex at nerve terminals.

Regulation of Presynaptic Ca^{2+} Channels by SNARE Proteins

A number of studies have documented that syntaxin-1A and SNAP-25 not only bind to presynaptic Ca^{2+} channels in order to closely couple the channels and the vesicle release machinery, but they are also capable of regulating channel activity, thus acting as a negative feedback mechanism for the modulation of synaptic transmission. As initially reported by Bezprozvanny and colleagues and shortly after by Wiser and colleagues, co-expression of syntaxin-1A with $Ca_v2.1$ or $Ca_v2.2$ channels in *Xenopus* oocytes results in a reduced availability of the channels to open and inhibits Ca^{2+} channel activity by shifting the voltage dependence of steady-state inactivation under long, depolarizing prepulses toward more negative membrane potentials. However, strong hyperpolarizing pulses can overcome this effect, implying that syntaxin-1A does not simply block or reduce expression of the Ca^{2+} channels. Interestingly, Zhong and colleagues demonstrated that the inhibitory effects of syntaxin could be relieved by co-expressing synaptotagmin, suggesting a dynamic process involving multiprotein interactions or the structural reorganization of these protein complexes.

Like syntaxin-1A, SNAP-25 reduces calcium channel-opening probability when co-expressed with N- and P/Q-type channels. However, as reported by Javis and Zamponi, in the presence of both syntaxin-1 and SNAP-25, the shift toward inactivation is ablated and the opening probability of the channels is restored to normal. Thus, depending on the protein(s) associated, the channels differ in their ability to contribute to Ca^{2+} influx. When in the presence of only syntaxin-1A or SNAP-25, the synaptic vesicles are unable to dock at the plasma membrane or near the channel, and the negative shift in inactivation potential reduces Ca^{2+} entry through this channel, thus preventing Ca^{2+} overload. In contrast, the formation of the SNARE complex mediates synaptic vesicles docking at release sites and concomitantly increases the channel availability for opening, thus favoring Ca^{2+} influx through the channels localized at the docked synaptic vesicles. In principle, such a mechanism could provide selective Ca^{2+} entry through channels bound to docked vesicles, whereas channels associated with one SNARE protein remain relatively inactive. This mechanism allows the modulatory interaction for the channels to be switched on and off at appropriate recycling stages of the SNARE proteins and synaptic vesicles. In addition, the inhibitory role of syntaxin-1 on channel opening is abolished in the presence of neuronal Sec-1 (nSec-1), a protein that blocks the assembly of the SNARE complex by locking syntaxin-1 in a closed conformation. Altogether, these findings support a model for the SNARE-mediated modulation of presynaptic Ca^{2+} channels: the channel activity is inhibited when it is associated with syntaxin-1 in a closed conformation and in the absence of the other SNARE proteins.

Stanley and Mirotznik revealed that syntaxin-1A regulates presynaptic calcium channels in intact neuronal terminals via its susceptibility to G-protein inhibition. Botulinum toxin, which cleaves syntaxin-1A, prevents G-protein modulation of presynaptic Ca^{2+} channels in chick calyces, suggesting a cross-talk between syntaxin-1A and G-protein effects on N-type Ca^{2+} channels. Subsequent studies by Jarvis and colleagues showed that the synprint site and $G\beta$ bind to distinct portions of syntaxin-1A and that expression of syntaxin-1A appears to be a prerequisite for tonic G-protein inhibition of the N-type Ca^{2+} channels. These results support a hypothesis that syntaxin-1A acts as a chaperone by tethering $G\beta$ to the N-type Ca^{2+} channels in synapses, thus facilitating G-protein regulation.

By combining site-directed mutagenesis with functional expression in *Xenopus* oocytes, Bezprozvanny and colleagues addressed an important question as to whether the anchoring and modulatory interactions between syntaxin-1 and Ca^{2+} channels are mediated by the same molecular determinant. Their studies showed that both the transmembrane region and a short segment within the H3 helical cytoplasmic domain of syntaxin-1A are critical for channel modulation but not for binding to the synprint site of the N-type Ca^{2+} channels. Given that this short segment is buried within the core of the four-helix structure of the SNARE complex, the modulatory action of syntaxin-1A can be enabled only after disassembly of the SNARE complex following synaptic vesicle exocytosis. The synprint site binds to the whole H3 region of syntaxin-1A, confirming the original biochemical findings of Sheng and colleagues. However, deletion of the synprint site weakened the modulation of the channels by syntaxin-1A, but did not abolish it, arguing that the synprint sequence acts as an important anchor in facilitating channel modulation but is not essential for the modulatory action. While the

precise site on the channels for syntaxin-mediated modulation remains to be determined, the identification of separate anchoring and modulation sites on the channels provides molecular and structural insights into how Ca^{2+} entry into the nerve terminals is tightly correlated to the recycling state of the release machinery.

Although the SNARE complex, together with synaptotagmin, is thought to be the minimal essential machinery required for Ca^{2+}-dependent synaptic vesicle fusion, a multitude of presynaptic proteins have been identified over the past decade, most of which have been shown to directly participate in or regulate the synaptic vesicle cycle via interactions with the SNARE proteins, thus having the potential to modulate the SNARE–synprint interaction. A direct interaction between Munc18 and the synprint site was reported, although the significance of this interaction in synaptic transmission remains to be elucidated. Rab-interacting molecule (RIM), an active-zone protein implicated in short- and long-term synaptic plasticity, has also been shown to interact with the synprint region *in vitro*. Since RIM interacts with multiple active-zone components and synaptic vesicle proteins, it is unclear how RIM modulates sequential steps in synaptic vesicle exocytosis and how these biochemical interactions translate into physiological functions. Cysteine string protein (CSP) was first identified as a synaptic vesicle-associated protein with the ability to modify Ca^{2+} influx in *Drosophila* and *Torpedo*. Subsequent studies demonstrated that CSP interacts with the synprint site of both P/Q- and N-type Ca^{2+} channels and that this interaction results in a robust tonic inhibition of channel activity by G-protein $\beta\gamma$ subunits. The ability of CSP to enhance G-protein signaling suggests that a channel physically coupled to a docked vesicle is more prone to G-protein inhibition than one uncoupled to a docked vesicle. These studies further support the notion that the functional activity of the presynaptic Ca^{2+} channels is regulated by the SNAREs and SNARE-binding proteins.

Modulation of the SNARE–Synprint Interaction

Second-messenger-activated regulation of neurotransmitter release via modulation of protein interactions within the exocytotic apparatus has a potentially important role in synaptic plasticity. Several protein kinases, including PKA, PKC, PKG, and CaMKII, are expressed in presynaptic terminals. Ca^{2+} channels and the SNARE proteins are phosphorylated by one or more of these kinases. Original *in vitro* biochemical studies by Yokoyama and colleagues revealed that phosphorylation of the synprint peptide with PKC and CaMKII strongly inhibits its binding to recombinant syntaxin-1A and SNAP-25 and also prevents its association with the native SNARE complex isolated from rat brain homogenates. Moreover, subsequent functional studies in both the Tsien and Zamponi laboratories consistently showed that PKC phosphorylation blocks the negative shift of steady-state inactivation of $Ca_v2.2$ channels, possibly by a reduced binding of syntaxin-1 to the synprint site. These studies suggest that phosphorylation of the synprint site by PKC or CaMKII may serve as a biochemical switch for the SNARE–synprint interactions, and thus phosphorylation is a candidate presynaptic mechanism for the regulation of neurotransmitter release.

Yokoyama and colleagues recently reported a more detailed analysis of these phosphorylation sites. The synprint site of $Ca_v2.2$ channels consists of two separate microdomains, each of which binds syntaxin-1 and SNAP-25 *in vitro* and is regulated by PKC phosphorylation at serines 774 and 898 and by CaMKII phosphorylation at serines 784 and 896. Each phosphorylation site can control syntaxin-1 and SNAP-25 binding to half of the synprint site, suggesting a bipartite structure for the synprint domain. However, phosphorylation of the intact $Ca_v2.2$ channels before exposure to syntaxin-1A reduces the binding affinity to syntaxin-1A, but does not completely prevent it or cause its dissociation. These observations are consistent with the functional study, in which PKC activation in the transfected tsA-201 cells does not completely dissociate syntaxin-1A from the channels, but does completely reverse the negative shift of steady-state inactivation caused by syntaxin-1A. Altogether, these findings support a notion that while PKC phosphorylation of $Ca_v2.2$ channels is sufficient to block the syntaxin-mediated modulation of channel function, it destabilizes but not completely disrupts its physical interaction with syntaxin-1A. As PKC phosphorylation reverses the syntaxin-1A effect on channel inactivation, this mechanism might contribute to increased Ca^{2+} entry at sites near docked vesicles, thus enhancing the effectiveness of Ca^{2+} influx during neurotransmission.

Conclusion

The interactions between the presynaptic Ca^{2+} channel synprint site and SNARE proteins not only provide a molecular basis for a physical and functional coupling between Ca^{2+} influx and subsequent exocytosis, but also provide a model for sequential protein–protein interactions at or near the Ca^{2+} channels – interactions that are either essential or modulatory steps in the release of synaptic vesicles. Further regulation is

imposed by interplay between the synprint site interactions and second-messenger modulation of calcium channels through phosphorylation and G-proteins. Altogether, the complexity of the interactions at and near the synprint site of the Ca^{2+} channels suggests that the mammalian brain has devised numerous pathways for the selective and precise control of sequential events, resulting in efficient vesicle release in the presynaptic nerve terminals.

Calcium Homeostasis in Glia

Introduction

All cells use changes in intracellular calcium concentration as a signal to regulate their physiological function. For glial cells, the study of calcium signaling has led to significant new insights into their functional roles in the nervous system. The technique of calcium imaging using fluorescent calcium indicators has been a driving force behind the increasing recognition that glial cells are active participants in most functions of neural tissues. Knowledge of the specific mechanisms of calcium signaling in glial cells represents an important foundation for an understanding of the unique functions of these cells in the physiological and pathological processes of the central nervous system.

Glia cells (astrocytes, oligodendrocytes, and microglia) all show increases in the concentration of cytoplasmic free calcium ($[Ca^{2+}]_i$) with multiple spatial and temporal patterns. Ca^{2+} signaling in astrocytes has been most commonly studied (see Figure 1). Increases in $[Ca^{2+}]_i$ may be localized in subcellular microdomains, propagated as waves within individual cells, or communicated from cell to cell as intercellular waves. Ca^{2+} increases may occur as single transients or as repetitive oscillations. While many of the patterns of glial Ca^{2+} signaling were originally observed in cell culture or *in vitro* in brain slice preparations, recent *in vivo* studies have confirmed that glial Ca^{2+} responses occur under physiological conditions in the intact nervous system.

Sources of Calcium in Glial Cells

Glial-cell Ca^{2+} signals may be generated by release of Ca^{2+} from intracellular stores, influx of Ca^{2+}, or a combination of the two. An individual Ca^{2+} response involves a complex interplay between different sources and sinks for Ca^{2+}. Because glial cells are 'nonexcitable cells' – that is, most glial cells don't generate action potentials – their Ca^{2+} signaling typically relies on release of Ca^{2+} from intracellular stores to a greater extent than in neurons, where Ca^{2+} signaling depends more on Ca^{2+} influx that is related to changes in membrane potential. A typical glial Ca^{2+} response is therefore slower and more sustained than that of a neuron.

Intracellular Calcium Release

Most glial-cell Ca^{2+} signaling responses involve release of Ca^{2+} from intracellular stores. This can be demonstrated by the occurrence of Ca^{2+} responses in the absence of extracellular $Ca^{2+}$and by the inhibition of Ca^{2+} responses by depletion of intracellular Ca^{2+} stores by the sarcoplasmic/endoplasmic reticulum adenosine triphosphatase (SERCA) Ca^{2+} pump inhibitors such as thapsigargin or cyclopiazonic acid. Ca^{2+} stores that are released by binding of intracellular messenger inositol triphosphate (IP_3) to IP_3 receptors on the endoplasmic reticulum appear to be the primary source for intracellular Ca^{2+} release in glial cells. Uncaging of IP_3 evokes Ca^{2+} responses in astrocytes similar to those observed in response to other stimuli. Conversely, inhibition of IP_3-mediated signaling by blocking the IP_3 receptor (IP_3R) with xestospongin or heparin or by buffering IP_3 blocks astrocyte Ca^{2+} responses. The role of Ca^{2+} stores released by ryanodine receptors is not as well defined. Astrocytes in culture have been shown to express ryanodine receptors associated with the endoplasmic reticulum, and caffeine and other ryanodine receptor agonists have been reported to evoke a Ca^{2+} response in some preparations but not in others. In general, however, pretreatment with ryanodine does not affect spontaneous or evoked Ca^{2+} signaling in glia, suggesting the ryanodine receptors do not play a primary role in most types of astrocyte Ca^{2+} signaling. Cells in the oligodendrocyte lineage also express ryanodine receptors which have been implicated in the generation of highly localized calcium release events, known as calcium 'sparks.' Ryanodine receptors may also co-localize with other proteins involved in calcium signaling in specific microdomains in oligodendrocyte progenitors. As in astrocytes, however, the function of ryanodine receptors and their corresponding calcium stores in oligodendrocytes remains uncertain.

SERCAs pump Ca^{2+} from the cytoplasm into membrane-bound stores. The function of these pumps has been investigated primarily with compounds that inhibit them – thapsigargin and cyclopiazonic acid. Application of these SERCA inhibitors to glial cells typically evokes a sustained increase in $[Ca^{2+}]_i$ and depletes intracellular Ca^{2+} stores, making the cell incapable of responding to subsequent stimuli that normally evoke Ca^{2+} release. Fluorescently tagged thapsigargin indicates that SERCAs are distributed throughout the cell in association with intracellular membranes and that in oligodendrocytes, SERCAs appear to be localized in proximity to mitochondria. Other studies indicate that SERCAs and IP_3Rs are

present in complexes of plasma membrane and endoplasmic reticulum, forming functional units for Ca^{2+} signaling that coordinate Ca^{2+} influx and Ca^{2+} release.

Capacitative Calcium Entry

Release of Ca^{2+} from intracellular stores in glial cells activates influx of Ca^{2+} through channels known as 'store-operated channels.' This Ca^{2+} influx, also known as 'capacitative Ca^{2+} entry,' is believed to be important in the refilling of depleted intracellular Ca^{2+} stores. Consistent with this role, capacitative Ca^{2+} entry has been observed to occur locally at sites where the endoplasmic reticulum is in proximity to the plasma membrane. Capacitative Ca^{2+} entry was initially believed to primarily involve channels in the class of transient potential channels. Subsequent studies, however, indicated that most store-operated channels are likely distinct from transient potential channels. The identity of these store-operated channels in glia, as in other cells, remains uncertain. Store-operated channels may be inhibited by dihydropyridines and activated by BayK 8644, compounds that had previously been considered to be specific to voltage-gated calcium channels (VGCCs). The lack of specificity of these compounds and the absence of consistent and specific inhibitors of capacitative calcium entry have been problematic in determination of the functional significance of capacitative calcium entry in glia. It is clear, however, that capacitative calcium entry can contribute substantially to the duration of a Ca^{2+} response that is triggered by an initial release of intracellular Ca^{2+}. Capacitative Ca^{2+} entry in astrocytes has been found to be inhibited by both arachidonic acid and zinc, suggesting that it may be actively modulated as a component of intercellular signaling. It has also been reported to be increased under hypoxic conditions, suggesting that it may play a role in the response of astrocytes to injury.

VGCCs

All glial cells express different types of VGCCs, and in each cell type, the number and type of channels expressed may vary with development and differentiation. Although they do not fire action

potentials, glial cells can show depolarization of membrane potential to a level that activates opening of voltage-gated channels. Astrocytes in culture express L-, N-, R-, and T-type calcium channels, but not P/Q-type channels. In cultured astrocytes, depolarization can evoke increases in $[Ca^{2+}]_i$ that are enhanced by BayK 8644 and inhibited by dihydropyridines. However, as mentioned above, these compounds may also modulate capacitative Ca^{2+} entry. In slice preparations, depolarization-evoked increases in astrocytic Ca^{2+} were found to be entirely generated by intracellular Ca^{2+} release activated by metabotropic glutamate receptors rather than by calcium influx through voltage-gated channels. These findings suggest that VGCCs do not contribute substantially to astrocyte calcium signaling under physiological conditions. However, different subtypes of Ca^{2+} channels have been reported to be upregulated in reactive astrocytes following brain injury, as well as pilocarpine-induced status epilepticus, suggesting that changes in the 'state' of astrocytes may result in an increased role for VGCCs.

Oligodendrocytes also express different types of VGCCs, whose level of expression may vary considerably with the stage of development and differentiation. Transient upregulation of R-type channels in oligodendrocytes has been reported during myelinogenesis. It has been suggested that VGCCs are important in the functional response of oligodendrocytes to axonal activity, and they may also be important in the setting of axonal injury.

Transient Receptor Potential Channels

Transient receptor potential (TRP) channels are calcium-permeable cation channels with polymodal activation properties. Although they have been widely studied in neurons and other cell types, there have been few reports of TRP channel expression in glia. One study implicated TRP channels in spontaneous Ca^{2+} oscillations in astrocytes. Others found a specific expression of a TRP channel subtype in oligodendrocytes and microglia. At this stage, however, the potential contributions of TRP channels to glial Ca^{2+} signaling, and their functional significance, have not been extensively characterized.

Mitochondria

Mitochondria may serve as both a buffer for increases in $[Ca^{2+}]_i$ in astrocytes and a source that contributes to Ca^{2+} signals. Studies using the mitochondria selective indicator rhod-2 indicate that mitochondrial Ca^{2+} increases and oscillates in synchrony with cytoplasmic Ca^{2+} in astrocytes stimulated with different ligands. Consistent with mitochondrial Ca^{2+} uptake, intercellular Ca^{2+} waves in astrocytes are associated with waves of mitochondrial depolarization measured using the indicator tetramethylrhodamine ethyl ester. Disrupting mitochondrial function with mitochondrial uncouplers has been reported to increase the rate of propagation of intercellular Ca^{2+} waves, suggesting that mitochondrial uptake serves as a buffering mechanism to reduce the propagation of increases in $Ca^{2+}{}_i$ concentration. In other conditions, disruption of mitochondrial function with uncouplers may decrease the Ca^{2+} response to specific ligands, indicating that mitochondrial Ca^{2+} release contributes to the response. Decreased mitochondrial buffering of Ca^{2+} may be associated with increased Ca^{2+} signaling in astrocytes from older animals, an effect that could be involved in changes in the function of astrocytes with aging.

Ligand-Evoked Calcium Signaling in Glial Cells

A wide variety of neurotransmitters, neuromodulators, growth factors, and cytokines can evoke Ca^{2+} signaling in glial cells. Most, if not all, transmitter receptors expressed on neurons are also expressed on some type of glial cell. However, glial cell Ca^{2+} signaling is predominantly evoked by metabotropic receptors (G-protein-coupled receptors that activate the formation of intracellular messengers) as opposed to ionotropic receptors (ligand-gated ion channels). While ionotropic receptors play specialized roles in some glial cell types, the majority of transmitter-evoked signaling responses identified thus far involve release of intracellular Ca^{2+} as opposed to Ca^{2+} influx. Of these, signaling by purinergic receptors (receptors for adenosine triphosphate (ATP), adenosine diphosphate, and adenosine) and glutamate receptors has received the most attention, in part because these receptors appear to play key roles in glial–glial, glial–neuronal, and glial–vascular signaling. But many other ligands also evoke Ca^{2+} signaling in glia through multiple distinct receptor systems.

The primary mechanisms for ligand-evoked Ca^{2+} signaling in glia are activation of phospholipase C (PLC) by Gq-protein-coupled receptors, phosphorylation of PLC by receptor tyrosine kinases, and calcium influx through ligand-gated channels. As described earlier, binding of ligands to metabotropic receptors, such as binding of ATP to purinergic receptors or glutamate to metabotropic glutamate receptors on glial cells, activates the G-protein subtype Gq, which in turn activates PLC, leading to the formation of IP_3. IP_3 then binds to IP_3Rs on intracellular membranes, releasing Ca^{2+} from membrane-bound

internal stores. Activation of G-protein-coupled receptors may evoke a single peak of increased $[Ca^{2+}]_i$ or sustained oscillations in $[Ca^{2+}]_i$. It has been suggested that the frequency and amplitude of these Ca^{2+} oscillations could enable frequency and amplitude modulation of intracellular and intercellular signaling. Localized Ca^{2+} responses to receptor activation in an individual cell can also be propagated throughout the cell as intercellular waves (see the section titled 'Intercellular calcium waves').

In addition to activation by G-proteins, PLC can be activated by phosphorylation by growth factors such as receptor tyrosine kinases. While most studies have focused on their downstream activation of nuclear transcription factors, Ca^{2+} signaling evoked by receptor tyrosine kinases may also be critical to generating a cell's functional response. The response of glioma cells to epidermal growth factor is a good example of this type of signaling. Binding of epidermal growth factor to its receptor results in dimerization of the receptor, which in turn leads to phosphorylation of PLC, causing formation of IP_3 and intracellular Ca^{2+} release. Unlike G-protein-coupled receptors, which evoke an immediate Ca^{2+} response, activation of receptor tyrosine kinases results in a $[Ca^{2+}]_i$ increase that may be delayed by up to a minute after exposure to the ligand. There may also be a sustained monophasic or oscillatory Ca^{2+} increase that continues for minutes after removal of the ligand, as well as a sustained increase in the extent of propagation of intercellular Ca^{2+} waves.

In glial cells, Ca^{2+} influx through ligand-gated ion channels such as *N*-methyl-D-aspartate (NMDA) receptors, or through voltage-gated Ca^{2+} channels in response to ligand-evoked depolarization, has been reported primarily in cells of the oligodendrocyte lineage. NMDA receptors have been found in oligodendrocyte progenitors and mature oligodendrocytes, as well as in intact myelin, where they are involved in oligodendrocyte Ca^{2+} responses to acute injury. Ca^{2+} influx through kainate receptors has been reported in Bergmann glia and may represent a mechanism by which they respond to the activity of Purkinje cells. Astrocytes and microglia express ionotropic purinergic (P2X) receptors, but in the case of astrocytes, attention regarding these receptors has been focused more on their potential role as a pathway for ATP release than as a pathway for Ca^{2+} influx (see the section titled 'Intercellular calcium waves').

Patterns of Calcium Signaling in Individual Cells

Ca^{2+} release and/or influx may occur at discrete sites within individual cells, resulting in 'microdomains' of increased $[Ca^{2+}]_i$. Localized increases in $[Ca^{2+}]_i$ may allow spatial discrimination of particular Ca^{2+}-dependent functions. There is growing evidence that multiple components of Ca^{2+} signaling machinery may be co-localized in discrete units with the cell. Independent Ca^{2+} signaling in individual processes has been demonstrated in astrocyte processes in Bergmann glia and hippocampal astrocytes in slice preparations. In hippocampal slices, Ca^{2+} transients in individual astrocyte processes were found to be independent of neuronal activity, whereas in Bergmann glia, they were evoked by activity of neighboring neurons. Similar localized Ca^{2+} responses may occur in cells of the oligodendrocyte lineage in response to axonal release of glutamate. Astrocyte end-feet also show highly localized Ca^{2+} signaling in response to neuronal activity or release of caged IP_3. Localized Ca^{2+} signaling in glial cells could represent a mechanism by which they can participate in cell-to-cell signaling with multiple spatially separate cells independently, with the potential for a coordinated response if the Ca^{2+} signal spreads throughout the entire cell. For example, Ca^{2+} signaling in individual processes of a single glial cell could serve to integrate input from multiple individual synapses or axons or, conversely, to convey signals to multiple neighboring neurons or vascular cells. Localized intracellular Ca^{2+} release within a single glial cell may be propagated as an intracellular wave throughout the cell. These intracellular Ca^{2+} waves are believed to be generated by diffusion of IP_3 and sequential release of Ca^{2+} from neighboring intracellular Ca^{2+} stores. Intracellular Ca^{2+} waves are commonly observed in glial cells in culture, as well as in brain slice preparations.

Intercellular Calcium Waves

In addition to Ca^{2+} changes occurring within individual cells, glial cells are capable of widespread intercellular communication of Ca^{2+} signals in the form of intercellular 'waves.' Intercellular Ca^{2+} waves in astrocytes were originally described as a delayed response to application of glutamate to astrocytes in culture. Glutamate evoked an initially simultaneous increase in $[Ca^{2+}]_i$ in a microscopic field of astrocytes, followed by multifocal intercellular Ca^{2+} waves that occurred throughout the field. Other studies showed that intercellular Ca^{2+} waves in astrocytes could be evoked by transient mechanical perturbation of the membrane of a single cell. Because it reliably evokes intercellular Ca^{2+} waves from a point source in a single cell, mechanical stimulation has been widely used as a method for evoking Ca^{2+} waves in glial cells and a variety of other cell types. Other conditions that evoke Ca^{2+} waves include local application of transmitters, electrical stimulation, or removal of

Figure 2 Intercellular calcium wave in glial cells. Image sequence showing intercellular calcium wave evoked by mechanical stimulation of a single cell in a mixed glial culture. Pseudocolor scale represents intracellular calcium concentration as measured by ratiometric fluorescence imaging with the indicator fura-2. Brief deformation of the membrane of a single cell (arrow) with a glass micropipette results in an increase in intracellular calcium concentration that is propagated as a wave to multiple surrounding cells.

extracellular Ca^{2+}. Limited intercellular Ca^{2+} waves may also occur spontaneously in purified glial cultures and to a much greater extent in glial cells grown in mixed culture with neurons, as well as in organotypic slice preparations. In organotypic hippocampal slice cultures, Ca^{2+} waves involving three to ten astrocytes occur spontaneously, whereas excitatory stimulation evokes broad curvilinear Ca^{2+} waves involving up to 100 cells. These Ca^{2+} wave fronts collide and annihilate and can form spiral patterns consistent with an excitable medium.

Initial observations suggested that calcium waves in glial cells are propagated from cell to cell via gap junctions (intercellular channels connecting the cytoplasm of adjacent cells). Calcium waves typically spread from cell to cell at specific sites of contact between neighboring cells, and the extent of intercellular spread of calcium waves was found to be correlated with the expression of connexin 43, the primary gap junction protein in astrocytes. However, subsequent studies indicated that intercellular calcium waves in astrocytes involve release of an extracellular messenger and activation of membrane receptors on neighboring cells. The primary messenger for intercellular Ca^{2+} waves has been found to be ATP. The apparently paradoxical involvement of connexins in intercellular Ca^{2+} waves mediated by release of ATP can be resolved by the observation that undocked connexin channels in individual cells, or 'connexin hemichannels,' can serve as a pathway for release of ATP from astrocytes. Other mechanisms of ATP release from astrocytes mediating intercellular Ca^{2+} waves, including P2X receptors, have been identified, suggesting that there may be multiple pathways for ATP release that are important for intercellular Ca^{2+} signaling. Connexin hemichannels, P2X receptors, and other potential pathways of ATP release are blocked by physiological concentrations of extracellular Ca^{2+} and Mg^{2+}. This can explain the observation that intercellular Ca^{2+} waves can be evoked by reduction of extracellular Ca^{2+}. The rate and extent of intercellular Ca^{2+} waves in astrocytes may depend, not only on the release of ATP, but also on the number and subtype of purinergic receptors that are expressed. See Figure 2.

Potential Functions of Glial Intercellular Ca^{2+} Waves

In a general sense, intercellular Ca^{2+} waves in glial cells enable a coordinated or spatially amplified multicellular response to a localized stimulus. Ca^{2+} waves may signal to neighboring glial cells of the same type, to different glial cell types, to neurons, or to vascular cells. One example is the potential role of intercellular Ca^{2+} waves in astrocytes in organizing a spatially propagated metabolic response. Astrocyte Ca^{2+} waves have been reported to drive parallel waves of increased intracellular Na^{+}. These Na^{+} waves, via glutamate-mediated glucose transport, in turn may trigger production and release of lactate, a primary metabolic substrate for neurons. This has been proposed as a mechanism by which a localized increase in neuronal activity could lead to a coordinated increase in delivery of metabolic substrates to surrounding cells. Another setting in which glial intercellular Ca^{2+} waves may be important is in the developing central nervous system. In the embryonic brain cortex, Ca^{2+} waves in radial glia have been reported to modulate neuronal migration. Intercellular Ca^{2+} waves in the retina may modulate the neuronal response to light, as well as mediate the vascular response to neuronal activity.

The extent to which intercellular Ca^{2+} waves occur in astrocytes *in vivo* is uncertain. Intercellular Ca^{2+} waves occur much more commonly in cell culture

than they do in brain slices. 'Physiological' stimulation in brain slices typically does not evoke cell-to-cell communication of Ca^{2+} responses in astrocytes, whereas Ca^{2+} waves are consistently observed in conjunction with the phenomenon of spreading depression (see the section titled 'Calcium signaling in cortical spreading depression and migraine') in brain slice preparations. It is therefore possible that under physiological conditions, astrocyte Ca^{2+} signaling involves very limited if any intercellular spread, whereas more-extensive propagation of Ca^{2+} waves may occur if a certain stimulus threshold is crossed.

Release of Signaling Molecules by Glial Calcium Signaling

One important function of Ca^{2+} signaling in glial cells is to trigger release of molecules that signal to other glial cells, neurons, or vascular cells. Calcium-dependent release of glutamate, ATP, D-serine (a modulator of NMDA receptor signaling), cytokines, and eicosanoids by astrocytes has been reported. While vesicular release of transmitters in the central nervous system had previously been considered to be exclusively a neuronal function, there is now extensive evidence for Ca^{2+}-dependent exocytotic vesicular release of glutamate by astrocytes. Astrocytes express all the necessary machinery for regulated vesicular release, including soluble N-ethylmaleimide-sensitive-factor attachment protein receptor proteins and vesicular transporters. Calcium-dependent plasma membrane fusion of vesicles has been visualized with total internal reflectance microscopy. A variety of studies indicate that vesicular release of glutamate may be a key mechanism for astrocyte–neuron signaling.

Mechanisms of Ca^{2+}-dependent release of ATP and D-serine by astrocytes have not been as clearly defined. As described earlier, release of ATP and glutamate through connexin channels, P2X receptor channels, or anion channels may be independent of changes in intracellular Ca^{2+} and may in fact depend to a greater extent on modulation of ATP release pathways by extracellular calcium than on changes in intracellular calcium. However, it is also possible that ATP and D-serine are released in vesicles, although this mechanism has not been as extensively characterized as it has for glutamate. In the case of eicosanoids, Ca^{2+} appears to trigger release of these molecules by activation of the phospholipase A2 pathway. Molecules produced by this pathway then have the capacity to diffuse directly through the plasma membrane into the extracellular space.

Ca^{2+} signaling may also be important for the release of signaling molecules by microglia. Ca^{2+}-dependent release of purines, cytokines, and nitric oxide by microglia has been demonstrated. Ca^{2+} may thereby serve as a critical trigger for the functional responses of activated microglia in the setting of inflammation and neuropathic pain.

Calcium Signaling in Astrocyte–Neuron Interaction

Ca^{2+} signaling plays a critical role in bidirectional glial neuronal signaling. Glial cells respond with increases in $[Ca^{2+}]_i$ to neuronal activity via neuronally released transmitters or possibly through changes in extracellular ionic concentrations associated with excessive neuronal activity. Conversely, increases in $[Ca^{2+}]_i$n in glial cells may evoke release of neurotransmitters, neuromodulators, or metabolic substrates that regulate neuronal synaptic strength, synchronization, or metabolic function. The pathway for Ca^{2+}-mediated glia–neuron signaling that has been most commonly reported in multiple preparations is astrocytic glutamate release activating synaptic or extrasynaptic neuronal glutamate receptors. But it is clear that other signaling molecules whose release is triggered by Ca^{2+} may also modulate neuronal activity. It is also possible that changes in extracellular K^+ evoked by Ca^{2+} increases in astrocytes may modulate the activity of neurons, as has been shown for vascular cells.

Calcium Signaling in Astrocyte–Vascular Interaction

The close proximity of astrocyte processes to both synapses and vascular cells, by virtue of their end-feet that ensheathe blood vessels, puts them in an ideal position to mediate changes in vascular tone that occur in response to neuronal activity. Multiple studies have now shown that calcium signaling in astrocytes evoked by either specific stimulation of astrocytes or by stimulation of adjacent neurons can result in either vasodilation or vasoconstriction. Intracellular Ca^{2+} waves along individual astrocyte processes leading to end-feet can be evoked by neuronal activity. This raises the possibility that a Ca^{2+} response initiated at a part of an astrocyte adjacent to a synapse could be spatially propagated as an intracellular wave to a different process contacting a blood vessel. In this way astrocytes could translate information about synaptic activity into changes in vascular tone, thus serving as a pathway for neurovascular coupling. Modulation of vascular tone may occur by multiple mechanisms, including calcium-dependent release of vasoactive messengers including eicosanoids, ATP, and nitric oxide, as well as calcium-activated K^+ channels that in turn control vascular tone by regulating local concentrations of extracellular K^+.

Calcium Signaling in Cortical Spreading Depression and Migraine

Spreading depression (SD) is a propagated electrophysiological wave that was described by Leão in 1944 as a direct current potential shift and depression of electroencephalogram (EEG) activity that spreads across the cortex at rates of 3–5 mm min^{-1}. In humans, SD has been demonstrated in the setting of brain injury. SD occurs in all gray matter regions of the central nervous system, although it is more readily provoked in some areas (e.g., cortex, CA1 region of hippocampus) than others. It can be evoked by mechanical stimulation, by electrical stimulation, or by local application of K^+, glutamate, or in some areas, acetylcholine. The temporal and spatial characteristics of intercellular Ca^{2+} waves in astrocytes are remarkably similar to those of spreading depression. In brain slice preparations, intercellular Ca^{2+} waves in astrocytes consistently occur in association with SD measured with either optical or electrophysiological approaches. In some reports, astrocyte Ca^{2+} waves preceded SD, whereas in others, Ca^{2+} waves occurred initially in conjunction with SD but extended beyond the point that SD decayed. In all reports, glial Ca^{2+} waves and SD could be pharmacologically dissociated, although inhibiting one affected the velocity and distance of propagation of the other. Thus, although pharmacological inhibition of one phenomenon does not exclude occurrence of the other, astrocyte Ca^{2+} waves and SD consistently occur together in the absence of pharmacological manipulation. One possibility is that they share common mechanisms for initiation and/or propagation but that additional factors specific to each individual process are required for their independent occurrence. And although they may not have a requisite interdependence, there are multiple potential mechanisms by which the two phenomena could interact with clinically important consequences.

Propagated waves of cortical activity and blood flow have been observed with positron emission tomography and magnetic resonance imaging techniques in patients with migraine. These waves have temporal and spatial characteristics that are similar to those of both astrocyte Ca^{2+} waves and spreading depression. A long-standing hypothesis is that the propagated changes in brain activity leading to the clinical migraine aura are caused by cortical SD (CSD). However, the classical EEG changes of CSD have never been directly demonstrated in migraine (possibly because of the lack of sensitivity of surface EEG). In addition, cortical waves of changes in blood flow in migraine patients can be seen in the absence of significant clinical symptomatology other than headache, an observation that is difficult to reconcile with a profound inhibition of neuronal activity, as occurs with CSD. One hypothesis is that intercellular Ca^{2+} waves in astrocytes, in the absence of the classical electrophysiological phenomenon of CSD, could underlie the propagated waves of cortical activity and blood flow in migraine.

Summary

The investigation of calcium signaling in glial cells has led to dramatic new information about the dynamic functions of glia, and in particular their active, bidirectional communication with neurons and vascular cells and resulting modulation of synaptic activity and vascular tone. The advance of *in vivo* imaging techniques promises to yield even more significant information about calcium signaling in glia and its roles in these and other physiological and pathological processes in the nervous system.

Introduction

Astrocytes can communicate with each other by waves of Ca^{2+} increases, which propagate with a speed of 10–20 μm s^{-1} from cell to cell and can extend for distances up to 500 μm. This phenomenon was first noted in 1990 while studying cultured hippocampal astrocytes in response to application of glutamate. In parallel with the Ca^{2+} wave propagation, ATP and glutamate concentrations can increase in the extracellular space. In the years following the initial astrocyte study, the astrocyte wave has been intensely studied in cell culture. This article provides a review of the initiation of Ca^{2+} waves in astrocytes (different cultures, and organotypic and acute slices) and the intra- and intercellular mechanisms controlling the wave. It also summarizes the role of Ca^{2+} waves in diseases, the influence of astrocyte Ca^{2+} activity on other cells, and the impact during development. Some mathematical models for describing mechanisms of Ca^{2+} waves are introduced.

Since some issues remain controversial we find it important to point out that different labs have used different preparations in their studies. Astrocytes can vary with respect to brain area, development, or simply culture condition. We feel that it is likely that there is diversity with respect to functions and properties of astrocytes.

Ca^{2+} Waves Can Be Elicited in Astrocyte Populations by Several Types of Stimuli

Different stimuli are applicable to trigger a Ca^{2+} wave. Ca^{2+} waves spread in response to glutamate application, and a variety of other stimuli have been reported. Waves can be triggered by electrical or mechanical stimulation (e.g., by poking an astrocyte with a patch clamp pipette). Such procedures will even work in Ca^{2+}-free solution, although the stimulus might trigger a decrease in Ca^{2+} in the stimulated cell. The lowering of extracellular Ca^{2+} by itself can be effective to initiate waves. During pathologic events, extracellular Ca^{2+} can decrease by as much as tenfold. Also, a Ca^{2+} increase seems to be sufficient to trigger waves, since application of the Ca^{2+} ionophore, ionomycin, can elicit a Ca^{2+} wave. Moreover, there are several substances which can induce a propagating wave if locally applied. These include ATP and norepinephrine, as shown in rat cortical astrocytes. Albumin applied to rat cortical astrocytes triggers oscillation in individual cells which are initially unsynchronized but become synchronized after several minutes of application, and oscillations are observed to spread through the astrocyte network as a wave. The proapoptotic protein Bax evokes Ca^{2+} signals and wave propagation among cells. These Ca^{2+} changes are speculated to correlate with proapoptotic activity of Bax. Also, diffusible substances such as nitric oxide, a potent vasodilator, can induce waves when applied locally.

Mechanism of Propagation: Involvement of Purinergic Signaling

The initial observation that isolated astrocytes which had no physical contact with other astrocytes in cell culture participated in the Ca^{2+} wave indicated that a substance in the extracellular space could mediate the wave. Ca^{2+} waves can propagate across cell-free lanes up to 120 μm apart (Figure 1). Suramin, an antagonist for purinergic receptors, was found to reduce astrocytic Ca^{2+} signaling, thus the activating substance was soon identified as ATP. Moreover, it was observed that apyrase, an ATP-degrading ectoenzyme, attenuates astrocyte Ca^{2+} signaling. Culture medium collected from astrocyte cultures during, but not before, Ca^{2+} wave propagation, contained ATP and could evoke Ca^{2+} waves when applied to another culture. This led to the concept that release of ATP, with subsequent activation of purinergic receptors, determines the propagating mechanism. As studied for cultured spinal cord astrocytes, activation of P2Y1 purinoreceptors is sufficient for the propagation of the wave, but a second metabotropic purinergic receptor is also involved. While real-time bioluminescence imaging in rat cortical astrocytes points to a restricted, brief, and abrupt point source of ATP, which challenges the regenerative ATP release, studies with labeled adenine nucleotide pools in murine astrocyte cultures indicate that astrocytes are capable of ATP-induced ATP release, which supports a role for regenerative ATP release in Ca^{2+} wave propagation (Figure 2).

Mechanism of Propagation: Involvement of Gap Junctions

Astrocytes in culture are commonly coupled by gap junctions, and therefore astrocytes form a syncytium of cells. The gap junction blockers halothane and

Figure 1 Model for Ca^{2+} waves due to regenerative ATP release. Release of ATP from the stimulated cell (red bolt) leads to activation of purinergic receptors on neighboring cells. These G-protein-coupled receptors stimulate via phospholipase C-activation inositol-3-phosphate production, which in turn triggers additional ATP release. ATP release can occur through hemichannels, P2X7 receptors, or anionic channels.

Figure 2 Model for Ca^{2+} waves due to a point source ATP release. ATP release occurs only from the stimulated cell. Passive diffusion activates purinergic receptors and thereby Ca^{2+} increases in neighboring cells.

octanol prevent intracellular waves from propagating between rat hippocampal astrocytes, but do not affect the velocity of Ca^{2+} spread within a given cell. Studies from cultured rat striatal astrocytes have led to the conclusion that the propagating mechanism is due to

Figure 3 Model for wave propagation via gap junctions. Increased inositol-3-phosphate (IP3)/Ca^{2+} spreads from the stimulated cell via gap junctions to (coupled) neighboring cells, where it triggers regenerative mobilization of IP3/Ca^{2+}.

production of inositol phosphate and its propagation through gap junctions (Figure 3).

Interaction between Purinergic Signaling and Gap Junctions

Several studies indicate complex interactions between purinergic signaling and gap junctional communication in astrocytes. In cultured spinal cord astrocytes, genetic deletion of the major astrocyte gap junction protein, connexin 43, does not significantly affect the propagation of Ca^{2+} waves. Moreover, deficiency in connexin 43 markedly potentiates responses to ATP and UTP, indicating an autocrine communication between functional gap junctions and the purinergic signaling system. This change in sensitivity after deletion of connexin 43 is due to changes in the subtype composition of metabotropic purinergic receptors, shifting from an adenine-sensitive P2Y1 to a uridine-sensitive P2Y4 receptor.

Connexin expression could also influence the release of ATP. There are several hypotheses concerning how astrocytes release neurotransmitter. Besides the established release pathway via Ca^{2+}-dependent exocytosis, one possibility is the release through so-called hemichannels, which represent half of a gap junction. These hemichannels are not pathways between cells, but rather between cells and the extracellular space, similar to conventional ion channels. Hemichannels are thought to be activated by a decrease in extracellular Ca^{2+} concentration. In a study of murine astrocytes, a Ca^{2+} wave triggered by mechanical stimulation was inhibited by the connexin channel blocker flufenamic acid. Since the hemichannel activator quinine evoked

ATP release and Ca^{2+} signaling, the authors concluded that ATP is released through connexin hemichannels. In contrast, with cultured spinal cord astrocytes, in a study based on analyzing connexin 43-deficient and P2X7-deficient mice, ATP was not released via hemichannels, but via a large purinergic receptor, the P2X7 receptor. Moreover, the commonly used gap junction blockers carbenoxolone, octanole, and flufenamic acid may also affect P2X7 receptor signaling.

Nitric Oxide Signaling Can Mediate Ca^{2+} Waves

Based on studies of mixed glia–neuronal and hippocampal slice cultures, not only ATP but also nitric oxide (NO) release could be an important mediator for propagating Ca^{2+} waves. Application of the NO donor molsidomine, or puffing aqueous NO, evokes a local intercellular Ca^{2+} wave, even in the absence of extracellular Ca^{2+}. In contrast to waves triggered by mechanical or electrical stimulation, the NO-triggered wave depends on ryanodine-sensitive stores, indicating that Ca^{2+} originates from a different storage compartment, as compared to the previously described waves.

Intracellular Mechanisms Controlling the Wave

As already mentioned, Ca^{2+} waves can propagate in the absence of extracellular Ca^{2+}. The intracellular Ca^{2+} increase is important for wave propagation. By using different Ca^{2+} chelators with different Ca^{2+} affinities, the wave is attenuated in relation to the strength of the chelator. 2-Bis(*o*-aminophenoxy) ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid (BAPTA), a chelator with high Ca^{2+} affinity, almost completely blocks the occurrence of Ca^{2+} waves. Most studies indicate that Ca^{2+} is released from the endoplasmic reticulum by activation of inositol-3-phosphate (IP3) receptors. Indeed, there is a very good correlation between the distribution of the IP3 receptors and sites with higher Ca^{2+} release kinetics (i.e., responses with higher amplitude and steeper rate of rise). The stores are filled by the thapsigargin-sensitive sarco/endoplasmic reticulum Ca^{2+}-ATPase (SERCA) pump and there exists a strong co-localization between IP3 receptors, SERCA pumps, and Ca^{2+} release sites. IP3-sensitive Ca^{2+} signaling involves the activation of protein kinase C and diacylglycerol (DAG), since Ca^{2+} dynamics have been shown to be linked to dynamics of protein kinase C and DAG translocation.

While most studies have confirmed that the thapsigargin-sensitive endoplasmic reticulum stores are the source for the cytoplasmic Ca^{2+} increase, the wave observed after application of the proapoptotic protein Bax is due to release of Ca^{2+} from mitochondria, and the NO-mediated wave is linked to ryanodine-sensitive stores.

Ca^{2+} Waves in Intact Tissue

All of the previously described experiments were done in culture. Cultured astrocytes are not a perfect model for healthy brain astrocytes. The increased levels of glial fibrillary acidic protein (GFAP) as compared to *in vivo* levels indicate that cultured astrocytes resemble reactive astrocytes as they occur after pathologic conditions. This is not much of a surprise, since culture conditions do not mimic the healthy brain. Moreover, culture conditions can influence the phenotype of astrocytes, and there is increasing evidence that astrocytes comprise a heterogeneous population within the intact brain. It is, therefore, essential to test and probe all of the different mechanisms in a more intact system, either brain slices or intact animals. First attempts to come closer to the *in vivo* situation involved the use of hippocampus slice cultures. In organotypic cultures from neonatal mice, Ca^{2+} waves involving hundreds of cells were observed to propagate in complex patterns, such as spiral wave fronts in the CA1 and CA2 regions. Similar to that reported for cultures, these waves were sensitive to thapsigargin and did not require the presence of extracellular Ca^{2+}. Studies in freshly isolated retinas from rats show that Ca^{2+} waves can be elicited by application of ATP and by electrical and mechanical stimulation, similar to the response in culture. Moreover, the wave propagates through a network of two glial cell types – namely, astrocytes and Müller cells. Interestingly, propagation in the astrocyte network employs a different mechanism, compared to propagation from the astrocyte to the Müller cell. While astrocyte-to-Müller cell signaling is very sensitive to purinergic antagonists or to the ATP-degrading enzyme apyrase, propagation within the astrocytes is much less affected. This observation has led to the conclusion that Ca^{2+} waves propagate in retina glial cells by two distinct mechanisms: while the wave propagating through astrocytes is dominated by diffusion of an internal messenger and requires gap junctions, the astrocyte-to-Müller signaling is primarily due to the release of ATP and activation of purinergic receptors.

Findings from two studies using slices from brain indicate diversity between astrocyte populations with respect to Ca^{2+} signaling. Using the corpus callosum as a model for the white-matter tract, it was demonstrated that the propagation of the wave among glial cells depends on a diffusible substance, since the

extent of propagation and the direction strongly depend on the perfusion of the slice. The ability of Reactive Blue 2 to block the response and the lack of effect of gap junction blockers indicate that the wave propagates due to ATP release and subsequent activation of purinergic receptors (Figure 4). This result is in contrast to findings from a study using cortex: in the cortical preparation, the propagation of the wave is strongly affected by gap junction blockers, but only weakly by purinergic receptor antagonists. The release of ATP could be monitored with 'sniffer cells': by seeding glioma cells with high-affinity purinergic receptors on the surface of the slice, the propagation of the ATP increase could be recorded as a Ca^{2+} signal. The involvement of gap junctions for the propagation of the wave is further supported by using mice deficient for the major astrocytic gap junction proteins, connexins 43 and 30. In this mouse line only local Ca^{2+} responses could be elicited in cortex and the wave fails to propagate over larger distances. Nevertheless, the ATP release monitored by sniffer cells was unaffected. This difference in Ca^{2+} signaling also finds its explanation in the distinct extent of electrical coupling between astrocytes in corpus callosum and cortex. When comparing biocytin injections in these two brain regions it became evident that astrocytes in cortex form large syncytia involving tens to hundreds of cells, while in the corpus callosum coupling can be absent or is restricted to a few cells (Figure 5). The extent of coupling does not necessarily predict the propagation mechanism: in hippocampus, where coupled and uncoupled astrocytes can be found, the propagation depends on a diffusible substance, since it is unaffected in mice deficient in connexins 30 and 43. It is, thus, possible that the conflicting data obtained in tissue culture may reflect the diversity of mechanisms expressed in the intact tissue. Recently, first reports of Ca^{2+} signaling in cortical astrocytes *in vivo* have been obtained. By imaging Ca^{2+} responses in astrocytes of superficial cortical layers using two-photon laser scanning microscopy, it was demonstrated that coordinated Ca^{2+} events can be recorded in anesthetized rats. These findings indicate that this Ca^{2+} activity also occurs in the live animal.

Figure 4 Propagation of an astrocytic Ca^{2+} wave in the corpus callosum acute slice. To illustrate the propagation of the Ca^{2+} wave, only those cells are displayed which were newly recruited to the population of Ca^{2+}-responsive cells. This was achieved by subtracting the previous image from the one which was displayed. The white areas represent the population of responsive cells at the times indicated. The first images show the cells responding close to the pipette briefly after stimulation (0 s). The left panel shows consecutive images, displaying the spread of the wave under control conditions. In the right panel only a local response was observed after applying the purinergic receptor antagonist Reactive Blue 2. Adapted from Schipke CG, Boucsein C, Ohlemeyer C, et al. (2002) Astrocyte Ca^{2+} waves trigger responses in microglial cells in brain slices. *FASEB Journal* 16: 255–257.

Control of the Wave by Receptors

A number of studies have indicated that the extent of propagation of the Ca^{2+} wave can be modulated by activating membrane receptors. Astrocytes have been shown to express essentially all known receptors for neurotransmitters and neuromodulators. This includes classical transmitter receptors and neuropeptide receptors, but also receptors for cytokines. The glucocorticoids methylprednisolone and dexamethasone potentiate long-range Ca^{2+} waves. Glucocorticoid treatment increases the resting cytosolic Ca^{2+} level and also doubles the extent and the amplitude of

Figure 5 Astrocytic coupling in the neocortex and in the corpus callosum. (a) Biocytin was injected into a cell of the neocortex and a cell in the corpus callosum within the same slice from a glial fibrillary acidic protein/enhanced green fluorescent protein (GFAP/EGFP) transgenic mouse. Astrocytes were selected using their fluorescence at 488 nm. Left: In the neocortex, the biocytin injection resulted in the labeling of a large population of astrocytes. Right: In the corpus callosum, only a single cell is stained with biocytin. The insert on the right is a magnified image of the single injected cell. Images are from a 150 μm-thick slice that was processed as a whole after injection of the two cells. (b) One cell in the cortex of a slice from a GFAP/EGFP transgenic mouse was injected with biocytin. After fixation, 50 μm cryosections were obtained from this 300 μm-thick slice. This procedure resulted in an improved biocytin visualization as compared to processing the entire 150 μm-thick slice. (c) Similarly as described in panel a, biocytin was injected into an astrocyte identified by its membrane currents in a slice from a Cx30(−/−)/Cx43(fl/fl):GFAP-cre(+) mouse. The right image is a magnified view of the overview on the left. No biocytin-positive cells could be detected, but the processes of the patched cell can be visualized. The soma of the filled cell is not visible, probably because it is destroyed or removed when removing the patch pipette. From Haas B, Schipke CG, Peters O, et al. (2006) Activity-dependent ATP-waves in the mouse neocortex are independent from astrocytic Ca^{2+} waves. *Cerebral Cortex* 16: 237–246.

Ca^{2+} waves in whole brain astrocyte cultures as compared with untreated controls. In response to an inflammatory condition, interleukin-1β (IL-1β) is produced both by intrinsic glial cells and by invading cells from the immune system. This cytokine influences the spread of Ca^{2+} waves in primary human fetal astrocytes. Treating these cultures with IL-1β for 24 h leads to a potentiation of intracellular Ca^{2+} waves. Moreover, a shift from gap junctional communication to P2 receptor-mediated pathways is observed after the treatment. Anandamide, an endogenous arachidonic acid derivative, is seen to block Ca^{2+} waves in striatal astrocytes that propagate via gap junctions.

The encephalic and telencephalic astrocytes express melatonin receptors which are involved in circadian and seasonal rhythms. In studies of these astrocytes, a substantial difference between mouse and avian astrocytes is found – namely, in avian

astrocytes the wave is more restricted. Application of 10 μm melatonin causes a 32% increase in the area in which the wave spreads. In contrast, in telencephalic astrocytes, melatonin has no effect. All of the studies described herein have been performed in cell culture and may reflect a heterogeneity of potential responses *in vivo*.

Disease

Spreading depression is a phenomenon associated with the aura of migraine. It occurs in humans and animals. Spreading depression can be measured by imaging an intrinsic optical signal. It is correlated to a Ca^{2+} increase in astrocytes, which can be simultaneously recorded. In the hippocampus, it has been demonstrated that spreading depression is accompanied by an astrocyte Ca^{2+} wave and that the astrocyte Ca^{2+} wave can be abolished in Ca^{2+}-free, ethylene glycol tetraacetic acid (EGTA)-containing solution, while the spreading depression still occurs. This indicates that spreading depression triggers the astrocyte Ca^{2+} wave. The wave associated with spreading depression is distinct from the intrinsically propagating wave, since there is a clear difference in the speed of the propagation. Spreading depression propagates at about 30–50 $\mu m\,s^{-1}$, while the pure astrocyte wave propagates at about half that speed. Interestingly, in the cortex, spreading depression is also associated with the Ca^{2+} wave but often it is observed that the astrocyte Ca^{2+} wave propagates even further. When the astrocyte wave is no longer associated with cortical spreading depression, it drops in speed, to a value similar to that recorded for the intrinsic wave in cell culture or in the acute slice.

Alzheimer's disease is associated with a deposition of amyloid beta peptide, which is an important constituent of the plaques. Exposure of astrocytes to the amyloid beta peptide results in an increase in the amplitude and velocity of evoked Ca^{2+} waves and increases the area in which the wave spreads. While control waves require extracellular ATP for wave propagation, the increase induced by amyloid beta peptide is completely sensitive to an uncoupler of gap junctions, indicating that amyloid beta peptide modulates gap junctions and thereby influences the astrocyte Ca^{2+} wave.

Interaction with Other Cells

Astrocytic Ca^{2+} waves spread not only between astrocytes, but also lead to responses in other cell types of the nervous system, including microglia and oligodendrocytes, and also neurons, endothelial, and meningeal cells (Figure 6). As discussed previously, the astrocyte Ca^{2+} wave depends both on gap junctions and on ATP signaling. Both mechanisms are not confined to astrocytes. Actually, most cells in the brain express purinergic system receptors and thus should sense ATP released from astrocytes, which makes it likely that in the brain the astrocyte wave involves other cell types. Moreover, in parallel with the propagation, not only ATP, but also glutamate, can be released into the extracellular space. While ATP release seems Ca^{2+} independent, glutamate release depends on an increases in Ca^{2+}.

In co-cultures of neurons and glial cells, the astrocyte wave triggers a Ca^{2+} response in those neurons which are in close contact to astrocytes. One lab has reported that this neuron glia signaling is sensitive to the gap junction blocker octanol, indicating either gap junctions between neurons and astrocytes or an octanol effect on astrocytic signaling. In another study using hippocampal neurons grown on hippocampal or cortical astrocytes, the response of the neurons to the astrocyte Ca^{2+} signal was shown to be blocked by antagonists against *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors, indicating that glutamate serves as a signaling substance.

In a study using slices containing the corpus callosum, it was evident that microglial cells and cells of the oligodendrocyte lineage also respond to an electrically elicited Ca^{2+} wave. While the response in the oligodendrocyte lineage cells could be recorded as a Ca^{2+} signal, this was not possible in microglial cells, since these cells do not take up ester dyes in slices. Therefore, the patch clamp technique was employed and a current response could be concommitantly recorded with the Ca^{2+} wave. This response consisted of a potassium conductance increase and was similar to the response of microglial cells to ATP.

Astrocytes are in an important strategic position concerning the coupling of neuronal activity to blood flow, since they enwrap blood vessels with their endfeet. Using co-cultures of primary astrocytes and endothelial cell lines as a model, it was demonstrated that Ca^{2+} waves induced by mechanical stimulation in a given cell can propagate from astrocytes to endothelial cells, and vice versa. The mechanism is similar to that shown for retina and corpus callosum – namely, release of ATP and subsequent activation of purinergic receptors on either astrocytes or endothelial cells. A similar interaction has been found in co-cultures of astrocytes with pia arachnoid cells, whereby Ca^{2+} activity is transmitted.

Ca^{2+} Waves during Development

Ca^{2+} waves have also been observed in radial glial cells during early development. These waves can

Figure 6 Schematic diagram illustrating intercellular communication between astrocytes and cells of the oligodendrocyte lineage, microglial cells, neurons, and endothelial and meningeal cells. Astrocytes can communicate intracellular Ca^{2+} signals to neighboring astrocytes via diffusion of the second messenger inositol-3-phosphate (IP3) through gap junctions or via the release of ATP. The communication between astrocytes and cells of the oligodendrocyte lineage and microglia is due to ATP release, which activates purinergic receptors. Cytokine release from microglia is modulated by ATP. As indicated, also astrocytes can release a number of substances in response to an elevation of $[Ca^{2+}]_i$. Modified from Kettenmann H and Schipke C (2004) Calcium signaling in glia. In: Hatton G and Parpura V (eds.) *Glia–Neuronal Signaling*, p. 303. Boston: Kluwer Academic Publishers.

occur spontaneously and depend on connexin hemichannels, purinergic receptors, and IP3 release. Disrupting the wave results in a decrease of cortical ventricular zone proliferation.

Modeling Astrocyte Ca^{2+} Waves

Several models have been developed for a mathematical description of astrocyte Ca^{2+} waves. One model is based on activation of purinergic receptors by ATP, which triggers the release of ATP in an autocrine manner, resulting in increasing intracellular Ca^{2+}. This model predicts the dependence of velocity on the type of P2Y receptor and the delay of the Ca^{2+} wave to the ATP wave. Another model relies on the spread via gap junctions as the essential mechanism based on observations in rat striatal astrocytes. This model predicts that the spatial range of the wave strongly depends on both signal initiation (i.e., activation of IP3) and regeneration of the IP3 signal, and accordingly the term 'limited regenerative signaling' is proposed. The crucial permissive factor is the gap junction permeability for IP3, and hence heterogeneity in gap junction composition can account for preferential pathways of wave propagation. The refractory period strongly depends on the refilling kinetics of the Ca^{2+} stores. In a third model, specialized areas which serve as amplification loci are proposed. They are considered to be areas of endoplasmatic reticulum containing higher density of IP3 receptors.

Calcium Waves: Purinergic Regulation

M L Cotrina and M Nedergaard, University of Rochester, Rochester, NY, USA

© 2009 Published by Elsevier Ltd.

Introduction

Nonelectrical cells rely on Ca^{2+} signaling as the key mode of communication with neighboring cells. This signaling mechanism is most relevant in astrocytic cells, the most abundant glial cell in the nervous system. Using Ca^{2+} waves, astrocytes can affect neuronal activity, and findings from numerous studies point to an important role for Ca^{2+} waves in regulating synaptic function. This form of communication occurs when Ca^{2+} signals that originate in one cell can spread over long distances and affect groups of cells, evoking intercellular Ca^{2+} waves. In cultured astrocytes, Ca^{2+} waves can be evoked by receptor activation (glutamate, ATP, or endothelin-1), by lowering of extracellular Ca^{2+}, or by intense neuronal firing in cultured organotypic tissue. A general feature of Ca^{2+} waves is that they propagate with a velocity of $\sim 20\,\mu m\ s^{-1}$ and expand over a maximal radius of $\sim$300–400 μm, thereby engaging 30–60 cells in a single wave. Despite controversies with regard to the mechanism of propagation, it is clear that Ca^{2+} waves require activation of phospholipase C (PLC), which produces inositol 1,4,5-trisphosphate (IP_3). In turn, IP_3 mobilizes Ca^{2+} from intracellular stores, resulting in further activation of PLC.

Current Models for the Propagation of Astrocytic Ca^{2+} Waves

Astrocytic Ca^{2+} signaling was originally proposed to depend on IP_3 and/or Ca^{2+} diffusion through gap junction channels, intercellular channels formed by proteins called connexins (model 1). Those signaling molecules were thought to promote subsequent Ca^{2+} increases in neighboring cells. This idea was supported by the experimental observation that C6 glioma cells, which lack gap junction proteins, allow the propagation of long-distance Ca^{2+} waves (>200 μm) only after transfection and overexpression of connexin 43 (Cx43). Overexpression of Cx32 in C6 glioma and HeLa cells later confirmed these observations.

This model was questioned by a study reporting that astrocytes with no physical contact with other astrocytes could also propagate Ca^{2+} waves, suggesting the existence of an extracellular mechanism for their propagation. This diffusible messenger was later identified as ATP, and parallel studies showed that ATP can mediate Ca^{2+} waves not only in astrocytes, but also in osteoblasts, liver, epithelial cells, and heart. This model for Ca^{2+} wave propagation (model 2) states that Ca^{2+} waves are regenerative and mediated by ATP release. Later evidence showed that astrocytes can, indeed, exhibit ATP-induced ATP release, but in a Ca^{2+}-independent manner, supporting the idea that Ca^{2+} waves can be regenerative, but not Ca^{2+} dependent for ATP release.

A third model challenged the idea of regenerative ATP release because Ca^{2+} waves never expand more than 300–400 μm beyond the point of origin and are therefore not truly regenerative. In fact, real-time bioluminescence imaging of extracellular ATP failed to support the concept of regenerative ATP release during Ca^{2+} wave propagation. So, model 3 states instead, that ATP is consistently released by a single cell, or from a point source only. A Ca^{2+} wave would thus be propagated by diffusion of the initially released ATP, rather than by sequential ATP release from other cells. Neighboring cells would, in turn, increase their intracellular Ca^{2+} in response to P2Y receptor activation, but would not actively participate in wave propagation with the Ca^{2+}-dependent release of additional ATP. This is consistent with studies performed with simultaneous monitoring of ATP and intracellular Ca^{2+} from astrocytic cultures. In this system, it has been observed that, upon mechanical stimulation, the Ca^{2+} wave is synchronized with the released ATP. However, extracellular ATP is the main mediator of intercellular Ca^{2+} wave propagation in a Ca^{2+}-independent manner, as abolishing Ca^{2+} increases does not preclude ATP release.

Mechanisms of Purinergic Release: Exocytosis versus Connexin Hemichannels

Several groups have confirmed that long-distance Ca^{2+} waves are mediated by purinergic signaling, but the mechanism by which ATP is released is still controversial. It has been speculated that connexin hemichannels could mediate ATP release, because several cell lines expressing Cx43, Cx32, or Cx26 all release five- to 20-fold more ATP than do mock-transfected, Cx-deficient control cells. In addition, gap junction hemichannels have a pore diameter of 10–12 Å and are permeable to large anions, including ADP and ATP. So, connexin proteins seem to regulate the propagation of Ca^{2+} waves not by allowing the passage of an intracellular messenger, but rather by potentiating ATP release. Later studies have documented that ATP release occurs concomitantly with an

increase in whole-cell current, supporting the concept of channel-mediated ATP release. The challenge, therefore, has been to test whether open connexin hemichannels can act as direct conduits for the efflux of cytosolic ATP.

It has been reported that astrocytes in culture express Ca^{2+}-activated currents that are sensitive to flufenamic acid (FFA), an agent that inhibits gap junction permeability. Mechanical stimulation that initiates Ca^{2+} waves promotes dye uptake and dye release, as well as ATP release, an effect that is also inhibited by FFA and potentiated by quinine, a hemichannel activator. However, an important criticism for some of the evidence in support of hemichannel-mediated release of ATP is that hemichannel opening probability would be small because an open channel this large would be deleterious to cells. In addition, most studies have tried to disclose hemichannel opening in the absence of Ca^{2+}, or in very low Ca^{2+} concentrations, conditions that are difficult to reconcile with normal cell function. So, what is the relevance of connexin hemichannels in normal physiology?

Some answers have come from the use of small mimetic peptides that correspond to portions of the connexin proteins. One of these peptides will only bind extracellular portions of the connexin protein when freely exposed and not engaged in the formation of a gap junction channel, and will, in addition, block hemichannel permeability. Using this tool together with dye uptake, it has been demonstrated that, in the retinal pigmental epithelium (RPE), ATP released by the spontaneous opening of gap junctional hemichannels promotes the propagation of Ca^{2+} waves and controls proliferation in the underlying retina. Most importantly, this study showed that calcium waves do not require ATP-induced ATP release, supporting the idea that ATP is released through connexin hemichannels in the trigger cell alone and diffuses passively to purinergic receptors in neighboring cells.

The use of specific peptides that block hemichannels but not proper gap junctions has demonstrated that increases in intracellular Ca^{2+} up to 500 nM can also trigger ATP release in a connexin-dependent manner. These studies are the first to demonstrate that ATP release through connexin hemichannels can happen under physiological conditions.

Data from cellular fractionation experiments have suggested that ATP is released by Ca^{2+}-dependent exocytosis of ATP-containing vesicles. It seems that these vesicles may be distinct from glutamate-containing vesicles, indicating that there may be separate exocytotic pathways for ATP and glutamate release, which may be differentially regulated. It has been also found that glia from the sciatic nerve exhibit ATP-mediated ATP release via exocytotic vesicles, release that can be regulated by the cystic fibrosis transmembrane conductance regulator.

It is possible that astrocytes can release ATP by several mechanisms, but additional studies are needed to establish the coexistence of these mechanisms, which are not necessarily mutually exclusive, and their implications for Ca^{2+} wave signaling.

The P2X7 Pore-Forming Receptor and mCa^{2+} Signaling

The family of purinergic receptors is composed of two types, ionotropic (P2X) receptors and metabotropic (P2Y) receptors. It is known that astrocytes express P2Y1, P2Y2, and P2Y4 and P2X7 receptors, and it is likely that several purinergic receptors contribute to wave propagation in astrocytes.

Astrocytes depend on P2Y1 and P2Y2 receptors for the propagation of Ca^{2+} waves. Overexpression studies have shown that the properties of intercellular Ca^{2+} waves depend on the particular P2Y receptor subtype involved, differentially affecting the efficacy, velocity, amplitude, range, and 'saltatory' nature of the Ca^{2+} wave propagation.

Among P2X receptors, P2X7 is particular in that it forms large ion channels in response to ATP or other ligands and is present in many cell types, including astrocytes. P2X7 receptors can mediate the release of excitatory amino acids, like glutamate and aspartate, disclosing a novel, ligand-stimulated, nonvesicular astrocytic route for glutamate release. P2X7 receptors are activated by high concentrations of ATP, do not desensitize, and, more importantly, depend on extracellular Ca^{2+} ions.

As P2X7 activation can promote Ca^{2+} signals in optic nerve glia and Ca^{2+} waves among bone cells, an alternative hypothesis that could explain ATP-mediated astrocytic Ca^{2+} waves is that P2X7 receptors, and not connexin hemichannels, are the main pathway for the release of ATP. Using spinal cord astrocytes from Cx43 and/or P2X7 receptor-deficient mice, it has been recently found that, contrary to previous ideas, P2X7 receptors, and not connexin proteins, could be responsible for intercellular Ca^{2+} wave amplification when cells are exposed to solutions with low concentrations of divalent cations. Interestingly, the same study reported that many of the compounds that block connexin hemichannels, and that have been used to document the involvement of hemichannels as ATP-releasing pathways, are also antagonists of the P2X7 receptor, raising the question of the true contribution of connexin hemichannels in ATP release and Ca^{2+} wave propagation. Nonetheless, it is worth noting that the absence of P2X7

Figure 1 An astrocytic Ca^{2+} wave evoked by focal electrical field stimulation in a hippocampal slice. The white arrowhead indicates the position of the stimulating electrode. The slice was loaded with the fluorescent Ca^{2+} indicator dye Fluo-4/AM for 1 h before two-photon laser scanning microscopy. The electrical stimulation evoked a Ca^{2+} wave that engaged multiple neighboring astrocytes expanding over a radius of 150–250 µm ($\Delta F/F$, fluorescence ratio).

receptor in the model used in this study did not prevent the occurrence of astrocytic Ca^{2+} waves that were similar, in radius and number of cells engaged in the wave, to what was seen under normal conditions (Figure 1). So, the development of agents that can be used specifically to block one pathway versus the other is clearly needed to elucidate the exclusive or overlapping roles of these ATP-releasing pathways in astrocytes.

As P2X7 receptors are not easily activated, their expression is low or absent in some brain regions, and low Ca^{2+} conditions are mostly attained under pathological conditions, it has been suggested that these receptors could be major contributors of Ca^{2+} signaling during inflammation, ischemia, or other pathological states. Support for this idea comes from different fronts. First, ATP release and astrocytic Ca^{2+} signaling are both triggered by traumatic injury. Second, injury is also associated with a decrease in extracellular Ca^{2+}, which enhances ATP release and Ca^{2+} signaling and increases the affinity of the P2X7 receptor. Third, P2X7 receptor can mediate cell death. On the basis of these findings, the contribution of the P2X7 receptors in the amplification of cell damage has been analyzed in a model of spinal cord injury. Using a novel bioluminescence technique in the intact, live animal, it has been found that the peritraumatic area after acute spinal cord injury exhibits unusually high levels of ATP release, which is accompanied by the subsequent cell death of spinal neurons that are highly immunoreactive for P2X7 receptors. Further studies in this model are needed to establish the source of ATP release during the injury period.

Purinergic Signaling and Ca^{2+} Waves in Neuronal Physiology

Spontaneous occurrence of ATP-dependent Ca^{2+} waves has been observed in radial glia of brain slices during early cortical development. Disruption of these waves altered cell proliferation in the ventricular zone, indicating that glial Ca^{2+} waves could control neuronal production in early development. It has been subsequently shown that glutamate release from neurons induces ATP release from astrocytes. This release causes homo- and heterosynaptic depression in co-cultures of hippocampal cells and in CA1 neurons of hippocampal slices. This signaling pathway seems to be sensitive to membrane ectonucleotidases, is dependent on Ca^{2+} and soluble *N*-ethylmaleimide-sensitive attachment factor receptor (SNARE) activity, suppresses excitatory synaptic transmission, and modulates synaptic plasticity. An important observation is the concomitant, adenosine-mediated heterosynaptic depression of neighboring, unstimulated pathways, placing astrocytes at a central position in the coordination of synaptic networks.

Astrocytic Ca^{2+} elevations that influence extrasynaptic receptors through the release of glutamate had been previously described. In this case, spontaneous, Ca^{2+}-dependent glutamate release from a single astrocyte was able to promote *N*-methyl-D-aspartate (NMDA) receptor responses in a synchronized manner in multiple neurons, indicating that an astrocyte can simultaneously affect the activity of many neurons that may not be directly connected through chemical synapses. Astrocytic Ca^{2+} events in response to glutamate have been recently described for first time *in vivo* upon sensory stimulation.

In summary, it is clear that, in the adult brain, nonsynaptic transmitter release originates preferentially from astrocytes, is Ca^{2+} dependent, can be spontaneously detected, has slow dynamics, and has differential effects, depending on the nature of the transmitter. In the case of ATP/adenosine, spillover of synaptic glutamate or extrasynaptic glutamate seems to initiate a negative feedback loop through a purinergic pathway. In the case of glutamate, a single

astrocyte has the ability to simultaneously affect the activity of many neurons that may or may not be part of the same neuronal circuit.

Involvement of Adenosine as Purinergic Mediator of Astrocytic Ca^{2+} Signaling

Adenosine has been traditionally considered an inhibitor of neuronal activity and a regulator of cerebral blood flow (Figure 2). The cellular origin and mechanisms of adenosine release have not been established, but it is clear that astrocytes can release adenosine, since activation of astrocytes is responsible for heterosynaptic depression in hippocampal slices. Massive release of purines, including adenosine, occurs after metabolic stress and trauma. It has therefore been hypothesized that ATP/adenosine may be more important during pathological states, because there is more energy demand (as during seizures) or because there is loss of metabolites (as during ischemia), conditions that promote a reduction in the ATP levels and an increase in adenosine and other adenine nucleotide levels. In support of this hypothesis, it has been found that astrocytes release ATP/adenosine under ischemic conditions.

Because extracellular ATP does not accumulate *in vivo* for long periods, as it is rapidly degraded by membrane ectonucleotidases to produce adenosine, it is plausible that purinergic Ca^{2+} signaling plays a critical role during pathological events through the actions of adenosine. Additional studies are needed to clearly elucidate the contribution of ATP and adenosine in both normal and pathophysiological events.

Conclusions

The existence of ATP-mediated astrocytic Ca^{2+} waves is well documented. However, the mechanisms for ATP release are still highly controversial and the proposed pathways of ATP release include hemichannels, vesicular release, P2X7 receptors, and ABC transporters. However, it is important to keep in mind that astrocytes are multifunctional cells, and therefore more than one mechanism of ATP release may exist. For example, the important task of potassium buffering is undertaken by several potassium channels expressed by astrocytes, including KIR4.1 and rSlo K (Ca), but also by the K^+–Na^+–Cl^- cotransporter. It is possible that different types of stimulation might activate different pathways of ATP release. Regional and developmental differences are also likely to play a role.

Future advances in the field depend on the development of pharmacological agents with minimal

Figure 2 Current model for the mechanism and actions of astrocytic purinergic Ca^{2+} signaling. During the propagation of a Ca^{2+} wave (bottom), a single astrocyte releases ATP by a mechanism that could involve connexin hemichannels, exocytotic vesicles, or the pore-forming P2X7 receptor. ATP then propagates by diffusion to neighboring astrocytes, connected by gap junctions. These astrocytes will, in turn, increase their Ca^{2+} levels through the action of the P2Y receptor (P2YR) but do not release ATP. Astrocytic adenosine, either directly released during Ca^{2+} wave propagation or converted from ATP through the action of ectonucleotidases, can affect surrounding neurons (top) by binding to A1 receptors (A1R). This action can cause heterosynaptic depression that suppresses excitatory synaptic transmission by decreasing glutamate release and activating hyperpolarizing K^+ channels, establishing a negative feedback loop on the neurons through a purinergic pathway (PLC, phospholipase C; IP_3, inositol 1,4,5-trisphosphate).

cross-reactivity among the different release pathways to determine their relative contributions. To achieve this goal, it will also be necessary to use imaging techniques that allow the visualization of ATP dynamics and electrophysiological recordings of channel conductance, as the sensitivity of biochemical analysis versus. imaging may also lead to dissimilar results. Another issue is that cultured astrocytes represent a poor model system for defining the signaling mechanisms and functional roles of astrocytes in intact brain. Astrocytes lose their polarized phenotype *in vitro* and may activate, in cultures, pathways of ATP release that do not exist *in vivo* or have a minor role. For example, culturing of astrocytes has been associated with a marked upregulation of SNARE proteins that are involved in vesicular cycling.

Future research will also need to define the involvement of purinergic signaling in both physiological and pathological conditions. An extensive literature documents the neuroprotective actions of adenosine and it will be interesting to define the contribution of astrocytes to neuronal survival in the setting of ischemia. Astrocytic purinergic signaling may represent a powerful target for future drug development that may decrease secondary stroke injury.

Calcium-Calmodulin Kinase II (CaMKII) in Learning and Memory

M N Waxham, The University of Texas Medical School, Houston, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Calcium is a simple divalent metal ion that has the distinction of directly or indirectly regulating almost every process in neurons. The highly reactive nature of calcium necessitates that cells maintain low levels (50–100 nM) of this toxic ion, and pumps, exchangers, and buffers all subserve this function. The opening of *N*-methyl-D-aspartate (NMDA) receptors or the opening of voltage-gated calcium channels leads to a rapid influx of calcium due to the large chemical gradient for this ion. While elevations in calcium can be quite varied, local concentrations reaching 10–100 μM have been estimated. Calcium can also be released from intracellular stores through activation of inositol 1,4,5-trisphosphate (IP_3) receptors or ryanodine receptors. The resulting temporal and spatial profiles of the calcium signal can thus be quite complex. These signals are decoded by the intracellular biochemical machinery into biological effects (neurotransmitter release, regulation of neurotransmitter biosynthesis, regulation of receptor and channel properties, and induction of synaptic plasticity). Many of the second messenger effects of calcium are mediated through the ubiquitous protein calmodulin. Calmodulin binds four calcium ions, inducing a conformational change that permits the protein to interact with and activate target enzymes. As such, calmodulin has no enzymatic activity; its function is to integrate the calcium signal and transduce it to other downstream enzymes.

This article focuses on one of the major classes of calcium/calmodulin-activated enzymes, the calcium/calmodulin-activated protein kinases (CaM-kinases). A discussion of the general characteristics of these enzymes is presented, followed by more detailed descriptions of individual members. One useful classification of the members of the CaM-kinase family is to consider whether they can phosphorylate a wide range of protein substrates (multifunctional) or whether they have a single or narrow set of protein substrates (substrate specific). This classification is adopted in this article with a discussion of the multifunctional kinases CaM-kinase kinase (CaMKK), CaM-kinase I (CaMKI), CaM-kinase IV (CaMKIV), and CaM-kinase II (CaMKII)) first, followed by a discussion of the substrate-specific kinases (CaMKIII and myosin light-chain kinase (MLCK)).

General Characteristics of Calcium/CaM-Kinases

All members of the CaM-kinase family catalyze the covalent transfer of a phosphate group from ATP to Ser or Thr residues in protein substrates, and, as the name implies, their phosphotransferase activity is initiated by the binding of calcium/calmodulin. The overall domain structure is very similar among family members (Figure 1), and their general characteristics are summarized in Table 1. The phosphotransferase reaction requires that ATP and protein substrates are bound simultaneously and that the amino acids involved in catalyzing the phosphotransferase reaction are properly oriented. Available data suggest that the catalytic domains of all members of the CaM-kinase family are architecturally similar. Two globular domains are evident; one that binds ATP and another that binds protein substrates, with a crevice in between the domains serving as the site for the phosphotransferase reaction (see Figure 2). Inactive CaM-kinases exist in a quiescent state through an autoinhibitory mechanism whereby a portion of the molecule interacts with the catalytic domain. In some cases, the autoinhibitory domain lies across the site for substrate binding and blocks access to the catalytic domain. In other cases, the autoinhibitory domain interacts with amino acids that prevent the proper formation of a catalytically competent active site for the phosphotransferase reaction. Sometimes a combination of these two mechanisms is evident. In either case, calcium/calmodulin binding relieves this inhibition, activating the enzyme. Several members of the CaM-kinase family are substrates for Ser/Thr phosphorylation and, in some cases, this phosphorylation is a prerequisite for activity (CaMKI and CaMKIV). In other cases, phosphorylation of the enzyme can alter its biological properties. For example, phosphorylation of CaMKII is critical for the enzyme's role in synaptic plasticity and learning and memory.

Multifunctional CaM-Kinases

CaM-Kinase Kinase

CaMKK exists in neurons and cells as a monomer of approximately 55–65 kDa and as two isoforms, α and β. CaMKK is held in an inactive state by its autoinhibitory domain, and binding of calcium/calmodulin relieves this inhibition, leading to phosphorylation of its substrates. The two best known substrates for CaMKK are CaMKI and CaMKIV, and phosphorylation of these substrates is necessary for their activation. Binding of calcium/calmodulin is

Figure 1 Line drawings identifying the domain structure of calcium/calmodulin (CaM)-kinases. The catalytic domains are shown in blue, the regulatory domains are shown in red, and the calmodulin-binding domains are shown in green. CaM-kinase II (CaMKII) is an oligomer and contains a domain necessary for oligomerization (yellow). CaMKIII (eEF-2K; elongation factor-2 kinase) has a recognition domain for eEF-2 in its C-terminal domain (orange), and its catalytic domain (hatched blue) bears little resemblance to other CaM-kinases. The actin-binding domain of smooth muscle myosin light-chain kinase (smMLCK) is shown as a white box. CAMKK, CaM-kinase kinase; skMLCK, skeletal muscle myosin light-chain kinase. Redrawn from Robison J and Colbran RJ (2004) Calcium/calmodulin-dependent protein kinases. In: Lennarz WJ and Lane MD (eds.) *Encyclopedia of Biological Chemistry*, vol. 1, pp. 281–286. Oxford: Elsevier.

Table 1 Physicochemical properties of the CaM-kinase family

Enzyme	*Structure*	*Subunit mol. mass (kDa)*	*Substrate specificity*
CaMKI	Monomer	42	Multifunctional
CaMKII	Dodecamer	50–68	Multifunctional
CaMKIII (eEF-2K)	Monomer	100	Restricted
CaMKIV	Monomer	65–67	Multifunctional
CaMKK	Monomer	55–65	Multifunctional
skMLCK	Monomer	67–150	Restricted
smMLCK	Monomer	130–210	Restricted

an important prerequisite for calcium/calmodulin-activated CaMKK to phosphorylate CaMKI or CaMKIV. The site on CaMKI and CaMKIV for CaMKK phosphorylation is either inaccessible or not in the appropriate conformation in the absence of calcium/calmodulin. CaMKK is also a substrate for phosphorylation. Protein kinase A (PKA) phosphorylates CaMKK, thereby inhibiting its activity. This inhibitory phosphorylation site is in CaMKK's calmodulin-binding domain and phosphorylation prevents calmodulin binding. CaMKK lies at the beginning of a signaling cascade, so inhibition of its activity through PKA-mediated phosphorylation also leads to suppression of CaMKI and CaMKIV activity.

CaM-Kinase I

CaMKI is a monomeric kinase of approximately 42 kDa (Table 1), and several isoforms of CaMKI have been described. It was the first of only two members of the CaM-kinase family whose crystal structure was determined (CaMKII was the second; see Figure 3). The crystallographic data permit a detailed understanding of how interactions between the autoinhibitory domain and the catalytic domain lead to suppression of activity. The autoinhibitory domain makes contacts with amino acid residues in both the ATP- and substrate-binding lobes, preventing access of these reactants to the catalytic site. Calcium/calmodulin binds to a domain adjacent to the autoinhibitory domain and in so doing removes the autoinhibitory domain from the catalytic site, permitting substrate binding. Calcium/calmodulin binding is also necessary to expose a specific Thr residue in the activation loop that serves as the substrate for CaMKK phosphorylation. When CaMKI is phosphorylated on this site, its activity rises by 10- to 20-fold but remains entirely calcium/calmodulin – dependent, even when phosphorylated.

CaMKI is found in both the cytosol and the nucleus and presumably has diverse functions. One of its best characterized substrates is synapsin 1. Synapsins are a family of vesicle-associated proteins of which the proposed function is to tether synaptic vesicles to the actin cytoskeleton within the presynaptic terminal, and several kinases have been identified that phosphorylate synapsin 1. Phosphorylation of synapsin 1 by CaMKI causes a decrease in the affinity of synapsin 1 for the vesicle, leading to increased mobility of the vesicle in the presynaptic terminal (Figure 4). CaMKI was also shown to modulate growth cone motility, and myosin II was identified as a substrate for the enzyme. Activation of CaMKI is also involved in activation of the extracellular signal-regulated kinase (ERK) signaling pathway that can lead to ERK-dependent long-term potentiation (LTP). Activity-dependent nuclear localization has also been shown for the δ isoform of CaMKI, further expanding the potential roles of CaMKI to include the regulation of gene transcription.

Figure 2 Ribbon diagrams showing the structure of the catalytic and regulatory domains of CaMKI and CaMKII. There is significant (>60%) amino acid homology between CaMKI and CaMKII across these domains. (a) The bilobed structure of CaMKI. The ATP-binding site is formed by the cyan domain, and the substrate-binding site is formed by the green domain. The catalytic cleft where the phosphotransferase reaction occurs lies between the two domains. The red domain represents the CaM-binding site, which lies across the catalytic cleft. Interactions of residues surrounding the CaM-binding domain with those in the two lobes of the catalytic domain maintain CaMKI in the inactive state. (b) The bilobed structure of the CaMKII catalytic domain. The colors of the domains represent features analogous to those described for CaMKI in panel (a). The autophosphorylation sites of CaMKII are also highlighted. The location of Thr286 is highlighted in yellow near the bottom of the structure. The location of Thr305 and Thr306 is shown in orange within the CaM-binding domain (in red). The ribbon diagrams were created in Chimera software and the protein database (PDB) files were obtained from the National Center for Biotechnology Information database.

Figure 3 Structure of CaMKII. CaMKII is a multisubunit complex that is unique in structure among the CaM-kinase family. There is an association domain located in the C-terminus of the subunit (see **Figure 1**) that directs the formation of a 12-subunit complex. The association domains form a central core and 12 foot-shaped catalytic domains can be seen extending away from the core on stalklike features. The architectural arrangement of the subunits was determined using cryo-electron microscopy and 3-D particle reconstructions and is visualized as a surface-rendered structure. A ribbon diagram of the crystal structure of the CaMKII catalytic domain is docked into one of the feet. A zoomed-in side view of one of the feet, showing the predicted orientation of the crystal structure within the envelope, is shown on the right side of the figure. The figure was rendered in Explorer software and the crystal structure was obtained from the National Center for Biotechnology Information database.

Figure 4 CaM-kinase modulation of neuronal functions. A presynaptic terminal contains transmitter-filled vesicles (green circles), some of which are associated with the actin cytoskeleton. Increased calcium, via voltage-activated calcium channels, and activation of the calmodulin pathway occur in the presynaptic terminal (not shown), leading to the activation of CaM-kinases and the regulation of tethering and transport of synaptic vesicles to the actin cytoskeleton. Phosphorylation of the synaptic vesicle-associated synapsin 1 (not shown) by CaMKI and CaMKII can release the vesicle from the actin cytoskeleton, making it available for exocytosis. Phosphorylation of myosin by myosin light-chain kinase (MLCK) is thought to facilitate the transport of vesicles within the presynaptic terminal. The membrane of the postsynaptic cell contains *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) subtypes of glutamate receptors. Calcium influx through calcium channels, such as the NMDA receptors, leads to the activation of calmodulin with the subsequent activation of the CaM-kinases. In the postsynaptic spine, CaMKII can autophosphorylate and can also phosphorylate AMPA receptors, potentiating their response to released glutamate from the presynaptic terminal. Increased calcium-bound calmodulin can similarly lead to the activation of CaMKK to phosphorylate and activate CaMKIV in the nucleus, which can subsequently phosphorylate substrates such as the transcription factor cAMP-response element-binding protein (CREB), leading to increased gene transcription. Redrawn and modified from Robison J and Colbran RJ (2004) Calcium/calmodulin-dependent protein kinases. In: Lennarz WJ and Lane MD (eds.) *Encyclopedia of Biological Chemistry*, vol. 1, pp. 281–286. Oxford: Elsevier.

CaM-Kinase IV

CaMKIV is found in neurons as a monomer of approximately 65 kDa, and its basic domain structure is similar to the other CaM-kinases (Table 1 and Figure 1). Analogous to CaMKI, activation of CaMKIV requires the binding of calcium/calmodulin and the phosphorylation of its activation loop by CaMKK. Once activated, CaMKIV undergoes an autophosphorylation reaction in a Ser/Thr-rich region of its N-terminus, and this intrasubunit autophosphorylation reaction is required for maximal activity. Once autophosphorylated, CaMKIV exhibits sustained activity even if calcium/calmodulin is removed from the enzyme. Thus, CaMKIV can exist in an activated state that outlives the calcium signal that initiated the autophosphorylation reaction. CaMKIV also autophosphorylates within its calmodulin-binding domain and this prevents calmodulin from rebinding to the enzyme. This autophosphorylation event would desensitize CaMKIV to subsequent activation by calcium/calmodulin until phosphatase activity removed phosphate from this site.

Activation of CaMKIV is linked to changes in gene transcription. CaMKIV is highly enriched in the nucleus and its best characterized substrates are nuclear transcription factors. These include cAMP response element-binding protein (CREB), serum response factor (SRF), and CREB-binding protein (CBP), among others. The phosphorylation of CREB by CaMKIV is the best characterized event in the nucleus and this occurs on Ser133, a site known to activate the transcriptional properties of CREB. The activation of CaMKIV is considered an important link between the transitions of short-term plasticity in neurons and long-term plasticity (Figure 4). The latter requires gene transcription and protein synthesis, and the activation of CaMKIV is thought to play an important step in linking the increased calcium signal to increased gene transcription. The sustained activation of CaMKIV, possibly mediated

through its calcium/calmodulin-independent activity, appears to be necessary for upregulation of gene transcription.

CaM-Kinase II

There are four genes in mammals that encode four distinct isoforms of CaMKII, α, β, γ, and δ which range in molecular mass from 50 to 68 kDa (Table 1). CaMKII is unique in structure among the family of CaM-kinases in that it exists in neurons as an oligomeric complex. The oligomer contains 12 catalytic domains that extend out from a central core (Figure 3) assembled through interactions between association domains that reside in the C-terminus of each subunit (Figure 1). The formation of oligomeric complexes relates to the high probability of CaMKII undergoing an important autophosphorylation reaction that regulates its properties (discussed later).

CaMKII holoenzyme assembly can occur between the different subunit isoforms, and the composition of the oligomer can dictate the enzyme's biological behavior. For example, the β subunit, and not the α subunit, contains an actin-binding domain that tethers CaMKII onto the actin cytoskeleton. If the β subunit is in a holoenzyme composed mostly of α subunits, the β subunit directs that assembly to the actin cytoskeleton. The association of βCaMKII with the actin cytoskeleton is decreased by binding of calcium/calmodulin. Thus, intracellular calcium increases lead to release of CaMKII into the cytoplasm by freeing it from the actin cytoskeleton and making it available to phosphorylate other protein substrates.

When activated by calcium/calmodulin, CaMKII subunits within the holoenzyme can phosphorylate each other in a process called autophosphorylation. There are parallels between constraints for the CaMKK phosphorylation of CaMKI or CaMKIV and this intersubunit phosphorylation of CaMKII. To be phosphorylated by CaMKK, CaMKI and CaMKIV must be in the calcium/calmodulin-bound form. This is also true for the autophosphorylation of subunits within the CaMKII oligomer; to be an effective substrate for autophosphorylation, the subunit within the CaMKII oligomer must be calcium/calmodulin bound. The subunit responsible for catalyzing the phosphorylation event must also be active through calcium/calmodulin binding. Because the subunits are physically linked within the holoenzyme, the probability of this autophosphorylation event happening is much greater than in the case of CaMKK and CaMKI or CaMKIV, which are constrained by their access to each other and diffusion-limited reaction steps.

One particular autophosphorylation site on the α isoform, Thr286, has received wide attention and, when autophosphorylated, has profound impacts on CaMKII activity. The location of Thr286 is identified in yellow in the ribbon diagram of the catalytic domain shown in Figure 2(b). Autophosphorylation increases the binding affinity of calcium/calmodulin by a factor of over 1000. This affinity is so tight that the process is referred to in the literature as 'calmodulin-trapping' to reflect the fact that dissociation of calmodulin slows significantly. Autophosphorylation also leads to a state of the kinase that continues to phosphorylate substrates even when calmodulin is removed. This is referred to as 'calcium/calmodulin-independent' or 'autonomous' activity. CaM trapping and autonomous activity sustain the activity of autophosphorylated CaMKII well beyond the duration of the calcium increase that triggered autophosphorylation. There are other sites of autophosphorylation on CaMKII. Another of significance is a site containing two adjacent Thr residues within the calmodulin-binding domain (Thr305 and Thr306 of αCaMKII) that, when phosphorylated, prevents calmodulin from binding. These sites are identified as orange residues in the ribbon diagram shown in Figure 2(b). This is analogous to the autophosphorylation that occurs in the calmodulin-binding domain of CaMKIV that also prevents calmodulin binding. Because the subunit no longer binds calmodulin, it cannot be active and phosphorylate other subunits or serve as a substrate for the autophosphorylation reaction. This sequence of events has been called 'inhibitory autophosphorylation.' However, if a subunit is phosphorylated at Thr286 and then at Thr306/306, it remains active because of the autonomous activity expressed when Thr286 is phosphorylated.

These autophosphorylation-induced changes in CaMKII properties have led to several hypotheses regarding CaMKII's role in neurons. The most prominent incorporate autophosphorylation and include the ability of CaMKII to decode calcium oscillations and sustain its activity well beyond the calcium signal. Because autophosphorylation of CaMKII requires that two calmodulin molecules are bound to adjacent subunits (one to activate kinase and one to expose substrate), during a brief calcium increase there is only a small probability that this arrangement would happen. As calcium oscillations increase in frequency, the probability of calcium/calmodulin binding to two adjacent subunits increases and autophosphorylation occurs. Recall that once a subunit is phosphorylated at Thr286, it 'traps' calmodulin because of the decreased off-rate, leading to an even greater likelihood of adjacent subunits being calcium/calmodulin bound and additional autophosphorylation.

The importance of CaMKII autophosphorylation in modifying neuronal processes has been studied extensively. Some of the most compelling data on

this topic come from studies in mice in which point mutations that were introduced into CaMKII prevent autophosphorylation of Thr286 (by replacing Thr286 with an Ala residue in the mouse germ line). These mice appear remarkably normal in the laboratory setting, but they show significant defects in forms of plasticity, such as LTP, and are impaired in a variety of learning and memory tasks. A similar approach was also taken to evaluate the role of the inhibitory phosphorylation sites (Thr305 and Thr306) that reside in the calmodulin-binding domain. Mice were created in which Thr residues were replaced with Val and Ala, which cannot be phosphorylated, or in which Thr306 was replaced with an Asp residue to 'mimic' phosphorylation through its negative charge. Blocking inhibitory autophosphorylation increased the amount of CaMKII associated with the postsynaptic density and lowered the threshold for inducing LTP. The Asp306 mice showed decreased CaMKII in the postsynaptic density, and both LTP and learning were blocked in these mice.

CaMKII is remarkably concentrated in neurons and can constitute up to a couple of percent of total brain protein, leading to the hypothesis it might serve a structural role. In fact, a picture is emerging for CaMKII as a scaffolding protein that serves in part to help organize proteins at neuronal synapses into molecular assemblies. CaMKII has been shown to interact directly with subunits of the NMDA receptor; α-actinin (an actin-binding protein); densin-180, a synaptic junction protein; and others. Because of CaMKII's oligomeric structure, one holoenzyme can bind to a number of different proteins simultaneously, providing the enzyme with a scaffolding function. Binding in a number of cases is modulated either through calcium/calmodulin activation of the kinase or through the subsequent process of autophosphorylation. These protein–protein interactions are thus driven through neuronal activity that leads to changes in intracellular calcium. These processes can be visualized in live neurons by tracking the activity-dependent translocation of CaMKII tagged with green fluorescent protein, which has been shown to drive CaMKII into synapses both in neuronal culture models and in living animals.

CaMKII phosphorylates a wide variety of substrates, including the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor, the NMDA receptor, nitric oxide synthase, and SynGAP, a synaptic GTPase-activating protein that modulates Ras activity. One of particular interest is the AMPA subtype of glutamate receptor, because AMPA receptors are responsible for producing currents that underlie glutamate-mediated synaptic transmission. Phosphorylation of AMPA receptors by CaMKII can be detected following stimuli that produce LTP, and this phosphorylation increases the single-channel conductance of AMPA receptors. Phosphorylation of a diverse family of protein substrates ties CaMKII activation directly into the regulation of the network of signaling proteins that control synaptic plasticity and neuronal excitability.

Substrate-Specific CaM-Kinases

CaM-Kinase III

CaM-kinase III (CaMKIII) is better known as elongation factor-2 kinase (eEF-2K), since elongation factor-2 is the only known substrate for this kinase. When phosphorylated by CaMKIII, elongation factor-2 activity is suppressed, inhibiting the growth of polypeptide chains during translation by dissociating elongation factor-2 from the ribosome. Thus, activation of CaMKIII through calcium/calmodulin binding is a means of coupling calcium increase in the cytosol to the suppression of protein synthesis.

CaMKIII is a monomer of approximately 100 kDa and is a cytosolic enzyme (Table 1). The catalytic domain of CaMKIII bears little resemblance to the catalytic domain of the other CaM-kinases. Following calcium/calmodulin binding, CaMKIII phosphorylates itself and, like CaMKII and CaMKIV, this autophosphorylation leads to calcium/calmodulin-independent activity. In addition, PKA can also phosphorylate CaMKIII and similarly induces calcium/calmodulin-dependent activity. Therefore, in the cellular setting, CaMKIII can respond to both calcium levels (through calmodulin) and cAMP levels (through PKA) in the downregulation of protein synthesis through the phosphorylation of elongation factor-2. CaMKIII is also phosphorylated and regulated through the rapamycin-sensitive mTOR (mammalian target of rapamycin) pathway by an as yet unidentified protein kinase.

Myosin Light-Chain Kinase

Isoforms of MLCK exist in smooth and skeletal muscle and in other tissues, including the brain. They all exist as monomers that can be quite variable in mass. The smooth muscle forms range in size from approximately 130–210 kDa and the skeletal muscle forms range from 67 to 150 kDa. This diversity in size is the result of mRNA splicing and/or alternative promoter usage in the gene. The skeletal muscle isoform is simpler in structure compared to the isoform from smooth muscle (Figure 1). MLCK contains the core catalytic domain, autoinhibitory domain, and calmodulin-binding domain; smooth muscle MLCK also contains an actin-binding domain, a fibronectin-binding

domain, and several other binding domains that regulate its localization. MLCKs of both types are maintained in an inactive state through the binding of an autoinhibitory domain to the catalytic domain. Specifically, the autoinhibitory domain binds to the protein substrate binding site but does not prevent binding of ATP. The substrate for MLCK is the regulatory light chain of myosin, and in muscle this is specifically associated with myosin II. In smooth muscle, the phosphorylation of the light chains associated with myosin dictates contraction by stimulating myosin ATPase activity. In skeletal muscle, phosphorylation of the regulatory light chain potentiates but is not fundamentally responsible for contraction.

Like other members of the CaM-kinase family, the MLCKs can serve as substrates for phosphorylation. The best studied effect is phosphorylation of a site within the calmodulin-binding domain that significantly decreases the affinity for calmodulin-binding. The kinase best characterized for mediating this phosphorylation in cells is CaMKII, but other kinases can phosphorylate this site *in vitro*. So, as calcium levels rise and calcium binds to calmodulin, calcium/calmodulin initially binds to MLCK, leading to phosphorylation of regulatory light chains and contraction. As the calcium levels increase further or are maintained, calcium/calmodulin activates CaMKII, leading to phosphorylation and desensitization of MLCK, decreased phosphorylation of regulatory light chains, and decreased contraction.

MLCK plays numerous roles in regulating neuronal function based on the multifaceted role of myosin in cell biology. Myosin-based transport in axons and nerve terminals is regulated through MLCK activity, and calcium-mediated recruitment of vesicles in presynaptic terminals is also regulated by MLCK activity (Figure 4). MLCK and the phosphorylation of myosin II are also found in postsynaptic spines, where they can modify receptor function via regulation of the actin–myosin cytoskeleton.

Summary

Calcium plays a fundamentally important role in regulating neuronal functions ranging from neurotransmitter release to synaptic plasticity to gene transcription. The calcium-binding protein calmodulin plays the role of transducing increased cytoplasmic calcium to the activation of downstream enzymes such as the family of CaM-kinases. This family of enzymes phosphorylates Ser/Thr residues in substrate proteins, altering their function. Many of the CaM-kinases are themselves substrates for phosphorylation, and, in some cases, this phosphorylation is essential for their activity or for their biological function. Thus this family of enzymes forms an enzymatic network that leads to temporal integration of the calcium signal. Certain members of the CaM-kinase family can phosphorylate a variety of substrates, providing the biochemical network a means of integrating well-coordinated responses. Importantly, several of these phosphorylation events lead to activity that outlives the calcium signal that initiated phosphorylation, providing a theoretical mechanism for short- and long-term plasticity.

Canal–Otolith Interactions

D Merfeld, Massachusetts Eye & Ear Infirmary, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The vestibular system, described in detail elsewhere, consists of two different types of end organs: the semicircular canals and the otolith organs. The three semicircular canals in each inner ear are nearly orthogonal; the afferent responses from these canals encode three-dimensional head rotation. The saccule and the utricle are otolith organs. The signals carried by the neurons innervating these two otolith organs encode gravity and linear acceleration in all three dimensions.

The nervous system faces several challenges when it tries to interpret the incoming sensory information from these vestibular end organs. The semicircular canals have high-pass filter dynamics, which make the canals insensitive to low-frequency rotations. The designers of amusement park rides (e.g., tilt-a-whirl) often use this characteristic, providing low-frequency rotations so that the semicircular canals provide information that is not veridical. The afferent signals from the otolith organs pose a different problem. Like all linear accelerometers, the otolith organ response is governed by Einstein's equivalence principle, which is based on the experimental finding that inertial mass and gravitational mass cannot be distinguished. Therefore, the otolith organs cannot distinguish inertial force due to linear acceleration from gravitational force. Hence, all linear accelerometers, including the otolith organs, respond to specific gravito-inertial force ($\boldsymbol{f}$), which is the vector sum of gravity ($\boldsymbol{g}$) minus linear acceleration ($\boldsymbol{a}$) and can be written as $\boldsymbol{f} = \boldsymbol{g} - \boldsymbol{a}$. The designers of other amusement park rides (e.g., gravitron) often use gravito-inertial equivalence to evoke illusory perceptions of motion or tilt.

Given these limitations, neither the semicircular canals nor the otolith organs are capable of providing unambiguous information encoding head motion and orientation to the brain. However, computational models with internal models as the key attribute have demonstrated that the information available from these two sensory systems can be combined to yield more accurate estimates of motion and orientation than is available from either sensory modality alone; experimental findings have confirmed many of these theoretical predictions. Specifically, information provided by the otolith organs influences and evokes rotational responses, even though the semicircular canals are specialized to respond to head rotation. Analogously, rotation information from the semicircular canals is used to help estimate how much of the otolith signal is due to gravity and how much is due to linear acceleration. Other sensory systems (e.g., vision) as well as efferent copy (or corollary discharge) mechanisms contribute to these perceptual and reflexive responses, but this article focuses exclusively on the sensory interactions between the semicircular canals and otolith organs.

In this article, we first provide necessary background information, including a number of definitions, before presenting experimental findings. When describing the experimental findings, we primarily focus on perceptual responses because perception is easier for many people to understand than theoretical modeling predictions and eye-movement recordings. We do this even though many experimental findings were forecast via theoretical predictions and even though some seminal results were first obtained via vestibulo-ocular reflex (VOR) measurements.

Background Definitions

A brief description of the predominant characteristics of the semicircular canals and otolith organs is essential to comprehend how the signals from these sensory systems interact. For similar reasons, we also describe the basic physics that underlies the physical cues measured by the vestibular system and the interaction of these physical cues.

We begin by defining a right-handed, head-fixed Cartesian coordinate system [x y z]. The x axis aligns with the naso-occipital axis and points toward the nose. The y axis aligns with the interaural axis and points toward the left ear. And the z axis is orthogonal to both the x and y axes and points toward the top of the head.

The predominant characteristics of the semicircular canals are that they respond to rotation and that their response dynamics to an angular velocity input are accurately represented by a first-order high-pass filter with a cut-off frequency of around 0.03 Hz or, equivalently, a time constant of approximately 5 s. Because the semicircular canals have high-pass filter dynamics, a step change in angular velocity yields an abrupt change in canal activation followed by a gradual exponential-like decay back to the baseline established when the head was stationary; in primates the afferent response decay has a time constant of around 5 s. If an abrupt deceleration is later applied

to bring the rotation to a stop, the high-pass dynamics yields a response in the opposite direction that again decays back to the baseline. The fact that the canals eventually signal no angular velocity during constant-velocity rotation is often used experimentally.

The predominant characteristic of the otolith organs is that they equivalently transduce gravity and linear acceleration. This concept can be clearly and concisely defined and explained using five standard facts or definitions:

1. Inertial mass is the same as gravitational mass ($m_i = m_g$), so a single mass ($m = m_i = m_g$) is defined. This experimental finding is reflected in Einstein's Equivalence principle, which states that gravitational forces cannot be distinguished from inertial forces due to linear acceleration.
2. Linear acceleration, $\boldsymbol{a}$, is the second derivative of position ($\boldsymbol{p}$) with respect to time ($\boldsymbol{a} = \mathrm{d}^2\boldsymbol{p}/\mathrm{d}t^2$). For example, when an object is dropped, gravity accelerates the object downward; this downward acceleration is gravitational acceleration. Because the otolith organs are fixed with respect to the head, they measure linear acceleration in head-fixed coordinates. Therefore, $\boldsymbol{a}$ is defined as a vector that represents linear acceleration of the head in head-fixed coordinates. This is the linear acceleration that would be measured by any linear accelerometer attached to the head.
3. On Earth, gravitational force per unit mass has a magnitude of approximately $9.8\,\mathrm{m\,s^{-2}}$ and pulls toward Earth's center; $\boldsymbol{g}$ is a vector that represents the magnitude and direction of gravity in head-fixed coordinates. This is the gravitational vector that would be measured by any linear accelerometer attached to the head.
4. Inertial forces were first defined by D'Alembert when he recognized that Newton's second law ($\sum \boldsymbol{F}_{\mathrm{est}} = m\boldsymbol{a}$) can be applied in rotating or accelerating environments when inertial forces (per unit mass) are defined as equal to the negative of linear acceleration ($\boldsymbol{i}_f = -\boldsymbol{a}$). Common examples of inertial forces include centrifugal force, which is the negative of centripetal acceleration; tangential force, which is the negative of tangential acceleration; and coriolis force, which is the negative of coriolis acceleration.
5. Gravito-inertial force per unit mass ($\boldsymbol{f}$) is defined as the vector sum of gravitational force per unit mass and inertial force per unit mass, $\boldsymbol{f} = \boldsymbol{g} + \boldsymbol{i}_f$.

Combining these facts and definitions generates the result that gravito-inertial force (per unit mass) is $\boldsymbol{f} = \boldsymbol{g} - \boldsymbol{a}$. This relationship is referenced repeatedly in this article because afferent responses from neurons innervating the otolith organs encode gravito-inertial force.

To better understand the interactions between rotational and gravitational cues, consider that rotation about an axis aligned with gravity (e.g., shaking one's head to signal no) does not influence the orientation of gravity relative to the head. But, whenever head rotation includes a component that is not aligned with gravity (e.g., nodding one's head to signal yes), the relative orientation of gravity with respect to the head changes, which is captured by the equation:

$$\boldsymbol{g} = -\int (\boldsymbol{\omega} \times \boldsymbol{g})\mathrm{d}t$$

where $\boldsymbol{\omega}$ represents the angular velocity of the head measured in head fixed coordinates. We can use this equation to keep track of the orientation of gravity with respect to the head, if we know the gravitational vector, $\boldsymbol{g}$, at just one point in time (initial condition) and measure or know the angular velocity of the head as a function of time. The gravity vector ($\boldsymbol{g}$) on the right-hand side of the equation can be thought of as the orientation of gravity now, whereas the gravity vector on the left-hand side can be thought of as later orientation of gravity due to angular rotation (e.g., the change in the orientation of gravity during head nodding).

Because the nervous system has access only to measurements of physical variables, not to the physical variables *per se,* it is crucial that neural representations be clearly delineated from the physical quantities they represent. The equations $\boldsymbol{g} = -\int (\boldsymbol{\omega} \times \boldsymbol{g})\mathrm{d}t$ and $\boldsymbol{f} = \boldsymbol{g} - \boldsymbol{a}$ represent real-world physics. Internal models of these physical effects can be represented by $\hat{\boldsymbol{f}} = \hat{\boldsymbol{g}} - \hat{\boldsymbol{a}}$ and $\hat{\boldsymbol{g}} = -\int (\hat{\boldsymbol{\omega}} \times \hat{\boldsymbol{g}})\mathrm{d}t$, where $\hat{\boldsymbol{f}}$, $\hat{\boldsymbol{g}}$, $\hat{\boldsymbol{a}}$, and $\hat{\boldsymbol{\omega}}$ are neural estimates of the physical variables ($\boldsymbol{f}$, $\boldsymbol{g}$, $\boldsymbol{a}$, and $\hat{\boldsymbol{\omega}}$) and where internal models are defined as neural systems that mimic physical relationships.

Canal Influences on Tilt Responses

Signals from the semicircular canals influence tilt responses. To demonstrate this, we describe responses during several different motion paradigms. When upright and stationary in the dark, normal humans accurately estimate and report their perceived orientation with respect to gravity. Because patients with absent otolith function do not perform this task with the same accuracy as normals, this demonstrates that the otolith organs are a contributor to our ability to estimate head orientation with respect to gravity. If the same normals are maintained upright with respect to gravity and rotated on a centrifuge, their otolith organs measure a tilted gravito-inertial force (Figure 1(a)). Initially, the perception of vertical does not deviate far from alignment with gravity (Figure 1(b)). However,

Figure 1 (a) Centrifugation physics: (b) small perceived roll tilt; (c) moderate perceived roll tilt; (d) large perceived roll tilts. When a subject is rotated at an off-center position as shown, an inertial force **(i_f)**, called centrifugal force, is present. This force sums with gravity **(g)** to yield the total gravito-inertial force **(f)** measured by the otolith organs, which is tilted with respect to gravity (θ). Perceived orientation of gravity **($\hat{g}$)** is tilted with respect to true gravity by an angle $\hat{\theta}$.

if this constant-velocity centrifugation is maintained, the perception of vertical shifts toward alignment with gravito-inertial force (Figures 1(c) and 1(d)).

The time course with which the perception of vertical aligns with gravito-inertial force is altered by the canal cues signaling rotation during centrifugation. In one experiment, subjects indicated their roll tilt perception (Figure 2, magenta) when seated at a fixed distance from the rotation axis and accelerated to a constant angular velocity. In another experiment, subjects were accelerated to a constant velocity while seated at the center of rotation. Later, when the canals no longer signaled angular velocity, the subjects indicated their roll tilt perception (Figure 2, cyan) while they were translated away from the center such that the forces measured by the otolith organs were nearly identical to those experienced during the fixed-radius trials. The primary difference between the signals from the canals and otoliths during these two motion paradigms was the presence (fixed-radius) or absence (variable-radius) of canal cues indicating yaw rotation. This difference in the canal cues led to a substantial difference in the time course of the reported roll tilt perception as was evident for both clockwise and counterclockwise rotations.

Figure 2 Perceived roll tilt during fixed-radius and variable-radius centrifugation versus time. Black lines show tilt angle (θ in Figure 1) of gravito-inertial force during centrifugation; yellow lines show average angle ($\hat{\theta}$ in Figure 1) of perceived tilt. Magenta and cyan indicate standard deviations for the fixed-radius and variable-radius conditions, respectively. CCW, counterclockwise; CW, clockwise. Reproduced from Merfeld D and Zupan L (2003) Influence of rotational cues on the neural processing of gravitoinertial force. In: Harris L and Jenkin L (eds.) *Levels of Perception,* pp. 341–373. New York: Springer, with permission from Springer-Verlag Heidelberg.

Roll tilt motion paradigms, paradigms that tilt subjects toward an ear-down position (Figure 3(a)), also demonstrate the influence of the semicircular canals on tilt responses. When humans are passively tilted in roll with their head located near the tilt axis, the otolith organs record variations in the gravitational forces relative to the head. In fact, because the head is not translating, but just tilting, there is no head linear

Figure 3 *Tilt* and *Tilt & Translation* tests: (a) schematic representations of the *Tilt* and the *Tilt & Translation* test paradigms; (b) verbally reported tilt angles; (c) verbally reported translation displacements. In (a), stimuli were provided by roll tilting the subjects. For the *Tilt* paradigm, the head was placed at the center of rotation ($R = 0$). For the *Tilt* & *Translation* paradigm, the head was placed above ($+R$) or below ($-R$) the tilt axis (⊗). The results in (b) and (c) are for sinusoidal roll tilts at 0.8 Hz with tilt amplitudes of 5° (▲), 10° (■), and 20° (▼). For 0.8 Hz sinusoids, the interaural component of gravity and the tangential acceleration null one another at approximately −38 cm, which is indicated by the red vertical lines. Vertical green lines indicate the head-centered (*Tilt* only) position. In (b), note that tilt perception remained accurate for all tested head positions and tilt angles, even at when no interaural otolith cues were available. In (c), note that significant translation was reported even when little or no interaural force was transduced by the otolith organs (red lines). Also note that accurate reports of little or no translation were provided with the head at the center of rotation (green lines). Error bars represent the standard error of the mean. Reproduced from Merfeld DM, Park S, Gianna-Poulin C, Black FO, and Wood S (2005) Vestibular perception and action employ qualitatively different mechanisms II: VOR and perceptual responses during combined *Tilt & Translation*. *Journal of Neurophysiology* 94: 199–205, with permission from the American Psychological Association.

acceleration. Therefore, the interaural component of the gravito-inertial force has a magnitude equal to the sine of the tilt angle $|f_y| = |g_y| = \|\boldsymbol{g} \sin \boldsymbol{\phi}\|$. When sinusoidal roll tilts having an amplitude less than 20° are performed at physiological frequencies (*c.* 0.5–1 Hz) in the dark, normals more or less accurately report how much they are tilted in roll. This is not surprising because the otolith organs accurately record head orientation with respect to gravity.

However, if the same tilt motion is repeated but now with the head located some distance below the axis of rotation, the head translates back and forth, like the bottom of a pendulum (Figure 3(a)). In this position, a sinusoidal interaural linear acceleration of the head is present at the frequency of the tilt motion; this tangential acceleration is in phase with the interaural component of gravity. For sinusoidal motion at small tilt angles ($\theta_{\max} < 20°$), there is one specific distance ($|R| \approx 9.8/(2\pi f)^2$) below the tilt axis where this tangential acceleration effectively cancels the interaural component of gravity, $g_y - a_y \approx 0$. When the head is located at this specific distance below the tilt axis, alterations in the interaural gravito-inertial force, which normally signal alterations in roll tilt, are subthreshold. Yet humans remain able to estimate their head tilt quite accurately even when tested using this motion paradigm (Figure 3(b)).

This is possible because the semicircular canals contribute to tilt responses. Specifically, as discussed earlier, head rotations that are not aligned with gravity yield changes in the relative orientation of gravity with respect to the head, $\boldsymbol{g} = -\int (\boldsymbol{\omega} \times \boldsymbol{g})\mathrm{d}t$. Studies show that the brain has implemented a distributed neural process that mimics this physical law, $\hat{\boldsymbol{g}} = -\int (\hat{\boldsymbol{\omega}} \times \hat{\boldsymbol{g}})\mathrm{d}t$. Such neural calculations are called internal models because they provide neural models that are internal to the brain of external relationships. The brain uses rotational cues from the canals via this internal model to help continually estimate the relative orientation of gravity. Neural recordings made in the vestibular nuclei of rhesus monkeys support these conclusions drawn from the perceptual data; these data demonstrate that rotational cues from the semicircular canals converge on neurons that predominantly respond to tilt stimuli.

In the presence of noise and other flaws, feed-forward estimates such as $\hat{\boldsymbol{g}} = -\int (\hat{\boldsymbol{\omega}} \times \hat{\boldsymbol{g}})\mathrm{d}t$ are imperfect. Therefore, such feed-forward neural calculations must be coupled with feedback measurements, such as those provided by the otolith organs and vision. Although motion paradigms can be defined that fool the brain into making erroneous estimates of the relative orientation of gravity, such feed-forward and feedback calculations are generally performed quite accurately. Therefore, within the normal physiological

range, our perception of vertical approximately aligns with gravity, $\hat{g} \approx g$. Furthermore, many neurons innervating the otolith organs accurately record gravito-inertial force, which can be represented as $\hat{f} \approx f$. Because it has been hypothesized that an internal model of gravito-inertial force ($\hat{f} = \hat{g} - \hat{a}$) is used to estimate linear acceleration, this suggests that for the roll tilt motion paradigms, linear acceleration is estimated as $\hat{a} = \hat{g} - \hat{f} \approx g - f = a$. These calculations suggest that, if the nervous system uses the internal models outlined here, the ability to estimate translation and/or respond to linear acceleration during the same tilt motion paradigms is also fairly accurate ($\hat{a} \approx a$). These predictions are evaluated in the next section.

Canal Influences on Translation Responses

The canals have also been shown to contribute to translation responses in both human and nonhuman primates. Illustrative reports of translation perception have been made during the passive roll tilt paradigms previously described. In these studies, humans accurately report the absence of head translation during sinusoidal whole-body-and-head roll tilts at frequencies around 0.5–1.0 Hz when a subject's head is located at or near the center of rotation such that the head does not translate. This is known to be true for peak roll tilts of up to 20°, which yield peak interaural forces of $3.4\,\mathrm{m\,s^{-2}}$ that are approximately two orders of magnitude above the human threshold for detecting linear translation ($\sim 0.05\,\mathrm{m\,s^{-2}}$) during pure translational motion. If humans simply used the presence of interaural otolith signals to indicate that they were translating, this gravitational signal would be incorrectly interpreted as being due to linear acceleration. How can humans accurately determine that they are not translating when tilted in roll with their heads at the center of rotation? This is possible because the subjects used their roll canal cues to help them keep track of the relative orientation of gravity with fairly high accuracy using internal models, as discussed in the previous section. For tilt motion stimuli with the head at the rotation axis, the force measured by the otolith organs is due to gravity alone ($f = g$). Because the subjects correctly attribute the interaural force measured by the otolith organs to the presence of gravity ($\hat{f} = \hat{g}$), this leaves no unaccounted accelerations to be transduced by the otolith organs ($\hat{a} = \hat{g} - \hat{f} = 0$). Therefore, when head tilt occurs with the head at the center of rotation, humans correctly estimate the absence of head translation because they correctly attribute the forces measured by the otolith organs to gravity.

But what happens when the head is placed some distance below the tilt rotation axis? As previously described, such motion results in head translation by an amount that depends on the distance from the center of rotation and the maximum tilt angle. In this case, subjects report the presence of head translation that is consistent with the actual head translation. The mechanisms previously outlined explain these findings. First, the canals again help the subjects to accurately estimate the relative orientation of gravity ($\hat{g} = g$). However, the gravito-inertial force measured by the otolith organs does not equal that due to gravity alone because the head is accelerating linearly during this motion paradigm ($\hat{f} = f = g - a$). Given an otolith measurement of gravito-inertial force ($\hat{f}$) and a relatively accurate estimate of gravity ($\hat{g}$), the remaining force component signaled by the otolith organs is correctly interpreted as being due to linear acceleration ($\hat{a} = \hat{g} - \hat{f}$), which approximately equals the true linear acceleration $\hat{a} \approx a$. This ability to report translational motion remained even when the head was located at the distance below the center of rotation where the interaural tangential acceleration canceled the interaural gravitational component due to the tilt via the motion paradigms already described (Figure 3(c)). In other words, because the roll canal cues contributed to the processing of the ambiguous gravito-inertial force transduced by the otolith organs, the subjects correctly reported interaural translational motion even when the interaural force cues measured by the otolith organs were subthreshold.

These human translation perception studies were inspired by earlier studies that reported similar findings via measurements of the translational vestibulo-ocular reflex (Figure 4), which is a reflexive rotation of the eye that enhances visual acuity during head motion by helping to compensate for head translation. The earlier VOR studies showed (1) that a horizontal translational VOR was evoked by sinusoidal interaural translation, (2) that no translational VOR was evoked by a sinusoidal roll tilt paradigm that provided nearly identical interaural forces, and (3) that a horizontal VOR was evoked by a motion paradigm that combined tilt and translation such that the interaural components of gravity and linear acceleration canceled one another. In other words, analogous to earlier translation perception descriptions, the monkeys responded with an appropriate horizontal VOR in response to the actual interaural translation even when the otolith organs did not register interaural force.

Figure 4 VOR recorded from a rhesus monkey. Torsional, vertical, and horizontal components of eye position (E_{tor}, E_{ver}, and E_{hor}, respectively) and slow phase eye velocity (Ω_{tor}, Ω_{ver}, and Ω_{hor}, respectively) during interaural translation and/or roll tilt at 0.5 Hz in complete darkness. The stimuli consisted of 'translation only,' 'roll tilt only,' 'roll tilt + translation motion,' and 'roll tilt − translation motion'. The stimulus traces (bottom) show sled position (H_{trans}) and roll tilt position (H_{roll}). Note that the horizontal VOR remained relatively constant for the three conditions that included translational motion. Red arrow indicates the row showing the horizontal slow-phase VOR response. Reproduced from Angelaki D, McHenry M, Dickman JD, Newlands S, and Hess B (1999) Computation of inertial motion: Neural strategies to resolve ambiguous otolith information. *Journal of Neuroscience* 19: 316–327, with permission from the Society for Neuroscience.

Furthermore, when the semicircular canal contributions were eliminated via a surgical procedure called canal plugging, the compensatory translational VOR evoked during the combined tilt and translation motion paradigm disappeared and a noncompensatory translational VOR was evoked during roll tilts alone. These findings emphasize the contributions of the semicircular canals to this translational VOR response because the responses changed from being compensatory to noncompensatory when the canal signals were eliminated.

Neural recordings from the flocculus and vestibular nuclei during similar motion paradigms have demonstrated similar influences of the semicircular canals on the processing of gravito-inertial force measured by the otolith organs. The canal–otolith interactions that are evident in the neural recordings, translational VOR, and human perception have all been modeled using the internal model mechanisms previously described.

Otolith Influences on Rotation Responses

Signals from the otolith organs representing gravity have long been known to influence behavioral responses evoked by rotation. Illustrative examples follow. As background, we first recall that step changes in angular velocity yield abrupt changes in canal activation followed by gradual exponential-like decays having a time constant of approximately 5 s and that rapid decelerations lead to similar responses in the opposite direction. Human rotation perception and angular VOR responses demonstrate dynamic response patterns that are qualitatively similar to

the canal afferent response, but these behavioral responses decay back to baseline more gradually than the canal signals. For Earth-vertical axis rotations, the decay time constant for these behavioral responses might be as long as 10–20 s. This prolongation of the behavioral responses via central processing is often called velocity storage.

The afferent canal signals are the same whether the rotation axis is aligned with gravity or is tilted with the respect to gravity. On the other hand, the behavioral responses evoked depend on the orientation of the rotation axis with respect to gravity. For example, if the subjects are brought to a stop following constant-velocity rotation about an Earth-horizontal axis (barbecue-spit rotation), both the postrotary perception of rotation and the postrotary reflexive eye responses (**Figure 5**) demonstrate a decay with a time constant around 5–10 s, more rapid than the 10–20 s decay time constant when the rotation axis was aligned with gravity. This influence has been attributed to the fact that otolithic and other graviceptor information contradicts the incoming rotational signal from the semicircular canals. After all, if a rotation were actually occurring about a tilted axis, the orientation of gravity would not remain static with respect to the head as is measured by the otolith organs.

Another influence of graviceptor cues on rotational responses is demonstrated most clearly by measuring the vestibulo-ocular reflexes of nonhuman primates, but, although much smaller, it can also be observed in humans. When nonhuman primates are upright in the dark and are decelerated to a stop following rotation about an Earth-vertical axis, the eye response is almost exclusively horizontal (i.e., left–right); the eye response includes little or no vertical (i.e., up-down) or torsional (i.e., rotations about the line of sight) response components (**Figure 6**). This is expected because the postrotatory canal cues signal a yaw rotation, which elicits an eye response that is primarily horizontal. However, when the subjects are tilted immediately after they have been brought to stop, the resulting eye response exhibits vertical and/or torsional response components in addition to the canal-evoked horizontal response component. These vertical and/or torsional response components contribute to shift the eye rotation axis toward alignment with gravity (**Figure 6**). To understand this influence, it is

Figure 5 Comparison of angular VOR following rotation (postrotatory) when the rotation axis was aligned with gravity (VERT) or Earth horizontal: (a) 0° and 90°; (b) 180° and 270°. In (a) 0° indicates that the subject was stopped in the supine orientation and 90° indicates right side down; in (b) 180° indicates the subject was prone and 270° indicates left side down. Numbers that appear just above abscissa (e.g., 5.6) accompanied by vertical lines indicate the mean duration of the rotational sensation in seconds following deceleration to a stop. Reproduced from Benson A and Bodin M (1966) Effect of orientation to the gravitational vertical on nystagmus following rotation about a horizontal axis. *Acta Otolaryngologica* (Stockholm) 61: 517–526, with permission from the Taylor & Francis Group.

Figure 6 VOR recorded from a rhesus monkey during constant-velocity rotation about an Earth-vertical axis and, following deceleration to a stop, immediately followed by a pitch or roll tilt: (a) pitch; (b) roll tilt. Top trace shows yaw rotation position; the second trace shows pitch or roll tilt. Torsional, vertical, and horizontal components of eye position (E_{tor}, E_{ver}, and E_{hor}, respectively) and slow phase eye velocity (Ω_{tor}, Ω_{ver}, and Ω_{hor}, respectively) are shown. Green lines indicate time of deceleration to a stop and tilt with respect to gravity. Data to left of green lines show horizontal eye response (indicated with green arrows) evoked by semicircular canals. Blue arrow shows torsional VOR that shifted the axis of eye rotation toward alignment with gravity following a pitch tilt. Red arrow shows the vertical VOR that shifted the axis of eye rotation toward alignment with gravity following a roll tilt. Reproduced from Angelaki D and Hess B (1994) Inertial representation of angular motion in the vestibular system of rhesus monkeys I: Vestibuloocular reflex. *Journal of Neurophysiology* 71: 1222–1249, with permission from Springer-Verlag Heidelberg.

important to recall that the available rotational signals provided by the canals and gravitational signals provided by the otolith organs are inconsistent with one another following a postrotatory tilt. This response axis shift has been attributed to an attempt by the brain to resolve the inconsistent information it is receiving from the vestibular organs, by aligning the rotation axis with gravity.

A third influence of graviceptor cues on rotational responses is measured when subjects are rotated at a constant velocity about a rotation axis that is tilted with respect to gravity. It has long been known that the VOR response evoked by such off-vertical axis rotations (OVARs) are prolonged relative to the VOR evoked by an Earth-vertical rotation (Figure 7). Indeed, instead of decaying to zero, the presence of the rotating gravity vector, as measured by the otolith organs, evokes a constant VOR response, sometimes called the bias, long after the canal cues have decayed to zero. In addition, the VOR also exhibits a sinusoidal response component that modulates at the frequency with which the subject is rotating with respect to gravity. Several different models, including leaky-integrators and the internal model approach presented previously for rotational influences on both tilt and translation responses, mimic these physiological findings.

Summary

The afferent signals from both the semicircular canals and otolith organs include ambiguities. The semicircular canals respond to head rotation but have a limited dynamic range that often results in afferent canal signals that are not veridical, especially at low rotation frequencies. The otolith organs equivalently respond to both gravity and linear acceleration. Helping resolve these ambiguities, the otolith signals contribute to rotational responses, and the semicircular canals contribute to both tilt and translation responses. The combined information from the semicircular canals and otolith organs yields more accurate estimates of motion and orientation than is available from either sensory modality alone.

Cardiovascular Function: Central Nervous System Control

A F Sved, University of Pittsburgh, Pittsburgh, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The basic goal of the cardiovascular system is to maintain appropriate blood perfusion of all tissues in the body. To attain this goal the cardiovascular system must be able to adapt rapidly to a variety of circumstances, ranging from rest to exercise to hemorrhage. Even rather routine physiological events require alterations in blood flow, such as increased gastrointestinal blood flow during the digestion of a meal or constriction of blood vessels in the legs while changing from a supine to a standing position. Regulation of blood flow to the various tissues requires regulation of mean arterial pressure and the degree of arteriolar constriction in each vascular bed. Mean arterial pressure is a function of cardiac output and the amount of resistance provided by the blood vessels. Each of these parameters is controlled, at least in part, by the nervous system.

The nervous system clearly can influence the cardiovascular system. While the autonomic nervous system plays the major role, other endocrine and behavioral responses arising from the central nervous system (CNS) also contribute. Neural control of the cardiovascular system cannot be fully appreciated by studying each of these control processes in isolation. Rather, cardiovascular regulation by the CNS must be considered as an integrated response involving neural, endocrine, and behavioral outputs (Figure 1). Thus, for example, in response to hypovolemic hypotension, such as occurs with hemorrhage, there is an increase in sympathetic neural activity to promote vasoconstriction and thereby increase blood pressure, an increase in vasopressin release to cause vasoconstriction and renal water conservation, and an increase in water and salt intake to restore the fluid deficit. This multiplicity of outputs allows compensatory backup mechanisms to operate when one or more of them are compromised, providing redundancy in the control processes of this critical physiological system.

Autonomic Control of the Cardiovascular System

In addition to local factors and hormonal influences, neural innervation of the blood vessels and heart plays a key role in cardiovascular regulation. Innervation of the heart is supplied by both the sympathetic and parasympathetic divisions of the autonomic nervous system, with parasympathetic (vagal) input slowing heart rate and sympathetic innervation increasing heart rate and contractile force. When viewed independently these actions seem to be antagonistic, but they are jointly regulated to act in concert; that is, one increases while the other decreases. In contrast, the arterioles, which are the key blood vessels involved in regulation of vascular resistance, receive only sympathetic innervation. While this sympathetic innervation of arterioles is typically vasoconstrictor via an action on α-adrenergic receptors, some blood vessels also contain β-adrenergic receptors that provide vasodilatory responses under certain conditions. Although arterioles receive only sympathetic innervation, it is important to note that these sympathetic vasoconstrictor nerves are active at rest and thus can be either excited or inhibited to produce vasoconstriction or vasodilatation, respectively. The sympathetic nervous system can differentially influence regional vascular resistances and thereby region blood flows by the selective regulation of sympathetic vasoconstrictor nerves that project to different tissues. Although the sympathetic nervous system has classically been considered to be regulated as a unit (i.e., the 'fight or flight response'), discrete and selective regulation of individual sympathetic nerves is now understood to be more the rule.

Parasympathetic innervation of the heart arises in the CNS from preganglionic parasympathetic neurons in the nucleus ambiguus and the dorsal motor nucleus of the vagus in the caudal brain stem. These cardiac parasympathetic preganglionic neurons are normally driven by a variety of excitatory synaptic inputs, though the brain circuits determining their activity at rest are still rather poorly delineated. Sympathetic innervation of the heart and vasculature arises from preganglionic sympathetic neurons in specific thoracic and lumbar spinal cord segments. These preganglionic neurons receive both spinal and supraspinal input, but in the absence of supraspinal input their activity is markedly limited. For example, high spinal cord transection reduces mean arterial blood pressure from approximately 100 mm Hg to 60 mm Hg, consistent with complete removal of resting sympathetic vasomotor activity. Such an observation, initially made back in the mid-nineteenth century, highlights the critical nature of supraspinal influences in the maintenance of arterial blood pressure and raises the question of what generates resting sympathetic vasomotor tone; this issue will be examined in more detail in the next section.

Figure 1 Overview of integrated brain control of the cardiovascular system. This schematic summarizes the CNS outputs contributing to cardiovascular regulation: parasympathetic (vagal) innervation of the heart; sympathetic innervation of the heart; sympathetic innervation of the vasculature; sympathetic innervation of the juxtaglomerular (JG) cells of the kidney that secrete renin, thereby generating angiotensin; sympathetic preganglionic innervation of the adrenal medulla controlling catecholamine secretion in to blood; vasospressin (antidiuretic hormone) secretion into blood; and behavioral responses, such as those involved in the regulation of blood volume and osmolality. Solid and dotted lines represent neural pathways; dashed lines represent hormonal influences. NTS, nucleus tractus solitarius; DMN, dorsal motor nucleus of the vagus; NA, nucleus ambiguus; RVLM, rostral ventrolateral medulla.

In addition to direct innervation of the heart and vasculature, the sympathetic nervous system also influences the cardiovascular system via a blood-borne, endocrine route. Catecholamine-secreting cells of the adrenal medulla are innervated by preganglionic sympathetic neurons. Catecholamines released into the blood from the adrenal gland have access to sympathetic neuroeffector junctions and are capable of eliciting sympathetic-like responses. Because the adrenal medulla typically secretes more epinephrine than norepinephrine, and β-adrenergic receptors are more sensitive to epinephrine than to norepinephrine, sympathetically evoked responses that are mediated by β-adrenergic receptors are more sensitive to adrenal regulation than are α-adrenergic receptor-mediated responses. Thus, since the heart and arterioles in skeletal muscle contain β-adrenergic receptors, whereas arterioles in other tissues have primarily α-adrenergic receptors, stimulation of the adrenal medulla more potently increases heart rate and skeletal muscle vasodilatation than it does vasoconstriction.

The sympathetic nervous system influences several other endocrine systems that have direct effects on the cardiovascular system. Renin release from the kidney juxtaglomerular cells into the circulation occurs in response to several factors, including increased

sympathetic outflow acting on β-adrenergic receptors. Renin released into the blood then initiates the generation of vasoactive peptides such as angiotensin II. Angiotensin II produces vasoconstriction by a direct action on angiotensin receptors located on blood vessels and also promotes vasoconstriction by acting on postganglionic sympathetic nerve terminals to enhance norepinephrine release. Circulating angiotensin also acts at brain sites lacking a blood–brain barrier (e.g., area postrema and subfornical organ) to further increase sympathetic vasomotor outflow and other responses consistent with increasing blood pressure and blood volume. Thus, angiotensin acts in a variety ways to increase arterial pressure, and the circulating levels of this peptide are controlled in large part by the brain via the sympathetic nervous system.

Sympathetic Vasomotor Tone Is Tonic and Driven from Supraspinal Sites

Following upon the observation that transections placed between the brain and spinal cord in experimental animals reduce arterial pressure to the same extent as does removing the sympathetic nervous system, experiments performed in Carl Ludwig's laboratory in the 1870s demonstrated that blood pressure was maintained with transections made in the brain at successively more caudal levels, until the transections were made in the medulla. These observations indicated that the minimal neural circuitry necessary for the maintenance of basal sympathetic vasomotor tone resides completely in the caudal brain stem. Multiple lines of evidence now support the notion that the neurons providing the key tonically active input to the sympathetic preganglionic vasomotor neurons reside in a discrete region of the rostral ventrolateral medulla (RVLM). The region near the ventrolateral surface of the medulla just caudal to the facial motor nucleus has neurons with anatomical projections to sympathetic preganglionic neurons that have firing properties consistent with them driving sympathetic vasomotor outflow. Stimulation of this region markedly increases blood pressure and sympathetic nerve activity whereas inhibiting neural activity in this region decreases arterial pressure to the same extent as does transection of the cervical spinal cord. Within the RVLM, at least two classes of spinally projecting sympathoexcitatory neurons can be distinguished based on neurochemical phenotype and electrophysiological criteria; while these two groups of neurons each contribute to cardiovascular regulation, the relative importance of these different cell types is unclear at present. Furthermore (as described in more detail later), the RVLM is not simply involved in the basal supraspinal drive of vasomotor tone. Rather, it appears to be a site where numerous and varied influences on sympathetic vasomotor tone are integrated.

The RVLM is not the only supraspinal site that provides direct innervation of sympathetic preganglionic neurons, but it clearly is the only one where acute inhibition of the neurons causes a marked decrease in arterial pressure to the same degree as does autonomic blockade. Nonetheless, other regions that innervate sympathetic preganglionic neurons, including the hypothalamic paraventricular nucleus, the pontine A5 area, and raphe pallidus, no doubt contribute to the supraspinal control of sympathetic vasomotor tone. Furthermore, all of these regions, in addition to giving rise to projections to the region of sympathetic preganglionic neurons in the spinal cord, also project to other regions involved in autonomic regulation, including the RVLM. For example, activation of the hypothalamic paraventricular nucleus increases sympathetic vasomotor tone and arterial pressure, and a portion of this response is mediated via activation of the RVLM. Thus, whereas the evidence suggests that resting sympathetic vasomotor tone is driven by the RVLM, the brain pathways involved in sympathetic vasomotor regulation are complex and interwoven.

Neural Control of the Heart Is a Balance between Sympathetic and Parasympathetic Influences

Heart rate is established by spontaneously depolarizing pacemaker cells in the sinoatrial node, and the rate of depolarization of these pacemaker cells is modulated by parasympathetic and sympathetic neural activity. Under basal resting conditions, heart rate reflects the balance of sympathetic and parasympathetic tone to the heart; in humans at rest, parasympathetic tone predominates and therefore resting heart rate is lower than is the intrinsic rate of the sinoatrial node. Due to the basal tonic autonomic control of the heart, heart rate can be increased by reducing parasympathetic activity and/or increasing sympathetic activity; the opposite responses slow the heart. These autonomic systems function in an integrated manner, and opposite changes in sympathetic and parasympathetic activity typically occur simultaneously to modulate heart rate.

The basal drive of cardiac sympathetic outflow, like sympathetic outflow to the vasculature, emanates principally from the RVLM, although the factors imparting this tonic discharge of RVLM neurons

are not fully understood. Cardiac parasympathetic preganglionic neurons in the brain stem are tonically active *in vivo*, largely reflecting input from the cardiovascular and respiratory systems. Indeed, heart rate fluctuates in phase with breathing, as a result of changes in cardiac vagal activity.

Heart rate can also be powerfully influenced by higher levels of the neuraxis. The importance of these inputs is highlighted by the ability to elicit lethal cardiac arrhythmias by stimulation of certain diencephalic and telencephalic structures that influence autonomic nerves.

Cardiovascular Homeostasis Results Primarily from a Negative Feedback Reflex

Under normal conditions, arterial pressure is maintained within very narrow limits, and this regulation is accomplished by a powerful negative feedback reflex, the baroreceptor reflex. As blood pressure begins to deviate from its regulated set point, the baroreceptor reflex rapidly compensates for this change, thereby maintaining arterial pressure within a narrow normal range. The afferent component of the baroreceptor reflex is derived from pressure-sensitive receptors associated with the aortic arch and the carotid sinus. These baroreceptor afferent nerves all project into the CNS via the IXth and Xth cranial nerves and terminate in a distinct region of the nucleus tractus solitarius (NTS). These afferents impact the activity of cardiovascular autonomic outflow, and much is known about the central neural pathways that connect the baroreceptor afferent signal projecting to the NTS to the preganglionic sympathetic vasomotor neurons in the intermediolateral (IML) and vagal cardiomotor neurons. The pathway mediating baroreceptor-evoked changes in sympathetic preganglionic neurons involves a projection from the NTS to neurons in the caudal ventrolateral medulla (CVLM). These cells in the CVLM provide inhibitory innervation of RVLM neurons that innervate sympathetic preganglionic neurons. Thus, the RVLM normally is involved both in the tonic maintenance of arterial pressure and its reflexive regulation. NTS baroreceptive neurons excite vagal preganglionic parasympathetic cardiomotor neurons in the nucleus ambiguus and dorsal motor nucleus, and this input is likely monosynaptic.

A considerable body of evidence suggests that glutamate and γ-aminobutyric acid (GABA) play dominant neurotransmitter roles in the baroreceptor reflex. For example, excitatory amino acid antagonists administered directly into the NTS, CVLM, or spinal cord completely eliminate baroreceptor reflex-evoked sympathetic vasomotor responses. Similarly, GABA antagonists injected into the RVLM block such responses. Still, many other inputs and neurotransmitters at these sites have been shown to modulate baroreceptor reflex function.

In addition to the direct autonomic control of the heart and vasculature, afferent inputs from arterial baroreceptors influence other brain outputs relevant to cardiovascular regulation.

Other Reflexes Influence Cardiovascular Homeostasis

Feedback from arterial pressure is not the only reflex involved in the short-term control of arterial pressure. Whereas it certainly is important to maintain stability of arterial pressure, a variety of conditions require arterial pressure or regional blood flow to change in an appropriate manner. For example, decreases in blood oxygen levels require circulatory adjustments to preserve oxygen delivery to the brain. Decreased blood oxygen content activates arterial chemoreceptors, located primarily in the carotid sinus and in the brain stem, which triggers reflex sympathetically mediated increases in vasoconstriction in most tissues, redirecting blood flow to the brain. The brain regions involved in this chemoreceptor reflex include the NTS as the site of termination of chemoreceptor afferent nerves and the RVLM as the site of the neurons that innervate sympathetic preganglionic neurons. Chemoreceptor and baroreceptor inputs typically do not influence the same NTS neurons, but convergence of these inputs at the level of the RVLM is extensive.

Skeletal muscle use during exercise also places demands on the cardiovascular system that must be integrated with overall cardiovascular regulation. Exercise is accompanied by increased cardiac output and a redistribution of blood flow to the contracting muscles and away from the kidneys, gut, skin, and resting muscle. This patterned cardiovascular response has been attributed to sensory feedback from the contracting muscles, central neural command that is initiated along with the cerebral signals to contract the muscles, or, most likely, a complex combination of these two mechanisms. Abundant data support the ability of muscle afferent nerves innervating the spinal cord to elicit reflexive cardiovascular responses similar to the responses produced by exercise. For example, in an anesthetized cat preparation in which the ventral roots can be stimulated to elicit isometric muscle contraction, blood pressure and heart rate will increase in proportion to muscle contraction, a response that is eliminated by section of the dorsal roots. However, other experiments point to central neural drive initiating the cardiovascular

response to voluntary muscle contraction. For example, in anesthetized cats, stimulation of the subthalamic locomotor region elicits a pattern of skeletal muscle contraction similar to walking and also elicits cardiovascular responses similar to those accompanying muscle use, even when the muscles are pharmacologically paralyzed. In humans, when the perceived exertion is increased by partially paralyzing the muscle, blood pressure and heart rate increase in proportion to effort rather than to muscle contraction. Such observations have led to the conclusion that under normal conditions either central command or muscle feedback is capable of eliciting the appropriate cardiovascular response, and that central drive predominates when there is a mismatch of signals.

Not all stimuli that evoke cardiovascular compensations are interoceptive. The behavioral alerting or defense reaction to a perceived threat or stressful stimulus serves as a good example of how cardiovascular compensations mediated by the CNS are integrated with other responses. When an organism is confronted with a threatening stimulus there is a generalized activation of the sympathetic nervous system. This sympathetic activation occurs along with an activation of the hypothalamic–pituitary–adrenal cortical axis and behavioral responses, to produce a highly integrated and coordinated defense reaction. The entire collection of responses, including autonomic, behavioral, and endocrine aspects, can be evoked by stimulation of discrete sites in the brain, such as the perifornical hypothalamus. The cardiovascular component of the defense reaction is highly patterned, including vasodilatation in skeletal muscle, vasoconstriction of most other vascular beds, and tachycardia. Two aspects of the central mechanisms mediating this cardiovascular response deserve mention. First, the response includes an inhibition of baroreceptor reflex function, mediated at least in part by inhibition of baroreceptor-sensitive neurons in the NTS. This ensures that the evoked increase in arterial pressure will not be counteracted by the baroreceptor reflex. Second, the patterned cardiovascular response is mediated through the RVLM. Thus, like other reflexively driven cardiovascular adjustments, the control of the sympathetic nervous system is exerted via spinally projecting neurons arising from the RVLM.

A Set Point for Arterial Pressure

Each of the responses noted in the preceding discussions, and short-term cardiovascular adjustments in general, represent changes in blood pressure or distribution of blood flow from some normal resting level or set point. But what sets the resting level of cardiovascular autonomic outflow upon which these reflexive or evoked changes occur? While the answer to this question is unclear at present, it appears to be determined by some critical input or inputs or else it is the result of some pacemaker or network property that can generate this baseline level of autonomic activity in the absence of any input. As an example of the former possibility, it might be that brain stem blood flow is sensed in some manner, and the 'set point' is determined, in the absence of other inputs, by maintaining brain stem blood flow at some level. In contrast, the brain might be capable of intrinsic generation of baseline cardiovascular autonomic outflow. While reports on pacemaker properties of sympathoexcitatory RVLM neurons are consistent with such a notion, current data suggest that these RVLM neurons *in vivo* do not generate such pacemaker potentials, but rather that all action potentials are preceded by excitatory synaptic potentials. Still, this does not rule out the possibility that the pacemaker neurons could be located elsewhere or that the baseline activity is an emergent property of a neural network.

The Nervous System and the Long-Term Control of the Cardiovascular System

In contrast to the established role of the brain in controlling and coordinating cardiovascular responses to acute stimuli, its role in the long-term control of blood pressure is less certain. Indeed, the autonomic nervous system is not essential for the maintenance of life under controlled conditions, and resting arterial pressure is relatively normal in the chronic absence of autonomic nervous system function. Furthermore, systems-level analyses of cardiovascular function highlight the blood volume-regulating capacity of the kidneys as the critical system involved in long-term cardiovascular control. In the models pioneered by Guyton and colleagues, in response to increased renal perfusion pressure resulting from increased arterial pressure, an increase in water and sodium excretion decreases blood volume and therefore blood pressure. Conversely, when blood pressure decreases, the reduction in glomerular filtration helps to stabilize blood volume. Since this pressure–volume regulatory capacity of the kidney is an intrinsic property of the kidney and has an infinite gain, it can precisely (although not rapidly) compensate for any change in arterial pressure. Nonetheless, the sympathetic neural innervation of the kidney modifies the pressure–volume regulatory capacity of the kidney by promoting sodium and water reabsorption. Thus, the long-term control of arterial pressure may normally depend upon sympathetic control of renal function, consistent with observations that renal denervation can produce a long-term decrease in arterial pressure.

There are additional data implicating the brain in the long-term control of arterial pressure, as manipulations in the CNS can result in chronic alterations in blood pressure.

Hypertension and the Central Neural Control of Cardiovascular Function

Chronically elevated arterial pressure is one of the most important risk factors for cardiovascular disease. Epidemiological data indicate that hypertension, typically defined in the clinic as systolic pressure >140 mm Hg or diastolic pressure >90 mm Hg, increases the risk of myocardial infarction (heart attack), stroke, congestive heart failure, and renal disease. It is estimated that more than 50 million adults in the United States, or approximately a quarter of the adult population, has hypertension.

Despite the widespread incidence of hypertension, its causes remain to be established in most instances. Indeed, no specific cause can be identified in more than 90% of cases of clinical hypertension; this is referred to as primary, or 'essential,' hypertension. Several lines of evidence suggest that the CNS may be important in the pathogenesis of hypertension. Possibly the most convincing are data that certain drugs used to treat hypertension target brain control of arterial pressure. Indeed, the understanding that some of the early drugs used to treat hypertension (e.g., clonidine and α-methyldopa) acted in the CNS to lower arterial pressure served as a major impetus for studies on the central neural control of cardiovascular function. This line of thought has also led to the hypothesis that hypertension, at least in some instances, may result from a central neural dysfunction. In addition to the fact that hypertension can be treated by drugs that act within the CNS, there are several reasons why such a hypothesis is attractive. First, the brain exerts powerful control over the cardiovascular system, and experimental manipulations within the brain can produce profound increases in arterial pressure. For example, destruction of the NTS or CVLM produces acute and severe hypertension in experimental animals. These responses can also be elicited by more selective pharmacological alteration of neurotransmitter mechanisms in these regions. Second, certain forms of experimental hypertension have been associated with changes in the synthesis, release, and receptor binding of specific neurotransmitters in specific CNS regions. For example, catecholamine synthesis is altered in several brain sites in models of hypertension in rats. Recent studies using viral vector transfection techniques to manipulate specific genes in specific brain regions provide compelling evidence that the brain is involved in the pathogenesis of hypertension in some experimental models.

Cataplexy

S Nishino, Stanford University School of Medicine, Stanford, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Cataplexy (one of the symptoms of narcolepsy) is a sudden drop of antigravity muscle tone triggered most often by positive emotional factors (such as laughter) and less frequently by negative emotional factors (such as anger or frustration).

Narcolepsy is a chronic sleep disorder that affects 0.02–0.05% of the general population and has also been reported in dogs (Figure 1(a)) and, more recently, in (genetically engineered) mice and rats. Human narcolepsy is caused by an interplay of genetic susceptibility and environmental factors, and the disease is tightly associated with human leukocyte antigen (HLA) DR2 and DQ6 (DQB1*0602). Although many autoimmune diseases are associated with certain HLA types, an involvement of autoimmune mechanisms with narcolepsy has not been demonstrated.

The symptoms of narcolepsy are often classified as the narcolepsy tetrad (excessive daytime sleepiness, cataplexy, hypnagogic hallucination, and sleep paralysis) or pentad (narcolepsy tetrad plus insomnia). Among these symptoms, cataplexy is pathognomonic for narcolepsy, and it occurs almost exclusively in idiopathic narcolepsy and in rare cases of symptomatic (or secondary) narcolepsy (i.e., narcolepsy associated with other neurological conditions such as a brain tumor or stroke). Sleep paralysis and hypnagogic hallucinations also occur in other sleep disorders such as sleep apnea (or even in healthy subjects, especially when their sleep–wake pattern is disturbed). Sixty percent of narcoleptic subjects diagnosed by the current International Classification of Sleep Disorders (ICSD-2) diagnostic criteria developed cataplexy, usually around the onset of sleepiness or within 3–5 years (narcolepsy with cataplexy). The other 40% of narcoleptic subjects do not exhibit cataplexy, but have rapid eye movement (REM) sleep abnormalities (i.e., sleep-onset REM periods) together with excessive daytime sleepiness (classified as narcolepsy without cataplexy). Thus, narcolepsy without cataplexy is also clinically common.

The French physician Gélineau (in 1880) first coined the term narcolepsy and described two cases of excessive daytime sleepiness, discussing how emotions influenced the onset of sleep attacks (a fall astasias was also accompanied with sleep attacks in one of these two cases). However, Lowenfeld (in 1902) is usually considered the first author to characterize cataplexy as part of the narcoleptic syndrome.

Clinical Features of Cataplexy

Severe cataplexy episodes produce a bilateral, generalized weakness of the antigravity muscles sufficient to cause a fall (although usually without injury; a video of cataplexy is available at the Stanford website). Other episodes may be partial, affecting only the face, vocal cords, or limb(s). Consciousness is not impaired unless the patient subsequently falls asleep (a transition to REM sleep often occurs). Calling the person's name or shaking his or her body can interrupt cataplexy, and patients can usually recover without any confusion. Patients can also recall events happening before and during cataplexy if they recover before falling asleep. During cataplectic attacks, the cortical electroencephalogram (EEG) is desynchronized and the EEG pattern is similar to that during waking and REM sleep (Figure 1(b) shows the EEG patterns during cataplexy in narcoleptic dogs). In contrast to epileptic seizures, no paroxysmal spikes or burst EEG patterns are observed. Neurological examinations performed at the time of an attack show a suppression of the platellar reflex. The duration of cataplexy varies from a split second to several minutes. Its frequency varies according to the time and individual subject – from less than one episode per year to several episodes per day. Cataplexy is currently treated pharmacologically, most often with tricyclic antidepressants (Table 1), but the antiepileptics are ineffective. The anticataplectic effect of tricyclic antidepressants (imipramine) was coincidentally found in the clinical practices in the 1950s. Tricyclic antidepressants are also effective for reducing sleep paralysis and hypnagogic hallucinations, but have little effect on excessive daytime sleepiness. Therefore, most narcolepsy–cataplexy patients need to take additional wake-promoting compounds such as an amphetamine, methylphenidate, or modafinil. Conversely, these wake-promoting compounds used for the treatment of excessive sleepiness have no (modafinil) or only moderate (amphetamine and amphetamine-like compounds) anticataplectic effects.

Cataplexy often worsens with poor sleep and fatigue. Patients may also experience status cataplecticus; this rare manifestation of narcolepsy is characterized by subintrant cataplexy that lasts several hours per day and confines the subject to bed. It can occur spontaneously or more often on withdrawal from anticataplectic drugs.

Figure 1 Continued

Table 1 Drugs commonly used for treatment of cataplexy

Drug	*Dosage*	*Side effects and comments*
Imipramine[a]	10–100 mg	Dry mouth, anorexia, sweating, constipation, drowsiness
Protriptyline[a]	5–60 mg	Dry mouth, sweating, anxiety, disturbed nighttime sleep
Clomipramine[a]	10–150 mg	Dry mouth, sweating
Fluoxetine[b]	20–80 mg	Few side effects, nausea, dry mouth
Venlafaxine[b]	75–150 mg	Few side effects, nausea
Sodium oxybate[c]	1.5–4.5 g bedtime and 2–3 h later	Morning sedation, nausea, dizziness, urinary incontinence

[a]Imipramine, protriptyline, and clomipramine are classical tricyclics.
[b]Fluoxetine is a serotonin selective reuptake inhibitor (SSRI) and venlafaxine is serotonin/norepinephrine selective reuptake inhibitor, which have less side effects.
[c]Sodium oxybate is not an antidepressant; it is a short-acting sedative. Taking sodium oxybate at night improves sleepiness and cataplexy the following day.

Physiological and Pathophysiological Aspects of Cataplexy

In humans, the first REM sleep episode occurs approximately 90 min after sleep onset and reappears every 90 min (every 30 min in dogs and cats). A total of four to five REM sleep episodes may occur during the night. Shortly after the discovery of REM sleep, it was found that in narcolepsy REM sleep often occurs at sleep-onset (sleep-onset REM periods) or even during short daytime naps (Figure 2). Ever since, cataplexy, sleep paralysis, and hypnagogic hallucinations have been often considered a disassociated manifestation of REM sleep; the occurrence of these symptoms is often explained by an abnormal rapid transition to REM sleep during active wake or sleep-onset. During REM sleep, complete and tonic inhibition of muscle tonus, together with phasic bursts of REMs and swift muscle twitching, occurs physiologically, and the amplitude recorded in the electromyogram (typically monitored in neck or chin muscles, combined with sleep EEG recordings) is the lowest. It is, however, the activity of pyramidal tract neurons in the motor cortex that mediate the limb movements, which are as high during REM sleep as during active waking. It is thought that the tonic inhibitory signal for muscle tonus originating in the dorsal pons overcomes this pyramidal motor activation system during REM sleep and that this results in complete muscle atonia during this sleep state. This notion is supported by brain lesion studies in animals. When the lesions are made in the dorsal pons, the phenomenon called REM sleep without atonia is observed, and the animals move their limbs during REM sleep. Similar phenomena (i.e., REM sleep behavior disorders) are also reported in humans associated with various neurological conditions (including stroke in the pons).

A series of experiments suggested that an executive mechanism of atonia during cataplexy shares a common pathway with atonia during REM sleep.

1. Electrophysiological experiments using familial narcoleptic Dobermans demonstrated that a population of cell groups in the brain stem that are responsible for loss of muscle tone during REM sleep are also active during cataplexy.
2. Experiments have also recently demonstrated that REM-off cells in the adrenergic locus coeruleus (LC) in the pons cease to discharge during cataplexy.
3. Experiments have shown that H-reflex activity (an electronically stimulated muscle response with monosynaptic latency due to excitation of Ia afferents in the spinal cord) profoundly diminishes or disappears during both REM sleep and cataplexy in humans.
4. The major mechanism of action of anticataplectics is thought to be the suppression of REM sleep by activating the central adrenergic system.

Therefore, the motor inhibitory components of REM sleep at the level of the lower brain stem and the spinal cord are also operative during cataplexy.

In contrast, mechanisms of the induction of cataplexy are not well understood. However, several

Figure 1 Cataplectic attacks in Doberman pinschers: (a) photos of attacks; (b) polygraphic recordings of cataplectic attacks observed in a narcoleptic Dobermans. Emotional excitations, appetizing food, or playing easily elicits multiple cataplectic attacks in these animals, and most attacks are bilateral (97.9%). Atonia was initiated partially in the hind legs (79.8%), front legs (7.8%), neck/face (6.2%), or whole-body/complete attacks (6.2%), and a progression of attacks was also seen (49% of all attacks). As shown in (b), a rapid transition from the waking state (desynchronized electroencephalogram (EEG) with high electromyogram (EMG)) to cataplexy (sudden reduction of EMG) is observed (left). During cataplexy (right), the EEG consists of low-voltage fast-wave, occasionally accompanied by rapid eye movement. EOG, electrooculogram.

Figure 2 Test results for a 10-year-old female narcoleptic patient: (a) all-night polysomnogram; (b) multiple sleep latency test. In (a), note the appearance of a sleep-onset REM period in the night recordings and marked sleep tendency. In (b), note a sleep-onset REM period at each daytime nap test. Vertical arrows indicate a verbal calls to awaken the patient at the end of each nap test. REM, rapid eye movement. Adapted from Honda Y (1988) Clinical features of narcolepsy: Japanese experiences. In: Honda Y and Juji T (eds.) *HLA in Narcolepsy*, pp. 24–57. Berlin: Springer.

experiments using narcoleptic Dobermans suggested that mechanisms for induction of cataplexy are different from those for REM sleep.

1. Cataplexy in narcoleptic dogs can be elicited anytime by emotional excitation, whereas occurrences of REM sleep in these animals are regulated by a normal 30 min cyclicity.
2. Injection of cholinergic agonist (carbachol) into the basal forebrain (anterior hypothalamus) induces long-lasting cataplexy-like atonia in narcoleptic dogs, but this manipulation does not affect the 30 min cyclicity of the occurrence of the phasic REM sleep phenomena (i.e., REMs).
3. Dopamine D2/3 receptor agonists potently aggravate and D2/3 receptor antagonists potently inhibit cataplexy in narcoleptic dogs, but these classes of compounds have little effect on the occurrences of REM sleep.

Many normal individuals report slight muscle weakness with intense emotion, and during laughter, the H-reflex is markedly reduced in controls and also in narcoleptic subjects. Cataplexy may thus result from excessive activation of the same descending motor inhibitory pathways that are active during strong emotions, but these conceptual (emotion-triggered) inhibitory pathways and mechanisms are not yet identified.

A series of pharmacological experiments using canine narcolepsy pointed out the importance of the cholinergic system and monoaminergic system for the regulation of cataplexy. Various manipulations and pharmacological compounds reduce cataplexy, but some may be nonspecific; if animals are afraid or do not feel comfortable, cataplexy is generally reduced. In contrast, only a limited class of compounds aggravates cataplexy. These include compounds that activate cholinergic neurotransmission (especially by cholinergic M2/3 receptor agonists) and compounds that reduce monoaminergic neurotransmission (especially by adrenergic α_2 agonists (presynaptic), α_1 antagonists (postsynaptic), and dopamine D2/3 agonists (presynaptic)). Thus, there is a similarity between the pharmacological control of cataplexy and that of REM sleep, but some discrepancies have also been noted with D2/3 compounds.

Cataplexy and Hypocretin/Orexin Deficiency

Cataplexy is also a hallmark symptom of narcolepsy in animals, such as dogs and mice. The identification

Figure 3 Absence of hypocretin signals and peptide in the hypothalamus of narcoleptic patients: (a) brain hypocretin levels in narcoleptic and control subjects; (b) hypocretin mRNA signal in the lateral hypothalamic area of control and narcoleptic subjects. In (a), cortical hypocretin-1 and hypocretin-2 (data not shown) concentrations were detectable in all controls (— indicates mean) and undetectable (— indicates the detection limit, 332 pg/g brain) in five of the six narcoleptic subjects. The difference in hypocretin concentrations (two narcoleptic subjects vs. two controls) was more pronounced in the pons where high concentrations are observed in the control subjects. In (b) preprohypocretin transcripts are detected in the hypothalamus of control (left) but not narcoleptic (right) subjects. C1/2, controls; f, fornix; N1/2, narcopleptic patients. Adapted from Peyron C, Faraco J, Rogers W, et al. (2000) A mutation in a case of early onset narcolepsy and a generalized absence of hypocretin peptides in human narcoleptic brains. *Nature Medicine* 6: 991–997.

Figure 4 Cerebrospinal fluid hypocretin-1 levels across various disease categories. Each dot represents a single patient. Hypocretin-1 values below 110 pg ml^{-1} were determined to be diagnostic for narcolepsy. Concentrations above 200 pg ml^{-1} best determined healthy control values. The number of patients with hypocretin values below or equal to 110 pg ml^{-1}, above 200 pg ml^{-1}, and between these two values is indicated for each category. CSF, cerebrospinal fluid; HLA, human leukocyte antigen. Adapted from Mignot E, Lammers GJ, Ripley B, et al. (2002) The role of cerebrospinal fluid hypocretin measurement in the diagnosis of narcolepsy and other hypersomnias. *Archives of Neurology* 59: 1553–1562.

of cataplexy in these animals led to the discovery of narcolepsy in these animal species. Studies in these animals (familial canine narcolepsy in narcoleptic Dobermans and gene-knockout mice) led to the discovery of the etiology of narcolepsy in animals. Mutation of one of the two hypocretin/orexin receptors and knockout of the hypocretin/orexin gene (preprohypocretin) causes narcolepsy in dogs and mice, respectively. The hypocretin/orexin system is a recently discovered hypothalamic neuropeptidic system. Hypocretin neurons are exclusively located in the lateral hypothalmic area, but project to most brain areas. Subsequent human studies revealed that the mutation in the hypocretin-related gene is extremely rare, and only one case of early-onset narcolepsy to date was identified as having a mutation in the preprohypocretin gene. However, cerebrospinal fluid (CSF) measures (and a small number of postmortem brain studies) found hypocretin ligand deficiency in most idiopathic narcolepsy–cataplexy cases (~90%) (Figures 3 and 4).

Figure 5 Monoaminergic and cholinergic control of sleepiness and cataplexy in relation to hypocretin input: (a) schematic; (b) hypocretin projections. As shown in (a), the stimulation of adrenergic transmission by adrenergic uptake inhibitors potently reduces cataplexy; this pharmacological property is probably involved in the mode of action of currently used anticataplectic agents (e.g., tricyclic antidepressants). The fact that both the presynaptic $\alpha 2$ autoreceptor stimulation and postsynaptic $\alpha 1$ blockade aggravate cataplexy is consistent with an inhibitory role of adrenergic transmission in the control of cataplexy. D2/3 autoreceptor stimulation aggravates both cataplexy and sleepiness, and amphetamines stimulate DA release at DA terminals and mediate EEG arousal. Muscarinic M2 stimulation induces behavioral wakefulness and cortical desynchrony in control dogs, but it induces cataplexy in narcoleptic dogs. As shown in (b), hypocretin-containing neurons project to these previously identified monoaminergic and cholinergic regions where hypocretin receptors (Hcrtr1/2) are enriched. Impairments of hypocretin input may result in cholinergic and monoaminergic imbalance and the generation of narcoleptic symptoms. BF, basal forebrain; D2/3, dopamine receptors; DA, dopamine; DR, dorsal raphe; EEG, electroencephalogram; LC, locus coeruleus; LDT, laterodorsal tegmentum; LHA, lateral hypothalamic area; M2, muscarinic receptor; NAc, nucleus accumbens; PPT, peduncle pontine tegmentum; PRF, pontine reticular formation; SN, substantia nigra; TMN, tuberomamillary nucleus; VLPO, ventrolateral preoptic area; VTA, ventral tegmental area.

Extended human studies further suggested that hypocretin deficiency is tightly associated with the occurrence of cataplexy and that most patients with narcolepsy without cataplexy and idiopathic hypersomnia and secondary excessive daytime sleep disorders (such as obstructive sleep apnea) have normal CSF hypocretin levels (Figure 4). A positive reading for HLA is also tightly associated with hypocretin deficiency. Hypocretin replacements are expected to be a new treatment for hypocretin-deficient narcolepsy, but this is not available due to low penetration (of the brain) of hypocretin peptides; the development of synthetic agonists are likely to be needed.

A significant degree of hypocretin deficiency already occurs around the disease onset and, in some case, before the onset of cataplexy. Moderate hypocretin deficiency is also reported in cataplexy associated with some secondary narcolepsy cases with brain tumors or vascular diseases. In these conditions, the degree of hypocretin deficiency is modest compared to most idiopathic cases (undetectably low), but projection and projection sites of the hypocretin system may also be damaged in these secondary cases. Thus, cataplexy may now appear to be a hypocretin-deficient pathological phenomenon. However, it is not known if impairments of the hypocretin neurotransmission instantly lead to occurrences of cataplexy or if any secondary changes are required to develop cataplexy. If some of these secondary changes are irreversible, hypocretin supplements (when they become available) may not be effective.

Cataplexy is also reported to occur in rare neurological conditions, such as the Nieman-pick type C (without sleepiness) disease, Prader–Willi syndrome, and myotonic dystrophy (with sleepiness). The involvements of the hypocretin system in cataplexy in these conditions have not been systematically studied.

Hypocretins are, in general, excitatory neuropeptides, and they project to most monoaminergic systems (such as the LC, dopaminergic ventral tegmental area and substantial nigra, serotonergic raphe, and histaminergic tuberomammillary nucleus) and cholinergic systems (such as the basal forebrain and brain stem cholinergic nuclei) and their terminal areas, and modulate their neurotransmissions. Hypocretin deficiency is thus likely to induce abnormalities in monoaminergic and cholinergic neurotransmissions (Figure 5). Indeed catecholamine contents (dopamine and norepinephrine) are increased in several brain regions, and this may be a compensatory increase due to the lack of excitatory inputs to these systems. This upregulation alone is not likely to prevent the occurrence of the symptoms of narcolepsy, and compounds that enhance the catecholaminergic neurotransmission are needed to control sleepiness and cataplexy. Considering the fact that compounds which shut down the catecholaminergic system (autoreceptor agonists, α_2 and D2/3 agonists) are very potent for inducing cataplexy in the canine model, a sudden decline of catecholamine tonus may be one of the most important mechanisms for triggering cataplexy; however, the precise mechanisms for this are still not understood. We can also assume that the disinhibition of executive components of REM sleep atonia and/or disfacilitation of tonic muscle activity due to the lack of the hypocretin signaling are likely to be involved in the occurrences of cataplexy. The link between this mechanism and the emotional component is still not known.

CCK/Gastrin and Receptors

M C Beinfeld, Tufts University School of Medicine, Boston, MA, USA

Discovery of Cholecystokinin

The biological activity that would eventually be called cholecystokinin (CCK) was discovered by Bayliss and Starling early in the twentieth century. They showed that intestinal acidification (which releases CCK) caused gall bladder contraction. Porcine intestinal CCK 33 was identified by Mutt and Jorpes in the 1960s. The name CCK/gastrin arose in 1975 with the discovery by Vanderhaeghen of CCK-like immunoreactivity in the brain with a gastrin antiserum which cross-reacted with CCK. It soon became clear based on its isolation by Dockray that this material was not gastrin, but CCK 8. Small amounts of gastrin are found in the brain and pituitary of several species.

Distribution of CCK

CCK is one of the most abundant neuropeptides in the brain, where it is widely distributed. It is also expressed in nerves and in endocrine cells in the intestine. Gastrin is highly homologous to CCK and may have arisen from CCK through gene duplication during evolution. CCK and gastrin share the same four C-terminal amino acids. Gastrin is expressed mainly in the stomach, with lesser amounts in the intestine, colon, and pancreas. Levels of gastrin in circulation are higher than CCK levels. Both peptides contain a sulfated tyrosine residue; CCK is completely sulfated, while some percentage of gastrin is not sulfated.

As mentioned, CCK is abundant and widely distributed in the brain. CCK-positive cell bodies are found in the cerebral cortex, amygdala (Amy), thalamus, hippocampus (Hi), olfactory bulb, and hypothalamus, and in various nuclei in the mesencephalon, ventral tegmental area (VTA), and substantia nigra (SN). The distribution of CCK cell bodies and their projections is shown in Figure 1.

CCK Biosynthesis

CCK is produced by a number of specific modifications of procholecystokinin (pro CCK) (Figure 2) as it passes through the secretory pathway. The sequence and structure of pro CCK and gastrin are similar and they both display tissue-specific processing. CCK 8 is the major form in brain, while intestine has larger forms.

The signal sequence of pre-pro CCK allows it to be inserted into the lumen of the endoplasmic reticulum (ER), where it is removed by the signalase enzyme located on the luminal surface of the ER membrane. Pro CCK is then folded and transported through the secretory pathway. In the trans-Golgi network (TGN), three out of four tyrosine residues in pro CCK are sulfated by protein tyrosine sulfotransferase, and pro CCK is sorted into secretory granules with the enzymes responsible for its processing. The processing of pro CCK occurs mainly at single Arg or Lys residues. The most likely candidate enzymes responsible for the endoproteolytic cleavages in CCK during its processing are the prohormone convertases (PCs), most notably PC1, PC2, and PC5. They are widely co-localized with CCK in the brain, and the inactivation of PC1 and PC2 causes tissue-specific decreases in CCK levels. After pro CCK is cleaved by PC-like enzymes, the extra arginine residues on the C-terminus of CCK 8 are removed by a carboxypeptidase-like enzyme, leaving a terminal glycine residue. The last step in CCK biosynthesis is the amidation of glycine-extended CCK peptides by peptidyglycine-α-amidating monooxygenase.

CCK Receptor Discovery and Distribution

The actions of CCK and gastrin are mediated through two distinct CCK receptors, called 1 and 2. The CCK 1 subtype requires the seven-amino-acid C-terminal peptide with its sulfated tyrosine residue. Unsulfated CCK 8, CCK 4, and gastrin are two to three orders of magnitude less potent. For the CCK 2 subtype, which detects gastrin equally and is sometimes called the gastrin receptor, only the four C-terminal amino acids are required. Both of these receptors have been cloned, and they share considerable homology. They are both classical seven-membrane-spanning domain receptors that interact with G-proteins after agonist binding.

Hundreds of CCK receptor antagonists have been synthesized; these differentiate between the CCK receptors and have allowed a detailed analysis of their pharmacology. Some selective agonists have also been made. The CCK 2 receptor is more abundant and widely distributed in the brain than is the CCK 1 receptor, although distinct populations of the CCK 1 receptor are present. The CCK 1 receptor is present on soma and fibers in the SN, VTA, nucleus accumbens (Acb), and dorsal striatum (DS), but not in the prefrontal cerebral cortex (PFC), Amy, or Hi. The CCK 2 receptor is present on soma and fibers in the SN, VTA, PFC, Acb, DS, Hi, and Amy.

Figure 1 Distribution of CCK neurons in the rat brain and pituitary. The solid circles represent CCK cell bodies and the straight lines represent their projections. Acb, nucleus accumbens; Amb, nucleus ambiguous; Amy, amygdala; AON, anterior olfactory nucleus; AP, anterior pituitary; Arc, arcuate nucleus of the hypothalamus; BST, bed nucleus of the stria terminalis; C, cerebellum; CC, corpus callosum; CPut, caudate-putamen; Cx, cerebral cortex; DMH, dorsal medial nucleus of the hypothalamus; EW, Eddinger–Westphal nucleus; Hi, hippocampus; ME, median eminence; NL, neural lobe of the pituitary; NST, nucleus of the stria terminalis; OB, olfactory bulb; PAG, periaqueductal gray; PVN, paraventricular nucleus of the hypothalamus; S, septum; SN, substantia nigra; SON, supraoptic nucleus of the hypothalamus; Th, thalamus; VMH, ventromedial nucleus of the hypothalamus; VTA, ventral tegmental area.

Figure 2 Sequence of mouse pro CCK. The cleavage sites are indicated by spaces and downward arrows; the CCK 8 sequence is underlined. CCK peptides are numbered backwards from the C-terminus of CCK 8. Stars mark the locations of the sulfated tyrosine residues. The order of cleavages producing CCK 8 is indicated by the roman numerals.

In the antrum of the stomach, CCK 2 receptors are present on D cells, while in the fundus, they are found on enterochromaffin-like cells, D cells, and parietal cells. CCK 1 receptors are found in the fundus on chief cells and in antral D cells and on pancreatic acinar cells in rodents but not humans. CCK 2 receptors are found in the pancreas on glucagon-producing cells in the islets.

The 'classical' biologically active processed forms of CCK and gastrin have a C-terminal amide moiety; however, glycine-extended CCK and gastrin peptides are also present. Both amidated and glycine-extended forms of CCK and gastrin are thought to promote growth of the gastrointestinal tract and may be involved in development and maintenance of gastrointestinal cancers. To better understand the trophic activity of glycine-extended CCK, effort has been expended in trying to clone a specific CCKGly or gastrinGly receptor. To date this has not succeeded.

CCK Receptor Structure and Function

The structure and activity of CCK receptors have been studied in great detail. Covalent chemical linkage of the peptide with the receptors followed by determination of where it binds has indicated that the two CCK receptors use different parts of their structure to bind the same ligands. The existence of receptors that are active in the absence of the peptide ligands (constitutively active) has been demonstrated and it appears that these receptors may contribute to gastrointestinal cancers.

Both the CCK 1 and the CCK 2 receptors have been shown to dimerize with each other. This dimerization

of the CCK 1 receptor was disrupted by binding of agonist, while CCK 2 receptor was not. The CCK 1 receptor has also been shown to dimerize with the CCK 2 receptor and to bind agonists normally. The receptor dimers displayed enhanced agonist-induced cell signaling and slower agonist-stimulated internalization. Cells expressing both receptors displayed enhanced growth, suggesting a possible role in cancer.

Intracellular Mediators of CCK Receptor Activation

The model that has been studied in the most detail is the rodent pancreatic acinar cell, which expresses mainly CCK 1 receptors. The AR42J pancreatic cell line and adrenal chromaffin cells which express the CCK 2 receptor have also been studied. In pancreatic acinar cells, CCK receptor activation recruits the heterotrimeric G-proteins G_q and G_{11} and results in increased levels of inositol trisphosphate, increased intracellular calcium, and activation of protein kinase C. CCK at higher concentrations can activate adenylate cyclase, increasing cyclic adenosine monophosphate (cAMP) levels. CCK also activates three mitogen-activated protein kinase (MAPK) cascades leading to extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK), and p38 MAPK. CCK also activates the nuclear factor-B (NF-B) pathway and the phosphatidylinositol 3-kinase/protein kinase B/molecular target of rapamycin (PI3K/PKB/m-TOR) pathway, which regulates protein synthesis. Activation of the CCK 2 receptor in gastric cancer cells activates protein kinase D2 and in human adrenal chromaffin cells it increases adenylate cyclase and cAMP.

Biological Activity of CCK

The actions of CCK in the brain are diverse and have been the subject of intense investigation. The development of specific agonists and antagonists and the use of rodent models that lack the receptors or the peptide have facilitated progress in elucidation of the functions of CCK. CCK released into circulation from the intestine following ingestion of food binds to CCK 1 receptors on the vagus nerve in the stomach and sends a signal to the brain to terminate the meal. CCK and leptin are thought to act together to reduce food intake.

CCK acting through the CCK 2 receptor on neurons in the rostral ventromedial medulla (RVM) has antiopiate activity. It inhibits morphine analgesia by inhibiting activation of pain-inhibiting output neurons of the RVM. CCK given into the RVM causes hypersensitivity that is antagonized by CCK 2 antagonist or by lesioning the dorsolateral funiculus. Continuous morphine produces sustained hypersensitivity that is reversed by CCK 2 antagonist and resulted in a fivefold increase in basal CCK levels in the RVM.

CCK is co-localized with dopamine (DA) in the VTA, and these neurons project to medial and posterior subdivisions (shell) of the Acb, the olfactory tubercle, and prefrontal cortex. CCK 1 receptors in the Acb shell display DA agonist-like activities (increased DA release and enhancement of DA-mediated behaviors), while in lateral portions of the Acb (core), CCK 2 receptors display DA antagonist-like activities (decreased DA release and inhibition of DA-mediated behaviors).

CCK acting through the CCK 2 receptor in the Hi is involved in spatial memory. CCK improves spatial memory in elderly rats and in rats in which DA has been depleted. CCK acting through the CCK 1 receptor is involved in maternal behavior and in infant–maternal recognition in sheep and in appetitive learning in infant rats. CCK released by a meal activates peripheral CCK 1 receptors to initiate these behaviors. CCK interacting with estrogen and endogenous opiates in the hypothalamus is involved in regulating sexual behavior in female rodents. A large body of literature has described the ability of CCK to trigger panic attacks in humans and to produce anxiety-related behaviors in rodents and primates. This is mediated through the CCK 2 receptor.

Cell Adhesion Molecules at Synapses

L F Reichardt and S-H Lee, University of California at San Francisco, San Francisco, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The structures and major intracellular interactions of several different synaptic adhesion molecules believed to play important roles at synapses are shown in Figure 1. One large class is the cadherin superfamily with more than 100 members which are defined by the presence of one or more ~110-amino-acid cadherin repeats in their extracellular domains. The cadherin superfamily is subdivided into classical or type I cadherins, atypical or type II cadherins, desmosomal cadherins, protocadherins, seven-pass transmembrane cadherins, Fat cadherins, etc. A second large group of adhesion molecules is the immunoglobulin (Ig) superfamily, members of which contain varying number of extracellular Ig domains. In some Ig superfamily members fibronectin type III (FNIII) repeats are inserted between the Ig and transmembrane domains. Neural cell adhesion molecule (NCAM), synaptic cell adhesion molecule (SynCAM), L1, the nectins, Side kicks (Sdk), synaptogenesis (SYG)/nephrin, dendrite arborization and synaptic maturation1 (Dasm1), synaptic adhesion-like molecule (SALM), leukocyte common antigen-related-receptor proteintyrosine phosphatases (LAR-RPTPs), and many other members of this family have been reported to play roles in synapse development in both vertebrates and invertebrates (Table 1). The neuroligins and neurexins are heterophilic adhesion molecules characterized by the presence of an acetylcholine esterase-like domain in the former and 1–6 LNS (laminin A, neurexin, sex hormone-binding protein) domains in the latter. Multiple genes and extensive splicing generate many isoforms of these proteins that promote differentiation of both excitatory and inhibitory synapses. Interactions mediated through constituents of the extracellular matrix (ECM) are essential for synapse development at the neuromuscular junction (NMJ), and also appear to be important modulators of central nervous system (CNS) synapse development and function. Both classical ECM receptors (including integrins and the dystroglycan complex) and novel receptors (such as the receptor tyrosine kinase MUSK) mediate synapse development through ligation to ECM constituents. Virtually all of the synaptic adhesion molecules described above interact with scaffolds and other proteins within the cytoplasm. These interactions function to localize synaptic adhesion molecules at synapses and to permit efficient activation of intracellular signaling cascades after synaptic adhesion molecule ligation. Many synaptic adhesion molecules contain PDZ (PSD-95/Dlg/ZO-1) domain-binding, polyproline and other motifs which interact with PDZ, SH3, and other domains of scaffold proteins. Scaffold proteins act as key organizers to control localization of SNAREs, receptors, other synaptic proteins and organelles on both sides of the synapse.

Classical Cadherins

Classic cadherins are a family of calcium-dependent, homophilic, cell–cell adhesion molecules that have been implicated in many developmental processes. Several studies indicate that N-cadherin functions as a synaptic recognition molecule. In *Drosophila*, absence of N-cadherin prevents synapse formation by the axons of photoreceptors in the medulla. The axons from the individual photoreceptors fail to establish stable connections with their target neurons in the medulla. Although analyzed in less detail, inhibition of cadherin function in the chick optic tectum also disrupts synapse formation by the axons of retinal ganglion cells. Extrapolating from these observations, it seems highly likely that a large number of cadherin members expressed in the vertebrate CNS also affect synapse formation with many having overlapping and redundant functions. Mutation of cadherin-11 has been shown to result in enhanced synaptic plasticity (long-term potentiation (LTP)) in the hippocampus through unknown mechanisms.

Much of the progress in understanding the roles of cadherins in forming adhesive junctions has been made in studies of epithelial adherens junctions that share many molecular components with neuronal synapses. These discoveries have provided important insights into the pathways regulating synapse formation. The 'core' cadherin complex is composed of a cadherin bound through its cytoplasmic domain to β-catenin which is bound in turn to α-catenin. In addition, the membrane-proximal portion of the cadherin cytoplasmic domain interacts less strongly with members of the p120 catenin family (p120 catenin, δ-catenin, p0071, and ARVCF). p120 catenins have been shown to regulate cadherin surface stability and clustering as well as regulate Rho-family GTPases. Cadherin adhesion regulates organization of the actin cytoskeleton via several pathways through (1) direct interaction of α-catenin with actin or actin-binding proteins, including α-actinin, vinculin, spectrin, afadin,

Figure 1 Structures and interactions of synaptic adhesion molecules. Top row of three diagrams illustrate interactions of the classical cadherin complex (left), protocadherin complex (middle), and neuroligin/neurexin complex (right). The second row depicts complexes formed by N(neural)CAM (left), L1-family CAMs (middle), and nectins (right). The bottom row illustrates interactions mediated as a result of integrin–ECM interactions (left), agrin/MUSK/dystroglycan interactions (middle), and laminin $\beta 2$–calcium channel association (right). A lower power schematic of the NMJ is depicted at the lower right corner of this figure. Agrin, laminin $\beta 2$, and laminin $\alpha 4$ chain-containing laminin trimers reside in the basal lamina depicted in this figure, while the agrin receptor MUSK is localized to the muscle plasma membrane. The three EGF-like repeats are not depicted in the β-neurexin structure. Pre, presynaptic compartment; Post, postsynaptic compartment; VDCC, voltage-dependent calcium channel; SC, Schwann cells. See text for details.

Table 1 Roles of adhesion molecules at the synapse

Function	*Molecule*	*Class*	*Place of action*	*Comment*
Target recognition	N-cadherin	Cadherin	Chick optic tectum, *Drosophila* visual system	Synaptic recognition
	Protocadherins	Cadherin	CNS?, spinal cord	Determination of synaptic connectivity
	Flamingo	Cadherin	*Drosophila* visual system	Interactions of R-cell growth cones with target neurons
	Neurofascin	Ig	Mouse GABAergic cerebellar Purkinje cells	Subcellular specification of GABAergic synapses
	Sidekick	Ig	Mouse retina	Lamina-specific synaptic connectivity in inner plexiform layer
	Nectin	Ig	Hippocampal pyramidal neurons	Regulation of axon–dendrite interactions
Induction and maturation of synapse	SynCAM	Ig	Hippocampal pyramidal neurons	Induction of synaptic differentiation
	Dasm, SALM	Ig	Hippocampal pyramidal neurons	Promotion of surface AMPA receptor expression and synaptic maturation
	LAR-RPTP	Ig	Hippocampal pyramidal neurons	Promotion of surface AMPA receptor expression and synaptic maturation
	Neuroligin/ β-neurexin		Hippocampal pyramidal neurons	Induction of synaptic differentiation
	Laminin β2 Laminin β4	ECM	Neuromuscular junction (NMJ) in *Drosophila* and mouse	Organization of active zone, alignment and maintenance of NMJ
	Reelin	ECM	Mouse cortex and cerebellum	Maturation of CNS synapses
	Syndecan-2	Proteoglycan	*Drosophila* NMJ, hippocampal pyramidal neurons	Postsynaptic maturation
	Versican	ECM proteoglycan	Chick optic tectum	Lamina-specific cue for presynaptic maturation of retinal ganglion axons
	CPG15 (neuritin)	GPI-linked surface protein	Motor neurons	Regulation of axonal branching and synapse maturation
Synaptic plasticity	Cadherin-11	Cadherin	Hippocampal pyramidal neurons	Regulation of hippocampal LTP
	NCAM, FasII, apCAM	Ig	Vertebrate CNS, *Drosophila* NMJ and *Aplysia* sensory neurons	Regulation of new synapse formation and structural synaptic plasticity
	Integrins	ECM receptor	Central excitatory synapse	Modulation of NMDA-mediated synaptic currents and synaptic plasticity

ZO-1, and formin-1 and through (2) regulation by p120 catenins of Rho GTPases and cortactin. Numerous kinases and phosphatases regulate the properties, stability, and interactions of the cadherin complex, including the protein kinases Cdk5, casein kinase I, Fyn, Yes, and Fer, and the protein tyrosine phosphatases PTP-μ, LAR, SHP1/2, and PTP1B. In addition to regulators of the actin cytoskeleton, the proteins in the cadherin complex interact with many additional proteins that control intracellular signaling pathways, including transcriptional regulators like Kaiso and T-cell factors (TCFs), scaffold proteins (such as A-kinase anchoring protein (AKAP)), and cytoplasmic enzymes including PI3 kinase, Cdk5, and receptor tyrosine kinases, plus cytoplasmic motor proteins and other proteins including presenillin. In addition, β-catenin and δ-catenin interact with PDZ-containing scaffold proteins that also mediate their synaptic functions.

Several of the catenins appear to function as effectors of cadherins in controlling synapse development. β-Catenin functions as a scaffold to localize synaptic vesicle pools to synaptic sites. The presence of α-N-catenin is required for normal spine maturation and stability. The absence of either δ-catenin or p120 catenin severely perturbs central synapses. Absence of p120 catenin reduces dramatically the density of dendritic spines and synapses. Absence of δ-catenin results in gross abnormalities in synaptic function and plasticity. In part, these proteins may function through regulation of the small G-proteins: Rac and Rho. They may also function through stabilization of surface cadherins or through regulation of tyrosine phosphorylation and control of cortactin activity.

Protocadherins

Protocadherins are characterized by the presence of four to seven extracellular cadherin (EC) motifs, which are distinguishable from those present in other cadherin members, and absence of the conserved

motifs in the classic cadherins that mediate interactions with β-catenin and p120 catenin family members. About 80 different protocadherins have been identified and genes of nearly 60 members are tandemly arrayed in three clusters: the α-, β-, γ-protocadherin genes (*Pcdh*-α, -β, and -γ) on a single chromosome in mammals. (α-Protocadherins are also known as CNRs, cadherin-related neuronal receptors.) Recent phylogenetic analysis has characterized several conserved motifs shared by an additional subfamily of protocadherins, the δ-protocadherins, whose genes are located on several different chromosomes. These include Pch1, Pch7, Pch8 (arcardlin), Pch9, and Pch11. The *Pcdh*-α and *Pch*-γ clusters contain two large genomic regions, with tandem arrays of large exons expressing the variable extracellular domains followed by a set of common exons, each encoding a small portion of the shared C-terminal cytoplasmic domain. *Pch*-β lacks a shared constant region. Protocadherins are highly expressed in the CNS with individual members differentially expressed in subsets of neurons, suggesting that they help generate specific synaptic connections within the CNS. Genetic deletion of the *Pch*-γ locus results in a reduction of inhibitory synapse density in the spinal cord. The mechanisms through which the protocadherins regulate synaptogenesis are not well understood. The strength of homophilic adhesion mediated by the extracellular domains of the protocadherins appears to be weaker than adhesion mediated by classic cadherin interactions. Recent evidence suggests that some protocadherins function through regulation of classic cadherin adhesion. Protocadherins may also have noncadherin proteins as ligands. For example, at least one of the Pch-α isoforms, Pch-α4, interacts through its RGD motif with β1 integrins. Protocadherin-7 interacts with PP1, a protein tyrosine phosphatase that dephosphorylates AMPA receptors and CAM kinase II.

NCAM

NCAM was the first Ig superfamily member reported to function at the synapse. NCAM is encoded by a single gene with three isoforms of 180, 140, and 120 kDa produced by alternative splicing. The two larger isoforms are transmembrane proteins, differing in the presence of a differentially spliced exon that encodes an insert in the cytoplasmic domain, whereas NCAM-120 is a glycophosphatidyl inositol (GPI)-linked protein that lacks a transmembrane and cytoplasmic domain. All isoforms have five Ig domains followed by two FNIII repeats. The NCAMs are believed to mediate both homophilic and heterophilic interactions. Recently identified interacting partners include the Ig-family cell adhesion molecule L1, the fibroblast growth factor (FGF) receptor, laminin, and some integrins. Intracellular partners include the protein tyrosine phosphatase RPTPα, the tyrosine kinase p59Fyn, and spectrin. The most remarkable feature of NCAM is that it is virtually the sole acceptor for long linear homopolymers of α2,8-linked sialic acid residues (polysialic acid, PSA). The major phenotypes of the NCAM knockout can be mimicked by the enzymatic removal of PSA, indicating that the major essential function of NCAM is to provide a substrate for PSA addition, which is highly charged, thereby increasing the volume of extracellular space and inhibiting adhesive interactions mediated through other cell adhesion molecules.

In vivo and *in vitro* results have demonstrated that NCAM regulates synaptic maturation at the NMJ and hippocampal synaptic plasticity (LTP), in part through associated PSA homopolymers. The NCAM homologs in invertebrates, *Drosophila* fasciclin II (FasII) and *Aplysia* apCAM, are involved in synapse growth, stability, and plasticity, and the expression of each is regulated by neuronal activity. Of particular interest, fasciclin II has been shown to function as both a permissive and restrictive regulator of synapse growth at the *Drosophila* NMJ, depending upon the comparative pre- and postsynaptic levels of this protein. The ability of fasciclin II to promote new synapse formation requires the presence of the *Drosophila* orthologs of amyloid precursor protein and the scaffold protein Mint. Fasciclin II forms a complex with each of these proteins, the latter through its PDZ-interaction motif. In *Aplysia* sensory neurons, downregulation of the NCAM homolog, apCAM, is required for the serotonin-induced enhancement of synaptic varicosity formation that accompanies synaptic facilitation. Normally, apCAM is downregulated following synaptic facilitation as a result of phosphorylation at a putative mitogen activated protein (MAP) kinase site. Overexpression of apCAM in sensory, but not motor neurons, completely suppresses the formation of new varicosities without interfering with the activation by serotonin of CREB. Thus, studies in both *Drosophila* and *Aplysia* indicate that NCAM homologs are important effectors of signaling pathways that control synaptic structural plasticity.

L1-Family CAMs

The L1-type cell adhesion molecules are glycoproteins with six Ig, five FNIII, a single transmembrane, and a cytoplasmic domain. Four members (L1-CAM, Neurofascin, Nr-CAM, and CHL-1) have been identified in vertebrates while *Drosophila* has only one homolog, Neuroglian. L1-type CAMs mediate several aspects of neuronal development, including neuronal migration, neurite extension, axon

pathfinding, myelination, fasciculation, synapse targeting, and LTP. Among these family members, the role and function of L1 have been particularly intensely studied. In addition to binding L1 molecules present on other cells, L1 associates with additional ligands, including the proteoglycan neurocan, several RGD-binding integrins, and the CAMs axonin-1/TAG, and contactin/F3/F11. L1 also interacts with the axon guidance receptor neurophilin in both *cis* and *trans* forms to form a receptor for Semaphorin 3A.

Of particular interest, localization of neurofascin at the initial axon segment of cerebellar Purkinje neurons results in specific localization of GABAergic synapses to this same region of the axon. At early stages of development both GABAergic synapses and neurofascin are less well localized. Refinement of neurofascin localization precedes and is required for localization of the GABAergic synapses. Neurofascin binds with high affinity to an isoform of ankyrin, an intracellular adaptor protein which is localized also to the initial axon segment and provides a scaffold for association with β-spectrin and the F-actin cytoskeleton. These interactions are required to localize both neurofascin and the GABAergic synapses. Observations in other CNS regions indicate that other L1 CAM family members are also preferentially localized to subdomains of neurons. It seems likely that they also help localize synapse formation. A number of human brain disorders have been linked to mutations in the L1 gene and L1 knockout mice reproduce several aspects of these phenotypes. It will be interesting to determine whether any aspects of the phenotypes associated with these disorders result from mis-targeting of synapses.

Other Synaptic Ig Superfamily Members

SYG-1 is a member of the Ig superfamily identified in a genetic screen for synapse mutants in *Caenorhabditis elegans* that contains four Ig's, a single transmembrane, and a cytoplasmic domain with a PDZ interaction motif. SYG-1 regulates the position of presynaptic terminal differentiation by HSNL axons which innervate the vulval muscles. It is related to *Drosophila* Duf/Kirre and the three vertebrate NEPH proteins that are important for organization of the slit diaphragm in the kidney glomerulus. SYG-1 binds to SYG-2, which has six Ig domains and one FNIII domain and is expressed transiently by primary vulval epithelial cells during synapse formation. SYG-2 provides an intermediate target that focuses accumulation of SYG-1 and synaptic vesicles. The mammalian homolog of SYG-2 is nephrin whose presence in podocytes is also essential for organization of the slit diaphragm in the kidney. The roles of the NEPH family and nephrin in vertebrate synapses are not yet known, but recent work, stimulated by the observations in *C. elegans*, has documented their expression patterns in the CNS. In addition, the NEPH proteins have been shown to interact with CASK, a constituent of the CASK/MINT/Veli complex, which is thought to participate in pre- and postsynaptic organization. Since both nephrin and the NEPH proteins are expressed in the CNS, it will not be surprising if they prove to have important functions there.

The Sdk CAMS, Sdk-1 and Sdk-2, contain six Ig domains, 13 FNIII repeats, a single transmembrane domain, and a cytoplasmic domain terminated by a PDZ domain-binding motif. Interestingly, in the retina the Sdk-1 and Sdk-2 proteins are found in nonoverlapping subsets of presynaptic (amacrine and bipolar) and postsynaptic (ganglion) cells that project to common inner plexiform (synaptic) sublaminae. Sdk-positive synapses are confined to specific sublaminae, and ectopic expression of Sdk in Sdk-negative cells redirects their arbors to Sdk-positive sublaminae, implying that the Sdk's may control laminar specificity within the retina. The interactions and signaling mechanisms controlled by the Sdks that regulate synapse location are not known.

Dasm1 is a recently reported Ig family member with five Ig-like domains, two FNIII domains, and a cytoplasmic domain with a C-terminal PDZ domain-binding motif. Dasm has been shown to promote dendritic elongation and branching as well as the maturation of excitatory glutamatergic synapses. Dasm interacts with PDZ-containing scaffold proteins, including Shank and S-SCAM. In its absence, α-amino-3-hydroxy-5-methylsoxazole propionate (AMPA) receptor-mediated, but not *N*-methyl-D-aspartate (NMDA) receptor-mediated, synaptic transmission is severely impaired in cultured hippocampal neurons. A Dasm mutant lacking the PDZ-interaction motif does not promote AMPA receptor-mediated synaptic transmission. The extracellular ligands for Dasm have not been identified.

The SALMs are another recently characterized family of five synaptic adhesion molecules (SALM1–5) that contain six leucine-rich repeats plus single Ig and FNIII repeats in their extracellular domains. The SALMs are transmembrane proteins with cytoplasmic domains terminated by a PDZ domain-binding motif. Some members of the SALM family have been shown to promote excitatory synapse formation through interactions with PSD-95 and other cytoplasmic scaffold proteins. Members have also been shown to interact with NMDA and AMPA receptors. It is not clear whether they function as typical cell adhesion molecules by mediating adhesion with other cells.

The four nectins (nectin 1–4) are transmembrane proteins containing three extracellular Ig-like repeats and a cytoplasmic domain terminated by a PDZ domain-binding motif. While each of the nectins mediates homophilic adhesion, they promote stronger heterophilic adhesion with other family members. Several nectins also interact with the integrin $\alpha_V\beta_3$. Each of the nectins interacts with the F-actin-binding protein afadin, thereby anchoring the nectins directly to the F-actin cytoskeleton. Through afadin-mediated interactions with α-catenin, the nectins recruit and collaborate with the cadherins to promote formation of adherens junctions in epithelial cells. Afadin also binds the small G-protein Rap1. The Rap1–Afadin complex has been shown to interact with p120 catenin and through p120 catenin to activate cadherin-mediated adhesion. Active (GTP-bound) Rap promotes maturation of dendritic spines in the CNS and it seems possible that this is, in part, through regulation of the afadin–nectin–cadherin complex. Nectin-1 is preferentially expressed in axons. Preferential engagement of heterophilic adhesion between axonal nectin1 and dendritic nectin3 may provide a basis for the preferential interactions of axons with dendrites versus other axons.

Members of the LAR family of receptor protein tyrosine phosphatases are transmembrane proteins with each containing three Ig and eight FNIII domains plus two cytoplasmic tyrosine phosphatase motifs. The cytoplasmic domains of these proteins interact with liprin-α/SYD-2, which binds to the PDZ-containing scaffold protein GRIP. This interaction promotes the surface expression and clustering of receptors at postsynaptic sites. In *Drosophila* and *C. elegans*, LAR and liprin-α have been also implicated in presynaptic terminal differentiation. In *Drosophila*, LAR-mediated synaptic differentiation is regulated by interactions of LAR with the cell surface-associated proteoglycans syndecan and dally-like. In cultured hippocampal neurons, LAR is concentrated at mature excitatory synapses where it promotes their development and maintenance through enhanced spine formation and surface AMPA receptor expression.

The four members of the SynCAM family (also known as nectin-like proteins) constitute a small subset of the Ig superfamily, each member of which contains three extracellular Ig domains and a PDZ-interacting motif in its short cytoplasmic domain. They were identified in a genomic search for members of the Ig superfamily capable of interacting with PDZ-domain-containing scaffolds. Similar to many other Ig family members, the SynCAMs mediate homophilic cell–cell adhesion. SynCAM1 is highly enriched in both presynaptic and postsynaptic membranes of neurons, whereas SynCAM3 is found in nonjunctional contact sites of presynaptic nerve terminals, axons, and glia cell processes. Clustering of SynCAM1 is sufficient to trigger differentiation of functional presynaptic terminals. SynCAM1 overexpression also increases synaptic function in immature excitatory neurons. Interactions mediated through association with PDZ-domain-containing scaffolds are essential for its synapse-inducing activities. The PDZ domain-binding motif in SynCAM binds to the PDZ domains present in CASK and syntenin.

Finally, another family of Ig superfamily members, named the netrin-G ligands (NGLs), have recently been implicated as regulators of synapse formation. The structure of the NGLs includes leucine-rich repeats plus an Ig domain in their extracellular domains, a single-pass transmembrane domain and a cytoplasmic domain terminated by a PDZ domain-binding motif. Three genes encode members of this family whose diversity is further increased by extensive differential splicing. The NGLs interact with the two members of the netrin-G family, proteins associated with the cell membrane through GPI motifs that are structurally related to, but functionally distinct from, the classical netrins that regulate axon guidance. The NGLs bind PSD-95, and NGL2 forms a complex in the brain with PSD-95 and NMDA receptors. Clustering of NGL2 has been shown to promote postsynaptic differentiation of excitatory, but not inhibitory synapses. NGL2 also induces presynaptic differentiation by contacting axons *in vitro* and it seems likely, although not proved, that differentiation is mediated through binding to netrin-Gs. Thus, interactions of the NGLs with nectin-G-proteins appear to be able to promote both pre- and postsynaptic differentiation *in vitro* and are strong candidates to control both the formation and specificity of synapse formation *in vivo*.

Neurexins and Neuroligins

Neuroligins are composed of a cholinesterase-like domain, an *O*-glycosylation region, a single transmembrane domain and a short C-terminal cytoplasmic tail containing a PDZ-binding motif. Three genes encoding neuroligins are present in the rat and mouse while five are present in the human genome. The first neurexin to be characterized was identified as a receptor for the spider venom constituent α-latrotoxin. There are three neurexin genes, each of which encodes two neurexin isoforms with one promoter initiating transcription of a long mRNA encoding α-neurexin isoforms while a second promoter located within an intron initiates transcription of a shorter mRNA encoding β-neurexin isoforms. The extracellular domain of α-neurexin contains three

epidermal growth factor (EGF)-like domains, each of which is flanked by a pair of LNS domains. Instead of six LNS domains, only one is present in the β-neurexins, which lack all of the EGF repeats. The extracellular domains of both α- and β-neurexins are followed by a transmembrane domain and a cytoplasmic domain containing a C-terminal PDZ-interacting site. Differential splicing of the transcripts from each of the neurexin and neuroligin genes generates a tremendous number of variants of each protein family. Recent results have demonstrated that splicing controls the specificity of neurexin–neuroligin interactions as well as their activities in promoting excitatory and inhibitory synapse formation. In addition to binding neuroligins, some, but not all isoforms of neurexins interact with dystroglycan.

On cultured hippocampal neurons, clustering of the β-neurexins or neuroligins triggers pre- or postsynaptic differentiation, respectively. In contrast to SynCAM, however, neuroligin overexpression does not result in enhanced synaptic transmission in immature excitatory neurons. Similar to the SynCAMs, the synapse-promoting activities of these proteins are dependent on their interactions with PDZ-containing scaffold proteins. The PDZ-interacting motif in neuroligin interacts with PSD-95 (which recruits AMPA and NMDA receptors) as well as with S-SCAM (which interacts with AMPA receptors and β-catenin). β-Neurexin interacts with the CASK/Mint/Veli complex, which is proposed to act as a scaffold for synaptic vesicle transport and localization. β-Neurexin also interacts with syntenin, which has recently been shown to interact with the presynaptic cytomatrix active zone protein ELKS/ERC2/CAST1, which binds in turn several additional active zone proteins, including piccolo, bassoon, and RIM. Interestingly, neuroligin1 is mainly localized to excitatory, whereas neuroligin2 is localized at inhibitory synapses. Overexpression and knockdown experiments *in vitro* suggest that the expression levels and localization of different neuroligins may play a crucial role in controlling the ratio of excitatory and inhibitory synapses. Mutations in human neuroligin genes are associated with a small percentage of autistic individuals.

ECM-Mediated Interactions

ECM molecules regulate synapse development in both the central and peripheral nervous systems. At the NMJ, several constituents of the basal lamina have been shown to be essential for normal synapse formation. Most importantly, the presence of nerve-derived agrin in the basal lamina and its receptor, the tyrosine kinase MUSK, in muscle are absolutely necessary for synapse formation and maintenance. In addition, several subunits of laminin also play important roles. The presence of the laminin $\beta 2$ subunit in the laminin trimer within the synaptic basal lamina appears to play two distinct roles. First, this subunit prevents invasion of the synaptic cleft by Schwann cells, thereby preserving communication between the motor axon terminal and the muscle surface. Second, this subunit directly binds to N-type calcium channels. In its absence few active zones are seen at NMJs, even at sites where Schwann cells have not invaded the synaptic cleft, and synaptic transmission is severely impaired. In contrast, although synaptic transmission is not impaired in its absence, the laminin $\alpha 4$ subunit functions to ensure proper alignment of active zones in the nerve terminal with folds in the postsynaptic muscle membrane. In laminin $\alpha 4$ mutants, the active zones and folds are no longer aligned with each other. Laminin $\alpha 4$ is largely excluded from the small regions of basal lamina aligned with the active zones and muscle folds, suggesting that it may inhibit the formation of these specializations. In addition to MUSK, the integrins and dystroglycan complex function as receptors for basal lamina proteins at the NMJ. Absence of $\beta 1$ integrins severely impairs NMJ. Mild deficits are observed in the absence of some constituents of the dystroglycan complex.

Although there have been many studies, there are less obvious roles for ECM constituents at synapses in the CNS. The ECM glycoprotein reelin, best known for its role in controlling neuronal migration in the cortex and cerebellum, also promotes maturation of many CNS synapses through the same signaling pathway important for its role in cell migration – Src-family kinase-mediated phosphorylation of Dab, following engagement of the reelin receptors VLDLR and apoER2. Several additional ECM receptors also affect synapse maturation. For example, the cell surface proteoglycan syndecan-2 is enriched in the mammalian hippocampus and promotes morphological maturation of dendritic spines in cooperation with the receptor tyrosine kinase EphB2. Syndecan-2 is a transmembrane glycoprotein with a cytoplasmic PDZ-interacting motif, which interacts with CASK, syntenin, and synbindin. As described previously, syndecan regulates LAR in *Drosophila*.

In *Drosophila*, elegant studies have demonstrated a crucial role for integrins in memory formation in the mushroom body. In hippocampal neuron cultures, several studies have demonstrated important roles for integrins in promoting synapse maturation. *In vivo* studies have shown that inhibition of RGD binding or β_1 integrin function through genetic or pharmacological techniques impairs long-term plasticity. Ligand engagement by integrins results in activation of several intracellular signaling cascades including those

initiated by Src-family, focal adhesion kinase, and integrin-linked kinases, plus recruitment of scaffolds and adaptor proteins, such as talin and paxillin that lead to reorganization of actin cytoskeleton.

Concluding Remarks

Much exciting evidence demonstrating important roles of synaptic adhesion molecules has been accumulated recently in both *in vivo* and *in vitro* model systems. We anticipate that future studies focusing on the crosstalk between different adhesion molecules will further illuminate our understand of synapse development and function.

Cell Culture: Autonomic and Enteric Neurons

P J Lein, A D Fryer, and D Higgins[†], Oregon Health and Science University, Portland, OR, USA

Introduction

The autonomic nervous system, which is responsible for maintaining homeostasis, is divided into the sympathetic and parasympathetic nervous systems. Each system is defined anatomically by preganglionic neurons located in the central nervous system, the axons of which synapse on postganglionic neurons located in the periphery, which in turn directly innervate target organs. While there are published examples of the isolation and maintenance of preganglionic autonomic neurons in culture, it is the peripheral postganglionic neurons that have principally been isolated for tissue culture, and these are the focus of this article. Also discussed is tissue culture of the enteric nervous system, which is distinct from the autonomic nervous system, but, like the sympathetic and parasympathetic nervous systems, is derived from the neural crest.

The culture of autonomic neurons, specifically postganglionic sympathetic neurons, has a long and rich history in neurobiological experimentation. Intact sympathetic ganglia maintained in culture as explants were first described by Lewis and Lewis in 1912, and the observation that a soluble factor produced by a mouse sarcoma stimulated profuse outgrowth of neurites from sympathetic explants in culture led to the discovery of nerve growth factor (NGF) by Levi-Montalcini and colleagues. Since this seminal discovery, sympathetic neuronal cultures have proved to be a powerful tool for identifying additional neurotrophic factors and for elucidating the molecular mechanisms by which NGF and these other factors regulate neuronal survival, differentiation, and function. Beyond this application, primary cultures of sympathetic neurons continue to be a popular and robust model system for elucidating basic cell and molecular mechanisms of neuronal development and differentiation, and for studying cell and molecular mechanisms underlying sympathetic physiology and pharmacology. With the exception of the chick ciliary ganglion, primary cultures of parasympathetic and enteric neurons have not been as widely used, and studies employing these culture models have focused largely on the electrophysiological and pharmacological properties of these neuronal cell types.

Neural Crest Cells

All the cells of the sympathetic, parasympathetic, and enteric nervous systems are derived from the neural crest. The neural crest also gives rise to cell types other than peripheral neurons and glia, and because of this vast repertoire and the fact that differentiation of neural crest cells is strongly influenced by environmental factors, neural crest cell differentiation has emerged as a powerful model system for identifying basic developmental principles governing the generation of diverse cell types in not only the peripheral but also the central nervous system. Neural crest cells have been cultured successfully from both rodent and avian species, and detailed descriptions of techniques for isolating and maintaining neural crest cells from these sources have been published. The development of neural crest cell culture proved critical for confirming that premigratory neural crest cells are pluripotent, and clonal analyses of cultured neural crest cells have yielded much of the experimental evidence upon which is based our current understanding of neural crest cell fate restriction as a function of developmental timing and location along the migratory pathway.

Cultured neural crest cells remain a popular model for identifying environmental cues that influence the migratory behavior and differentiation of neural crest cells, including those progenitor cells that give rise to the sympathetic and enteric nervous systems. For example, the isolation and culture of a sympathoadrenal progenitor from migrating neural crest cells was instrumental in identifying the roles of fibroblast growth factor (FGF) and glucocorticoids in determining whether these progenitor cells differentiate into sympathetic neurons or adrenal chromaffin cells. Studies of cultured sympathoadrenal progenitor cells were also critical for demonstrating that FGF induced NGF responsiveness in these cells, providing some of the first evidence that differentiation signals involve a cascade of responses to multiple agents. Culture of crest-derived cells immunoselected from within the bowel provided critical confirmation of *in vivo* observations suggesting that laminin promoted neurogenesis of enteric precursor cells. This model system has since been used to identify additional factors that promote differentiation of both enteric neurons and glia. Other applications of crest cell cultures include determination of the intracellular signaling pathways that mediate the effects of environmental cues on migration and differentiation of sympathetic and enteric precursors, and

[†]Deceased

the identification of genomic and proteomic profiles associated with specific states of determination.

Sympathetic Neurons

Sympathetic neurons have been cultured from prevertebral and paravertebral ganglia isolated from diverse species, ranging from bullfrogs to humans, at varying developmental stages, including early embryonic development of the ganglia, when a significant percentage of ganglionic neurons are still undergoing cell division, as well the mature and even aging organism. However, cultures of sympathetic neurons are most commonly derived from prenatal (19–21 days) or early postnatal (1–14 days) rat superior cervical ganglia or embryonic chick chain ganglia. The easiest type of culture to prepare is an explant in which the intact ganglion is maintained in culture. Because of the profuse outgrowth of neurites from explanted ganglia, this preparation has been used extensively as a bioassay for neurotrophic factors and for studies of axonal growth cone behavior, including the identification of attractive and repulsive axonal guidance cues. Dissociated cultures, however, allow visualization of neurons in their entirety, which facilitates electrophysiological recording and microinjection and enables studies of sympathetic structure and function at the subcellular level. A third culture paradigm that has been used with sympathetic neurons is the Campenot chamber, in which the media bathing distal axons is physically separated from that bathing neuronal cell bodies and proximal processes (see Figure 1). This culture system consists of attaching a compartmented Teflon insert to a collagen-coated substrate using vacuum grease. Neurons are plated into one compartment and axons grow under the grease barriers into adjacent compartments. Axons are encouraged to grow through the grease barrier by scoring parallel tracks in the collagen substrate prior to attaching the Teflon insert, such that the tracks run from the left compartment into the right compartment. These tracks expose the tissue culture plastic that the axons will not grow across. When assembled correctly, minimal exchange of fluids or solutes takes place between compartments, which allows various factors to be presented selectively to neuronal cell bodies or distal axons and permits selective biochemical analyses of individual compartments. Data collected using these compartmented cultures have significantly advanced our understanding of the molecular mechanisms of anterograde and retrograde signaling. Campenot chambers have also been used successfully with sensory neurons, but to date there are no published articles reporting its adaptation to central neurons. (Detailed protocols for harvesting, plating, and maintaining sympathetic neurons using each of these three culture paradigms are provided in the literature listed under 'Further reading.')

Hundreds of articles have been published describing the behavior of sympathetic neurons in tissue culture. This system has proved popular for several reasons. First, these neurons are relatively easy to isolate, since sympathetic ganglia are prominent, anatomically discrete entities that are accessible at varying life stages, ranging from early ganglionic development (embryonic days 14 and 15 in the mouse and rat, respectively) through adulthood. Second, this preparation yields one of the most homogeneous neuronal cell populations available in vertebrates. Sympathetic ganglia contain a large population of principal neurons (>20 000 in the rat superior cervical ganglion), a small population (approximately 300 cells) of interneurons or small intensely fluorescent cells (SIF), and ganglionic glial cells. Ganglionic glial cells and other nonneuronal cells can be eliminated in culture using antimitotic agents, and interneurons do not survive in

Figure 1 Schematic of Campenot compartmented chambers. (a) Top view, showing neurons plated in the center chamber of the classic Campenot Teflon insert (Camp10, available from Tyler Research Corporation, Edmonton, Alberta, Canada). Neurons typically extend axons under the barriers into the adjacent side chambers within 7 days after plating. (b) Side view, showing neurons plated in the far left chamber that have extended axons through the center chamber and into the far right chamber.

dissociated cell culture in standard serum-free culture media. Thus, changes in these cultures in response to an experimental manipulation tend to be uniform throughout the cell population. Third, the growth factor requirements of sympathetic neurons are well established, which allows the use of defined medium, and a variety of defined media and substrates work well for growing and maintaining sympathetic neurons. These neurons will grow in either the absence or presence of glia or target cells and can be maintained for up to 6 months in culture. Most importantly, when grown under the appropriate *in vitro* conditions, cultured sympathetic neurons express many of the properties expected of mature sympathetic neurons *in situ*, including synthesis and release of norepinephrine, normal electrophysiological properties and responsiveness to appropriate neurotransmitters, and a dendritic morphology that approximates that seen *in situ*. Finally, a wealth of data in the peer-reviewed literature facilitates correlation of *in vitro* and *in situ* sympathetic development, function, and plasticity. The most significant limitations of the model include the limited amounts of RNA and protein available from the sympathetic ganglia, which may restrict biochemical studies, and difficulty in manipulating gene expression. Recent advances in techniques for expressing cDNA in primary neuronal cell cultures are rapidly overcoming this latter disadvantage. There are publications reporting the successful application of lipid-based delivery systems (specifically, Lipofectamine 2000; Invitrogen), nucleofection (Amaxa), and adenoviral vectors to cultured sympathetic neurons. The reported transfection efficiencies are relatively low (ranging from 10% to 20%, with lipofection and nucleofection up to 30% to 50% with viral infection), which is adequate for endpoints based on individual cell analyses, such as morphological analyses, but may be problematic for many biochemical endpoints.

Sympathetic cultures offer particular advantages for the study of neuronal development and plasticity. The development of sympathetic neurons is critically dependent on their environment, and this plasticity is retained in tissue culture, where mechanisms can be more readily studied. It should be noted, however, that the plasticity exhibited by sympathetic neurons in culture has some practical disadvantages. The morphological, electrophysiological, and pharmacological properties of these neurons can be affected by basic parameters of the culture system, including cell density, serum, substratum, and media components such as insulin and potassium. Thus it is necessary to be certain that the culture conditions chosen are appropriate for a particular study. Nonetheless, studies of cultured sympathetic neurons have provided significant insights in terms of the identification and mechanistic characterization of environmental factors that regulate some of the most essential properties of these neurons, such as their morphology, receptor profile, and neurotransmitter phenotype. A significant advantage of sympathetic cultures with respect to studies of neuronal morphogenesis is that, unlike cultured central neurons, it is possible to control when dendritic growth occurs. Thus, sympathetic neurons can be grown under conditions in which <5% of the neuronal cell population extends dendrites, but the addition of the appropriate stimulus (bone morphogenetic proteins or Matrigel) will trigger dendritic growth in >95% of the neuronal cell population (**Figure 2**). Other widespread applications of sympathetic neuronal cultures include studies of (1) growth cone behavior, structure, and biochemical composition, (2) synaptogenesis, (3) the cytoskeleton in a variety of cellular functions, including axonal and dendritic outgrowth, axonal transport, and subcellular trafficking, (4) factors that regulate transmitter release, (5) signal transduction downstream of receptor activation, and (6) molecular mechanisms of apoptosis. A well-established application that is gaining in popularity is the use of sympathetic neurons co-cultured with target cells to study neuron–target interactions. Historically, sympathetic neuron and target cell co-cultures were used to study the influence of target on neurotransmitter phenotype. More recently, sympathetic neurons co-cultured with target tissue are being used to study the role of target-derived trophic factors on the formation and function of sympathetic synapses on heart; sympathetic control of energy homeostasis via modulation of adipose tissue function, and sympathetic regulation of immune responses via innervation of the spleen and lymph nodes.

Parasympathetic Neurons

Parasympathetic ganglia are considerably smaller than sympathetic ganglia. They range in size from as few as 2 or 3 cells to as many as 30 cells. Because of their location, usually buried within end organs, and their diffuse nature, they have received less attention as *in vitro* models than have sympathetic and sensory ganglia. Professor Geoffrey Burnstock first maintained parasympathetic nerves in cell culture in the early 1980s, initially by explant and later by dissociation of tissues. Parasympathetic nerves have now been isolated from ganglia in many different organs, including lungs, heart, bladder, and submandibular glands (enteric nerves will be considered separately).

In vitro studies on parasympathetic neurons indicate that factors affecting growth of sympathetic neurons do not automatically transfer to the parasympathetic cultures. For example NGF is required

Figure 2 Sympathetic neurons do not extend dendrites in culture unless provided the appropriate environmental stimulus. Phase-contrast (a, c) and fluorescence (b, d) micrographs of rat sympathetic neurons injected with Lucifer yellow during the third week *in vitro*. Neurons grown in control cultures in the absence of nonneuronal cells and serum (a, b) typically extend only one process, which is axonal in nature. Neurons exposed to bone morphogenetic protein-7 (50 ng ml^{-1}) for 7 days were multipolar, having several tapered dendrites and one axon. Scale bar = 100 μm.

to maintain sympathetic neurons in culture. While NGF is commonly added to parasympathetic cultures, many labs do not use it, thus parasympathetic neurons do not require NGF to survive. Cell lines also do not mimic parasympathetic function. Neuroblastoma cells release acetylcholine, but regulation of receptor expression is mediated by different pathways in neuroblastoma and parasympathetic neurons. To identify the physiology and pharmacology of this branch of the autonomic nervous system, it is necessary to isolate and study the parasympathetic neurons. Since isolation of parasympathetic neurons is not yet routinely done, the technique will be described here.

Most studies with parasympathetic neurons isolate them from rats, rabbits, or guinea pigs. It is not necessary to isolate parasympathetic nerves from fetal animals. Although most tissues are derived from young or newborn animals, there appears to be little difference between cells isolated from young versus older animals. We have recently isolated and maintained parasympathetic neurons from adult human trachea.

Isolation of parasympathetic ganglia involves dissecting out the muscle containing the ganglia followed by mechanical removal of as many nonneuronal cells as possible. For example, airway epithelial cells are wiped away with sterile cotton swabs. The tissue is gently minced, and then digested enzymatically. This usually requires incubation with trypsin (0.25%) and collagenase (0.2%) or protease (0.2%) at 37 °C for 60–90 min. Thicker tissues can be incubated with the enzymes at 4 °C for 1–18 hours to allow enzyme penetration of tissues, followed by incubation at 37 °C to activate the enzymes. Enzymatic digestion is usually accompanied by gentle agitation or pipetting to disperse the cells. This procedure results in suspension of neurons, glial cells, smooth muscle cells, fibroblasts, and, depending upon the tissue of origin, endothelial or epithelial cells.

Cultures can be enriched for neurons by preplating the cell suspension on plastic dishes to remove fibroblasts and muscle cells. In addition, the antimitotic agent cytosine arabinoside (5 μM) can be added to cultures a day or two after plating to kill dividing cells. Over several days, the cultures consist predominantly of neurons. A major caveat of working with parasympathetic ganglia is that, unlike sympathetic ganglia, cultures derived from parasympathetic ganglia are heterogeneous. This is less an issue in electrophysiological, immunocytochemical, or transmitter release studies, but is a major factor when measuring protein or mRNA by Western blot or polymerase chain reaction

(PCR). In these latter experiments, controls must be added for the presence of nonneuronal cells.

Parasympathetic neurons grow best on extracellular matrix-coated slides or culture dishes. Some laboratories maintain them in Rose chambers (two coverslips, separated by a plastic washer, that are clamped together, which can be purchased from Bellco Biotechnology, product 1943–11111). Cells are usually grown in standard medium, such as medium 199, Ham's F12, or L-15, that is supplemented with 10% fetal calf serum, 0.5% glucose, and NGF (50 ng ml^{-1}), or in serum-free medium supplemented with transferrin (10 μg ml^{-1} avian transferrin or 20 μg ml^{-1} rat transferrin), sodium selenite (5 ng ml^{-1}), glutamine (20 μg ml^{-1}), insulin (5 μg ml^{-1}), NGF (20–50 ng ml^{-1}), and bovine serum albumin (1 mg ml^{-1}). Some laboratories additionally include penicillin and streptomycin in the culture medium.

Parasympathetic neurons originally appear as spherical cells that settle onto the substrate over the 48 h after plating. Neurites initially appear as small commas, and extend over the first 3 days. By 2–3 days after plating, neurons are clearly visible. Parasympathetic neurons grow in dense clusters with outwardly radiating and fasciculated neurites (Figure 3). The choice of plating matrix can influence aggregation of the cells: they form dense clusters if grown on polylysine (this substrate yields fewer cells overall), and smaller clusters (with increased cell survival) when grown on collagen, laminin, or Matrigel. Parasympathetic neurons can be maintained in culture for 7–10 days. It is rare that cultures survive in excess of 14 days, which is another difference from sympathetic cultures.

Parasympathetic neuronal cultures have been used to describe receptor distribution and neurotransmitter content (as determined primarily by immunocytochemistry), and, more recently, to characterize the molecular mechanisms underlying interactions between parasympathetic nerves and inflammatory cells. Acetylcholine release in response to electrical field stimulation or nicotine has also been measured. However, it cannot be assumed that all parasympathetic neurons behave the same way. For example the distribution of purinoceptors for adenosine 5′-triphosphate (ATP) is different in parasympathetic neurons originating from heart and lung versus those derived from submandibular or otic ganglia. Much is still unknown about the basic cell biology of parasympathetic nerves. No studies have been carried out that characterize the growth and differentiation of parasympathetic nerves; indeed, even the characterization of neurites as axons or dendrites is lacking in this neuronal cell type. Recent work demonstrating that parasympathetic nerves can be transfected (Figure 4) suggests the exciting possibilities of future studies of the cell and molecular mechanisms regulating the

Figure 3 Phase-contrast image of parasympathetic neurons from guinea pig trachea, plated on Matrigel and maintained in serum-free medium for 7 days.

Figure 4 Primary cultures of parasympathetic neurons were plated on Matrigel and maintained in serum-free medium for 4–5 days. Cells were transfected with cDNA encoding enhanced green fluorescent protein (eGFP) using the transfection reagent Optifect (Invitrogen). An enhanced yellow fluorescent protein (eYFP) plasmid (3 μg) was incubated with Optifect (Invitrogen, 10 μl) in 200 μl of OptiMEM at room temperature for 5 min. Cells were incubated with 200 μl of eYFP/Optifect solution in 1 ml of culture medium at 37 °C in 5% CO_2 for 6 h, then rinsed with phosphate-buffered saline and fixed with 3.7% paraformaldehyde.

development, growth, and plasticity of parasympathetic neurons.

Cardiac Ganglia

Cardiac neurons appear in culture singly or as clusters, with neurites extending for hundreds of micrometers. When isolated from rats, the soma are 25–35 μm in diameter, depending upon the degree of flattening. Nuclei are approximately 5×10 μm. All cells from rat and guinea pig cardiac ganglia express acetylcholinesterase, suggesting that they are all cholinergic, and have functional M1 and M2 muscarinic receptors evenly distributed along cell bodies and neurites. However, they are actually a heterogeneous population, with three distinct electrophysiological phenotypes, and a subpopulation immunoreactive for dopamine β-hydroxylase or tyrosine hydroxylase, suggesting the presence of SIF cells. Half of all neurons in these cultures are immunoreactive for neuropeptide Y and a smaller percentage express vasoactive intestinal peptide, but tachykinin-expressing cells are not detected. Thus, cardiac parasympathetic ganglia in cell culture maintain a considerable degree of neuronal specialization, as is seen *in vivo*.

Tracheal Ganglia

Parasympathetic ganglia from trachea were initially isolated from young rats, but cultures from mature guinea pigs and adult human organ donors have been isolated and maintained in cell culture for several weeks (see reports from laboratories of Professors Burnstock and Fryer). Tracheal ganglia behave similarly to nerves *in vivo* as they release acetylcholine, express nitric oxide synthase, and, depending upon the presence of NGF, express substance P. M2 muscarinic receptors are evenly distributed along on cell bodies and neurites and function to inhibit acetylcholine release. Similar to nerves *in vivo*, inflammatory cells adhere to parasympathetic nerves in culture, and this effect is regulated by expression of chemotactic cytokines and adhesion molecules by the parasympathetic nerves. Parasympathetic nerves also release some noradrenaline and have functional α_1 adrenoceptors and γ-aminobutyric acid ($GABA_A$) receptors. As with cardiac nerves, cultured ganglia from the trachea appear to maintain all characteristics of their *in vivo* counterparts.

Chick Ciliary Ganglion Neurons

One parasympathetic ganglion that has been well studied in cell culture is the avian ciliary ganglion, because it is relatively large, discrete, and easily located outside of the eye. It should be noted that, in sharp contrast to the bird, rodent ciliary ganglia are small and dispersed, thus ciliary ganglia isolated from chick may not be an accurate model of the physiology of this ganglion in mammals. The chick ciliary ganglion contains two distinct neuronal cell populations. Ciliary neurons are large, myelinated cholinergic neurons that innervate striated muscle in the iris and ciliary muscle. It is the choroid neurons, small, unmyelinated cholinergic neurons that supply the arterial vasculature of the choroid layer, that are the parasympathetic component of these ganglia. Ciliary neurons require neurotrophic factors, such as ciliary neurotrophic factor, to support their survival in culture. Neurotransmitter expression in the choroid cells is controlled by target tissues, in this case the eye, and this interaction may not be representative of parasympathetic neurons as a class. Despite these drawbacks, the ciliary ganglion has been a popular system for neuronal cell culture, and a great deal is known about the growth requirements and behavior of this class of chick parasympathetic neurons.

Enteric Neurons

The enteric nervous system is considerably more complex than is other peripheral neural tissue. Neuronal cells bodies reside in the submucosal and myenteric ganglia, and consist of at least 14 different neuronal cell types, including interneurons, afferent neurons, and both excitatory and inhibitory motor neurons, that collectively express diverse neurotransmitters in addition to acetylcholine, including substance P, enkephalins, nitric oxide, ATP, and GABA. The enteric nervous system is highly autonomous: nerves form extensive synaptic contacts with one another and are capable of integrated reflex activity in the absence of central connections. Thus, in both its structure and its function, the enteric nervous system bears a greater resemblance to the central nervous system than to other peripheral neural tissues.

Isolation of enteric neurons is similar to that of parasympathetic neurons and involves enzymatic digestion of tissue containing the ganglia with subsequent plating on matrix gels or polylysine. Enteric neurons can survive in culture up to 3 weeks and the diversity of neuronal cell types found *in situ* is represented in culture. Individual enteric neurons are characterized by markedly diverse morphology and they retain the variety of neurotransmitters found *in situ*. Their electrophysiological properties appear to be similar to those of enteric nerves in the intact animal. Cultured enteric ganglionic glial cells

continue to synthesize intracellular glial proteins expressed by their *in situ* counterparts, including glial fibrillary acidic protein and glutamine synthetase, suggesting the feasibility of using enteric nerve cultures to study nerve–glial cell interactions.

A complication of interpreting any study involving cultured enteric neurons is the paucity of information regarding differential effects of environmental factors on different neuronal cell types within the heterogeneous population of neurons that comprise the enteric culture system. Few attempts have been made to discriminate between effects on axons versus dendrites within any individual neuron, although a number of studies have examined factors that promote neurite outgrowth. Glial cells are not required for neurite development in culture, but when they are present, enteric nerves will extend processes along them. Neurite length is enhanced by NGF, consistent with observations that enteric neurons express both the low-affinity NGF receptor (p75) as well as tyrosine kinase (Trk) receptors. Neurite outgrowth is also promoted by cyclic adenosine monophosphate (cAMP) via complementary but independent pathways, as evidenced by observations that inhibitors of cAMP have no effect on NGF-induced neurite growth, and that cAMP, but not NGF, enhances neurite branching in the myenteric nerves. Neurite length is also enhanced by ciliary neurotrophic factor, insulin-like growth factors, leukemia inhibitory factor, and interleukin-6 (IL-6). The greatest enhancement of neurite length, however, is provided by glial-derived neuronal factor (GDNF), which also induces larger clusters of cell bodies and increases neuronal survival in culture. IL-6 induces a greater number of neurites, but GDNF promotes increased neurite length.

While much research on enteric neurons in culture has demonstrated that these neurons retain the characteristics of cells found *in situ*, there is evidence that at least some neuronal cell types retain the plasticity that has been observed in other neural crest derivatives. Thus, exposure to heart-cell conditioned medium induces substantial, but not uniform, changes in both their electrophysiological and transmitter-related properties (increasing the percentage of neurons that express 5-hydroxytryptamine, while decreasing the percentage of neurons expressing vasoactive intestinal peptide and substance P).

Conclusions

Almost everything we know about the development and physiology of autonomic nerves has been derived from studies of sympathetic neurons, in large part because of the relative ease with which this neuronal cell type can be isolated and maintained in culture. Recent advances in methods for manipulating gene expression in cultured sympathetic neurons and for culturing sympathetic neurons in the presence of target tissues or ganglionic glia ensure the continued widespread use and popularity of this *in vitro* model system for discovery-based and mechanistic research. The recent development of techniques for the isolation and maintenance of parasympathetic and enteric neurons in cell culture will enable a more detailed understanding of the basic cell biology of these other peripheral neural systems, thereby refining and extending current paradigms of peripheral nervous system development, physiology, and pharmacology.

Cell Culture: Primary Neural Cells

R G Giffard and Y-B Ouyang, Stanford University School of Medicine, Stanford, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neural tissue is composed of many different cell types: neurons, astroglia, oligodendroglia, microglia, endothelial cells, and other perivascular cells. Within these broad classes are many subsets, particularly of neurons and astrocytes. This complexity makes it difficult for neuroscientists to determine which cells are affected by a particular drug or manipulation and whether effects are direct or indirect actions on the cells of interest. The major advantages of using dissociated-cell culture to study the nervous system are (1) reduced cell complexity, (2) the ability to carry out biochemical analysis of individual identified cell types, (3) the ability to completely control the cellular environment, and (4) manipulation of gene expression in individual cell types. Cell cultures are advantageous for methods such as individual cell imaging and electrophysiology (Figure 1). The major disadvantages of primary neural cell culture are the loss of normal synaptic pathways, the loss of normal anatomic relations, and changes in gene expression. However, studies indicate that most neural cell types express similar properties *in vitro* and *in vivo*. For example, astroglia produce vimentin, their typical intermediate filament protein glial fibrillary acidic protein (GFAP; Figure 1, middle panel), and neurotrophic factors. Oligodendroglia and Schwann cells can make myelin and neurons in culture, form synapses, express appropriate neurotransmitter receptors, and conduct action potentials, as well as express neurofilaments and growth cones.

Primary Cultures versus Cell Lines

Primary cultures are prepared directly from brains isolated from animals. The tissue is dissociated by enzymatic and mechanical means into a suspension of single cells and plated onto a culture dish or other surface. Some types of cells, especially those isolated from embryonic brain, may undergo a period of proliferation. In the case of astroglia, once the individual cells approach confluence and contact one another, they stop dividing and begin to differentiate. Differentiation may be incomplete because of lack of normal cell partners or differentiation signals. Primary cultures have been used extensively to determine mitogenic and differentiation signals for individual cell types, as in studies of stem cells and the fates of their progeny cells. In this way, many factors that determine the differentiation fates of brain progenitor cells have been demonstrated. Once the cells are taken up from the dish and replated, they are termed secondary cultures, though some workers still use the term 'primary culture' to refer to cells isolated from tissue even after one or two passages. If normal cells are kept in culture and allowed to divide and expand in number, either they become senescent, if they are normal cells, or mutations occur that allow the cells to continue to divide and be passaged. At that point a cell line has been generated. Another method is to take a primary cell and transform or immortalize it with an oncogene, often of viral origin. A third method is to use cells derived from a tumor of the cell type of interest.

Cell lines are convenient in that they can be maintained indefinitely in culture and generate large numbers of cells, but they have significant drawbacks in that they are not normal cells, and after long-term passage, they accumulate genetic alterations and often, when given differentiation cues, do not fully replicate the patterns of gene expression characteristic of either primary cultures or brain cells *in vivo*. Despite this, some lines express a reasonably stable phenotype and have been used extensively for study.

One problem with mature neurons is that they are nondividing postmitotic cells and cannot be subcultured. Second, though there are cell lines that express some of the individual characteristics of differentiated neurons such as neurotransmitters, ion channels, receptors, and other neuron-specific proteins, they generally do not replicate the full phenotype of a specific neuronal subtype. PC12 cells derived from a pheochromocytoma, which have been studied extensively and are used to represent a specific population of nerve cells, only partially replicate the phenotype of the sympathetic neurons they otherwise resemble.

Glial cells can be subcultured, at least for several generations. However, the properties of the cultured cells often change gradually with passaging, as more rapidly dividing cell populations come to predominate and more 'differentiated' cells, which divide more slowly, are lost. Although many cell lines derived from glial tumors have been developed, they are used less commonly than are primary astrocyte cultures as astrocyte cultures are relatively easy to prepare and generally can be prepared in adequate quantity. In the case of one cell line said to resemble oligodendrocytes, the cells were not competent to form myelin.

Figure 1 Left panel: Photomicrograph of a fluorescence image from tetramethylrhodamine ethylester (TMRE), a potentiometric fluorescent dye that incorporates into mitochondria in a mitochondrial membrane potential-dependent manner, demonstrating punctate perinuclear mitochondria in cultured cortical astrocytes. Middle panel: Glial fibrillary acidic protein (GFAP) immunostaining of cortical astrocytes. Right panel: Neuron-specific enolase (NSE) staining of cortical neurons.

Different Types of Primary Neural Cell Culture

Regardless of the type of cells to be grown, all methods for preparing primary cell cultures share several common features: Start with the brain region containing the cells of interest, dissect the region free of surrounding tissue, and dissociate the tissue. The single-cell suspension that is obtained is then placed on a suitable substrate and in an appropriate medium inside a temperature- and gas-controlled incubator.

The appropriate developmental age should be chosen to prepare specific populations of cells. For example, cortical neurons are generally prepared from rat or mouse embryos at day 14 (E14) or 15 (E15), hippocampal neurons from slightly older embryos (E18 to E19), and glia from rat or mouse pups 0 to 2 days after birth. Neurons are much less susceptible to damage during dissociation before they have developed extensive axonal and dendritic arbors and have become highly innervated. They may also be less dependent on their target cells for trophic support at early stages in their development. Glial cultures, which derive predominately from populations of progenitor cells, are prepared most easily when the number of these progenitors is near its peak, during the early postnatal period.

Neurons

There are many subtypes of neurons. When plated onto an appropriate substrate, primary neurons begin to extend processes within several hours, finally developing distinct axons and dendrites, forming synapses with one another, expressing the receptors and ion channels characteristic of the corresponding cell type *in situ*, and demonstrating spontaneous electrical activity, including producing action potentials.

Because neurons in primary cultures are essentially postmitotic and committed to differentiation at the time they are introduced into culture, the morphological and physiological properties of the cell population in culture correspond closely to the characteristics of the cell population present in the tissue of origin. Motor neurons express properties reminiscent of motor neurons, Purkinje cells of Purkinje cells, and so on.

One limitation of primary neuronal cultures is that they often contain a heterogeneous population of cells. Choice of tissue to culture is an important determinant of the cells in culture, and superimposed on the cell types present in the initial tissue is the ability of each cell type to survive under the conditions chosen for the culture. Choice of conditions can bias cell survival – some cell types do better in high serum, some in low, and some in fully defined culture medium. In some brain regions there is a predominant cell type, such as pyramidal neurons in hippocampus or granule cells in cerebellum. Alternatively, unwanted cells may be killed, either by specific cytotoxins or by complement-mediated lysis using antibodies against cell antigens. Another important strategy for isolating specific cell types from heterogeneous regions is called immunopanning. In this method, surfaces are coated with antibodies to surface determinants specific to an individual cell type, and the dissociated cells are then allowed to settle onto the coated surface, and nonadherent cells are removed. Often several rounds of panning are used to remove undesired cell types as well as to select desired cell types. This technique has been used successfully to isolate individual cell types from optic nerve, as well as from other starting material. The principal disadvantage of this approach is that it is difficult to isolate large numbers of cells this way, but the purity of the cell type is high.

Brief Protocol: Cortical Neurons

Primary cortical neuronal cultures are prepared from fetal mice at 15 days' gestation. Neocortexes are dissected free of meninges, treated with 0.25% trypsin for 20 min, mechanically dissociated and plated as a single-cell suspension in minimal essential media plus 5% fetal bovine serum (Hyclone) and 5% equine serum at 3.5 hemispheres per 10 ml medium. After 24 h *in vitro*, 60% of the plating medium is replaced with glial conditioned medium and B-27 serum-free supplement (2%; Gibco, Grand Island, NY) is added. Glial cell proliferation is then inhibited by addition of cytosine arabinoside (3 mmol l^{-1}). Cells are incubated in a humidified incubator at 37 °C with a 5% CO_2 atmosphere without further medium changes until use. These cultures contain <1% astrocytes at all durations in culture studied as determined by immunostaining for GFAP and neuronal nuclei and neuron-specific enolase.

Astrocytes

Astrocytes are the most numerous cell type in the brain. For decades, astrocytes were considered non-excitable support cells. This view has changed radically during the past 20 years. Astrocytes are now appreciated to perform multiple essential functions in normal brain: They are dynamically involved in synaptic transmission, metabolic and ionic homeostasis, the inflammatory response, antioxidant defense, trophic support of neurons, as well as the establishment and maintenance of the BBB. Astrocytes respond to signals from and signal actively to neurons, endothelium, and microglia. Because of the heterogeneity of nervous tissue, the small-size cell bodies, and the diffuse distribution of glial cells, it has been difficult to investigate the function of glia including astroglia *in situ*. In primary culture it is relatively easy to obtain pure preparations of astrocytes with greater than 95% homogeneity. The main contaminant is microglia, and additional steps can be taken to reduce the number of microglia to less than 1%. Some use dibuturyl cyclic adenosine monophosphate to induce morphological differentiation of astrocytes into more stellate shapes than are observed without this treatment. Within a week or two, immature astrocytes isolated from newborn brain will divide and form a confluent monolayer when plated at low density or, when plated at higher density, a layer of cells that may be a few cells thick in places. Conditions are chosen to preclude the survival of neurons.

While it is generally difficult to produce large amounts of cells from neuronal or microglial primary cultures for biochemical analysis, this is much less true of astrocyte cultures. In contrast, since astrocytes divide readily in culture, relatively large amounts of cells suitable for biochemical as well as morphological or physiological analysis can be produced.

Brief Protocol: Cortical Astrocytes

Primary astrocyte cultures are prepared from 1-to-2-day-old postnatal mice. Neocortexes are dissected free of meninges, treated with 0.25% trypsin for 20 min, mechanically dissociated and plated as a single-cell suspension onto either Primaria tissue culture plates or flasks (Becton Dickinson), poly-D-lysine coated tissue culture plastic containers, or glass coverslips at a density of two hemispheres per 10 ml. Plating medium consists of Eagle's minimal essential medium supplemented with 10% fetal bovine serum and 10% equine serum, 21 mmol l^{-1} (final concentration) glucose (Sigma Chemical, St. Louis, MO), and 10 ng ml^{-1} epidermal growth factor. Cultures are maintained at 37 °C in a 5% CO_2 incubator. Astrocyte cultures are postmitotic by days 7 to 14 in culture and generally contain <5% microglia and insignificant numbers of neurons or oligodendrocytes. The cultures increase expression of GFAP between 7 and 15 days *in vitro*, similar to what has been reported *in vivo*.

Microglia

Primary cell cultures are also used for the study of microglia, the population of macrophages resident in the central nervous system (CNS). Microglia are present in all brain areas but not uniformly distributed, being enriched in grey matter and with a relatively distinct perivascular population. The morphology of microglia *in vivo* varies according to their location and microenvironmental factors and ranges from compact amoeboid cells to ramified, branched cells, with considerable variation in the length and complexity of branching of the processes. Their plasticity is emphasized by their rapid morphological changes in response to a variety of stimuli, including mechanical or pathological insults. In culture, microglia can adopt three distinct morphologies: amoeboid, bipolar, and ramified, similar to what is seen *in vivo*. Microglia often appear as loosely attached cells atop monolayers of type I astrocytes, and can be harvested by shaking to produce relatively pure preparations.

Brief Protocol: Microglia

Cultures are prepared by shaking off from mixed glial cultures from mice at postnatal days 1 to 3. Whole cerebral hemispheres are removed and freed of meninges. Minced pooled tissue is treated with 0.25% trypsin, centrifuged, and dissociated into a

single-cell suspension by gentle trituration. Cells are plated at a density of two hemispheres per 10 ml in Eagle's minimal essential medium supplemented with 10% equine serum, 10% fetal bovine serum, 21 mmol l^{-1} (final concentration) glucose in flasks. Cells are incubated at 37 °C in a 5% CO_2 incubator. Medium is changed after 2 to 3 days *in vitro*. Microglia are harvested from mixed glial cultures between 7 and 14 days *in vitro*. After shaking at 160 rpm for 30 min on an orbital shaker, the medium is collected and centrifuged at 800 *g* for 10 min to collect the cells. Plates are coated with Collagen I (50 μg ml^{-1}; Sigma Chemical) for 10 min and washed; then microglia are plated at a density of 3×10^5 cells ml^{-1} in Eagle's minimal essential medium supplemented with 5% equine serum, 5% fetal bovine serum, and 2 mmol l^{-1} glutamine. After 1 h, wells are washed with medium to remove unattached astrocytes. Macrophage colony-stimulating factor (100 ng ml^{-1}; Sigma Chemical) is then added. This method yields cultures that contain >99% microglia as determined by histochemical staining with *Griffonia simplicifolia* B4-isolectin (IB-4; Sigma Chemical).

Oligodendrocytes

Oligodendrocytes, the myelinating cells of the CNS, develop from precursor cells known as O-2A progenitors. Although oligodendrocytes traditionally have been defined as myelinating cells, a number of recent reports suggest that these cells play additional roles. For example, oligodendrocytes in culture express a variety of trophic molecules.

Culturing oligodendrocytes is somewhat more difficult than culturing the other cell types discussed so far. In some cases, mixed glial cultures are the starting point. In other cases, white matter areas are isolated as starting material. When dissociated cells from cerebral hemispheres are cultured, they develop into a monolayer consisting mainly of astrocytes, with oligodendrocyte lineage cells on top of the monolayer. Similar to the case for microglia, cells enriched in oligodendrocyte lineage cells can be obtained from mixed glial cultures by shaking them off the monolayer and replating after centrifugation. Another method for obtaining purer cultures of oligodendrocytes or oligodendrocyte precursors is immunopanning. In this technique, dishes are coated with antibodies against a particular cell surface antigen, the cell suspension is added to the dish to allow selective binding of cells that express that antigen, and unbound cells are removed. Often several panning steps are done sequentially.

Brief Protocol 1: Forebrain Oligodendrocytes

Forebrains are dissected from newborn rats and cultured in nutrient medium-15 (NM-15) containing Minimum Essential Medium with Earle's salts and L-glutamine, heat-inactivated fetal calf serum (15%), glucose (6 mg ml^{-1}), and penicillin–streptomycin (0.5 U ml^{-1} and 0.5 μg ml^{-1}, respectively; Invitrogen, Rockville, MD) for 7 to 10 days. To eliminate microglia, glial cultures are shaken at 300 rpm for 10 min, and the supernatant is discarded. After recovery in NM-15, the oligodendrocyte type-2 progenitor cells and oligodendrocytes are separated from underlying astrocytes by shaking at 250 rpm for 12 to 16 h. Oligodendrocyte lineage cells are plated onto 35 mm poly-D-lysine-precoated dishes for immunocytochemical study or onto aminoalkysilane-precoated slides (Sigma, St. Louis, MO) for other studies in NM-15 medium at a density of 3×10^4 cells cm^{-2}. After 24 h in oligodendrocyte medium, NM-15 medium is aspirated and replaced with chemically defined medium consisting of a 1-to-1 mixture of Ham's F12 and Basal Medium Eagle containing 6 mg ml^{-1} glucose and 6.6 mmol l^{-1} glutamine (Invitrogen) and 25 μg ml^{-1} insulin, 20 nmol l^{-1} progesterone, 60 μmol l^{-1} putrescine, 30 nmol l^{-1} selenium, 100 μg ml^{-1} transferrin, 0.5 μmol l^{-1} thyroxin, 0.08 μg ml^{-1} triiodothyronine, 6.6 mmol l^{-1} glutamine, and penicillin–streptomycin (0.5 U ml^{-1} and 0.5 μg ml^{-1}, respectively; Sigma). Cultures are maintained for 96 h in oligodendrocyte medium, after which >90% of the cells in culture are oligodendrocyte lineage cells, either A2B5-positive or myelin basic protein-positive by immunocytochemical staining. The remaining nonoligodendrocyte cells are OX-42-positive or ED-1-positive microglia or GFAP-positive astrocytes.

Brief Protocol 2: Immunopanning

Cells are plated on 100 mm petri dishes that were sequentially treated with biotinylated antimouse immunoglobulin G (1:100, 12 h, 4 °C; Vector Laboratories, Burlingame, CA), A2B5 antibody with 5% bovine serum albumin (BSA) (12 h, 4 °C), and 5% BSA (4 h, room temperature; Sigma). Cells are incubated in these dishes for 30 min at 37 °C. After three culture washes in NM-15, bound cells are scraped, centrifuged (at 500 rpm for 5 min), resuspended in NM-15, and plated.

Brain Endothelium

Endothelial cells that line the microvasculature of the CNS differ fundamentally from other vascular

endothelia in their capacity to regulate the passage of molecules and cells to and from the neural parenchyma and constitute the BBB. This selectivity resides in specialized features unique to CNS endothelia, including expression of tight intercellular junctions that markedly limit paracellular permeability, as well as a unique pattern of receptors, transporters, and nonselective drug export pumps that protect the CNS from a large variety of potentially harmful hydrophobic compounds.

Although much has been learned about the unique properties of brain endothelium from *in vivo* studies, the limitations imposed by whole-animal experiments have led to the development of techniques to isolate and culture CNS-derived endothelial cells from various species. Unfortunately, when cultured alone these endothelial cells usually fail to develop functional tight junctions. To address this limitation, coculture systems have been developed in which brain endothelial cells, especially of bovine origin because of the availability of large amounts of material, are grown on microporous filter inserts in the presence of primary culture astrocytes in order to mimic the anatomical and functional relationship between brain endothelium and surrounding astrocyte foot processes. These coculture systems exhibit a much better correlation to *in vivo* permeability of standard molecules and high levels of electrical resistance.

Brief Protocol: Brain Endothelium

Primary cerebral microvascular endothelial cell cultures are prepared from young mouse brains. Gray matter from 2- to 3-week-old mice is homogenized in calcium and magnesium free Hank's balanced salt solution containing 0.35% collagenase and 0.2% BSA for 2.5 h at 37 °C. Tissue is resuspended in 25% BSA, then centrifuged at 4 °C for 20 min at 528 *g*. The pellet containing brain capillaries is incubated in 0.1% collagenase/dispase in bicarbonate containing M199 media (Gibco-BRL 11150-059) for 2 h at 37 °C to remove pericytes. The cells are pelleted, resuspended, then centrifuged on a Percoll gradient (11 ml Percoll in 21 ml Earle's balanced salt solution) at 733 ***g*** for 10 min at 4 °C. The capillary microvessel endothelial cell layer is collected, washed in M199 media, and plated on collagen-coated plates at 10^6 cells ml^{-1} in E-STIM endothelial cell culture media (Becton, Dickinson, Franklin Lakes, NJ) supplemented with 10 ng ml^{-1} epidermal growth factor plus penicillin–streptomycin (100 U ml^{-1}). Cultures are fed every 3 days.

Cell Replacement Therapy for Huntington's Disease

O Isacson, McLean Hospital/Harvard Medical School, Belmont, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Why Neuronal Regeneration Therapeutic Strategies for Huntington's Disease?

Although new genetic information, including identification of specific markers and development of genetic models, is available for several neurological diseases characterized by regional neuronal loss including Huntington's disease (HD), these genetic studies have not yet resulted in advances in treatments for patients, except better diagnosis. Even if new pharmacological methods are developed to retard the genetic component of cell death, it is likely that cell regeneration therapies would also be required when HD brain cell death is delayed (even with more than 20 years delay since the average age of onset is 44 years) or is already apparent as the disease presents with symptoms. Moreover, since cell transfer or genesis may be possible prior to neuronal dysfunction, selectively vulnerable neurons and glia can be replaced prior to breakthrough symptoms. Consequently, there is a need for research that defines the potential and basic cellular mechanisms for neuronal replacement. In HD, while there is a genetically predetermined process causing neuronal death of neurons within the patient's caudate-putamen, implanted neural tissue (neurons and glia) lacking the mutated gene may substitute the disease-prone neurons and reconstitute functional neuronal connections. Such transfer of neurons and glia may also contribute to a slowing down of the neurotoxic processes evident in HD striatum since neurotrophic factors are produced by progenitor cell or fetal neural grafts. Furthermore, the demonstrated reconnection of host afferents with implanted neurons, and presence of normal glia, may offer resistance to cell loss caused by the progressive pathology of HD. An effective cell regeneration therapy for HD will likely involve anatomical precision and feedback control of local neurotransmitter release. In the future, neural replacement could perhaps be combined with other factors that promote regeneration and recovery of function.

Cell Transfer and Stem Cell Approaches for HD

Experimental progenitor cell transplantation HD paradigms have revealed data about structural brain repair. Several studies have confirmed and extended the initial discovery in rodent models of functional effects of striatal neuronal replacement in a primate model of HD. This underscores the validity of the approach as an example of the innovative nonpharmacological therapeutic research to broaden the horizon for HD patients. Data indicate that regenerating striatal neurons can replace neurons lost in the primate striatum to form novel axonal connections and synapses that can improve function. Fetal brain cells are an unlikely cell source for large-scale clinical and application unless derived via stem cells; however, they are *a priori* experimentally useful cells to test hypotheses and mechanisms to replace damaged circuitry, because fetal neural cells inherently possess cellular feedback systems for neurotransmitter, neurotrophic, and synaptic interactions. In future clinical cellular regeneration trials, donor cells may be derived from stem cells, genetically engineered cells, or redifferentiated tumor cell lines. Success with such cell sources is more reasonable and likely after mechanistic and detailed investigations can demonstrate safe and effective functional repair of structural brain damage using phenotypically normal striatal progenitor brain cells, serving as an exploratory standard of cellular regeneration therapy for neurodegenerative conditions.

Immunology and Inflammation Issues Specific to Neural Intracerebral Cell Transfer

The presumption that the brain is an entirely immunologically privileged transplantation site has been challenged. This concept was originally based on studies of discordant graft survival in such neural sites as the cornea, the anterior and posterior chambers of the eye, and the brain as compared to other implantation sites in the body. The relatively limited host immune response within the brain was thought to depend on a combination of factors, including the near absence of lymphatic vessels within the brain and the existence of the blood–brain barrier (BBB) that prevented immediate T cell and humoral immune access to graft cells within the brain. The transplantation of neural tissue itself (except for its blood vessels) into brain cells was even less immunogenic than other transplanted tissues, given the very low levels of MHCI expressed on neural tissue (especially neurons). However, experience with xenotransplantation to the rat brain demonstrated that graft survival is low (but not zero) without systemic immune suppression. Thus, the brain location has

immune surveillance. The same principles apply for immune suppression, since the overall frequency of xenograft rejection in the rodent brain can be greatly reduced with the aid of cyclosporine A. This immune suppression (as for FK506) is probably primarily through blocking the proliferation of T-cytotoxic cells (CD8+) by inhibiting interleukin-2 (IL-2) production from T-helper cells (CD4+), thereby markedly reducing cell-mediated cytotoxic rejections of xenotransplants mediated by T cell recognition of foreign MHC. These successful cell transfers to brain between species have been demonstrated in studies using several fetal donor tissue species. Research results suggested that the major mechanisms involved in xenograft rejection in the adult brain were T cell mediated (and MHCI dependent) and were therefore controllable using standard immune suppression procedures employed in allografting. Numerous studies of neural grafting within species, including the rat brain and human brain, had demonstrated that fetal donor allografts survive in the absence of immune suppression. However, the rodent host brain does not present a full model of primate immunology since hyperacute rejection (complement cascade leading to cell lysis after attachment of preformed antibodies found in blood to xenoantigens on foreign tissue) is rarely seen. Such species-specific humoral factors can participate in early and sometimes also in graft rejection processes. After the BBB is sealed following surgery, sensitization of the host to the xenograft by peripheral skin grafts causes high serum titers of antibodies recognizing the foreign donor cells, but this postengraftment sensitization does not usually produce significant graft rejection. In contrast, presensitization in rodent models, created by first transplanting a skin graft peripherally and then compromising the BBB by implanting fetal neural cells to the brain (in allo- or xenograft combinations) will lead to significant, although partial, rejection of the grafts. These results using presensitization in rodents are probably analogous to the normal status of natural inherited complement-mediated hyperacute rejection seen in primates and humans, thus making the human brain less hospitable to xenotransplantation of new cells for repair and regeneration than several other species.

Deriving and Examining Stem Cells for Functional Experimental Repair in HD Transgenic Models

Designing or selecting cells for neurodegenerative therapies is a new discipline. Genetic engineering of embryonic stem (ES) cells is possible, since ES cells are continuously dividing in their native uncommitted state and can therefore be made to adopt or modify genes under selection that become stable genomic components. Such work signifies an opportunity to design cells by insertion, deletion, or tagging of specific transcription factors or proteins, not only for Parkinson's disease (PD), but possibly also for HD, amyotrophic lateral sclerosis (ALS), ischemia, and general spinal cord damage. Stem cell biology and cell design may eventually get on an equal therapeutic footing with drug-related design processes. This would be of value for regenerative medicine by providing neurons and cells to treat patients with diseases that are currently inadequately served by pharmacological medicine. For HD, the cells most vulnerable to the disease process and consequently most needed for cell replacement or regeneration originate during embryological development in the striatum (caudate and putamen) region (Figure 1). At that time the lateral ganglionic eminence (LGE) of the ventricular wall grows to adulthood by generating a population of γ-aminobutyric acid (GABA) ergic projection neurons (~95% of striatal neurons), which eventually connect with distant synaptic targets in the pallidum and substantia nigra. A smaller (~5%) interneuron population is also present in the striatum (Figure 1). The powerful influence of the GABAergic projection neurons on motor initiation is revealed by their dysfunction and degeneration in HD, where during some stages of the disease involuntary movements are particularly dramatic. The neural mechanisms responsible for such involuntary movements involve overactive thalamocortical circuitry that has lost gating motor control provided by the striatal neurons linked up in these motor loops. Striatal projection neurons are defined during development by transcription factor activations that specifically include Dlx-1 and Dlx-2 as well as Pax6 and Gsh2 (Figure 1).

Several interneuronal types are interspersed in the local circuitry, but these neurons are relatively spared in this disease process. While attempts to prevent the effects of the disease-provoking HD gene have been underway for almost a decade, currently there are no treatments or a cure. Given that HD, like most neurodegenerative diseases, even if slowed by years, will eventually cause major loss of select neurons and their synapses, it is reasonable to also develop synapse repair and replacement strategies. As for PD, there have been some basic research and initial proof of principle in HD patients, showing that appropriate cell and neuronal replacement is possible. Nonetheless, the technical and conceptual hurdles in applying these scientific insights to clinical trials have proved

Figure 1 Diagram illustrating the specification of striatal medium-sized spiny neurons (MSNs) and cortical pyramidal neurons by induction factors (black) through phenotypic markers (red) from an embryonic stem cell. The MSNs are GABAergic projection neurons that comprise the predominant cell type in the striatum (>90%). In addition, the MSNs are the susceptible cell type that degenerates in HD. The glutamatergic pyramidal neurons project to the MSNs in the striatum and may contribute to MSN degeneration in HD. to be greater than expected, and the absence of reliable and reproducible donor cell sources has retarded the progress of the new cell therapies. The generation of a reliable stem cell generated striatal projection neurons in a cell culture system, or by induction of transplanted genetically engineered ES or progenitor neurons *in situ* by temporally controlled activation of transcription factors controlling cell fate, are scientific avenues providing data and insights for potential future therapeutic neuronal and synaptic repair for HD.

Clinical Exploratory Trials of Transplanting Fetal Striatal Cell and Neurons to Patients with HD

A few pilot clinical trials have been conducted using striatal fetal neurons of the human LGE (USA and France). One patient from a trial died 18 months after transplantation from cardiovascular disease, and postmortem histological analysis demonstrated surviving transplanted cells with typical morphology of cells derived from the developing striatum. Selective markers of both striatal projection and interneurons showed positive transplant regions clearly innervated by host TH fibers. There was no histological evidence of immune rejection. Notably, neuronal protein aggregates of mutated huntingtin, which is typical HD neuropathology, were not found within the transplanted fetal tissue. These data support the idea that implanted neural cells lacking the mutant HD gene may be able to replace damaged host neurons and reconstitute damaged neuronal connections even in patients in whom there is a genetically predetermined process causing neuronal death within the HD striatum. This was the first demonstration that grafts derived from human progenitor striatal tissue can survive, develop, and are unaffected by the disease process, at least for 18 months, after transplantation into a patient with HD. A recent clinical study of five patients demonstrated some improvements in 60% of the patients. Most plateaued 2 years after cell implantation. Progression of motor disability continued despite the implanted cells, and by 4–6 years after the surgery, the clinical improvements were no longer apparent. Although initial exploratory neurotransplantation of fetal cells has advanced to the clinic, the importance of independent research in HD animal models is more apparent than ever (note experience from PD). It is vital to fine-tune knowledge of cell selection, immune responses, graft survival, donor–host cell interactions, synapse formation, and behavioral consequences in order to safely and successfully apply these new procedures.

Cell Replacement Therapy: Mechanisms of Functional Recovery

Functional Recovery

The first clear demonstrations of functional recovery after transplanting embryonic nerve cells in the brain were published in 1979. Two parallel studies showed recovery of motor asymmetries in hemiparkinsonian rats following implantation of embryonic dopamine cells to replace lost dopamine cells destroyed by neurotoxic lesions.

Since then, functional recovery has been observed in many different model systems: in sensory, motor, cognitive, motivational, and neuroendocrine functions; in rats, mice, hamsters, cats, dogs, monkeys, and humans; implanted in diverse sites in the brain, spinal cord, and peripheral nervous systems; following lesions made by traumatic, ischemic, excitotoxic, mechanical, or genetic lesions, and in aged animals; and involving transplantation of primary embryonic neurons, glia, engineered cells, stem cells, and other artificial matrix and cell-based systems. As a phenomenon, functional recovery takes place following transplantation of appropriate cells, and a considerable amount has been learned in the last 25 years about the techniques and protocols to achieve favorable outcomes.

Over the past 15 years, similar procedures have been applied to patients with neurodegenerative disease, first in Parkinson's disease (PD), and subsequently in Huntington's disease (HD), Alzheimer's disease (AD), stroke, motor neuron disease (amyotrophic lateral sclerosis, ALS), spinal cord injury, retinal degeneration, and multiple sclerosis, although not always with the degree of therapeutic benefit as had been hoped for based on the preceding experimental and preclinical work. Thus, increasingly, understanding the mechanisms of graft function is seen as an imperative not just for better neurobiological understanding of transplantation biology but in order to develop more effective cell-based therapies for patients based on rational design rather than empiricism alone.

Mechanisms of Functional Recovery

The first studies of nigral grafts in hemiparkinsonian rats observed recovery of sensorimotor deficits and motor rotation asymmetries, the magnitude of which correlated with the extent of dopamine replacement measured biochemically, and the extent of dopamine fiber outgrowth from the implanted dopamine cells measured histologically. Moreover, fiber outgrowth, reformation of synaptic connections, dopamine replacement, and functional recovery, all developed over a similar time course. It was therefore natural to assume that the recovery was attributable to the implanted cells providing a specific dopamine replacement and reinnervation in the host brain. However, subsequent experience has demonstrated that although this may be a factor, a variety of alternative more or less specific mechanisms can be hypothesized (see Table 1), and in fact there is evidence for each of the alternatives operating in different circumstances.

Nonspecific Mechanisms

Neurosurgical lesion of the caudate nucleus was proposed as a potential treatment to controlling selected symptoms of PD in the 1950s. More recently, we have seen the widespread development of thalamic, pallidal, and subthalamic lesions and stimulation for similar purposes, with growing evidence that 'deep brain' subthalamic stimulation can be particularly effective in alleviating disease symptoms. It has therefore been proposed that grafts might exert their effects not by a specific influence of the implanted cells but as a result of collateral damage caused by the neurosurgical operation.

Although some nonspecific contribution cannot be ruled out, it seems unlikely to provide a general explanation for the recovery observed either in patients or in animal models. Thus, in PD, recovery is slowly progressive with growth and integration of the grafts, rather than acute as would be expected of a nonspecific effect; recovery is dependent upon specific cell types being used to replace the particular cells lost to the disease (e.g., nigral dopamine cells for PD) and is not observed with implantation of other unrelated cell types; if the grafts do not survive, any recovery is marginal; and removal of the graft either by rejection or explicit surgical removal reinstates the original deficits. Perhaps most dramatically, in another model system, when circadian rhythms are reinstated following transplantation of embryonic basal hypothalamic cells in hamsters with focal suprachiasmatic nucleus lesions, transplanting between normal and mutant hamsters with shortened circadian period, the period of the restored rhythm follows that of the donor, not that of the host animal prior to lesion. In other situations, recovery that was at first thought to be attributable to nonspecific effects of the surgery has turned out to be attributable to specific but

Table 1 Alternative mechanisms of functional recovery

Mechanism	*Description*
Nonspecific	Surgical damage recruits intrinsic processes of compensation or redundancy
Pharmacological	The graft secretes neuroactive molecules to restore disturbed neurochemical function
Trophic	The graft secretes neurotrophic molecules to promote intrinsic plastic potential of host neurons
Glial support	The graft replaces lost glia, e.g., to promote remyelination or toxic buffering
Pathway repair	The graft provides substrates for axon growth to allow circuit regeneration in the adult CNS
Neuronal reinnervation	Grafted neurons reinnervate host brain to restore lost synaptic innervation
Circuit reconstruction	Grafted neurons establish afferent and efferent connections with host neurons so as to integrate functionally into host neuronal circuitry
Full network repair	The grafts provide full structure repair of neuronal circuits of the host brain

unanticipated mechanisms. Thus, in early clinical trials of adrenal medulla, the modest recovery observed in patients in whom the chromaffin cells themselves were seen not to survive turned out to be attributable to trophic influences of the grafts on the host brain (see below).

Pharmacological Mechanisms

A more plausible mechanism for recovery observed in a variety of model systems is pharmacological replacement of essential neurochemical signals lost to the disease process. Dopamine replacement by L-3,4-dihydroxyphenylalanine (L-dopa) can alleviate many symptoms of PD; cholinesterase inhibitors promote cholinergic transmission in the cortex and can alleviate some of the memory and cognitive symptoms associated with aging and dementia; hormone replacement can alleviate hypothalamic neurohormonal deficiencies such as diabetes mellitus or sexual dysfunction. Consequently, it is plausible that the grafts that are seen to alleviate symptoms in animal model systems of each disease are having their effect by replacement of deficient dopamine, acetylcholine, vasopressin, or gonadotrophin, respectively. The mechanism by which the grafted cells exert their functional effects could be considered to be, essentially, pharmacological, albeit utilizing a delivery system that allows stable, long-term delivery at physiological concentrations into precisely defined targets. Support for this position comes from the effectiveness of grafts that are unequivocally secretory, such as following encapsulation of neurons within semipermeable polymer capsules that allow diffuse release across the membrane but not cellular contacts between graft and host.

When the implanted neurons are seen to reinnervate the brain in each case, which in most cases they do, it can be experimentally difficult to resolve the extent to which the actual mechanism of recovery is due to pharmacological replacement, such that the reinnervation is essentially an epiphenomenon. In fact, there are several reasons to believe that for many grafts reinnervation is important. Nigral grafts that do reinnervate the dopamine-depleted host striatum have a different time course and more complete profile of functional recovery than explicit dopamine replacement into the same sites, whether delivered via minipumps, encapsulated cells, or either *in vivo* or *ex vivo* gene therapy, and the time course and extent of recovery correlates higher with outgrowth and synapse formation than with the numbers of cells surviving in the grafts. Similarly, intraventricular hypothalamic grafts only restore circadian rhythms and sexual function when associated with fiber reinnervation, not with cell survival within self-contained implants. Nevertheless, many developments involving encapsulation, gene therapy, and stem cell alternatives are predicated upon a pharmacological mechanism being sufficient; for some applications this is possible, but it must be borne in mind that optimal recovery in other applications will require the implanted cells to establish explicit connections with the host brain (see below).

Trophic Mechanisms

The role of the trophic environment to promote graft survival, growth, and integration has long been recognized, and conversely there is growing recognition that grafts can provide a source of trophic molecules to promote intrinsic processes of plasticity and repair in the damaged brain. This was first observed with adrenal grafts in the dopamine depleted brains of parkinsonian mice in which the intrinsic dopamine systems had been lesioned with the peripherally administered toxin MPTP. Although the catecholamine-secreting chromaffin cells themselves did not survive in the grafts, the host brain exhibited significant sprouting of spared dopamine fibers in the ventral striatum which extended to reinnervate the areas of extensive denervation in the dorsal striatum, and provided a more plausible mechanism for the observed recovery.

A range of trophic molecules have now been identified that promote the survival, growth, and differentiation of dopamine and other neurons in the developing embryo; that similarly promote cell survival *in vitro*;

and, critically for the present discussion, that can provide neuroprotection of host neurons to various toxic, traumatic, and disease-related assault. Thus, to take three examples, GDNF can protect dopamine neurons, CNTF can protect striatal and motor neurons, and NGF can protect cholinergic neurons from toxic lesions *in vitro*, leading to the proposal that treatment with these factors might promote survival, retard degeneration, and slow disease progress in PD, HD and ALS, and AD, respectively. In each case, the technical challenge is to achieve targeted delivery across the blood–brain barrier to the precise sites where neuroprotection is required and without the side effects that follow systemic administration. Identification of cells that spontaneously secrete relevant factors (such as the NGF-secreting mouse submaxillary gland) or *ex vivo* genetic manipulation of neutral cells to provide high levels of secretion of specific relevant trophic factors can provide an effective source of cells for transplantation and neuroprotection, and is now a major topic of research effort, not just in experimental studies but also in developing clinical trials for a variety of diseases.

Glial Support

Other diseases, such as multiple sclerosis, involve loss of the glial oligodendrocytes that myelinate axons and enable sultatory conduction within the neuronal pathways of the brain. Endogenous remyelination can be promoted by glial replacement, which is achieved most effectively in experimental models of focal demyelination by implantation of the oligodendrocyte precursors. There are several key issues associated with translating this into an effective clinical strategy: first, the sporadic progression of the disease with recurrent development of further inflammatory plaques needs to be halted, to which end significant advances are now being achieved by treatment with anti-inflammatory agents such as the Campath antibodies; second, whereas in some situations demyelination might be relatively focal and hence easily targeted, new strategies are required for reconstructing relatively dispersed foci of demyelination, perhaps by recruiting the capacity of precursor cells for migration; third, after prolonged demyelination in advanced disease, the integrity of demyelinated axons can itself be compromised, so effective treatments must be associated with strategic timing and additional neuroprotection.

In other situations, glial and mixed neuronal-glial grafts may provide stabilization of the central nervous system (CNS) environment. Such a strategy has been applied in spinal cord injury where embryonic cell grafts can occupy the cavity and prevent the progression of syrinx expansion; such a strategy may be anticipated to provide maximal benefit when the syrinx is in the process of extending rostrally to invade critical cervical levels of the spinal cord.

Pathway Repair

In contrast to the considerable regenerative potential of the peripheral nervous system (PNS), the mature CNS does not typically support long-distance axon growth through nontarget areas to distant targets, even when the neurons themselves retain the capacity for extensive elongation of neurites. Various lines of evidence suggest this is at least in part related to the surface expression by glia of inhibitory molecules, such as NoGo. To overcome this constraint, peripheral nerve grafts or tracks of permissive glial cells, such as Schwann cells, can be implanted to bridge sites of pathway transection and provide a glial substrate to promote and guide long-distance axon growth in the adult CNS. For example, oblique glial tracks can promote regeneration of axons across the nigrostriatal pathway, whether from nigral grafts implanted homotopically in the substantia nigra or indeed from intrinsic nigral dopamine neurons disconnected from striatal targets by a knife-cut axotomy of the projection.

The use of bridge grafts to promote pathway reconstruction has been explored in most detail in the spinal cord, where transection of ascending sensory and descending motor projections can result in major clinical disability. Considerable advances have been achieved in combining glial bridges alongside treatment with neuroprotective and anti-inhibitory molecules in bridging complete spinal transections such that host axons can sprout and grow across the site of injury and back into the distal spinal cord. However, further elongation of the axons in the distal cord and targeted reinnervation of their specific targets, whether in the brain stem and thalamus, or onto motor neurons in the ventral horns, remains extremely limited. Indeed, there is growing evidence that a greater degree of functional benefit may be achieved, at least with presently available technologies, by transplantation of regulatory neurons involved in less precisely organized projections, such as raphé grafts in the transected spinal cord, which although not restoring voluntary locomotion can reinnervate and restore important sympathetic functions such as bladder control.

Neuronal Reinnervation

As outlined above, many plastic neuronal populations (such as those derived from the developing

embryonic brain) can be grafted into the mature nervous system, and give rise to extensive neuronal innervation. Moreover, such grafts typically do make morphologically normal synaptic contacts with their appropriate targets. The fact that developing neurites can follow abnormal routes to reach appropriate targets suggests that even in the adult brain at least some of the developmental signals directing axonal elongation and targeting remain present. However, whether such grafts are functional depends critically upon the normal organization of the intrinsic pathway. In essence, regulatory systems such as many hypothalamic cell populations or monoaminergic and cholinergic neurons of the brain's isodendritic core can routinely be seen to alleviate the functional consequences of specific loss of the same populations of cells in diverse experimental models. Conversely, there is much poorer evidence that grafts in more precisely topographic systems (such as within the cortex, corticothalamic or thalamocortical systems, or within visual pathways) can exhibit any comparable recovery. This suggests that in the former case relatively diffuse reinnervation can still achieve functional reactivation or inhibition of the targets required for regulatory or 'gating' control, whereas in the latter case the developmental signals necessary to reestablish the 'point-to-point' connectivity, and required to restore relay of precisely patterned information, are no longer operative in the adult brain, at least within the relatively crude circumstances involved in cell transplantation. As a consequence, there is no simple principle that applies equally in all circumstances; rather, the functional efficacy of a graft will depend critically on the underlying organization of the normal system that is to be replaced or repaired.

Circuit Reconstruction

In most model systems, there is little evidence that grafted cells become fully integrated into the circuitry of the host nervous system sufficient as to restore integrated neuronal information processing. However, evidence of such a level of reciprocal graft–host integration is emerging in one particular model system: transplantation of striatal neurons in animals with lesions of intrinsic striatal circuits that mimick the core pathology seen in HD. Not only do striatal tissue grafts survive in the excitotoxically lesioned striatum, but they also have the capacity both to attract cortical, thalamic, and brain stem reinnervation by the normal population of host afferents that have lost their intrinsic targets, and to give rise to efferent projections to the normal proximal targets in the globus pallidus and in many cases more distally to the substantia nigra. Grafted medium spiny cells thereby become established into a connected host–graft–host neuronal circuitry that recapitulates the normal corticobasal ganglia circuit. Higher cognitive and executive functions mediated at the cortical level, and known to be dependent upon the integrity of this connected corticostriatal circuit, are restored following striatal transplantation that reconnects the circuit. Moreover, more detailed behavioral analysis has shown restitution of motor learning and habit formation believed to be mediated at the striatal level, and parallel recording studies have established long-term plasticity (involving both potentiation and depression) at the reformed host-graft synapses, which suggest a physiological substrate for the reestablished capacity for motor learning in the grafted brain.

Thus, at least in this one model system, there is growing evidence that under appropriate (albeit infrequent and perhaps fortuitous) circumstances, grafted neurons can truly integrate into the neuronal circuitry of the host brain so as to restore intrinsic information-processing abilities lost to an experimental lesion. The extent to which a similar strategy will find application in the related human disease HD is under current evaluation, and firm conclusions are still premature. Nevertheless, the experimental studies on the requirements for relearning in grafted animals suggest that it will not be sufficient simply to reimplant the lost neurons to restore the damaged circuitry; rather, a systematic program of rehabilitation will be required to recapitulate the learning of motor skills and habits that we routinely first acquire in normal childhood.

Full Network Repair

Notwithstanding the dramatic advances for repair and recovery so far achieved in animal models of spinal cord injury, stroke, or HD, no grafts approach full reconstruction of the normal circuitry. Even in the striatal graft model, the reformation of connections is incomplete and does not approach normal density, nor complex refinement of connections, and no model shows full functional recovery on all aspects of the underlying neurodegeneration or disease. Thus, full repair is not yet possible with available technologies in any neuronal system of the adult brain. It remains a matter of speculation whether the limits of current technologies are simply a matter of refinement. It is more likely that we have not yet identified all principles necessary to achieve complete reconstruction of the damaged nervous system.

Matching Donor Cells, Mechanisms, and Applications

The prospects of developing cell replacement strategies for CNS damage and neurodegenerative disease

remain optimistic. Nevertheless, consideration of the mechanisms by which grafts exert their functional effects in the host brain indicates that a common strategy is unlikely to fit all applications, and different solutions will be required for different diseases. To date, most studies have focused simply on identifying the cells that are lost and seeking alternative cell sources and surgical strategies for their replacement. The outcome has typically been that recovery is partial, some but not all symptoms show some alleviation, and the best recovery is seen on somewhat artificial measures of neuronal dysfunction rather than on the symptoms that are likely to be of most concern to patients. Amphetamine-induced rotation in the unilateral lesion model of parkinsonism is a powerful surrogate variable for evaluating experimentally the levels of underlying nigrostriatal loss and reinnervation, but hardly has face validity to the akinesia, rigidity, tremor, and dyskinesias experienced by PD patients.

To improve on this mismatch between the clinical demands and the animal models, the first requirement is to embed transplantation studies within the context of a detailed functional analysis of the underlying neuronal organization. What exactly is the level of repair required to achieve functional recovery on the symptoms of greatest practical concern? This analysis will constrain the options available for transplantation, since different sources of cells and different transplantation strategies will be required if the need is to restore functional neuronal connections, than if a pharmacological, trophic, or neuroprotective strategy can be effective.

Similarly, with the contemporary focus on developing alternative sources of stem cells or *ex vivo* gene therapy, the new therapies will find different applications depending on the functional demands placed upon them. Encapsulation of cells engineered to express particular trophic molecules may be highly effective for neuroprotection early in disease, and may promote intrinsic regeneration later in the disease course, but can never be effective in replacing a critical neuronal circuit whose component cells are already lost. Neuronal transplantation can be considered to be coming of age to the extent that the development of new strategies for therapy and repair is based on rational design rather than simple empirical cell replacement.

Cell Replacement Therapy: Parkinson's Disease

P Brundin and A Björklund, Wallenberg Neuroscience Center, Lund, Sweden

Introduction

Cell replacement therapy for Parkinson's disease (PD) is based on the idea that implanted immature dopamine neurons may be able to substitute for the lost nigrostriatal neurons. The principal limitations of this approach are the practical and ethical problems associated with the use of tissue derived from aborted human embryos or fetuses and also the large numbers of donors needed to obtain good therapeutic effects. To date, differentiated neuroblasts and young postmitotic dopamine neurons have been used for transplantation. However, progenitors taken at earlier stages of development might prove more effective in the future. Efforts are under way to expand multipotent neural stem or progenitor cells *in vitro* and control their phenotypic differentiation into a dopaminergic neuronal fate. Initial results suggest that *in vitro* expanded cells can survive and function after transplantation to the striatum in the rat PD model, but the number of surviving dopamine neurons has in most cases been very low. With further development, expanded progenitors or dopamine neuron precursors, possibly modified by cell engineering techniques, may offer new sources of cells for replacement therapy in PD.

History

The first studies on the transplantability of brain catecholaminergic (including dopaminergic) neurons were conducted by Seiger and Olson in the early 1970s. These studies in rats showed that immature, developing dopamine neurons from the ventral midbrain can survive transplantation to the anterior eye chamber and extend an extensive axonal terminal network on the underlying iris. The experiments showed that dopamine neurons have to be obtained at embryonic or fetal stages of development, ideally at the time of development when they are generated. Inspired by these early observations, in 1979 Björklund and Stenevi and Perlow et al. showed that fetal dopamine neurons can survive, grow, and function after transplantation to the brain in rats subjected to a 6-hydroxydopamine (6-OHDA) lesion of the intrinsic nigrostriatal dopamine system. Extensive animal experiments in rodent and primate models of PD during the subsequent decades have shown that immature dopamine neurons and neuroblasts can survive and reinnervate the denervated striatum, as well as restore dopamine synthesis and release in the area. Based on these animal studies, the first clinical trials using cells obtained from embryonic human ventral mesencephalon (VM) were carried out in 1987–89. The observations from these initial trials were quite encouraging. To date, several hundred patients have received dopamine cell transplants in open-label and double-blind, placebo-controlled trials with mixed results.

Studies in Rodents and Primates

The dopamine neurons used for transplantation are harvested from the VM (i.e., the region containing the developing substantia nigra and the ventral tegmental area) at the time when the dopamine neurons are born – that is, from 13- to 15-day-old fetuses in the rat and 6- to 8-week-old human aborted embryos. In most cases, the cells are transplanted into the striatum (i.e., close to the denervated target cells). Thereby they can extend a new terminal network in the host striatum and establish functional synaptic contacts with the striatal target neurons. Only approximately 10% of the dopamine neurons that are implanted survive the graft surgery, and various neuroprotective agents and growth factors have been employed to boost this survival rate to some extent. Coadministration of growth factors such as glial cell line-derived neurotrophic factor can promote axonal outgrowth from the transplants.

Experiments performed in rodents and primates in which the nigrostriatal dopamine system is destroyed either by the 6-OHDA toxin (in rats) or by MPTP (in monkeys) have shown that grafted dopaminergic neuroblasts reverse some, but not all, motor symptoms associated with the loss of the intrinsic nigrostriatal system. The functional effect develops gradually: the first transplant-induced effects on motor behavior are seen after 3–6 weeks with rodent cells and after a few months with human dopamine neurons. Functional recovery is correlated with growth of axonal processes from the grafted cells and establishment of a new dopamine-containing terminal network in the host striatum. Rodent studies have shown that the grafted dopamine neurons are spontaneously active and can restore a tonic release of dopamine to near-normal levels within the reinnervated area. Several observations clearly indicate that the functional recovery is dependent on a specific interaction between dopamine neurons and the host striatum: (1) the recovered function is maintained only with continued

survival of the grafted neurons, (2) dopamine neurons transplanted outside the basal ganglia induce no improvement, and (3) non-dopaminergic neurons grafted to otherwise effective striatal sites exert no effect.

In rats with 6-OHDA lesions, intrastriatal VM grafts containing between 1000 and 2000 surviving dopamine neurons (approximately 10–15% of the number of dopamine neurons normally present in the adult substantia nigra) are known to be sufficient to reverse some behavioral deficits. They can restore striatal dopamine levels to approximately 10–30% of normal, *in vivo* striatal dopamine synthesis to approximately 20–30% of normal levels, and striatal dopamine release (as measured by microdialysis in the area densely innervated by the grafted neurons) up to 40–100% of the levels seen in the intact striatum. Using multiple graft placements, it has been possible to obtain a striatal dopamine innervation density in the range of 40–75% of normal (as assessed by tyrosine hydroxylase immunoreactivity). Even with such large grafts, the recovery of lesion-induced motor deficits is incomplete and varies depending on the type of test. Thus, motor asymmetry assessed by drug-induced turning behavior is completely reversed, whereas several aspects of spontaneous motor behavior, such as stepping, forelimb use, and postural balance, are only partly restored.

There are several possible reasons why graft-induced functional recovery is limited to certain basic aspects of motor function, whereas impairments in more complex motor behavior are influenced to a lesser extent, if at all. The transplants are placed in an ectopic location (i.e., in striatum rather than substantia nigra) in order to obtain extensive reinnervation of the striatum from the grafted neurons. This may impose limitations on their functionality because the grafted dopamine neurons are likely to lack crucial afferent regulatory inputs. In the intact brain, baseline striatal dopamine neurotransmission is normally maintained by tonic synaptic and nonsynaptic dopamine release, which is largely independent of changes in neuronal impulse flow in the nigrostriatal pathway. In grafted animals, the establishment of a new dopamine-storing terminal network in the host striatum is closely correlated with the onset of graft-derived dopamine release and reversal of dopamine receptor supersensitivity. This suggests that the grafted neurons are spontaneously active and release dopamine at both synaptic and nonsynaptic sites at a near-normal rate. The grafted neurons are probably not entirely devoid of host afferent control, but these contacts might not be fully appropriate for normal function. In 1991, Fisher et al. showed that more than 50% of the grafted neurons respond to stimulation of either frontal cortex or striatum, and burst firing, which normally depends on a functional cortical input, is present in a portion of them. Neuroanatomical data also indicate that some afferent inputs (e.g., from premotor cortex and/or striatum) may contribute to the functional efficacy of intrastriatal dopamine neuron transplants. An alternative explanation for incomplete functional recovery seen in animals with intrastriatal dopamine neuron transplants is that the graft-derived innervation is confined to the striatum, whereas the denervating lesion also involves other nonstriatal areas. The inability of intrastriatal VM grafts to provide complete functional recovery may be due to the fact that limbic and cortical areas, as well as other parts of the basal ganglia, remain denervated and thus unaffected by the transplanted cells. In support of this view, in 2001 Kirik et al. showed that graft-reduced functional recovery is more pronounced in animals with partial lesions of the nigrostriatal pathway, in which the denervation is confined to the striatum, than in animals with lesions which involve both striatal and nonstriatal areas. This indicates that it may be functionally important that part of the nonstriatal dopamine projections remains intact. These spared portions of the host dopamine system, particularly those innervating nonstriatal forebrain areas, may be necessary for the VM grafts to exert optimal functional effects.

Clinical Trials

In 1990, for the first time, neural transplants were reported to survive and reduce neurological symptoms in a PD patient. The donor tissue was obtained from embryos at routine abortions. The trials were preceded by an ethical debate. In many countries, it was considered justifiable to use donor tissue from abortions if clearly separated from the transplantation surgery and the women undergoing abortions had given their informed consent. In the first trial, tissue was dissected from the VM of multiple 6- to 8-week-old human embryos, mechanically dissociated, and then injected into the striatum using stereotactic surgery on one side of the brain in a patient receiving immunosuppression. After 4 or 5 months, the patient started to exhibit a progressive reduction in bradykinesia and rigidity, whereas the tremor remained largely unaffected. Using positron emission tomography, it was possible to monitor an increase in fluorodopa uptake in the graft site, indicating that dopaminergic neurons in the implant had survived. Several subsequent reports confirmed that grafted embryonic neurons can alleviate symptoms and replace the dopaminergic neurotransmission that is lost in PD. In extreme cases, the fluorodopa uptake

approached that of a normal striatum, comparable to the 10–30% of normal levels seen in the PD patients prior to surgery or in unoperated parts of their brains. Ten years after surgery, which is the longest reported follow-up, transplanted neurons have been shown to still be alive and capable of releasing dopamine. Functional positron emission tomography studies have indicated that the grafted cells integrate with basal ganglia – cortical circuits that participate in fine motor control. This functional integration seems to take several months longer than for the grafted neurons to start producing dopamine and appears to coincide with further improvements of symptoms.

The brains of a few patients who died several years postoperatively (unrelated to the graft surgery) have been examined microscopically. These have revealed that approximately 5–10% of the grafted dopaminergic neurons survive and extend a dense network of axons into the host brain. Interestingly, some of the grafts are infiltrated with immunocompetent cells. Although the brain is an immunologically privileged transplantation site (i.e., histoincompatible grafts survive longer in the brain than in peripheral sites), it is clear that transplant rejection can take place in the brain. The level of immunosuppressive treatment that is required to avoid rejection with certainty is not known. Consequently, different clinical trials have employed widely different strategies to deal with the risk of immune rejection.

Approximately 300 patients have undergone cell transplantation surgery in several small clinical trials. However, not all patients benefited to the same extent. Approximately one-third of patients demonstrated remarkable recovery and were able to stop taking anti-parkinsonian medication, one-third were moderately improved, and one-third exhibited no clear lasting benefit from the surgery. Variation in outcome was evident even among patients operated at the same surgical center. The small trials were conducted in independent centers and therefore not coordinated with each other. As a consequence, there were several potentially important variations in the experimental protocols regarding, for example, disease stage and age of patients, donor tissue age, numbers of donors, graft storage and preparation technique, surgical methodology, and the use of immunosuppression. Therefore, it is difficult to compare the results from the different centers and devise a protocol that would have a good chance of reproducible success. Another shortcoming of the initial neural transplantation trials was that they were open-label (i.e., both the patient and the investigator were aware that the patient was receiving a graft). This meant that there was a risk that the reported beneficial effects of the transplants were due to a placebo effect or observer bias.

In the mid-1990s, the US National Institutes of Health (NIH) sponsored two large randomized, double-blind, placebo-controlled clinical trials with neural transplants in PD. The outcomes of these trials, published in 2001 and 2003, were largely disappointing to patients and researchers. In brief, there was no significant symptomatic relief in the grafted patients compared to the control subjects, according to primary outcome parameters. The positron emission tomography scans and postmortem morphological examinations showed that grafted dopamine neurons had survived, despite the lack of clear beneficial effects of the surgery. Although individual patients in these two trials may have experienced graft-related improvement, these findings clearly question whether cell transplantation is a viable strategy for PD. It is important to note, however, that there are several outstanding issues regarding how the trials were performed. First, the donor tissue was stored prior to surgery for between 2 days and 4 weeks, which may have added variability in the quality of the implants. Second, in one of the trials an unconventional frontal (as opposed to dorsal) stereotactic approach was used to target the putamen. The impact of this surgical technique on graft function is not known. Third, in one of the trials no immunusuppression was given, and in the other it was limited to a 6-month administration of cyclosporine. Fourth, there is an indication that younger PD patients who are still responsive to anti-parkinsonian medication respond better to the surgery than aged patients, and selection of relatively old patients may have affected the overall outcome. Taken together, the two NIH-sponsored trials provided very valuable information but clearly showed that neural grafts do not reliably provide clinically valuable effects with the particular protocols they employed.

Aside from the lack of graft-induced benefit, the first of the two NIH-sponsored trials also reported that some patients (approximately 15%) experienced involuntary movements (dyskinesias) that were caused by the implants. This finding was unexpected and it was particularly disturbing that the dyskinesias did not improve when the anti-parkinsonian medication was terminated. Some of the patients from open-label trials and the patients in the second NIH-sponsored trial were also found to have developed graft-induced dyskinesias of varying severity. The reports of graft-induced dyskinesias and problems in obtaining suitable donor tissue in a reproducible manner brought clinical transplantation trials in PD to a standstill in the early 2000s. The pathogenetic mechanisms underlying the involuntary movements

are not understood. Several possible explanations have been proposed, including that there is too much or unregulated dopamine release from the implants in certain striatal regions, that non-dopaminergic neurons in the implants influence the striatum, or that inflammation due to an immune response triggers the movements. Concerted efforts in experimental animals are currently under way to elucidate why neural transplants can sometimes elicit this undesirable side effect. It is of vital importance to understand when, how, and why graft dyskinesias occur because they could conceivably also develop following transplantation of stem cell-derived neurons.

Future Cell Replacement Strategies

It is important to emphasize that so far no systematic stem cell transplantation trials have been performed for PD. The cells used in clinical trials have all been postmitotic immature neurons that have already been committed to the dopaminergic neuron fate. Stem cells are characterized by their ability to self-renew and to differentiate into many different forms of cells. There are various types of stem cells related to the age of the organism in which they are found and their anatomical location. Research is ongoing in experimental models of PD aimed at developing a therapy based on neurons derived from stem cells.

An existing proposal is to utilize endogenous neurogenesis in the adult brain as a source of new dopamine neurons. Under normal conditions, neurogenesis takes place in the adult mammalian brain in at least two regions, namely the dentate gyrus of the hippocampus and the subventricular zone, which supplies the olfactory bulb with new neurons. Claims that new dopaminergic neurons can be generated in the substantia nigra of adult rodents and that lesion-induced motor deficits can be reversed are highly controversial, with several studies disputing these findings. Extensive basic research is needed before adult neurogenesis can be proposed as a strategy for brain repair in PD.

Currently, it seems more feasible that it will be possible to transplant neurons derived from stem cells in PD. These stem cells are essentially one of two transplantable types – adult-derived or embryonic stem (ES) cells. Concerning stem cells obtained from adults, several investigators have suggested that it may be possible to transplant dopamine neurons derived from stem cells located outside the central nervous system. These neurons would be the result of a phenomenon called transdifferentiation; that is, the stem cells differentiate into a cell type that is not associated with the anatomical structure in which they are located. For example, it has been suggested that neurons suitable for transplantation can be generated from stem cells residing in bone marrow or skin. These ideas have been questioned, and it is currently unclear if neurons can be generated by transdifferentiation. In some experimental paradigms in which transdifferentiation was initially suggested to have taken place, the host neurons appear to have undergone fusion with injected stem cells. Another option is to harvest stem cells from the developing or adult nervous system and coax them by specific culture media or genetic modification into becoming dopamine neurons. Although there exist several cell culture protocols that allow propagation of central nervous system stem cells *in vitro*, it is difficult to manipulate these to differentiate into dopamine-producing neurons that can survive grafting. Therefore, new experimental strategies need to be developed before neural stem cells can provide a reliable source of dopamine neurons for transplantation in PD.

The most promising option for a stem cell therapy in PD is to employ ES cells. The ES cells are derived from the inner cell mass of a blastocyst and can be propagated in large numbers *in vitro*. Mouse ES cells can be induced to differentiate into dopamine-producing neurons. These neurons have successfully been grafted to rodent models of PD, in which they innervate the brain and reverse lesion-induced motor deficits. Dopamine neurons have also been derived from nonhuman primate ES cells and successfully grafted to monkeys. In addition, research has demonstrated that it is possible to generate dopaminergic neurons from human ES cells in culture. Unfortunately, the success rate has been low when transplanting dopamine neurons derived from human ES cells into rat models of PD. This problem needs to be resolved before translation into a clinical protocol can continue. Possible explanations are that the dopaminergic neurons die because they are particularly sensitive to the grafting procedure and/or that they downregulate some key phenotypic or regulatory proteins after implantation into the adult brain.

At least three other important issues need to be resolved before dopaminergic neurons derived from human ES cells can be tested in PD patients. First, ES cells are pluripotent and therefore they can form teratomas (tumors containing tissues from all three germ layers) upon grafting. A clinical protocol would require that all pluripotent stem cells are purged from the transplant preparation. Even a single remaining pluripotent or otherwise tumorigenic stem cell could have devastating consequences for a PD patient receiving an intracerebral implant. Second, most current cell culture protocols for human ES cells include animal-derived products (culture media, feeder cells, etc.). To eliminate the risk of transfer of potentially dangerous zoonooses (e.g., species-specific

retroviruses) and to reduce the risk of graft rejection due to transfer of animal-derived molecules to the graft cells, the ES cells should be grown without any animal products present. Third, further research is required to analyze the type of dopaminergic neurons that are generated from ES cells. It is important that the dopamine neurons used for cell replacement therapy have a midbrain-specific phenotype. To be fully functional in the striatum, it is likely that they need to possess the properties of substantia nigra dopaminergic neurons because the specific physiological features of nigral neurons differ from those of dopaminergic neurons from other brain regions. Advances in transcriptional control have provided information that can help devise protocols that generate large numbers of midbrain dopamine neurons from human ES cells. Overexpression of key regulatory transcription factors, for example, can be used to achieve a high yield of dopamine neurons from mouse ES cells. Future research will reveal if that is also the case for human ES cells.

Cell–Cell Communication through the Extracellular Space

K Fuxe, Karolinska Institutet, Stockholm, Sweden
L F Agnati, University of Modena, Modena, Italy

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In any computational system (network), three aspects are of fundamental importance: modalities according to which computation is carried out in its computing elements (nodes), communication pathways (channels) among its nodes, and processes that allow signal transmission along the channels. Sometimes these aspects are not easily separated, as seems to be the case for the central nervous system (CNS). This article briefly discusses these aspects and some views on their biochemical and biophysical substrates.

Two competing theories on interneuronal communication have dominated neuroscience from the dawn of the modern discipline in the 1890s: the neuron doctrine and the theory of the diffuse nerve network, supported by Cajal and Golgi, respectively. The article provides a brief account of a view on interneuronal communication in the brain that reconciles these apparently opposing views. This unifying theory considers two main classes of intercellular communication which can be distinguished on the basis of the communication channels connecting communicating cells in the CNS: volume transmission (VT), which uses the extracellular space as a communication channel, and wiring transmission (WT), which uses cellular substrates (e.g., axons and synaptic contacts) as a communication channel. Thus, WT mode is characterized by physical contact (gap junctions) or quasi-contact (chemical synapses) between the cells of the net.

Furthermore, a biochemical mechanism, the receptor–receptor interaction (RRI), is discussed since it suggests a mechanism capable, *inter alia*, of integrating WT and VT signals at the plasma membrane level. In the early 1980s, Agnati and Fuxe introduced the concept of direct physical interactions between receptors at the membrane level and called the phenomenon RRIs. During the 1980s and after, they provided the first experimental observations for the existence of such direct physical interactions between receptors at the membrane level. Their proposal was supported by biochemical binding analysis in cell membrane preparations and by indirect evidence from functional studies in animal models. From the beginning, RRIs have been considered as an important case of protein–protein interactions. In 2002, the concept of WT and VT was extended to molecular networks, and RRIs have been considered examples of a 'wired' communication between computing 'nodes' in a molecular network, whereas the intracellular diffusion of second messengers between molecular nodes is an example of VT in molecular networks. In view of the existence of an organized extracellular matrix which is a molecular dynamic structure capable of storing and releasing signals (e.g., trophic factors) and interacting with receptors on the cell membranes (e.g., integrins), we have proposed the existence of a global molecular network (GMN) enmeshing the entire CNS. Because of the heuristic importance of this theory and, in particular, its potential value as a unitary frame for the CNS integrative action, a brief account of this theory is given.

Communication Processes in the Brain: WT versus VT

WT and VT in the Cellular Networks

The integrative actions of the CNS depend on all cell types present in it. Not only neuronal networks but also mainly complex cellular networks should be considered. A complex cellular network (CCN) can be defined as the set of cells of any type which exchanges signals in a certain volume of brain tissue and, due to this cross-talk, is capable of integrating inputs to give appropriate outputs. Let us consider some main aspects of VT versus WT (Figure 1).

Characteristics of the channel allow VT to be distinguished from WT VT is characterized by a channel with a poorly defined physical substrate and signal transmission takes place by diffusion and/or convection in the medium interposed between nodes. 'Transmission privacy,' when present, is usually given by the chemical code (e.g., the specificity of the chemical signal/receptor recognition process).

WT is characterized by the transmission of the signal along a channel with a well-defined physical substrate; thus, a 'wire' links the source node with the target node. Transmission privacy, which is usually present, is given by the fact that the channel is a private channel. Classically, in the case of CCN the WT channel between neurons is formed by axons and synapses.

Main features of VT and WT It is sometimes possible to summarize the main features of VT and WT in absolute terms but more often by means of a comparison between them:

Figure 1 Schematic representation of the main characteristics of VT in the cellular networks of the brain. The main sources of VT signals are illustrated, as well as the energy gradients making their migration in the extracellular space of the brain possible. DA, dopamine; ECF, extracellular fluid; GABA, γ-aminobutyric acid; VT, volume transmission; WT, wiring transmission.

- *Main characteristic of VT.* A structurally poorly defined channel, made by the medium which pervades the network, is always interposed between the source node and the target node.
- *Main characteristic of WT.* A structurally well-defined channel connects the source node with the target node when the two nodes are not in direct physical contact.

Besides the type of channel, additional criteria help to differentiate VT from WT and also to classify different types of VT and WT, namely the distance between the source and the target of the signal and the type of signal. The source–target distance (in the case of the absence of a structurally well-defined channel) provided indirect evidence for the existence of VT based on the demonstration of the so-called 'transmitter–receptor mismatches' – that is, the spatial uncoupling between the release sites of a transmitter and the receptors capable of its recognition and decoding.

Transmitter–receptor mismatches have been especially studied in the nucleus accumbens, in which dopamine (DA)-terminal/DA D1 receptor mismatches have been observed. This mismatch can be linked to a possible role of uncoupling proteins (UCPs) in VT via their generation of thermal gradients, enhancing migration of DA signals by microconvection.

Functional implications of VT and WT for brain integrative functions VT and WT have different characteristics and thus are employed for different functions. From a physiopathological standpoint, it should be noted that in some instances, VT can play a vicarious role in the presence of a WT deficit.

VT occurs mainly in cells that communicate at a distance longer than a synaptic cleft by means of chemical signals or physical signals. These signals diffuse in the extracellular space (ECS) medium interposed

between the source and the target cell where the signal is decoded.

Thus, the following features can be distinguished: the type of VT signals, modalities of VT signal release, pathways for VT signal migration, energy gradients for VT signal migration, and decoding systems for VT signals. Diffusion of chemical VT signals in the brain is made possible by concentration gradients, and convection of VT signals is favored by thermal gradients (produced by both localized high neuronal firing and UCPs) and by the heart-produced pressure waves within the skull (tide hypothesis). It is clear that VT is very well suited for functions that do not require prompt activation of effector systems but, rather, make possible their long-lasting activation, as observed for hunger, sexual arousal, mood, and sleep. These functions are carried out especially at the level of the so-called visceral or limbic brain, where Nieuwenhuys, on the basis of his neurochemical mapping studies, suggested that a paracrine-like transmission was in operation.

WT occurs mainly in chemical synapses, gap junctions, and specialized close membrane juxtapositions in which any movement of substances, such as ions, metabolites, and transmitters, can affect juxtaposed processes of other cells. It is clear that WT is very well suited for functions that need prompt activation of effector systems and/or prompt change in the level of their activation or even their inhibition. Functions under main WT control are motor control, face recognition, and language. These functions can be carried out especially at the level of the phylogenetically most recent brain, the neopallium.

The Concept of RRIs and Receptor Mosaics

As indicated previously, these two concepts are strictly interrelated since the physical interactions among receptors in a receptor cluster are at the core of the concept of receptor mosaic (RM). Thus, the development of the two concepts and their experimental demonstration are strictly linked to each other.

Emergence of the Concept of RRIs and RMs

The hypothesis that some elaboration of information could occur at the membrane level was included in the electrophysiological concept of integration of the local currents at the level of the axon hillock leading to the triggering of or failure to trigger the action potential by the nerve cell. Even more closely linked to the concept of RRI is the hypothesis of Hodgkin and Huxley that ion fluxes via an ionotropic receptor can cause changes in the membrane potential, which in turn can change the conformation of membrane proteins such as ion channels. In fact, based on this proposal it was reasonable to deduce that the affected proteins could also be other receptors.

Cross-talk between receptors: The classical view It is therefore possible to maintain that the first proposal on RRIs could be made as an obvious consequence of Hodgkin and Huxley's hypothesis on the gating of ion channels (e.g., changes in conformation of proteins) in response to changes in the membrane potential. However, the first real demonstration of an indirect RRI was provided by Greengard in 1976, who showed that metabotropic receptors could alter the conformation of other membrane proteins, such as receptors, via a process of phosphorylation/dephosphorylation. During the same time period, Lefkowitz and Limbird demonstrated a site–site interaction between β-adrenergic receptors in erythrocyte membrane preparations (Figure 2).

RRIs: A new integrative mechanism at the membrane level In the 1980s, a new paradigm was proposed that one receptor (e.g., for peptides) could change conformation of another receptor for a completely different ligand (e.g., monoamines) via a direct physical interaction at the intramembrane level, and this interaction could also occur within a cluster of topographically ordered receptors of different classes called RMs. Furthermore, in 1987, Fuxe and Agnati introduced a proposal that can be viewed as an *ante litteram* program of proteomics: "Very likely we will find that some sophisticated elaborations of information are performed at membrane level, via interactions within and among different classes of macromolecules (such as receptors, ion pumps, ion channels. . . ."

RRIs make possible a vast miniaturization of the computational circuits and provide the cell with a first microcircuit capable of integrating and filtering extracellular signals and that can be subtly modulated by the intracellular biochemical machinery in terms of changes in number, subtype, and topology of the receptors in the RM (Figure 3).

Hence, the concept of the RM is important since it means that one can produce markedly different molecular aggregates of receptors by putting together similar building blocks to construct functionally different assemblies. These can store information and at the synaptic level change the synaptic weight, and thus be involved in at least some forms of learning.

Figure 2 Schematic of the development of the concept of receptor–receptor interactions. Two classes are indicated, namely the indirect interactions between receptors involving a bioelectrical mechanism (change of membrane polarization) or an enzymatic mechanism (phosphorylation/dephosphorylation) and direct interactions based on intramembrane receptor–receptor interactions in heteromers or homomers with or without the involvement of adapter proteins.

Biochemical mechanisms involved in the assemblage of RMs have been partially clarified, and classification of RMs based on the absence or presence of classical cooperativity has been performed.

Implications of the Concept of RRIs and RMs

A new way to look at the decoding of extracellular signals arose from these two innovative concepts. Thus, special microdomains are present in the membrane and molecular networks are present in these specialized domains (Figure 3). Based on these concepts and data of our group and other groups, new characteristics of the cell biochemical machinery have been discovered and new possibilities for handling the huge number of chemical and electrical signals impinging on the cell have been described.

Biochemical implications

- Via the intramembrane regulation of receptor signaling, the biochemical pathways in the cytoplasm toward especially the nucleus can work on 'conditioned' signals. The regulation by RRIs involves modulation of receptor recognition (K_D and B_{max} values) and of G-protein coupling leading to modulatory actions in the activation or inhibition of multiple effector systems associated with the plasma membrane, such as ion channels and enzymes (e.g., adenylate cyclase).
- The RRI may make possible the appearance of novel receptor subtypes such as the $GABA_B$ receptor. Also, A1R/P2Y1R heteromerization leads to the appearance of an A1 receptor with a binding site showing P2Y agonist-like pharmacology. Thus, the

Figure 3 (Top) The importance of receptor multiplicity and topology in the assemblage of the receptor mosaics (RM). (Bottom) Schematic illustration of the RM (more than two receptors) as an integrative unit before sending the information into the vertical molecular networks involving multiple effectors and as part of horizontal molecular networks in the lipid rafts of the plasma membrane.

pharmacology of the binding pockets in the receptors participating in the formation of the heteromer may become markedly modulated.

- The conformational changes in the receptors caused by the RRI may lead to the formation of novel interactions with other membrane proteins, especially other receptors, including ligand-gated ion channels and different types of G-proteins. Thus, novel recognition-decoding systems may be formed and others may disappear, with the RM having novel interactions with other membrane-associated proteins such as scaffolding and adapter proteins.
- The RRIs also have a major impact on receptor co-trafficking, receptor maturation, cell surface expression, and internalization. Such events are of major relevance for sensitization and desensitization of receptors and especially for their cross-modulation.

RRIs between synaptic and extrasynaptic receptors integrate WT and VT signals The direct D5–$GABA_A$ and D1–NMDA receptor interactions are examples of paramount importance of such integrations since in the first case the GABA WT can be integrated with the DA VT and in the second case the Glu WT can be integrated with the DA VT.

VT integration with WT allows *inter alia* the combination of the main functional characteristics of the two communication modes. For example, it allows the prompt WT activation of the effector systems and their long-lasting activation via VT. This combination of the two modes can optimize the response of the organism to internal and/or external demands. An example is the 'fight-or-flight' reaction, in which a prompt response is needed that has to be backed up by sustained activation of the CNS alert systems and the cardiovascular and motor apparatuses.

RRIs: Relevance for Molecular Neuropsychopharmacology

Data from our group and other groups have demonstrated the existence of D2/A2A/mGluR5 mosaics at the level of the basal ganglia. On the basis of this evidence, new pathogenetic mechanisms and

therapeutic approaches have been proposed for Parkinson's disease and schizophrenic syndromes. Furthermore, our group has demonstrated GalR/5HT 1A mosaics in the tel- and diencephalon. Thus, it has been suggested that this RM may be a target to investigate pathogenetic mechanisms of depression and for the development of new antidepressant treatments.

Pathological Implications and Novel Treatments of Parkinson's Disease, Schizophrenia, and Depression

Development of A2A receptor antagonists in the treatment of Parkinson's disease based on the A2A/D2 receptor interaction in the dorsal striatopallidal GABA pathway Antagonists for A2A receptors may represent novel antiparkinsonian drugs targeting the A2A/D2 heteromer in the striatopallidal GABAergic neurons innervating the external segment of globus pallidus, where the antagonistic A2A/D2 receptor interaction occurs, leading to reduced D2-mediated inhibition of the dorsal striatopallidal GABA pathway which causes motor inhibition.

Development of mGluR5 antagonists for treatment of Parkinson's disease based on multiple mGluR5/A2A/D2 receptor interactions in the dorsal striatopallidal GABA pathway A series of reports indicate the usefulness of employing not only A2A antagonists but also mGluR5 antagonists and their combinations in the treatment of Parkinson's disease by increasing D2 signaling in A2A/mGluR5/D2 RMs located mainly in perisynaptic regions of glutamate and DA synapses on dendritic spines of striatopallidal GABA neurons and also by reducing glutamate release from corticostriatal glutamate terminals, where A2A and mGluR5 can interact synergistically in A2A/mGluR5/D2 RMs to increase glutamate release.

Development of agonists with combined A2A agonist/mGluR5 agonist properties for the treatment of schizophrenia based on multiple mGluR5/A2A/D2 receptor interactions in the ventral striatopallidal GABA pathway Experimental evidence suggests that synergistic interactions between A2A and mGluR5 receptors based on the existence of A2A/mGluR5 heteromeric complexes in postulated extrasynaptic mGluR5/A2A/D2 RMs of the ventral striatopallidal GABA neurons play a major role in increasing activity of this pathway and removing it from D2-mediated inhibition. This has been demonstrated in dual-probe microdialysis studies on this GABA system using co-perfusion with A2A and mGluR5 agonists.

Thus, we have advanced the proposal based on the DA hypothesis of schizophrenia that A2A agonists may be novel antipsychotic drugs by antagonizing D2 receptor signaling via an A2A/D2 intramembrane RRI in the ventral striatopallidal GABA system. The A2A agonist CGS21680 was shown to have an atypical antipsychotic profile by reducing the amphetamine and PCP-induced locomotor activity in doses failing to cause catalepsy. Furthermore, injection of the A2A agonist into the nucleus accumbens reversed prepulse inhibition by apomorphine, and combined treatment with subthreshold doses of a D2 antagonist and an A2A agonist led to activation of the ventral striatopallidal GABA pathway. The A2A agonist demonstrates antipsychotic-like activity in *Cebus apella* monkeys without production of extrapyramidal side effects, highlighting the development of novel A2A agonists as a strategy for treatment of schizophrenia based on their atypical antipsychotic profile.

Development of galanin receptor antagonists for treatment of depressive illness based on galR/5-HT1A receptor interactions In 1988, galanin was shown to reduce the affinity of 5-HT1A receptors in the ventral limbic cortex, providing the first evidence for the existence of antagonistic intramembrane GalR/5-HT 1A receptor interactions. In 1991, the reciprocal interaction was demonstrated with evidence that 5-HT1A receptor activation leads to an increase in the affinity of galanin receptors in various regions of the tel- and diencephalons. This increase in galanin recognition may be part of an intramembrane inhibitory feedback mechanism to reduce overactivation of 5-HT 1A signaling that occurs via the interface in a postulated GalR/5-HT 1A heteromeric complex. Also in 1991, the relevance of this RRI for depression was discussed in the context of the 5-HT hypothesis of depression, and the proposal was made that galanin receptor antagonists, by enhancing postjunctional 5-HT1A-mediated transmission in the forebrain, may represent novel antidepressant drugs. Galanin receptor antagonists may also produce antidepressant effects by blocking galanin receptors in the dorsal raphe, which inhibit the 5-HT releasing activity and firing of the ascending 5-HT pathways to the tel- and diencephalon. The galanin receptor on the HT cell bodies interacts with the 5-HT1A autoreceptor, but the functional outcome of this interaction remains to be clarified with regard to 5-HT1A autoreceptor signaling. An increased density of galanin receptor agonist binding sites has been found in the dorsal raphe in a genetic model of depression, leading to a feedback inhibition of galanin synthesis with reductions of galanin immunoreactivity in the dorsal raphe.

WT and VT in the Molecular Networks: Horizontal versus Vertical Molecular Networks

The RMs are located at the plasma membrane level and are part of horizontal molecular networks (HMNs) made by membrane-associated or membrane-integral proteins. Thus, HMNs represent the molecules located within a membrane microdomain, or associated with the plasma membrane microdomain, that are physically connected (WT) or communicate via a signal released and diffusing within the membrane (VT) (e.g., diacyl glycerol).

Vertical molecular networks (VMNs) go deep into the cytoplasm, often reaching into the nucleus to phosphorylate transcription factors. Here, WT is the transmission of signals along assembled protein modules that work as a wire. The best example is the Raf-MEK1/2-ERK1/2 cascade operating via protein–protein interactions to enter the nucleus and phosphorylate transcription factors such as Elk1. The main instance of VT in the VMN is the release of second messengers, especially calcium ions, leading to waves of calcium forming intracellularly.

HMNs are two-sided input/output networks – that is, they can receive signals from the extracellular as well as the intracellular environment of the cell and can give responses aimed at maintaining cell homeostasis, which affect both the extracellular and the intracellular environment of the cell. Thus, HMNs work as complex interfaces between the extracellular and intracellular environments and have been indicated as a target of electronic and chemical signals present at the local circuit level. Lipid rafts have emerged as specialized membrane platforms for HMNs. Our proposal of HMNs has similarities with Lisanti's proposal of signalosomes the view of the RM as an integrated input unit to the molecular networks, and with Bockaert's proposal of G-protein-coupled receptors (GPCRs) organized in a functional unit.

HMNs are formed by different classes of molecules, and some of them are targets for other cytoplasmic and extracellular molecules. Of obvious importance are those acting on the GPCRs (and hence on RMs) because they regulate the level of inputs to the cell biochemical machinery (i.e., to the VMNs). Among these are molecules controlling GPCR function (e.g., regulators of G-protein signaling), molecules controlling GPCR internalization and/or having scaffolding and adapter functions (e.g., β-arrestins and caveolins), or molecules controlling GPCR desensitization (e.g., GPCR kinases, which are key modulators of GPCR signaling can also interact with caveolins). These are some of the molecules that likely control the inputs that reach the VMNs and address the signal impinging on the cell only to some of the VMNs among all those that are potentially interconnected with the HMNs.

The Extracellular and Intracellular Molecular Networks: A GMN Enmeshes the Entire CNS

Molecular networks are composed mainly of proteins and carbohydrates, which fill up the ECS and the interior of the cells and interact with each other at the boundaries of these compartments, namely at the plasma membrane levels, to form a GMN. Thus, the GMN pervades the intra- as well as the extracellular environment of the entire CNS (Figure 4). From a functional standpoint, proteins are likely to be the most important building blocks for all the molecular networks. For those located in the ECS (the extracellular part of the GMN), carbohydrate-associated proteins also have an important scaffolding role.

A GMN is made by the extracellular matrix molecular net (the extracellular part of the GMN) and by the intracellular molecular nets. The intracellular part of the GMN communicates with the extracellular part of the GMN mainly via specialized 'windows' (e.g., the lipid rafts), where, for example, an integrin receptor permits a link between the extracellular matrix (ECM) network and the cytoskeleton, especially the microfilaments (twisted pairs of actin filaments). The extracellular part of the GMN is made by elements that can carry out a scaffolding and a computational role. Signals can be produced, elaborated, and/or released to be transmitted by the extracellular part of the GMN. Among these signals are several growth factors and hyaluronan and hyaluronan fragments.

Structure and Function of the Extracellular Part of the GMN

Hyaluronan is the backbone of several ECM molecular complexes and highly suited for space invasion. Furthermore, several ECM molecules tend to occupy a lot of space in view of the mutual repulsion of their numerous negatively charged residues. The hyaluronan molecule in solution can be viewed as a highly organized extended dynamic coil that can undergo sharp kinks, bends, and folds while maintaining distinctive hydrogen bond conformations. The characteristic chain reorganization time would be within a nanosecond timescale. This dynamic flexibility would give it excellent space-invading properties and, at the same time, promote very rapid recovery times after mechanical perturbation and distortion. Thus, hyaluronan is one of the fundamental blocks of

Figure 4 Illustration of the intracellular and intercellular molecular networks and how they can form a global molecular network (GMN) via interactions with the membrane-associated molecular networks (horizontal molecular networks).The GMN partially overlaps and interacts with the cellular networks composed of nerve and glial cells, giving a new model of the brain networks.

the extracellular part of the GMN which has been modeled in a simple way by Yamaguchi using the hyaluronan–lectican–tenascin R model of the brain ECM (Figure 5).

The extracellular part of the GMN, as well as the intracellular nets (microtubules, neurofilaments, and microfilaments) are made by building blocks that create, via protein–protein and protein–carbohydrate interactions, a high-order supramolecular structure. The extracellular part of the GMN has both a scaffolding role in enabling the appropriate location of the CNS components and a functional role in cooperating in the maintenance of the microenvironment around cells and in the creation of preferential diffusion pathways. The extracellular part of the GMN also affects the communication processes in the cellular circuits. Intercellular WT (i.e., synaptic contacts, but also gap junctions and specialized membrane juxtapositions) is regulated via the control of the cellular circuit geometry, as well as the control of the cell-to-cell connection efficacy. Intercellular VT (i.e., signal diffusion) is regulated via the control of the net tightness and the ECS medium fluidity, altering tortuosity in the diffusion pathways where VT signals released by a cell migrate in the ECS to reach the target cells (Figure 5).

In turn, the CCNs affect the GMN molecular composition and topology, both its extracellular part and its intracellular part. Thus, there is a complex interplay between the molecular and topological organization of the GMN and the intercellular WT and VT, and these interactions lead to optimal tuning of the integrative actions of the CNS.

A New Model of Brain Networks: Partially Overlapping Cellular and GMNs with a Nested Organization

According to Apathy's theory and as described in our own work, we have suggested the existence of a GMN enmeshing the entire CNS (Figure 4). Thus, the view of the brain as a system of neuronal (or also 'cellular') networks or even the view of the brain as a system of 'nested networks of networks'

Figure 5 Illustration of the role of the extracellular matrix – built *inter alia* of hyaluronan, tenascin, and lecticans – in intercellular and intracellular information handling. The size of the meshes and the degree of hydration will control the diffusion pathways in the extracellular space and thus VT. The tenascin interaction with the integrin receptor illustrates how, via WT, the extracellular molecular network can interact with the intracellular molecular networks, in this case the actin component of the cytoskeleton.

organized as Russian dolls are no longer tenable. Thus, we propose a new model of brain networks, namely as a system of nested but partially overlapping networks. According to this proposal, the GMN is superimposed on the cellular networks, and these networks sometimes operate in parallel and sometimes in series. Communication processes within these networks and between them occur via VT and WT.

This model allows a different approach to brain function and thus to the physiology and pathology of the brain. In particular, learning processes can occur simply via changes in the communication channels between nodes – that is, between cells in the case of CCN or between macromolecules in the case of molecular networks as described by the 'Turing B-type unorganized machine.' Furthermore, 'temporal difference learning' can be transferred to the molecular level if we accept that also at this level VT and WT can be in operation.

In addition, besides the classical models of learning based on WT, it may be proposed that also VT and a proper mix of VT and WT can allow very effective learning processes. It should also be noted that according to our old RM hypothesis of the engram, learning at the molecular level (RM formation and consolidation) can be the result of a common operation between molecular and cellular networks, and in this process the extracellular molecular network can also contribute to the RM assemblage. Hence, future investigations likely will establish that a continuous interchange of information and reciprocal plastic adjustments between CCN and GMN occur during learning and that membrane-associated molecular networks (i.e., the HMN and especially the RM) have a special role in such a fundamental process, as hypothesized approximately 25 years ago.

Pathological and Therapeutic Implications of the Current View

This new model of the brain networks communicating via VT and WT opens up a new understanding of

brain physiology and pathology both in neurodegenerative diseases and in mental diseases such as schizophrenia, depression, and addiction, as well as in brain tumor development. The intramembrane RRIs taking place via heterodimers and RMs represent a new principle in molecular medicine allowing integration of signals already at the level of the plasma membrane. They open up new targets for treatment of receptor dysfunction known to occur *inter alia* in neurological and mental disorders.

Cells: 5-Hydroxytryptamine Receptors

E J Mylecharane, The University of Sydney, Sydney, NSW, Australia

© 2009 Elsevier Ltd. All rights reserved.

Introduction: Background and Scope

5-Hydroxytryptamine (5-HT; enteramine; serotonin) has a long history in mammalian species studies. In the latter part of the nineteenth century, its existence was recognized as a vasoconstricting factor in serum, and its effects were able to be negated by passage through the lungs; its source was subsequently found to be platelets. In the 1930s–1940s, Erspamer and his colleagues in Italy knew it as the main hormone from enterochromaffin cells in the gastrointestinal tract mucosa, and named it enteramine. At the Cleveland Clinic in the United States, Rapport, Green, and Page isolated the serum vasoconstricting factor in 1948, and named it serotonin. Rapport determined its structure as an indolealkylamine, 5-hydroxytryptamine, in 1949 (Figure 1). Pharmacological studies in the early 1950s, by Reid and Rand in Australia, and in Erspamer's laboratory, soon confirmed that serotonin and enteramine were in fact 5-HT.

About 99% of the 5-HT in mammals is synthesized in enterochromaffin cells; approximately 90% is stored in the enterochromaffin cells, and 9% is taken up by platelets. The remaining 1% of the 5-HT in mammals is synthesized and stored in neurons. Recognition of 5-HT as an important neurotransmitter began with its discovery in the mammalian brain, by Twarog in 1953 in Cleveland, and in Gaddum's laboratory in 1954 in Britain. Most of the neuronal 5-HT is present in the central nervous system (CNS), where it has complex roles in the regulation of a host of functions, including sensory perception (e.g., pain, vision, audition), body temperature, neuroendocrine secretion, mood and emotional behavior, cognition, appetite, sexual activity, and sleep, as well as contributing to the regulation of the autonomic nervous system (ANS). A small fraction of the neuronal 5-HT is located in some peripheral parts of the ANS.

Receptors mediating 5-HT actions were first identified in Gaddum's laboratory in 1954, and were named D and M receptors. In the late 1970s, radiolabeled ligand binding sites for 5-HT in the brain were identified by Peroutka and Snyder, and named 5-HT_1 and 5-HT_2. D receptors seemed to correlate with 5-HT_2 binding sites, but M receptors and 5-HT_1 binding sites did not. The surge in development of a number of 5-HT receptor agonists and antagonists in the early 1980s led Bradley and colleagues to propose a rational 5-HT receptor classification scheme in 1986, comprising three types, 5-HT_1-like, 5-HT_2, and 5-HT_3 (the latter two types broadly encompassing the D and M receptors, respectively). The possibility of at least three 5-HT_1-like subtypes was recognized.

In 1994, Hoyer and colleagues proposed an expanded 5-HT receptor classification incorporating seven types (three of which included subtypes), based on many newly developed selective 5-HT receptor agonists and antagonists, improved understanding of receptor-coupling ('transduction') mechanisms, and rapid progress in using recombinant molecular biology techniques to determine receptor structure (as protein amino acid sequences). This classification, one of the first adopted by the International Union of Pharmacology (IUPHAR) in accordance with agreed criteria and principles, remains intact (subject to some subsequent minor adjustments – e.g., human primacy where species differences occur, and status based on further evidence): 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-ht_{1e}, 5-HT_{1F}; 5-HT_{2A}, 5-HT_{2B}, 5-HT_{2C}; 5-HT_3; 5-HT_4; 5-ht_{5a}, 5-ht_{5b}; 5-HT_6; and 5-HT_7 (lower case letters are used for recombinant receptors not yet found in a native tissue, or not yet pharmacologically evaluated). The 5-HT_3 receptor is a ligand-gated ion channel receptor. All the others are G-protein-coupled receptors with seven transmembrane-spanning regions. The current detailed IUPHAR classification is accessible via http://www.iuphar-db.org/GPCR/index.html.

This article provides a pharmacological and physiological survey of the 5-HT receptors located on the ANS neurons: sympathetic and parasympathetic neurons; the enteric nervous system (ENS; an important part of the ANS); and the sensory afferent and CNS neurons contributing to ANS regulation. 5-HT receptors on autonomic neuroeffector cells are also surveyed. In considering the extensive 5-HT receptor-mediated actions in the ANS, an ambiguity is readily apparent – there is relatively little 5-HT neurotransmission in the ANS, its main location being within the ENS (which comprises sensory neurons, interneurons, and motor neurons, and functions as a complex and independent autonomic regulatory system in the gastrointestinal tract). A few vasculatures are innervated by 5-HT-containing neurons, and 5-HT is present in some sympathetic ganglia within small intensely fluorescent cells (which may function as interneurons). 5-HT also serves as a neurotransmitter in some CNS pathways regulating the ANS (as CNS interneurons, or as direct innervation

to preganglionic ANS neurons). Nevertheless, the peripheral components of the ANS are able to be extensively affected by 5-HT released from enterochromaffin cells and platelets, acting as an autacoid or paracrine mediator, with physiological regulatory or homoeostatic roles, and defense or pathological roles.

5-HT receptor agonists and antagonists are used therapeutically in relatively few disorders related to ANS function, mainly for gastrointestinal disturbances (e.g., gastroesophageal reflux, gastroparesis, irritable bowel syndrome, and vomiting and nausea in cancer chemotherapy and radiotherapy), the cranial vascular disturbances of migraine, and control of 5-HT-induced systemic disturbances in carcinoid syndrome (enterochromaffin cell tumors). In contrast, drugs affecting 5-HT actions (i.e., 5-HT receptor agonists and antagonists, and drugs that alter 5-HT synthesis, storage, release, reuptake, and metabolic degradation) have many therapeutic uses for disorders such as migraine, depression, anxiety, schizophrenia, cognitive dysfunction, drug dependence and abuse, eating disorders, and sleep disturbances, largely on the basis of their CNS effects. Adverse effects of these drugs include many ANS disturbances in cardiovascular, bronchial, gastrointestinal, urogenital, and body temperature regulation; thus, an understanding of 5-HT actions on the ANS may contribute to better therapeutic outcomes. An important aspect is acute 5-HT toxicity (serotonin syndrome) due to overdosage or combinations of 5-HT activity-enhancing therapeutic and illicit drugs. Four principal features of serotonin syndrome are diarrhea, hypertension or hypotension, profuse sweating, and rapid hyperthermia, clearly involving major ANS dysfunction (the others are confusion, agitation, tremor, hyperreflexia, and clonus); hyperthermia is the most likely to lead to a fatal outcome.

Figure 1 5-Hydroxytryptamine.

Sympathetic Neuron 5-HT Receptors

Preganglionic

Sympathetic preganglionic neuron cell bodies are located in the CNS, in thoracolumbar spinal nuclei. Their relatively short axonal projections innervate the paired paravertebral sympathetic ganglia, located bilaterally along the vertebral column (including the superior and middle cervical ganglia, the stellate ganglia, the thoracic ganglia, the lumbar ganglia, and some sacral ganglia), and the midline prevertebral sympathetic ganglia (celiac, aortico-renal, and the superior and inferior mesenteric ganglia). Some longer axonal projections innervate terminal sympathetic ganglia closer to their target structures (e.g., the adrenal medulla and the hypogastric plexus). Table 1 summarizes 5-HT receptor-mediated actions in sympathetic preganglionic neurons.

Sympathetic preganglionic cell bodies are regulated by various CNS neurotransmitters, including 5-HT, from supraspinal CNS presympathetic inputs,

[a]E, neuroexcitation; I, neuroinhibition; ?, possible attribution based on limited evidence.
[b]Receptor subtype not determined.
[c]Neuroinhibition in dogs and guinea pigs is mediated by a 5-HT_1 receptor (subtype not determined); in rats, both rodent 5-HT_{1B} receptors and 5-HT_{1D} receptors contribute to neuroinhibition.
[d]Neuroinhibition mediated by 5-HT_{1B} receptors in various species (including rats), and also 5-HT_{1A} and 5-HT_{1D} receptors only in rats.

including the rostral and caudal ventrolateral medulla (RVLM and CVLM, respectively; see later). Electrophysiological studies have consistently demonstrated neuroexcitatory effects of 5-HT; however, 5-HT-induced neuroinhibition has been reported in a small percentage of cells in some studies. The 5-HT receptors mediating neuroexcitation have not yet been defined with appropriate selective agonists and antagonists; some studies suggest 5-HT_2 receptor-mediated neuroexcitation, but 5-HT_1 and 5-HT_7 receptors cannot be ruled out. No information is available regarding 5-HT receptor-mediated neuroinhibition in these cells.

5-HT_3 receptor-mediated neuroexcitation has been directly identified in sympathetic preganglionic axons. A 5-HT_3 receptor may also mediate neuroexcitation in the terminals of these preganglionic neurons, but this remains to be confirmed with selective antagonists. Presynaptic neuroinhibition resulting in decreased acetylcholine release from sympathetic preganglionic terminals is more difficult to investigate, because changes in postsynaptic response alone are insufficient to distinguish presynaptic from postsynaptic sites of action. 5-HT has a presynaptic neuroinhibitory effect on acetylcholine release in cervical, stellate, and splanchnic ganglia, but the receptor involved has not yet been defined; a 5-HT_1 receptor subtype (possibly 5-HT_{1B} or 5-HT_{1D}) is most likely.

Postganglionic

Table 1 also summarizes 5-HT receptor-mediated actions in sympathetic preganglionic neurons, which have relatively long axonal projections to their target cells, tissues, and organs. Electrophysiological studies have confirmed that a 5-HT_3 receptor mediates 5-HT-induced neuroexcitation, resulting in rapid depolarization, in superior cervical, celiac, and inferior mesenteric ganglia cell bodies. 5-HT also elicits a slow depolarization in a substantial proportion of cell bodies tested in the celiac and inferior mesenteric ganglia. The 5-HT receptor responsible for this slow depolarization is not a 5-HT_3 receptor; its identity remains unknown, but it has been suggested that it might be the so-called orphan 5-HT_{1P} receptor, which is located in the ENS (see later) and has not yet been incorporated into the IUPHAR classification of 5-HT receptors. In addition, 5-HT elicits neuroinhibition in cervical ganglion cell bodies, via an as yet unidentified 5-HT receptor; a 5-HT_3 receptor is not involved.

5-HT_3 receptor-mediated neuroexcitation has been identified in sympathetic postganglionic axons (recorded as depolarization in superior cervical ganglia) and in terminals (recorded as increased noradrenaline release from terminals in isolated heart preparations, accompanied by increased heart rate). 5-HT-induced presynaptic neuroinhibition resulting in decreased noradrenaline release from sympathetic postganglionic terminals in vascular tissues was first demonstrated by McGrath in the mid-1970s, using dog saphenous vein preparations, and recording decreases in smooth muscle contraction and radiolabeled noradrenaline release, in response to electrical stimulation. The role of presynaptic neuroinhibition of noradrenaline release from vascular sympathetic postganglionic terminals in 5-HT-induced vasodilation *in vivo* was clarified in the mid-1980s in the author's laboratory. Although 5-HT-induced direct vascular smooth muscle relaxation (see later) and release of endothelium-derived relaxant factor (EDRF; generally nitric oxide) contribute to *in vivo* vasodilation, presynaptic neuroinhibition of vascular sympathetic tone is a major factor in some regional circulations (e.g., in dog femoral and common carotid arterial circulations). In these studies, vasoconstrictor tone was established with normal vascular sympathetic tone, or with a direct vasoconstrictor agent after abolition of vascular sympathetic tone; the 5-HT-induced vasodilation was entirely dependent on vascular sympathetic tone. 5-HT-induced presynaptic neuroinhibition of vasoconstrictor responses to electrical stimulation of vascular sympathetic postganglionic terminals *in vivo* has also been demonstrated in experiments analogous to those *in vitro*. Other vasculatures in which presynaptic neuroinhibition of sympathetic postganglionic terminals has been identified include the vena cava, and coronary arterial, renal, and systemic (in pithed rats) circulations. A 5-HT_{1B} receptor is generally responsible for these effects. In rats, the rodent 5-HT_{1B} receptor is involved; this receptor is a species homolog of the human 5-HT_{1B} receptor, although its pharmacology is very different from that of the human homolog. There is evidence that in rats, both 5-HT_{1A} and 5-HT_{1D} receptors also contribute to the 5-HT-induced presynaptic neuroinhibition at vascular sympathetic postganglionic terminals. 5-HT-induced presynaptic neuroinhibition of noradrenaline release from sympathetic postganglionic terminals has also been demonstrated in some nonvascular tissues: dog, guinea pig, and rat heart; rat vas deferens; and bovine ovarian follicle. 5-HT_1 receptors (subtypes not yet identified) are responsible in all except rat heart, in which the rodent 5-HT_{1B} receptor and the 5-HT_{1D} receptor contribute to this presynaptic neuroinhibition.

Parasympathetic Neuron 5-HT Receptors

Preganglionic

Parasympathetic preganglionic neurons have relatively long axons, which project to ganglia located close to their target organs and tissues. Their cell

bodies are located in the CNS, in midbrain, brain stem, and sacral spinal nuclei. No parasympathetic preganglionic neuron roles for 5-HT receptors have yet been found in the facial and glossopharyngeal cranial nerves, or in vagal nerves projecting to lungs, kidneys, and gastrointestinal tract as far as the beginning of the distal colon. As summarized in Table 2, the main nuclei in which 5-HT receptors may have a parasympathetic preganglionic neuron role include the dorsal motor vagus (DMV) and the nucleus ambiguus in the medulla (providing vagal nerve outflow to the heart), and sacral spinal nuclei (providing pelvic nerve outflow to the urinary bladder and erectile tissue). DMV and nucleus ambiguus neuroinhibition may be 5-HT_{1A} receptor mediated, as it can be directly elicited by selective 5-HT_{1A} receptor agonists, but this remains to be confirmed with investigations involving selective antagonists and the elimination of indirect mechanisms. 5-HT_{1A} receptor mediated and 5-HT_3 receptor-mediated neuroexcitation of these CNS nuclei cell bodies are probably indirect actions, because the 5-HT-induced neuroexcitation is blocked by both 5-HT_3 and glutamate receptor antagonists in the DMV, and the invariable neuroinhibition mediated by 5-HT_{1A} receptors may result in disinhibition of neuroinhibitory input of γ-aminobutyric acid (GABA) neurons regulating DMV and nucleus ambiguus neurons. The only confirmed 5-HT receptor-mediated action on cell bodies in these nuclei is 5-HT_{2C} receptor-mediated neuroexcitation in sacral spinal nuclei, producing increased outflow to erectile tissue. Parasympathetic preganglionic regulation of urinary bladder function is known to involve 5-HT_{1A} receptor-mediated neuroinhibition, and 5-HT_{2C}, 5-HT_3, and possibly 5-HT_7 receptor-mediated neuroexcitation, but the CNS locations of these supraspinal and spinal nuclei are unknown (see later). A 5-HT_{1A} receptor-mediated neuroexcitation in sacral spinal segments is probably indirect, similar to that in DMV and nucleus ambiguus neurons.

At parasympathetic preganglionic terminals of the oculomotor cranial nerve in the ciliary ganglion, 5-HT decreases acetylcholine release via presynaptic neuroinhibition, possibly mediated by a 5-HT_4 receptor, but this remains to be confirmed with selective 5-HT_4 receptor agonists and antagonists. In the vesical ganglion, which regulates urinary bladder function, 5-HT_{1A} receptors mediate a presynaptic neuroinhibition of acetylcholine release from the preganglionic neuron terminals of the pelvic nerve.

Postganglionic

Table 2 also summarizes 5-HT receptor-mediated actions on parasympathetic postganglionic neurons, except for the very few vagal postganglionic neurons in the gastrointestinal tract myenteric plexus; these postganglionic neurons are regarded as an integral part of the ENS (see later). Electrophysiological studies can determine the location of receptors on cell

bodies, or on terminals remaining in cardiac and smooth muscle preparations stripped of neuronal plexuses, but this is precluded when postganglionic neuron function is monitored indirectly (e.g., via neurotransmitter efflux or neuroeffector cell response) because the postganglionic axons are very short.

5-HT_3 receptor-mediated neuroexcitation has been confirmed in oculomotor and pelvic nerve parasympathetic postganglionic cell bodies in the ciliary and vesical ganglia, respectively. In support of the latter conclusion, indirect studies show that 5-HT_3 receptor-mediated neuroexcitation of pelvic nerve parasympathetic postganglionic neurons increases acetylcholine release and urinary bladder smooth muscle contraction.

In cardiac parasympathetic postganglionic terminals, 5-HT_3 receptor-mediated neuroexcitation is responsible for increased acetylcholine release and a consequent decrease in heart rate. 5-HT enhances electrically stimulated bronchial smooth muscle contraction by a mainly presynaptic neuroexcitation, resulting in increased acetylcholine release from vagal parasympathetic postganglionic terminals, via a 5-HT_3 receptor. Studies on pelvic parasympathetic postganglionic terminals in human urinary bladder detrusor smooth muscle preparations have confirmed that 5-HT_4 and 5-HT_7 receptor-mediated presynaptic neuroexcitation results in increased acetylcholine release, and 5-HT_{1A} receptor-mediated neuroinhibition decreases acetylcholine release. 5-HT_3 receptors are not present on these terminals (in contrast to their presence on the postganglionic cell bodies). In mouse urinary bladder detrusor muscle, a rodent 5-HT_{1B} receptor-mediated neuroexcitation may be responsible for increased acetylcholine release from pelvic parasympathetic postganglionic terminals, but confirmation with more selective agonists and antagonists is needed.

ENS Neuron 5-HT Receptors

An understanding of ENS neuroanatomy and physiology provides some insight into the ENS roles of 5-HT and 5-HT receptors. Most of the peripheral neuronal 5-HT is in ENS neurons. ENS 5-HT interacts with 5-HT receptors on particular ENS neurons: submucosal and myenteric intrinsic primary afferent neurons (cholinergic, with cotransmitters calcitonin gene-related peptide in submucosal cells, and substance P in myenteric cells), which regulate gastrointestinal smooth muscle peristaltic and secretory reflexes via other interneurons; and extrinsic primary afferent neurons (which provide afferent information to the CNS via vagal and spinal afferent neurons, with cell bodies outside the gastrointestinal tract). Little is known about 5-HT receptor-mediated regulation of the very few parasympathetic postganglionic cholinergic motor neurons in the ENS which innervate smooth muscle (~1000 in the entire human small intestine, compared with approximately 10^8 ENS neurons). 5-HT from enterochromaffin cells in the mucosa can also interact with ENS 5-HT receptors.

Table 3 summarizes the 5-HT receptor-mediated actions in ENS neurons; the 5-HT_{1A} receptor-mediated action is neuroinhibitory, whereas those mediated by 5-HT_3, 5-HT_4, and 5-HT_7 receptors, as well as the so-called orphan 5-HT_{1P} receptor, are

[c]The so-called orphan 5-HT_{1P} receptor, found in the gastrointestinal tract but not in the CNS, has not yet been incorporated into the IUPHAR classification of 5-HT receptors; some hydroxylated indalpines are selective agonists, and the dipeptide *N*-acetyl-5-hydroxytryptophyl-5-hydroxytryptophan amide is a selective antagonist.

all neuroexcitatory. Electrophysiological studies with selective 5-HT receptor agonists and antagonists have confirmed all of the 5-HT receptor types and subtypes responsible for these ENS actions, except for the possible involvement of 5-HT_7 receptors in myenteric intrinsic primary afferent cell neuroexcitation.

5-HT_{1A} receptor-mediated neuroinhibition has been found only in myenteric intrinsic primary afferent neurons. 5-HT_3 receptor-mediated neuroexcitation elicits fast depolarization in submucosal and myenteric intrinsic primary afferent cell bodies, and in myenteric terminals. Gastrointestinal stimuli (via mechanosensitive and chemosensitive receptors) activate 5-HT_3 receptor-mediated neuroexcitation in the vagal and spinal axons of extrinsic primary afferent neurons, and 5-HT_3 receptor-mediated neuroexcitation can also be elicited in the vagal afferent cell bodies in nodose ganglia. The presynaptic 5-HT_4 receptor-mediated neuroexcitation in submucosal and myenteric intrinsic primary afferent terminals enhances fast depolarizations and increased release of acetylcholine and its cotransmitters. 5-HT_{1P} receptor-mediated neuroexcitation produces slow depolarization in submucosal and myenteric primary afferent cell bodies. Recent studies in guinea pigs have shown an extensive presence of 5-HT_7 immunoreactivity in myenteric cells. A selective 5-HT_7 receptor antagonist enhanced peristaltic activity in these studies; the blockade of a 5-HT_7 receptor-mediated neuroexcitatory action of 5-HT in myenteric cells might allow the normal release of nitric oxide from these cells to make a greater contribution to gastrointestinal smooth muscle relaxation (in tandem with 5-HT_7 receptor-mediated smooth muscle relaxation; see later).

ANS Sensory Afferent Neuron 5-HT Receptors

In addition to the ENS extrinsic primary afferent neurons; see earlier, the other important ANS afferent neuron inputs regulated by 5-HT receptors are the heart and lung vagal afferents and the carotid body glossopharyngeal afferents (i.e., parasympathetic afferents, with cell bodies in nodose-petrosal ganglia). The so-called sympathetic afferent neurons convey ANS information to the CNS via sympathetic nerve trunks, dorsal roots, and the spinal cord, but little is known about the role of 5-HT receptors in these afferents. 5-HT_3 receptors are the principal 5-HT receptors with a confirmed role in ANS sensory afferent neurons, as summarized in Table 4.

A 5-HT_{2A} receptor-mediated neuroexcitation has been identified in rat cervical vagal afferents. Intravenous injection of 5-HT_3 receptor agonists produces neuroexcitation in unmyelinated vagal afferents in the heart (in the ventricular walls), which then elicits a rapid-onset decrease in heart rate and blood pressure (the so-called Bezold–Jarisch-like effect that mimics the reflex response to increased left ventricular or atrial pressure). In the lungs, 5-HT_3 receptor-mediated neuroexcitation of unmyelinated vagal afferents in collagenous alveolar tissue produces a protective nociceptive reflex which includes ANS disturbances (bronchoconstriction, and decreased heart rate and blood pressure), as well as rapid shallow breathing, dyspnea, apnea, and pain. 5-HT_3 receptor-mediated neuroexcitation of carotid body chemoreceptors results in reflex vasoconstriction, adrenal medulla catecholamine release, increased blood pressure, and

decreased heart rate (similar to the chemoreceptor reflex response to decreased blood flow, low O_2 levels, high CO_2 levels, and acidemia); a 5-HT_{2A} receptor-mediated neuroexcitation may also contribute to the activation of this carotid chemoreceptor response. Neuroexcitatory 5-HT_3 receptors mediating a fast depolarization have been identified in nodose-petrosal ganglia cell bodies.

5-HT Receptors on CNS Neurons Regulating the ANS

Most of the vagal and glossopharyngeal sensory afferent neuron input from the abdominal and thoracic viscera projects to the nucleus tractus solitarius (NTS) in the medulla; some vagal afferents terminate in the DMV, the area postrema, and the supramedullary reticular formation. Ascending spinal sympathetic and lumbosacral parasympathetic afferents also project to the NTS. Sensory input is relayed by the NTS to medullary nuclei, which regulate efferent ANS pathways (the RVLM and CVLM, the DMV, and the nucleus ambiguus). The NTS also innervates medullary raphe nuclei (the main location of CNS 5-HT neurons). Supramedullary contributions to central ANS regulation include those from the reticular formation, the hypothalamus, and the thalamus. Table 5 summarizes 5-HT receptor-mediated actions in the main regulatory nuclei; the roles of 5-HT in the other ANS-regulating CNS regions are yet to be explored.

Little is known about the role of 5-HT in the NTS. 5-HT_3 receptor-mediated neuroexcitation releases NTS glutamate (neuroexcitatory), but the role of these 5-HT_3 receptors in regulating ANS reflexes (e.g., baroreceptor, chemoreceptor, Bezold–Jarisch) remains uncertain, because the outcomes are mainly assessed indirectly (i.e., as ANS sympathetic neuron firing, or neuroeffector events such as cardiovascular parameters, rather than neuronal activity in complex regulatory nuclei). A 5-HT_3 receptor-mediated presynaptic release of glutamate and GABA (neuroinhibitory) from vagal afferent terminals in the NTS may indirectly activate or inhibit particular NTS interneurons or second-order neurons projecting to ANS-regulating medullary nuclei.

In studies utilizing direct drug administration, 5-HT_{1A} receptor-mediated effects on RVLM neurons (which innervate thoracolumbar sympathetic preganglionic neurons) are involved in inhibition of vascular sympathetic tone in splanchnic, renal, and lumbar sympathetic neurons, but cardiac sympathetic tone is unaffected. Whether this inhibitory effect on RVLM neurons is a direct neuroinhibition, or an

[g]Neuroexcitation mediated by 5-HT_3 receptors is probably indirect.

indirect effect via neuroinhibition of an excitatory interneuron synapsing with RVLM neurons, remains to be determined. 5-HT_{2A} receptors mediate CNS neuroexcitation, and intracerebroventricular injection of 5-HT_{2A} receptor agonists increases cardiac and vascular sympathetic tone. In direct administration studies in the RVLM, however, there is a 5-HT_{2A} receptor-mediated increase in vascular, but not cardiac, sympathetic tone; thus, the CVLM may be responsible for regulation of cardiac sympathetic tone.

As noted earlier, cell bodies of vagal and sacral segment parasympathetic preganglionic neurons are, respectively, located in the DMV and the nucleus ambiguus (innervating the heart), and in spinal nuclei (innervating urinary bladder, and erectile tissue). The relevant information on 5-HT receptor-mediated actions in these preganglionic cell bodies is included in Table 2, and also in Table 5 for convenience.

Numerous 5-HT receptor-mediated actions contribute to the CNS regulation of ANS functions in micturition. Mechanisms involving 5-HT_{1A} receptor-mediated neuroinhibition, and 5-HT_{2C}, 5-HT_3, and possibly 5-HT_7 receptor-mediated neuroexcitation, have been identified, but the specific CNS nuclei involved have not yet been clearly confirmed. The study of these mechanisms has been limited to comparisons between supraspinal and intrathecal drug administration, so that sites in the brain can be distinguished from sacral spinal sites. These studies have not utilized direct drug administration to particular CNS nuclei; intracerebroventricular administration has often been used, but this is not sufficient to identify the CNS nuclei involved.

Autonomic Neuroeffector Cell 5-HT Receptors

Table 6 summarizes 5-HT receptor-mediated actions on neuroeffector cells associated with the ANS. The only ANS neuronal source of 5-HT available to act on autonomic neuroeffector cells is limited to 5-HT-containing neurons in sympathetic nerves innervating some cerebral, basilar, vertebral, and mesenteric blood vessels. Enterochromaffin cell 5-HT activates ENS neurons (see earlier), but there is no evidence that 5-HT-containing ENS interneurons act directly on gastrointestinal smooth muscle. 5-HT receptors mediate EDRF release from endothelial cells in many vasculatures, but there is no conclusive evidence that 5-HT releases EDRF in association with ANS-induced vasodilation in the few vasculatures with cholinergic postganglionic innervation (erectile tissue, salivary, and sweat glands).

5-HT_{2A} receptors on ANS neuroeffector cells are the most widely distributed, mediating smooth muscle contraction throughout the vascular system, and in bronchial, intestinal, urinary bladder, and uterine smooth muscle, as well as increasing atrial rate and contractile force in rats (but not other species). Contraction mediated by 5-HT_{2B} receptors is limited to stomach smooth muscle. 5-HT_{1B} receptor-mediated smooth muscle contraction is principally confined to cranial and coronary arteries. Increases in cardiac muscle rate and contractile force are mediated by 5-HT_4 receptors (humans, pigs), and by 5-HT_3 and 5-HT_7 receptors in other species. 5-HT_4 receptor-mediated smooth muscle relaxation occurs in particular gastrointestinal tract regions and in pulmonary veins; 5-HT_4

[d]Contraction mediated by 5-HT_{1B} receptors in cranial, coronary, pulmonary and umbilical arteries, and saphenous vein, and by 5-HT_{2A} receptors widely distributed in arterial and venous circulation; relaxation mediated by 5-HT_4 receptors in pulmonary vein, and by 5-HT_7 receptors widely distributed in arterial and venous circulation.
[e]Regional differences: contraction mediated by 5-HT_{2A} receptors in intestine, 5-HT_{2B} in stomach, and 5-HT_4 in esophageal sphincter, ileum, and colon (longitudinal); relaxation mediated by 5-HT_4 receptors in esophagus and colon (circular), and by 5-HT_7 in intestine.

receptors contract smooth muscle in other parts of the gastrointestinal tract. 5-HT_7 receptors mediate vascular and intestinal smooth muscle relaxation.

Conclusion

Almost all of the functional 5-HT receptor types and subtypes in the IUPHAR 5-HT receptor classification are known to be present on ANS neurons, the exceptions being 5-HT_{1F}, 5-HT_{2B}, and 5-HT_6 receptors. The most widely distributed receptors are the neuroinhibitory 5-HT_{1A} and neuroexcitatory 5-HT_3 receptors, located on sympathetic, parasympathetic, and ENS neurons; neuroexcitatory 5-HT_3 receptors are also present on ANS sensory afferent neurons. Neuroinhibitory 5-HT_{1B} and 5-HT_{1D} receptors are confined to sympathetic postganglionic neurons; 5-HT_{2A} and 5-HT_{2C} neuroexcitatory receptors are found only on ANS sensory afferent and parasympathetic preganglionic neurons, respectively; neuroexcitatory 5-HT_4 receptors are present on parasympathetic postganglionic and ENS neurons; and neuroexcitatory 5-HT_7 receptors are located on parasympathetic postganglionic neurons. 5-HT-induced effects in central ANS regulatory neurons may be mediated by 5-HT_{1A}, 5-HT_2, and 5-HT_3 receptors, but are not yet confirmed. 5-HT_{2A} receptors are the most widely distributed receptors on ANS cardiac and smooth muscle neuroeffector cells. 5-HT_4 and 5-HT_7 receptors are present on cardiac, vascular, and gastrointestinal neuroeffector cells. The remaining locations are on vascular (5-HT_{1B}), gastrointestinal (5-HT_{2B}), and cardiac (5-HT_3) cells. The neuroexcitatory orphan 5-HT_{1P} receptor is confined to the ENS.

The principal therapeutic usage of 5-HT receptor agonists and antagonists in disorders related to ANS function is in gastrointestinal disorders, based mainly on 5-HT_4 receptor-mediated neuroexcitation in the ENS, and gastrointestinal smooth muscle contraction and relaxation, as well as 5-HT_3 receptor-mediated neuroexcitation in the ENS. Metoclopramide, a 5-HT_3 receptor antagonist and 5-HT_4 receptor agonist, is effective in the treatment of nausea and vomiting, gastroparesis, and gastroesophageal reflux disease. 5-HT_4 receptor partial agonists (cisapride, tegaserod) are effective in gastroparesis and irritable bowel syndrome, respectively. 5-HT_3 receptor antagonists (e.g., granisetron, tropisetron, ondansetron, dolasetron) are highly effective in controlling severe nausea and vomiting produced by cancer chemotherapy and radiotherapy, as well as postoperative nausea and vomiting.

Therapeutic usage of 5-$HT_{1B/1D}$ receptor agonists (e.g., sumatriptan, zolmitriptan, naratriptan) in migraine is based on selective cranial arterial vasoconstriction, but in some cases their efficacy may also involve CNS actions. 5-$HT_{2A/2B/2D}$ receptor antagonists (e.g., pizotifen, methysergide) can prevent migraine attacks; the mechanisms are uncertain, but may include regulation of cranial arteriolar vasculature. 5-HT_2 receptor antagonists are used in carcinoid syndrome to suppress excessive ANS neuroeffector cell responses to enterochromaffin cell 5-HT, especially in gastrointestinal, vascular, and bronchial smooth muscle. The wide distribution of 5-HT receptors in the ANS may be exploited in the future as new therapeutic targets; disorders of urinary bladder function may be a promising field.

Introduction

Modern microscopy techniques have revolutionized the analysis of living cells. With the development of new optical technologies (e.g., laser technology and confocal scanning microscopy), together with the availability of powerful numerical image processing (deconvolution techniques and computational adaptive optics), optical microscopy has moved beyond the traditional two-dimensional imaging toward the reproduction of high-resolution, three-dimensional (3-D) objects. Moreover, the development of video and digital image processing is allowing visualization of cellular movement and behavior. However, obtaining in real time noninvasive, high-resolution 3-D images, which are critical for elucidating the relationship between the dynamics of cell morphology and physiological or pathological processes, remains a technical challenge, especially since most biological cells are usually transparent (i.e., they differ only slightly from their surroundings in terms of optical properties, including absorbance and reflectance) and thus preclude the generation of adequate contrast required to obtain high-resolution video microscopy.

Consequently, many modes of contrast-enhancing techniques have been developed to overcome this limitation. Among these, fluorescence microscopy in a confocal configuration (confocal fluorescent laser scanning microscopy (CLSM)) and its extension to multiphoton fluorescent excitation is a powerful and widely used cellular imaging technique in biology.

CLSM has permitted in particular, in combination with the utilization of specific fluorescent cellular probes, the observation of dynamic processes in living cells ranging from the fusion of vesicles to the concentration changes of specific intracellular signaling molecules. The CLSM optical sectioning capacity, limited to approximately 500–800 nm in axial direction, provides a first step in the 3-D location of intracellular dynamic processes. The 3-D representation of cellular morphology is obtained by the processing of the diffraction-limited image sets, consisting of serial optical sections, using 3-D reconstruction and rendering algorithms.

However, in the field of fluorescence imaging, several pioneering super-resolution technologies, termed 4 Pi microscopy, I^5M microscopy, and stimulated emission depletion (STED) microscopy, are currently taking the resolution beyond the classical Abbe's resolution limit. Specifically, STED microscopy, utilizing reversible saturable optical fluorescence transitions, is a very promising super-resolution technology which can, in principle, break the diffraction barrier.

Nevertheless, the use of fluorescent probes, although they are attractive as chemically specific contrasting agents, is associated with undesirable side effects such as photobleaching, which could ultimately compromise attempts to improve resolution, and photodynamic damage to biological samples, particularly in the confocal observation mode, which concentrates high optical energies. The acquisition rate is also intrinsically limited by the serial acquisition of the image pixels, which precludes the possibility of simultaneously obtaining real-time and high-resolution 3-D images.

On the other hand, phase contrast (PhC), initially proposed by F Zernicke for image contrast, as well as Normarski's differential interference contrast (DIC) are two other widely used contrast-generating techniques available for high-resolution light microscopy. In contrast to fluorescence techniques, PhC and DIC allow the visualization of transparent specimens, particularly the fine subcellular structural organization, without using any staining contrast agent. These two noninvasive contrast-generating techniques, PhC and DIC, result from their capability of transforming in detectable intensity modulation, the minute relative phase shift that transparent microscopic objects, including living cells, induce between the transmitted wave light and the undeviated background wave (PhC) and between two orthogonally polarized transmitted waves (DIC). However, PhC and DIC do not allow the direct and quantitative measurement of phase shift or optical path length. Indeed, PhC suffers from well-known optical artifacts, namely the halo and shading off, making the intensity modulation at any pixel not directly proportional to the phase change due to the corresponding area of the cell. Regarding DIC, the intensity modulation is proportional to the spatial directional gradient along the shear direction of the intracellular refractive index, resulting in a spurious asymmetry into the image. Consequently, the interpretation of minute DIC or PhC signal variations in terms of the corresponding cellular morphometry or shape changes remains elusive.

In contrast, by using the coherence property of light (i.e., the light property that maintains a well-defined wavefront over a certain propagation length), interferometric techniques have the capability to provide a direct measurement of the optical path length based on an interference between the light wave passing the

specimen, called the object wave, and a reference wave. Specifically, the optical path length difference, or the corresponding relative phase shift between the object and reference waves, is coded in the resulting interferogram as an intensity modulation that can be recorded by any photosensitive media, which respond to the light intensity only.

Basically, interferometric detection makes it possible to quantitatively measure a phase shift corresponding to a fraction of the wavelength of the used coherent light wave (e.g., a few nanometers). However, because phase shifts are very sensitive to experimental artifacts, including lens defects and noise originating from vibrations or thermal drift, temporal phase shifting interferometric techniques require very demanding and costly optomechanical designs. Accordingly, their applications have been limited to a few fields, such as metrology and astrophysics. In addition, classical interferometric techniques are based on phase measuring procedures that require multiple interferogram acquisitions and phase modulation devices. Because of these technical constraints, very few attempts to use interferometric phase measurement techniques have been reported in biology for real-time living cell imaging.

Digital Holographic Microscopy

Holography Principle

Holography, initially proposed by Gabor in the late 1940s and which enjoyed a revolution in the early 1960s due to emerging laser technology, is a particularly attractive two-step interferometric imaging technique because it provides the opportunity to capture, on a single frame, both the amplitude and the phase data of the object wave (i.e., the coherent light wave diffracted by the observed specimen) (Figure 1).

The first step consists of photographically recording the interference pattern resulting from the interference of the object wave with the reference wave (Figure 1(a)). The resulting pattern was called a hologram by Gabor, in reference to the Greek word 'holos,' meaning 'whole.' The second step is the reconstruction of the object wave. This is achieved through the diffraction process of a coherent wave by the developed hologram, which can be realized either as a reflective or a transparent medium (Figure 1(b)). Specifically, from the diffraction process results a reconstructed object wave, which is an exact replica of the original wave, diffracted by the specimen. This means that you would then see the reconstructed image in its perfect three-dimensionality, exactly as if the original object were before you actually generating the diffracted wave.

However, despite the outstanding opportunities for capturing and displaying 3-D scenes, classical holographic microscopy suffers from technical constraints similar to those of other interferometric techniques.

In contrast, digital holography is achieved by using an electronic camera to record digital holograms and by applying fast numerical procedures to propagate and therefore reconstruct the object wave. Basically, the whole diffraction process, in which the coherent wave re-illuminates the hologram (Figure 1(b)), is numerically achieved by a computer according to the diffraction theory. This numerical approach of holography was proposed for the first time more than 30 years ago. However, only the development of a solid-state image sensor, with high spatial resolution

Figure 1 (a) Hologram formation and recording on a photographic plate. (b) Hologram reconstruction by re-illumination of the photographic plate by a coherent wave.

and extended dynamic range (including CCDs or complementary metal oxide semiconductor (CMOS)), combined with current computer power makes the numerical reconstruction of digitally recorded holograms efficient and has stimulated the reassessment of digital holography as a powerful 3-D imaging tool.

Within the framework of microscopy, numerical processing of holograms presents the unique advantage of offering not only the means to reconstruct an exact replica of the object wavefront but also the means to reshape it. Such a numerical reshaping allows correcting experimental artifacts, including lens defects and aberrations. Moreover, compensating for noise is also an issue. Specifically, the perturbing effects of time drifts, erratic fluctuations, or vibrations can also be eliminated to a large extent by numerical treatment of holograms, providing the temporal stability required to observe dynamics processes in particular. Moreover, it is also possible to simulate the effect of optical components (lenses, filters, etc.) on the reconstructed wavefront. Consequently, *a posteriori* numerical remodeling of the reconstructed object wavefront can provide the stigmatism required to form a high-resolution image, which is usually achieved by high-precision lenses such as microscope objectives.

Digital holographic microscopy (DHM) is thus an interferometric technique in microscopy that is considerably simpler to implement than classical interference microscopy while providing a reliable and quantitative phase mapping of the observed specimen, with an accuracy corresponding to optical path length variations of a few nanometers.

DHM Setup

The experimental setup of DHM presented in Figure 2(a) is basically a Mach–Zehnder interferometer. Light transmitted by the specimen and collected by a microscope objective (MO) forms the object wave O, which interferes with a reference wave R to produce the hologram intensity I_H recorded on a standard black-and-white CCD camera. A typical interference fringe pattern is shown in Figure 2(b).

The hologram acquisition rate and time are camera limited (typically 25 holograms per second with a standard 512×512 CCD camera, decreasing to approximately $10\,s^{-1}$ for a higher-resolution camera (1024×1024)). The hologram reconstruction rate is approximately 15 images per second for a 512×512 pixel hologram with a standard personal computer.

The numerical processing of hologram constitutes a radically novel approach in the field of digital microscopy in the sense that it performs a numerical reconstruction and optional reshaping of complex wavefronts. The need for complex optical adjustments is therefore avoided. For instance, the task of orienting a mirror or a beam splitter with translational or rotational degrees of freedom – which has to be performed very accurately in classical interferometry – is simply replaced by the digital adjustment of specific parameters involved in the hologram numerical reconstruction. Even more relevant is the digital correction of the wavefront deformation induced by the MO to form a magnified image, which scrambles the wavefront deformation produced by the specimen.

Figure 2 (a) Basic configuration for digital holographic microscopy (DHM). A laser diode produces the coherent light ($\lambda = 658$ nm), which is divided by a beam splitter (BS). The specimen (S) is illuminated by one beam through a condenser (C). A microscope objective (MO) collects the transmitted light and forms the object wave (O) which interferes with a reference beam (R) to produce the hologram recorded by the digital CCD camera. (b) Typical example of a hologram acquired by the camera (1024×1024 pixels).

To practically illustrate the benefit of performing numerically the adjustment of reconstruction parameters in digital holography, let us consider its experimental counterpart in interferometric microscopy: the well-known Linnik interference microscopy. Close matching of the optics in the two separate interferometer arms requires a mechanical design providing exceptional precision and stability. Specifically, the introduction in the reference arm of a second identical microscope objective is needed, and this must be aligned with exceptional mechanical precision. In contrast, numerical hologram processing adds unmatched flexibility: it permits to correct the phase aberrations introduced by the MO without physically adding a second identical MO in the reference arm, thus providing a mean to significantly simplify the optical design of DHM. Moreover, it allows to compute the reconstructed object wave at any distances from the MO exit pupil and to correct the associated optical aberrations. This feature provides a means of refocusing purely numerically the out-of-focus planes and thereby extending the depth of focus without any mechanical action. Thus, image information, even for an optical system with a high numerical aperture and high magnification, is no longer limited to a single plane.

Furthermore, processing and reconstructing numerical holograms *a posteriori* provides an effective means of significantly improving the phase temporal stability: for each pixel of the reconstructed image, a standard deviation, over 60 min periods, as low as 0.7° and 0.2° for a 16-frame average can be achieved. This result is equivalent to an axial sensitivity of $\lambda/1800$. In comparison, the transverse resolution of the reconstructed phase distribution is diffraction limited and thus depends on the NA and the wavelength of the coherent light source used. For example, at the wavelength of $\lambda = 658$ and for a 60×, 1.4 NA microscope objective, the transverse resolution is *c*. 0.3 μm.

Cellular Imaging

As presented in Figure 3(a), the cell culture is enclosed in a perfusion chamber and transilluminated. The object wavefront recording on the CCD encodes the phase shift related to neurons, as well as the wavefront deformation induced by the MO that is numerically corrected during the reconstruction process. A typical reconstructed quantitative phase image of a living cell in culture, presenting in color-coded 3-D perspective, is shown in Figure 3(b).

It is important to note that the interpretation of this phase information in terms of height data is not straightforward. Indeed, the images obtained give the planar distribution of phase delays due to the higher speed of light in the perfusion medium (physiological solution) compared to the intracellular compartment. This is generally addressed by using the notion of refractive index ($n = c/v$), defined as the speed of light in vacuum (c) divided by the speed of light in the medium (v), and by expressing the phase information (ϕ) in terms of optical path length ($\mathrm{OPL} = \phi \cdot \lambda/2\pi$), a physical quantity defined by the product between an average refractive index and

Figure 3 Digital holographic microscopy (DHM) of living mouse cortical neurons in culture. (a) Schematic representation of cultured cells mounted in a closed perfusion chamber and transilluminated. (b) Three-dimensional perspective image in false colors of living neurons in culture. Each pixel represents a quantitative measurement of the cellular optical path length (OPL), with a sensitivity corresponding to a few tens of nanometers. By using the measured mean value of the neuronal cell body refractive index, resulting from the decoupling procedure, scales (right) which relate OPL (deg) to morphology in the *z*-axis (μm) can be constructed.

the thickness of the sample. In the current case, for each pixel i of the absolute phase image resulting from the wavefront reconstruction, we have

$$\mathrm{OPL}_i = (\bar{n}_{c,i} - n_m)d_i + n_m D \quad [1]$$

where d_i is the cellular thickness corresponding to the pixel i of the reconstructed image, $\bar{n}_{c,i}$ is the intracellular mean refractive index along the corresponding cellular thickness d_i, n_m is the constant refractive index of the surrounding medium, and D is the thickness of the flow chamber. The product $n_m D$ is a reference value that can be measured anywhere outside the cell. Monitoring this reference value is important because it enables the compensation of mechanical or thermal instabilities and drifts of the setup during the experiment. The cellular quantitative phase contrast, explicitly given by $(\bar{n}_{c,i} - n_m)d_i$ for each pixel i, results from the fact that the intracellular refractive index is different from the refractive index of the perfusion solution n_m. It has been noted that cellular material, including proteins, lipoproteins, and nucleic acids, contributes to increase the intracellular refractive index to values significantly larger than n_m, in direct proportion to the amount of non-aqueous material present (dry mass), whether in the dissolved phase or not. However, the intracellular refractive index value is mainly determined by the concentration of proteins within the cell because their concentration, in terms of weight per volume, is considerably greater than that of the other solutes. Thus, the OPL contrast is an intrinsic contrast directly proportional to the amount of cellular material in the light path, sometimes referred as the 'dry mass' of the cell.

Practically, the refractive index of the perfused solution $n_m = 1.3336 \pm 0.0002$ (at $\lambda = 658$ nm) was measured with an Abbe refractometer. For cells in culture with a mean intracellular refractive index $\bar{n}_c$ of approximately 1.375 according to the rare value found in the literature and the measurements achieved with DHM (the decoupling procedure), the phase measurement pixel accuracy of 0.2°, dictated by overall experimental noise and resulting from the average over 16 frames, corresponds to a phase sensitivity of approximately 10 nm. Basically, the similar values of $\bar{n}_c$ and n_m contribute to decrease the phase sensitivity, equivalent to $\lambda/1800$ in a reflection configuration, by a factor of approximately 25. Cells in culture induce a typical OPL contrast within the range of 50–200° corresponding to a signal-to-noise ratio of approximately 1000–250. Most important, these well-contrasted quantitative phase images are obtained without contrasting agents and at very low light level illumination intensity. The typical measured irradiance at the specimen plane was approximately 200 μW cm^{-2}, which is several orders of magnitude lower than the power used in classical CLSM.

In order to adequately interpret the quantitative phase images, an experimental protocol called the decoupling procedure can be applied to calculate separately the intracellular refractive index and the corresponding cellular morphometry (i.e., the cellular thickness). This decoupling procedure, performed in a fast exchange time perfusion chamber, consists of perfusing, consecutively with the standard perfusion solution, a second solution with the same osmolarity but with an altered refractive index, $n'_m = n_m + \delta n$, and recording the two corresponding holograms. The two resultant reconstructed phase distributions provide, according to eqn [1], a system of two equations that hold for each pixel i, allowing to calculate $\bar{n}_{c,i}$ and the corresponding cellular thickness d_i. This decoupling procedure provides a thickness of 1–3 μm for the neuronal processes and approximately 11 μm for the cell body (Figure 3(b)).

Real-Time Visualization of Cellular Dynamics

DHM has the capability to address specific biological questions concerning living cells and involving cellular morphological changes induced by agonist-mediated activation of specific membrane receptors. To illustrate how the information contained in the receptor-mediated phase signal changes is related to the underlying cellular process, the DHM visualization of the well-known acute Na^+- and Cl^--dependent excitotoxicity neuronal swelling, mediated by sustained application of the excitatory neurotransmitter glutamate at high concentration, is presented. Indeed, glutamate activates postsynaptic receptors, including the ionotropic *N*-methyl-D-aspartate (NMDA), 2-amino-3-(3-hydroxy-5-methylisoxazol-4-yl) proprionate (AMPA), and kainate receptors. Upon their activation, their associated ion channel opens to allow the influx of Ca^{2+} and Na^+ ions. Consequently, perturbations in systems using glutamate result in excessive activation of the previously mentioned receptors leading to excitotoxicity characterized by two main components: (1) an acute Na^+- and Cl^--dependent component marked by immediate cell swelling and (2) delayed cell degeneration related to the influx of Ca^{2+}, whose mechanisms are not clearly elucidated.

The neuronal swelling associated with the excitotoxic effect of glutamate has been induced by prolonged application of the neurotransmitter (50 μM for 5 min) on primary culture of mouse cortical neurons. As indicated in Figure 4, the typical response

Figure 4 Real-time observations of optical path length (OPL) changes produced by prolonged glutamate applications (a). Neurons were observed in a control solution, glutamate, and pharmacological agents were applied as indicated in (b). Prolonged glutamate application induces a large nonreversible OPL decrease of approximately 70°. Such large OPL responses can be completely inhibited by co-application of 20 μM CNQX, a specific AMPA/kainate ionotropic glutamate receptor antagonist, and MK-801 (5 μM), a specific NMDA receptor antagonist. (a) The curves represent the evolution of the OPL averaged in the domain delimited by a red circle in the inset, representing the image of the OPL spatial distribution.

of such prolonged glutamate applications is large OPL decreases of several tens of degrees. These large OPL decreases quickly become irreversible as the glutamate concentration and application time increase. The receptor-specific nature of this response is demonstrated by the suppression of OPL response inhibition resulting from the co-application of MK801 and CNQX, two specific antagonists of NMDA and AMPA/kainate ionotropic receptors, respectively.

Figure 5 illustrates the typical phase distribution changes of two neuronal bodies (Figure 4 inset) induced by glutamate perfusion. The two images on the left ('standard') were acquired just before glutamate application. The images on the right ('excitotoxic') were acquired when the phase stabilized approximately 10 min after the onset of glutamate perfusion. This representation of the phase distribution shows a global phase decrease accompanied by cellular body enlargement.

In contrast to the cellular surface enlargement consistent with neuronal swelling, the global phase decrease is difficult to interpret as a cellular swelling. However, the decoupling procedure providing an image of the surface morphometry, in which each image pixel represents the cellular thickness, allows the clear assessment of the expected excitotoxic neuronal swelling (Figure 5(b)).

From such morphometry images (Figure 5(b)), absolute cellular volume, as well as relative volume variations can be calculated. The neuronal shape variations can also be quantitatively observed and indicate that excitotoxic neuronal body swelling is a spatially heterogeneous and anisotropic process presenting a cellular thickness decrease in some central regions of the neuronal body.

On the other hand, the glutamate-mediated excitotoxicity induces an intracellular refractive index decrease. The typical values are 1.387 before

Figure 5 (a) Color-coded quantitative phase images of two neuronal cell bodies (Figure 4 inset) before ('standard') and approximately 10 min after the onset of the glutamate perfusion ('excitotoxic'). (b) Morphometry of the two cell bodies corresponding to standard and excitotoxic conditions. The *z*-axis (cellular thickness) is expressed in micrometers. Neuronal cell body boundaries were identified by a gradient-based edge detection algorithm.

glutamate application and 1.373 after neuronal swelling. This refractive index decrease is consistent with a water influx accompanying ion entry through the glutamate ionotropic receptors, resulting in a dilution of the intracellular protein concentration, the cellular component, which largely determines the intracellular refractive index value. Consequently, the *a priori* paradoxical phase signal decline results from the intracellular refractive index decrease leading to a decreasing of the product $(\bar{n}_{c,i} - n_m)h_i$ in eqn [1] despite the increased neuronal thickness h_i.

The temporal dynamics of both the 3-D cellular morphometry and the intracellular refractive index during excitotoxic neuronal swelling can be studied simultaneously.

Nanoscale Cellular Fluctuations

The DHM high axial sensibility allows noninvasive observation of cellular fluctuations at the nanoscale. As an illustration, the dynamics of red blood cells (RBCs), known to exhibit natural membrane fluctuations involving cytoskeleton, is presented. RBC

natural fluctuations are assessed by comparing the phase temporal fluctuations corresponding to RBC regions with the phase fluctuations of reference regions in which there is no biological material, corresponding to the experimental noise. Typical RBC and reference phase fluctuations are presented in Figure 6.

DHM can also perform a complete spatial mapping (Figure 7) of the RBC phase fluctuations (i.e., phase fluctuations in any specific cellular microdomains), providing a more comprehensive visualization of such a dynamic cellular process. As presented in Figures 7(a′) and 7(b′), mapping of the phase standard deviation allows clear discrimination between the RBC phase fluctuations and the random reference phase fluctuations resulting from the experimental noise. Specifically, this is expressed by the appearance of high standard deviation regions accurately corresponding to the body of living RBCs.

On the other hand, the decoupling procedure allows the calculation of the RBC intracellular refractive index values, as well as its temporal fluctuations. By considering the measurements of the experimental phase stability, the intracellular refractive index and its temporal variations, the cellular RBC membrane fluctuations can be calculated from the RBC phase signal fluctuations (Figure 6, red line). A typical intracellular refractive index value of approximately 1.41 ($\lambda = 658$ nm) was measured for living RBCs. Concerning the RBC membrane fluctuations, typical amplitudes of a few tens of nanometers with spatial variations have been obtained. It is also important to note that the temporal phase signal fluctuations provided by DHM permit a direct frequency analysis of the cellular fluctuations.

Conclusion

DHM is an optical imaging technique in which quantitative phase contrast images of transparent living cells can be obtained from a single recorded hologram, without the use of any staining agent. The interferometric principle applied to the phase detection, as well as the numerical hologram reconstruction, allows monitoring cell dynamics with a nanometer axial sensitivity. These dynamic phase images, containing information about both the cell morphometry and the intracellular refractive index, can be unambiguously interpreted due to the decoupling procedure. The capability of DHM to monitor noninvasively receptor-specific biological processes in living cells is illustrated by the visualization of the well-established

Figure 6 Real-time observation of red blood cells (RBCs) and reference phase temporal fluctuations. The red line shows the pixel phase temporal fluctuation corresponding to an RBC region indicated by the red arrowhead in the inset, representing a quantitative phase image of an RBC. Similarly, the blue curve represents the pixel phase temporal fluctuations associated with a reference region outside the RBC indicated by the blue arrow. Living RBCs were observed in high-efficiency particulate air (HEPA) buffer.

Figure 7 (a, b) Quantitative phase images of fixed and living RBCs, respectively. Each pixel value of the corresponding images (a′ and b′) is the standard deviation of the phase signal fluctuations evaluated during a 10 s interval.

glutamate receptor-mediated excitotoxic neuronal swelling. Specifically, the study of the cell shape dynamics, including membrane nano-movements, with a subwavelength axial accuracy can be addressed. In addition, the high-accuracy measurement of the intracellular refractive index, a poorly documented parameter, provides information on cell content. Because the intracellular refractive index is related to the composition of the intracellular medium, particularly proteins, spatial refractive index mapping represents a promising way to monitor the local modifications of intracellular protein distribution that occur during cellular processes.

Central Gustatory System and Ingestive Behavior

A C Spector, Florida State University, Tallahassee, FL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

There is no mystery concerning the primary role of the gustatory system. Its main function is to provide information about substances that will be potentially ingested and, in this sense, its input to the central nervous system helps guide feeding and drinking. The chemical response properties of the taste receptor cells coupled with their location at the opening of the alimentary tract leave little doubt. Taste receptor cells are found in teardrop-shaped clusters called taste buds. These specialized epithelial cells serve as chemosensory contact receptors for chemicals that are in solution. The adequate stimuli for these receptors tend to consist of compounds that are not exceptionally volatile and thus do not optimally stimulate the olfactory system. Most nutritive chemicals in nature, however, are found in mixtures and so chemosensory guidance of feeding and drinking involves an interaction between the taste, smell, touch, and temperature of a given food or fluid. The perceptual consequence of the integration of these signals is referred to as flavor.

Peripheral Taste Nerves

Rodents have been the animal model of choice for molecular, anatomical, and physiological examinations of the gustatory system, and thus much of the information in this article is based on such findings. In rodents (and humans), taste buds are distributed in relatively distinct fields in the oral cavity, each innervated by different branches of cranial nerves (CNs). The taste buds of the anterior tongue are innervated by the chorda tympani nerve and those in the palate are innervated by the greater superficial petrosal nerve, both of which are branches of the facial nerve (CN VII). Taste buds in the posterior tongue papillae (special epithelial structures that house taste buds) are innervated by the glossopharyngeal nerve (CN IX) and those found in the laryngeal epithelium are innervated by the superior laryngeal branch of the vagus nerve (CN X). In teleost fish, the taste buds innervated by the facial nerve, which in some species such as the channel catfish are distributed throughout the body surface, are critical in food search, whereas those innervated by the glossopharyngeal and vagus nerves are critical in food-elicited oropharyngeal motor activity. Although in rodents there is evidence of some degree of functional specialization regarding the sensory role of the gustatory nerves, it appears to be more complex than what has been observed in fish and remains to be fully understood.

Central Taste Pathways

The axons of the gustatory nerves in rodents synapse with second-order neurons in the rostral portion of the nucleus of the solitary tract (NST) in a rough topographic manner with the facial nerve fibers terminating most anterior and the vagal nerve fibers terminating most posterior, but there is significant overlap in these terminal fields (Figure 1). Neurons responsive to taste stimulation in the rostral NST intermingle with those responsive to mechanical and thermal stimulation of the oral cavity. Indeed, some neurons are responsive to all three types of stimulation. Vagal sensory axons arising from the major organs of the body terminate in the caudal portion of the NST in a viscerotopic manner. Thus, taste-responsive neurons are intermixed with neurons responsive to oral somatosensory stimuli and adjacent to neurons responsive to visceral stimuli. This general anatomical relationship is maintained throughout much of the central gustatory system and provides a structural basis for the integration of these sensory signals in the service of regulating feeding and drinking.

Neurons in the rostral NST project to local brain stem nuclei involved with controlling salivation and oral motor behavior. In rodents and lagomorphs, the main ascending gustatory pathway starts with the ipsilateral projection from taste-responsive neurons of the NST to the parabrachial nucleus (PBN) – an area of cells in the dorsal pons that surrounds the brachium conjuctivum (thus the name 'parabrachial'). The axons from taste-responsive neurons in the PBN form two major ascending pathways. In addition, a subset of these cells projects caudally to the premotor neurons of the medullary parvocellular reticular formation involved in the control of oral movements. One of the pathways destined for the forebrain terminates in the parvicellular subdivision of the ventral posteromedial nucleus of the thalamus, which in turn projects to insular cortex. In general, thalamocortical pathways are the conventional route of transmission of sensory input to cortex. The second forebrain taste pathway emerging from the PBN consists of axons terminating in several ventral forebrain structures, including the lateral hypothalamus, bed nucleus of the stria terminalis, central nucleus of the amygdala, and

Figure 1 Schematic of the major pathways of the ascending gustatory system in rodents. The percentages in parentheses represent the approximate percentage of total taste buds located in the indicated peripheral fields (blue-shaded boxes) based on a rat model; the remaining 5% are distributed in other locations in the oropharyngeal cavity. Green-shaded boxes represent hindbrain taste nuclei and some associated local reflex structures receiving input from the NST. Red-shaded boxes represent the thalamocortical taste pathway and yellow-shaded boxes represent ventral forebrain structures receiving projections from the gustatory zone of the PBN. For simplicity, descending connections are not shown. CT, chorda tympani nerve; GSP, greater superficial petrosal nerve; LT, lingual-tonsilar branch of the glossopharyngeal nerve; SLN, superior laryngeal nerve. Roman numerals in parentheses represent the indicated CN. See text for more detail. substantia innominata – all known to be involved with the regulation of motivated behavior. It has been proposed that the thalamocortical pathway plays a privileged role in sensory discriminative aspects of gustatory processing associated with stimulus identification, whereas the ventral forebrain pathway is more involved with processing the hedonic characteristics of taste stimuli. Although there are findings in the literature that provide support for some features of this theoretical organization, evidence for this strict anatomical segregation of function remains to be found. Many of these forebrain sites are anatomically interconnected. Moreover, the insular cortex and the taste-responsive ventral forebrain structures send projections back to the PBN. Indeed, electrical stimulation of some of these forebrain sites has been shown to influence the response properties of PBN neurons during oral taste stimulation.

In rodents, the PBN appears to represent a critical anatomical hub in the gustatory system. In the

primates examined, however, gustatory projections from the NST bypass the PBN and synapse directly with thalamic neurons, which in turn project to the insular and opercular cortex. The orbitofrontal cortex, which receives some other sensory inputs, is considered a secondary cortical area for taste. Limbic forebrain structures in primates apparently derive their taste input from these cortical areas. The significance of the anatomical differences in the central gustatory pathways between rodents and primates remains to be understood.

Functional Contributions of Taste to Ingestive Behavior

The contribution of taste signals to the control of ingestive behavior is manifest in at least three ways – stimulus identification, ingestive motivation, and digestive preparation. Stimulus identification refers to the process by which animals innately or conditionally associate a taste stimulus with particular external or, more often, internal environmental events. The distinguishable qualities of taste compounds, such as the sweetness, saltiness, sourness, and bitterness that humans report, allow animals to discriminate between sapid stimuli to adjust their behavior accordingly. Although most researchers agree that there are a limited number of taste qualities, the exact number is debated and species differences are evident; for example, cats do not respond to 'sweet-tasting' compounds in the same manner that rodents and humans do. This appears to be due to a genetic abnormality that prevents the synthesis of the T1R2 protein which is part of the heterodimeric receptor that binds with sweet-tasting ligands. Because cats are carnivores, however, an absence of carbohydrate detection would not be expected to have a serious consequence on the biological fitness of these animals.

Ingestive motivation refers to the characteristics of a taste compound that either promote or discourage ingestion. Many animals will work to obtain taste stimulation. For example, in behavioral testing chambers rats will press levers in order to receive small aliquots of sucrose solution. Animals will also avoid ingesting certain compounds such as toxic plant alkaloids that are bitter tasting to humans. Taste stimuli are also capable of triggering oral motor reflexes (called taste reactivity) that facilitate either ingestion or rejection of substances in the mouth. Thus, taste stimuli possess a hedonic valence ranging from negative (e.g., aversion) to positive (e.g., reward), and this is commonly referred to as palatability. One area of the brain that receives direct or indirect input from some of the ventral forebrain taste structures and is implicated in the processing of rewarding stimuli, including palatable taste solutions, is the nucleus accumbens (NAc) shell. It has been shown in rats that dopamine release in the NAc shell increases during sham feeding of sucrose in a concentration-dependent manner. In sham feeding, the ingested contents drain out of a surgically implanted gastric cannula that is left open during the test, and thus postingestive stimulation is minimized if not entirely absent.

The palatability of a taste stimulus can be altered by conditioning. Anyone who has tasted a relatively new food or fluid and then soon afterwards has had the misfortune of becoming nauseated and vomiting knows how powerful such learned associations are, as that same food or fluid will be subsequently avoided sometimes for a lifetime. This type of robust learning, referred to as conditioned taste aversion, is very pervasive in mammalian species and has obvious adaptive value. On the other hand, the palatability of a taste stimulus can also be enhanced through conditioning by pairing its ingestion with nutritive postingestive consequences. It is important to recognize that stimulus identification and ingestive motivation, although frequently related, are nonetheless dissociable processes; two taste stimuli can be equally avoided or preferred (i.e., have equivalent palatability) but possess discriminable taste qualities.

Finally, digestive preparation refers to the physiological reflexes such as salivation that are stimulated by taste stimuli and facilitate the digestion and assimilation of ingested substances.

Neural Coding of Taste Quality

With the previous functional framework in mind, efforts have been made to try to understand the mechanics of the neural circuitry underlying these various taste processes. One long-standing goal of researchers has been to discover how the nervous system represents the qualitative features of a taste stimulus that subserve identification. Two theories of the neural coding of taste quality have dominated the literature – the labeled line theory and the across-neuron pattern theory. The labeled line theory postulates that a given taste quality arises from the necessary and sufficient activity in a specific class of neurons defined by its electrophysiologically assessed response properties. For example, the activity in S-units, so called because these neurons respond optimally to sucrose and other sugars, would give rise to a sensation of sweetness, and activity in N-units, which are maximally responsive to NaCl, would give rise to saltiness, and so on. The across-neuron pattern theory postulates that the pattern of activity from the entire population of taste-responsive neurons serves as the code for taste quality.

Proponents of the across-neuron pattern argue that there are too many neurons in the central gustatory

system that are broadly tuned, responding to more than one qualitative class of taste stimuli (e.g., sucrose and NaCl), for a putative labeled line to unambiguously represent a single taste quality. Although it is true that the breadth of tuning varies widely across taste-responsive neurons in the nervous system likely arising from converging peripheral inputs, some neurons are rather narrowly tuned and it remains unclear to which functions a given taste-responsive neuron contributes. Theoretically, narrowly tuned units could potentially be involved in labeled line coding for taste quality and more broadly tuned units could be involved with processing some other stimulus dimension such as hedonic valence. Complicating matters further is the suggestion that the temporal pattern of activity could possess information related to taste quality over and beyond the accepted view that a general increase in overall firing rate is related to increased intensity of the stimulus. Indeed, some researchers are employing computational models that incorporate both spatial and temporal coding features to examine the activity in ensembles of taste-responsive neurons. The neural coding problem has been challenging to solve partly because variations in taste quality do not ostensibly map onto a continuous physical dimension of the stimulus in a manner such as the wavelength of light does for color or the frequency of sound does for pitch, rendering the experimental search for orderly principles of representation difficult.

Hindbrain versus Forebrain Taste Function

Insight into some fundamental aspects of the functional organization of the central gustatory system has come from experiments with decerebrate rats. In this experimental preparation, the forebrain is neurally disconnected from the rest of the nervous system. These animals do not voluntarily eat or drink, they have impaired thermoregulation, and they are hyperresponsive to innocuous stimuli. Indeed, animals that survive the surgery can be maintained for months if they are fed by gavage and their core temperature is maintained by external adjustments. Remarkably, intraoral infusions of taste stimuli through chronically implanted cannulae in decerebrate rats elicit the full range of concentration-dependent oral motor responses in a manner similar to that in intact control rats.

These taste-triggered reflexes, collectively referred to as taste reactivity, are divided into two classes of behavior. The ingestive class, which in rodents includes tongue protrusions, mouth movements, and paw licks, is observed upon stimulation with normally preferred chemical compounds such as sucrose and is associated with ingestion. The aversive class, which in rodents includes gapes, chin rubs, forelimb flails, and head shakes, is observed upon stimulation with normally avoided compounds such as quinine and is associated with rejection. Various forms of taste reactivity can be seen across mammalian species and are evident in human neonates. Indeed, there is evidence that infants born with severe anatomical abnormalities of the forebrain also display taste reactivity. Thus, these findings suggest that basic taste-elicited reflexes are hardwired and that the caudal brain stem is sufficient for these responses to be maintained in the absence of a forebrain.

Intact rats that have a single pairing of sucrose with visceral malaise (induced by a drug or other chemical) will subsequently display aversive, instead of ingestive, taste reactivity to the sugar. Such conditioned taste aversions cannot be acquired by decerebrate rats even after multiple pairings. Thus, the forebrain appears to be necessary for the hedonic valence of a taste stimulus to be changed through conditioning, at least from positive to negative.

Similar impairments in conditioned taste aversion acquisition can be obtained in rats that have more focal lesions centered in the gustatory zone of the PBN bilaterally. Interestingly, rats with PBN lesions can express a presurgically learned taste aversion and can postsurgically learn to avoid fluid stimuli with some nontaste flavor cues. It would appear, then, that the deficit is not attributable to an inability to (1) sense visceral malaise, (2) detect the presence of taste stimuli, (3) recall a taste–malaise association, or (4) display avoidance behavior. Rather, the failure of rats with PBN lesions to acquire conditioned taste aversions appears to be due to an inability to integrate taste and visceral signals. Consistent with this view, rats with gustatory PBN lesions are also unable to learn a conditioned taste preference when ingestion of a specific taste solution is paired with intragastric infusions of a nutritive substance. Because a lesion in this obligate forebrain taste relay deprives downstream brain structures of taste-evoked input, it is difficult to determine the critical brain site(s) involved in any resulting impairments. It could be the PBN itself or any of the forebrain sites to which it projects. Indeed, lesions in some of those forebrain sites can also produce deficits in taste aversion learning, and the experiments with decerebrate rats, in which the PBN was presumably intact, implicate the forebrain as playing a major role in taste-viscerosensory integration.

Taste and Sodium Appetite

A superb example of a taste-guided behavior that involves an interplay between stimulus identification

and ingestive motivation in an ecological context is the phenomenon of sodium appetite. When omnivorous and herbivorous mammals are depleted of body sodium, these animals display heightened search behavior for the electrolyte coupled with increased ingestion of the mineral when found. Deer congregating around salt licks in the winter, when food sources are scarce, provide one illustration in the wild. In the laboratory, the potentiated licking elicited by saline solution in Na^+-depleted rats is relatively chemospecific and is generally not observed when other cations, such as potassium and calcium, are offered, with the exception of lithium. The ability of rats to distinguish sodium from other cations appears to arise from a special ion channel thought to be a member of the epithelial sodium channel (ENaC)/degenerin family, expressed in some taste receptor cells, although the exact nature of the channel is debated. Actually, ENaCs are found in a variety of sodium absorbing tissues including the distal tubule of the kidney, where the hormone aldosterone, released from the adrenal cortex under conditions of body Na^+ deficiency, upregulates the expression of ENaCs, which in part promotes the reabsorption of sodium.

Neurons that respond rather selectively to orally applied sodium salts can be found in both the peripheral and the central gustatory system. These narrowly tuned sodium-responsive units no longer respond to the cation if the tongue is treated with the diuretic drug amiloride, which blocks sodium entry through ENaCs. This effect appears to be limited to the neurons that respond more selectively to sodium because under amiloride blockade, sodium can still stimulate other taste neurons that respond to a wider range of electrolytes. Amiloride, which is tasteless to rats, completely eliminates the selective licking responses toward sodium salts induced by sodium depletion. Thus, at least in rats, natural selection seems to have favored similar mechanisms for the conservation of body sodium to prevent further loss and for the identification of external sources of sodium to facilitate repletion when the animal is challenged with a deficiency of this critical cation.

Although when depleted of sodium intact rats display an enhancement of ingestive taste reactivity and increase intake in response to intraorally delivered sodium chloride, decerebrate rats do not. Likewise, rats with bilateral lesions of the PBN do not display potentiated ingestive responses to sodium chloride. Thus, expression of sodium appetite appears to require the forebrain. Once again, the forebrain is implicated in the integration of taste and visceral signals.

Conclusion

This article provides only a brief overview of some fundamental features regarding the functional neuroanatomy of the central gustatory system within the context of the control of ingestive behavior. There is still much to learn. The advent of modern techniques to measure and manipulate brain function offers promise in efforts to understand the neurobiology underlying the sense of taste.

Central Pattern Generators

Introduction

Repetitive (cyclic) movements underlie crucial behaviors like locomotion (walking, swimming, crawling, and flying), as well as essential vegetative functions like respiration, heartbeat in some invertebrates, chewing, and gut movements. Although both sensory feedback and neuromuscular dynamics play an important role in shaping rhythmic motor output, the basic rhythmic activity patterns are generated by central circuits called central pattern generators (CPGs). These CPGs can, when properly activated, produce rhythmic network activity in the absence of external timing cues, that is, without rhythmic sensory feedback or rhythmic activation by descending neurons.

The most unambiguous demonstration of this principle comes from experiments with isolated parts of the nervous system that produce rhythmic activity *in vitro*, either spontaneously or in response to pharmacological activation. The overall patterning and phasing of such activity very often is surprisingly similar to the basic intact motor behavior and is therefore referred to as a fictive motor pattern or a fictive behavior (e.g., fictive locomotion). Among the first successful demonstrations of the existence of CPGs were experiments with locusts. Those experiments showed that the rhythmic motor output to flight muscles can be generated in the deafferented thoracic nerve cord in an immobilized animal (Figure 1(a)). Possibly the most robust mammalian fictive motor pattern is the respiratory rhythm that can be recorded from slice preparations of the brain stem. This activity occurs spontaneously, without electrical stimulation or pharmacological activation (Figure 1(b)).

Much effort has gone into understanding the basic cellular and network mechanisms of rhythm generation, with the ultimate goal of linking circuit operation to basic behaviors. Invertebrate CPGs have been invaluable in this endeavor, predominantly because many invertebrate circuits consist of a limited number of individually identifiable neurons with large cell bodies. This makes them tractable systems for establishing circuit connectivity and allows repeated measurements of intrinsic membrane and synaptic properties in unambiguously identified neurons across many different preparations.

In vertebrates, identifying neuron types and characterizing their properties and connections on the basis of electrophysiological and anatomical criteria have been more difficult but have been somewhat successful in the spinal cord of lamprey, amphibians, and cat. Recently, progress has been made in applying new, sophisticated molecular techniques to the study of motor pattern generation, particularly in mice and zebra fish. Such approaches may allow the use of markers for transcription factors to identify groups of neurons and establish the circuit architecture underlying motor pattern generation.

In the following discussion, general principles are introduced that have emerged from the study of a wide range of invertebrate and vertebrate preparations. Mechanisms governing the function of CPGs, the dynamics of their cellular components and their network operations, as well as context-dependent activation and coordination are discussed.

Cellular and Network Mechanisms of Rhythm Generation

Rhythmic motor patterns almost always consist of sequential or alternating activation of antagonistic groups of muscles, and this sequence is seen in the timing of bursts of action potentials between groups of neurons in the underlying CPG. How this rhythmic activity is generated and how bursting and specific relative timing between different neurons is achieved depend on the circuit architecture, the properties of synaptic connections, and the intrinsic membrane properties of CPG neurons.

Synaptic Properties

Even though a wide variety of synapse types may be found in any given CPG, synchronization of neurons that fire in the same phase of the pattern is often achieved or aided by electrical coupling through gap junctions between these neurons, whereas alternating activity is often based on reciprocal inhibitory connections.

Many chemical synaptic interactions in CPGs are based on spike-mediated mechanisms; that is, transmitter is released in response to presynaptic action potentials. However, local interneurons often also rely on graded synaptic transmission; that is, they release transmitter as a graded function of presynaptic membrane potential. In general, it is not clear what the functional significance of graded versus spike-mediated transmission is in the specific context of rhythm generation. However, in a given circuit, the dynamics of these two types of transmission and their interaction with intrinsic neuronal membrane

Figure 1 Generation of motor patterns in the absence of sensory feedback. (a) In the locust, rhythmic motor output to flight muscles can be generated in the deafferented thoracic nerve cord in an immobilized animal with wind stimulation to the head. Alternating activity between elevator and depressor motor neurons is generated even though no movement is produced and no sensory feedback reaches the central nervous system. properties can be quite different, and CPGs exploit the possibilities of both for dynamic circuit operation.

Many synapses show considerable short-term plasticity such as depression, facilitation, or mixtures of both. In CPGs, synaptic dynamics can strongly influence the frequency of rhythmic network activity and the relative timing between different groups of neurons. This is because in rhythmic systems, depression and facilitation cause the strength of a synaptic connection to be dependent on rhythm frequency and on the duty cycle, the number of spikes, or the spike frequency of the presynaptic neuron. In the leech heartbeat CPG, the synaptic strength of connections from a single presynaptic neuron onto several postsynaptic neurons peaks at different times during a single presynaptic burst, as a result of different synaptic dynamics at these connections. Because of synaptic depression, some synaptic connections in the crustacean stomatogastric ganglion become weaker and peak later the faster the rhythm is, and this can help maintain stable relative timing between neurons at different rhythm frequencies.

Intrinsic Neuronal Properties

As in all neural networks, activity does not depend only on synaptic connections but also on a potentially rich complement of voltage-gated ion channels that determine a neuron's intrinsic membrane properties and therefore how it behaves in isolation and in response to synaptic input. A number of intrinsic properties are commonly found in CPG neurons (Figure 2). Among them are endogenous bursting properties, postinhibitory rebound, plateau properties, spike frequency adaptation, and restorative sag potentials.

Endogenous bursting means that a neuron can generate membrane oscillations in the absence of synaptic inputs (Figure 2(a)). This is an important mechanism of rhythm generation in a number of systems (see the section titled 'Pacemaker and network-based mechanisms').

In other neurons, bursting can be generated on rebound from inhibitory synaptic input (Figure 2(b)). This is an important mechanism for the production of alternating activity, and the time course of this rebound is an important determinant of relative timing between alternating rhythmic neurons.

The term plateau potential, or bistable membrane behavior, describes the ability of neurons to generate sustained firing in response to brief and relatively weak depolarizing input (Figure 2(c)). If an input crosses a certain threshold, firing activity outlasts the stimulus significantly and can either self-terminate eventually or be shut off by (again, relatively weak) hyperpolarizing input. Plateau properties can therefore uncouple neuronal firing from the duration and strength of excitatory input.

Many CPG neurons show spike frequency adaptation; that is, their firing slows down or ceases during sustained depolarization (Figure 2(d)). This can be an important mechanism to ensure that network activity

Figure 2 Intrinsic neuronal membrane properties in central pattern generators. Neuronal activity is critically dependent on intrinsic membrane properties that determine how a cell responds to synaptic input. In the absence of synaptic input, some commonly found membrane properties can be demonstrated by assessing the voltage responses to current injection. (a) Endogenous oscillators produce rhythmic activity in the absence of synaptic drive. Rhythmic activity in such neurons can be reset by current injection. Solid lines above the recording trace indicate the cycle duration, and broken lines indicate the unperturbed cycle duration. Whether the following cycle of bursting is advanced or delayed depends on both the sign and the phase of the current injection. The dependency on phase is an important characteristic of oscillators because it determines how synaptic input affects rhythmic activity. (b) Postinhibitory rebound is an overshooting response following hyperpolarizing input that can trigger a burst of action potentials. (c) Plateau potentials are persistent depolarizing responses to brief depolarizing input of sufficient amplitude. The depolarizing response either eventually self-terminates or can be terminated by brief and relatively weak hyperpolarizing input. (d) Spike frequency adaptation is a waning response to continuous depolarization of constant amplitude. Spiking activity can cease before the depolarizing input is shut off. (e) Escape from inhibition is a depolarizing response to hyperpolarizing input and can enable the neuron to eventually start firing action potentials again, despite continuing hyperpolarizing input.

does not get locked into the firing phase of neurons that inhibit functional antagonists.

Neurons that have hyperpolarization-activated inward currents can produce restorative sag potentials in response to inhibitory input; that is, they slowly start to depolarize during sustained hyperpolarization (Figure 2(e)). This is an important mechanism for neurons to escape from inhibition.

The ionic basis and the dynamics of the voltage-activated ion channels that are responsible for these properties are relatively well understood in a number of systems, at least to the point that most of the complement of ionic conductances have been identified, characterized, and attributed to certain functions. Some properties are mediated by similar conductances across many cell types and systems, whereas others can be based on a variety of different ionic mechanisms. Even though it is a reasonable approach to attribute certain aspects of a neuron's behavior to specific ionic conductances, especially if pharmacological block of this conductance abolishes this behavior, some caution is advisable. The influence that a specific ionic conductance has on a cell's behavior also depends on the overall complement of other conductances and the relative densities between them. In realistic computer models of neurons, changing the balance between the same set of conductances can change the activity patterns and responses to synaptic input radically.

Pacemaker and Network-Based Mechanisms

Where does the actual rhythmic activity originate? In principle, rhythm generation can be based on intrinsic oscillatory cellular properties or can emerge from synaptic interactions of neurons that are not intrinsically capable of generating rhythmic activity (Figure 3). In the first case, rhythmic network activity is based on the endogenous bursting properties of a core group of neurons that drive bursting in other cells (Figure 3(a)). Such neurons are referred to as endogenous bursters, oscillators, or pacemaker cells. These neurons synapse onto follower cells that burst as a consequence of rhythmic synaptic input but are tonically active or silent when synaptic input is removed experimentally. Follower neurons can have feedback synapses onto the pacemaker cells and can have rich synaptic interactions with other follower neurons (Figure 3(b)). Feedback synapses onto the pacemaker can play an important role in setting both frequency and the phasing of the pattern.

In other networks, rhythmic activity is generated in the absence of any cell-autonomous burst mechanisms and is the result of network connectivity. What may be the simplest form of network-based

Figure 3 Network mechanisms of rhythm generation. The core mechanism of rhythm generation in a central pattern generator can be based either on endogenous bursting properties or on synaptic interactions of neurons that are not intrinsically capable of generating rhythmic activity. (a) Endogenous oscillators provide synaptic input to follower cells that allows the latter to burst rhythmically, in this case in rebound from inhibition. When synaptic interactions are blocked, the endogenous oscillator continues to cycle, whereas the follower neuron is either silent or fires tonically. (b) Feedback synapses from follower neurons to endogenous bursters can have significant influence on the pattern frequency and phasing. (c) A commonly found network-based mechanism of rhythm generation is reciprocal inhibition. This mechanism is often referred to as half-center oscillation. When synapses are blocked, both neurons are silent or fire tonically. (d) Endogenous bursters can be synaptically coupled to coordinate their bursting and/or stabilize regular rhythmic activity.

mechanisms of rhythm generation is the so-called half-center oscillation (Figure 3(c)). Here, reciprocal inhibition leads to alternating patterns of activity between neurons. The transitions from firing in one neuron to firing of the other neuron can be due to such things as release from inhibition when the active neuron shows spike frequency adaptation. Alternatively, the inactive neuron's intrinsic membrane properties can allow it to escape from inhibition, reach threshold, and in turn inhibit the other neuron.

It is not always straightforward to distinguish between cell-autonomous and network-based mechanisms. Some neurons have conditional oscillatory properties; their ability to generate rhythmic activity in synaptic isolation depends on the presence of neuromodulators and, in the intact system, can be dependent on the way the CPG is activated. In addition, pairs of neurons may have strong reciprocal synaptic connections that are essential for establishing robust and regular bursting with specific frequencies and relative timing but may also show endogenous bursting in synaptic isolation, even if this bursting is less robust (Figure 3(d)). In fact, a number of circuits show characteristics of both pacemaker-driven and network-based bursting. The circuit motif of reciprocal inhibition, often thought to be a hallmark of network-based rhythm generation, is also widespread in systems that are dominated by pacemaker neurons. In general, which mechanisms dominate may depend on context and how the circuit is activated. That being said, pacemaker-driven rhythmic networks control the mammalian respiratory rhythm and the pyloric rhythm of the crustacean foregut, two motor patterns that are continuously active. In contrast, network-based mechanisms appear to play the most important role in a range of circuits regulating locomotion, a behavior that is executed only in specific contexts.

Activation and Neuromodulation of CPGs

Most rhythmic motor behaviors can occur over a wide range of frequencies and with different durations and relative timing of activity between the muscles involved. For example, movement of a joint can be fast or slow, occur over different angles, and require different relative muscle activation for flexion and extension, dependent on the specific behavioral context. This flexibility is at least partly due to neuromodulators that potentially shape CPG activity into many different forms. The presence of neuromodulators in some cases is required even for the basic operation of a CPG, but in all cases it provides fine-tuning of rhythmic activity. Understanding CPG operation, therefore, requires understanding of not only circuit architecture and the intrinsic dynamics of neurons and synapses; in addition, it requires knowledge of the complement of neuromodulatory substances that affect a given circuit and the consequences that the presence of these substances has for circuit operation. This includes identifying which neurons in a CPG each substance targets and which receptors and ion channels in each cell type are affected. In addition, it is crucial to identify the source of modulatory substances and to know when and how they are released.

Complement and Source of Neuromodulators

The substances that act as neuromodulators can be very diverse and include classical transmitters such as γ-aminobutyric acid and glutamate, biogenic amines

such as dopamine and serotonin, a wide variety of peptides, and even gases such as nitric oxide. It is tempting to attribute certain global functions to a single modulator, but the idea that in a specific behavioral context, one modulator is released that changes the motor pattern in the desired way is unlikely to be true. In all systems where the effort has been made, a multitude of substances have been found, and it is more likely that in any given context, different combinations of these substances control CPG operation.

One of the most extensively studied systems in that respect is the stomatogastric ganglion (STG) of crustaceans, which contains CPGs that control the movement of different parts of the stomach. Here, almost 30 different substances have been identified that affect circuit operation (Figure 4(a)). These substances reach the STG through the circulatory system as neurohormones or are released into the neuropil by descending modulatory neurons or sensory afferents. Some of the substances are present in both delivery systems, presumably with different consequences because of differences in concentration and spatial distribution. In general, neurohormones affect circuits globally because they have access to the entire nervous system. In contrast, release from neuromodulatory terminals is locally restricted. That being said, paracrine release can lead to a fairly extensive diffusion of these substances, and many modulator actions are likely to be mediated through extrasynaptic receptors.

In some systems, even the CPG neurons themselves can have modulatory cotransmitters. This intrinsic modulation means that the properties of the circuit can be changed as a function of its own activity. In general, cotransmission is a widely found strategy in the modulation of CPGs. In the STG, different identified projection neurons that release the neuropeptide proctolin can elicit different forms of CPG activity. This is partly because they have different complements of cotransmitters that are released at the same time as proctolin.

Divergence and Convergence of Neuromodulator Action

Each modulator has a specific effect on circuit operation because it targets a specific subset of cells in the circuit. It may have different subcellular actions in each cell. In addition, different cells have different combinations of receptors to neuromodulators. Modulators can have a variety of effects in a single neuron (divergence), and different modulators can act on the same subcellular target in a given cell (convergence). In the pyloric circuit of the STG, all these mechanisms have been described.

Dopamine changes the activity of pyloric neurons, particularly the phase relationships, that is, the relative timing between them (Figure 4(b)). These effects are based on a wide variety of actions on synaptic and intrinsic neuronal properties (Figures 4(c) and 4(d)). Dopamine enhances the strengths of some chemical synapses and reduces the strength of others. In extreme cases, it can unmask synaptic connections that are not measurable in the absence of dopamine, and it can completely abolish others. In addition, it can alter the strength of electrical coupling between neurons.

Dopamine also affects a number of different voltage-dependent ion channels in pyloric neurons. It has several targets in each neuron, and these sets of targets differ across neurons. In addition, it can have a different effect on the same type of current in different neurons and either enhance or reduce it. In contrast to this divergence of dopamine actions, other substances converge onto the same target. Receptors for many different neuromodulatory substances are found in each pyloric neuron. A large portion of these, particularly the neuropeptides, act on the same voltage-dependent, nonselective, cation channel. In this case, the specificity of neuromodulator action results from different neurons in the circuit having different subsets of receptors.

Descending Commands and the Activation of Specific Patterns

What are the mechanisms of the decision-making process necessary to determine whether a specific motor pattern is elicited or not? This is particularly important in motor behaviors that are elicited only in specific behavioral contexts, but it is also true for specific different forms of continuously active motor output. In some cases, activating a single neuron, or a network of a few, can be sufficient to elicit an entire motor program.

The CPG for swimming in *Tritonia* can be activated by a pair of interneurons called dorsal ramp interneurons (DRI). A swim pattern is maintained as long as DRI is active. DRI is necessary and sufficient to elicit the swim pattern and therefore satisfies the rigorous definition of what is commonly called a command neuron. It receives rhythmic feedback from the CPG and therefore fires rhythmically during fictive swimming. However, it is not part of the CPG, as hyperpolarizing it during a swim pattern that is elicited by electrical stimulation of the CPG does not disrupt CPG activity. It receives excitatory input from sensory neurons and a trigger neuron, Tr1 (Figure 5(a)). A brief stimulation of this trigger neuron is sufficient to elicit a swim pattern that outlasts the stimulus substantially. However, DRI can also elicit the swim pattern when Tr1 is hyperpolarized, so Tr1 is sufficient but not necessary in triggering swimming.

Figure 4 Neuromodulation of central pattern generators (CPGs). (a) The stomatogastric ganglion is modulated by many substances. These substances are either released into the circulatory system (mostly by the pericardial organs) and reach the stomatogastric ganglion (STG) as neurohormones or are released into the neuropil by descending modulatory neurons. (b) Dopamine changes the activity and the phase relationships (relative timing) of CPG neurons in the pyloric circuit of the stomatogastric ganglion. Intracellular recordings show the activity of neurons representative for different phases in the triphasic pyloric rhythm. The bar plots show the activity phases of these neurons in one normalized cycle. (c) Dopamine enhances or reduces chemical synaptic connections and also alters electrical coupling between pyloric neurons. The presynaptic neuron was electrically stimulated and the voltage response in pre- and postsynaptic neuron recorded. Note that chemical synapses are graded. (d) Convergence and divergence of neuromodulator action. Dopamine acts on various voltage-gated ion channels in pyloric neurons. It can act on different subsets of these channels in different neurons and affect the same channel type in different ways in different neurons. In contrast, many modulators, predominantly neuropeptides, activate the same voltage-dependent nonselective cation channel in pyloric neurons. Such a clear role for descending neurons as in the case of DRI has been found in a number of systems, but it is most likely more common that CPGs are controlled by networks of higher-order neurons and modulatory projections. In that case, different forms of network output can be generated dependent on the relative contribution of different higher-order neurons. In *Aplysia*, the feeding CPG can generate output that is coordinated in two essentially different ways (Figure 5(b)). One pattern corresponds to a motor pattern that is used during the ingestion of food. Here, the radula, the mouth part apparatus of mollusks, is protracted while it is open and retracted after a bite, while it is closed. The other pattern corresponds to the rejection of food, when the radula is protracted while it is closed, and retracted while it is open. The choice between these patterns is biased by the relative activity of descending neurons. In the example shown in Figure 5(b), an ingestive pattern is generated when two interneurons, CBI-2 and CBI-3, are activated simultaneously. An egestive (rejection) pattern is generated when CBI-2 is activated while CBI-3 is silent.

In vertebrates, spinal CPGs are subject to modulation by a variety of substances that activate and shape the output patterns they produce. These inputs stem from descending neurons and intraspinal systems. In addition, activation of spinal CPGs is strongly controlled by inhibition from higher centers. An important role in this is played by the pallidum, the output layer of the basal ganglia. The pallidum in turn receives inhibition from the striatum, which is activated by cortical and thalamic inputs. Removal of inhibition in general is an important mechanism of motor program selection. However, to what extent this is a direct influence on the CPGs or rather affects the command circuits that activate CPGs is not clear in most cases.

Coordination of CPGs

Modular Organization of Rhythmic Motor Behaviors

How many CPGs are there? Rather than having one dedicated network for a relatively complex motor behavior like swimming or walking, central pattern generation is inherently modular. 'Unit oscillators' control antagonistic muscle activation for the movement of a single segment or a single joint in an appendage. These rhythm-generating networks need to be coordinated in specific ways to produce specific types of behaviors. For example, swimming movements in lamprey and leech are based on right-left alternation of activity at the segmental level, and this activity can be elicited in reduced preparations with only one or a few segments of the isolated nervous system intact. However, the undulatory movement of the whole body depends on coordination of these segmental patterns along the body axis, in these cases a fixed anterior–posterior phase lag that ensures a sine wave-like movement with a wavelength that matches the body length (Figure 6(a)). In the lamprey, this coordination is largely due to central interneuronal coupling so that even the isolated spinal cord displays an intersegmental phase lag similar to that found in the intact animal.

Coordination through Central Coupling or Sensory Feedback

In principle, several mechanisms can be involved in coordinating unit CPGs (Figure 6(b)). Apart from central interneuronal coordination, movement generated in response to motor commands in turn produces sensory (e.g., proprioceptive) feedback that can aid in coordinating adjacent oscillators in several ways. In some cases, sensory feedback from one part of the body has access to CPGs controlling adjacent parts of the body. In other cases, movement of one part of the body is transferred via mechanical coupling to other parts of the body, which in turn provide sensory feedback to the local oscillators. In the leech, the intersegmental phase lag during fictive swimming in the isolated nerve cord is reduced in comparison with intact animals. In the intact leech, sensory feedback has been shown to play an additional role in coordinating segmental oscillators. Coordination is even found across segments between which the nervous system had been severed, so that no direct neuronal communication was possible. Therefore, this interaction must have been provided through mechanical coupling.

Sensory feedback plays a particularly important role in shaping motor output and coordinating unit CPGs in behaviors that are heavily dependent on cycle-by-cycle corrections. Terrestrial locomotion takes place in a considerably less-constant medium than do swimming or flying. Therefore, it is no

Figure 5 Motor pattern selection. (a) In the *Tritonia* swim system, activation of dorsal ramp interneurons (DRI) is necessary and sufficient to elicit a swim motor pattern. DRI receives excitatory input from sensory neurons and the trigger neuron Tr1. Transient stimulation of Tr1 elicits a swim pattern that outlasts Tr1 activity. (b) In the *Aplysia* feeding system, different relative firing activity of commandlike neurons biases the central pattern generator to express either an egestive or an ingestive motor pattern. These motor patterns correspond to the rejection of food, when the radula is closed during protraction and open during retraction, and to the ingestion of food, when the radula is open during protraction and closed during retraction. When the interneurons CBI-2 and CBI-3 are activated simultaneously, an ingestive motor pattern is elicited. When only CBI-2 is active, an egestive pattern is elicited. coincidence that much effort has gone into understanding the sensory control of walking. In addition, walking requires a rather complex set of coordinating mechanisms (Figure 6(c)). In a single leg joint, antagonistic muscles need to be coordinated to produce alternating contractions. This alternating activity has to be coordinated across several joints to produce alternating stance and swing, that is, a phase in which the leg is on the ground and propels the body, and a phase in which it is off the ground and moves forward to initiate the next stance. Each step sequence has to be coordinated with the step sequences of the contralateral leg and legs in other segments to produce a specific gait. In the stick insect, CPGs controlling different leg joints are operating largely independently in the absence of sensory feedback. Proprioceptors that measure movement in one joint, and mechanoreceptors that measure load or cuticle strain, can entrain and reset CPGs controlling adjacent joints. In contrast, the motor output of the deafferented lumbar spinal cord of the cat resembles stepping movements of the hindleg, with the correct sequence of activation of motor pools controlling hip, knee, ankle, and foot. However, this motor pattern is drastically modified by sensory feedback from predominantly muscular sense organs measuring movement and force.

In addition to modular CPGs that are coordinated for a specific behavioral task, many behaviors involve movements of different body parts that are not part of the same cyclic repetition of sequential muscle activations and run at different speeds. Such coordination

Figure 6 Coordination of motor patterns in different parts of the body. (a) Lamprey swimming consists of a mechanical wave that is transmitted along the anterior–posterior body axis. Alternating right–left activity is expressed with a fixed phase lag between adjacent segments. This pattern of coordination is also seen in the isolated spinal cord during fictive swimming. (b) Schematic of possible coordinating influences between local oscillators. CNS, central nervous system. (c) Coordination of joints and limbs during walking. Alternating extensor (E) and flexor (F) activity is produced at each leg joint (H, hip; K, knee; A, ankle; F, foot), and all joints are coordinated to produce stance and swing phase of the single leg. All limbs are coordinated to produce different gates when activated by supraspinal commands. For example, walking involves mutual inhibitory interaction between right and left, whereas excitatory interaction underlies galloping. (a, c) Adapted from Grillner S (2006) Biological pattern generation: The cellular and computational logic of networks in motion. *Neuron* 52: 751–766.

may be important to avoid mechanical interference between different parts of the body or to tie related behaviors into the same context of operation. For example, the mammalian respiratory rhythm can be coupled to the locomotor pattern during walking or running so that the duration of a respiratory cycle is an integer multiple of the locomotor cycle.

Flexibility of Motor Pattern Coordination

What is the advantage of a distributed, modular arrangement of CPGs? The absence of a dedicated circuitry for a complete behavior means that unit pattern generators can be coordinated in different ways to produce different motor output. We can walk, run, jump, and dance, behaviors that all require alternating activity of antagonistic muscles controlling our leg joints, but with different temporal relationships between different joints and legs. Mammals can walk or gallop, the former requiring alternating activity between left and right and the latter requiring synchronous activation. In the lamprey, the intersegmental phase lag shown in Figure 6(a) represents the appropriate coordination for forward swimming. This pattern can be reversed to allow backward swimming. It is interesting that this reversal can also be observed in the isolated spinal cord when the more posterior segments are stimulated appropriately.

Multifunctional Neurons and Circuits

The concept of pattern-generating modules seems to imply that the circuitry that is responsible for controlling local movements is exclusively dedicated to this one specific task. However, there is evidence from a number of systems that shows that this is not true. In the leech nervous system, almost all neurons that are active rhythmically during fictive swimming are also activated during fictive crawling. These motor patterns are mutually exclusive, and the activity phase of particular neurons in the locomotor cycle can be very different between both motor patterns. In the brain stem, pattern generation for breathing, gasping, and possibly other related behaviors like swallowing and coughing share some of the neuronal

elements. In the crustacean stomatogastric ganglion, CPG neurons can simultaneously express frequency components of different rhythms that control different parts of the stomach and run at different speeds. Some of these neurons can even completely shift coalitions and, dependent on conditions, can be integral parts of different CPGs at different times.

CPGs as Test Beds for General Principles of Circuit Function and Dynamics

Obviously, analysis of CPG function plays an important role in understanding the neural basis of many motor behaviors and has important implications for the understanding of motor function-related disorders and central nervous system injuries. In addition, studies of CPGs have also elucidated important general principles of network function. Rhythmic firing is a common, if not the prevalent, form of network activity in the brain, spanning systems functioning in a wide range of contexts, from sensory processing to cognitive tasks. Many of the principles that govern these brain functions may be shared with those found to underlie rhythmic motor pattern generation. Furthermore, much of our understanding of circuit dynamics comes from studies of CPGs. This includes both general principles of neuromodulation and important concepts of long-term homeostatic regulation of neuron and network properties. One reason for the successful use of CPGs in studies of network dynamics is that regular rhythmic motor output is relatively easy to measure and quantify. Therefore, CPGs are tractable systems for analyzing the consequences of pharmacological, genetic, or other experimental manipulations on network function.

Central Pattern Generators: Sensory Feedback

W O Friesen, University of Virginia, Charlottesville, VA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Originating near the beginning of the twentieth century, two seemingly incompatible theories informed much of the debate concerning the neural origins of rhythmic movements in animals. One theory, put forth most clearly by Charles Sherrington, held that locomotory patterns, although coordinated by the central nervous system (CNS), arise from sensory feedback and reflexes. Although counterexamples were offered by several investigators, this theory was widely accepted before the 1960s. The second theory, ably proposed by T Graham Brown, held that central pattern generators (CPGs) formed by inhibitory neuronal circuits within the CNS are the source of rhythmic movement patterns. The latter theory gained renewed support from the work of Donald Wilson on locust flight in 1961 and finally became dogma during subsequent decades as more and more CPG circuits were identified in both vertebrates and invertebrates. Near the end of the twentieth century, the importance of sensory feedback for the expression of efficient locomotion received new recognition, leading to a convergence of the two theories. The consensus is that the neuronal circuits underlying locomotion comprise a distributed system that includes both central oscillators and sensory feedback components.

The reemerging recognition that sensory feedback plays an essential role in animal locomotion (and other rhythmic movements) includes the realization that sensory neurons exhibit many of the characteristics that define elements of a CPG. Thus it has now been demonstrated that sensory neurons (1) express rhythmic activity during locomotion, (2) make synaptic contacts with CPG interneurons, and (3) can entrain the CPG when they are stimulated rhythmically. Systems that provide examples of these characteristics include locust flight, swimming in leeches and lamprey, crayfish swimmeret beating, and walking in stick insects and crayfish.

What Is Sensory Feedback?

The neuronal activity patterns that underlie rhythmic movements in a wide variety of animal species are generated by complex neuronal circuits, the CPGs, located within the CNS. In addition, a multitude of sensory receptors, found in the joints, muscles, and other structures of the periphery, detect internal joint positions and movements as well as environmental factors. The overt movements that constitute animal behavior arise from the interplay between the CPGs and sensory feedback from these body structures. Because animals live in environments that are characterized by both temporal change and spatial unpredictability, the instinctive, inherited CPG control circuits cannot be expected to, and do not in fact, generate movement patterns that ensure adaptive behavior. Consequently, CPGs underlying all animal movements are subject to inputs via receptors that monitor the execution of motor commands in relationship to the environment and then provide inputs to motor neurons and to the central neuronal circuits that form the essential core of CPGs. Such inputs modify the neuronal activity patterns arising from the CPG with critical effects on movement amplitude, phase relationships, and the cycle period (or, equivalently, the frequency) of movements. The focus here is on the relationship of CPGs and sensory feedback in a few well-studied invertebrates and a primitive fish, the lamprey. A schematic overview of one such system, which controls the swimming movement in the medicinal leech, illustrates the general properties of the interactions between CPGs, motor output, and sensory feedback (Figure 1).

Why CPGs Are Subject to Sensory Feedback

In many animal preparations, the output of the CPG can be observed in greatly reduced preparations, which often include only parts of the CNS. Comparisons of CPG neuronal motor output with activity patterns observed in intact, behaving animals provide the basis for the concept of a CPG, and, more germane here, the comparisons have revealed deficits in motor patterns that arise when sensory feedback is absent. Most prominent, and most important, among such deficits are that neuronal activity patterns generated by CPGs in isolation have increased cycle periods, reduced activity amplitudes and suboptimal phase relationships. Moreover, in the absence of sensory cues, or internal changes in state, motor output tends to represent rather simple movements, such as straight-ahead locomotion, rather than the more complex movements observed in the intact animal.

Unpredictable development There are numerous factors that mandate sensory feedback if animals are to behave adaptively, including body growth during development and maturation. Amplitude and frequency of movements alter with growth; hence, one major consideration is the matching of CPG output to

Figure 1 Schematic model for the neuronal control of swimming in the leech. Two segmental central pattern generators (CPGs) within ventral nerve cord ganglia are represented by unit oscillators (∼). These unit oscillators are interconnected and mutually entrained by intersegmental axons that run through nerve cord connectives. The cycle period of the CPG is greater than in the intact animal, whereas intersegmental phase lags are smaller. Segmental motor neurons driven by the CPGs control muscle contraction in their individual segments (red arrows from CPG). When swimming movements are generated by the intact animal, tensions in the body wall, arising from local motor neuron output, mechanical coupling between body wall segments (dashed arrows), and the environment provide sensory feedback (blue arrows) to the CPG. This rhythmic input acts to decrease cycle period and to increase intersegmental phase lags in the intact leech. Symbols: SR, stretch receptor; ∼, CPG. Reprinted from Yu X and Friesen WO (2004) Entrainment of leech swimming activity by the ventral stretch receptor. *Journal of Comparative Physiology* 190: 939–949, figure 6, © 2004 Springer-Verlag, with kind permission of Springer Science and Business Media.

the natural, resonant frequency of limb or body. Although development changes in the CPG and the body structure may be coordinately regulated by genetics, maturation processes depend also on the environment. With the latter not fully predictable, sensory feedback that modifies CPG frequency, phase, and amplitude provides a means of ensuring that body movements are efficient at all stages of growth.

Unpredictable environment Animals live in a wide variety of habitats. Some, like fish or flying insects and birds, move in nearly homogeneous media; nevertheless, obstacles, turbulence, or temperature clines are unpredictable, setting up the essential requirement for sensory input to the CPG, even for swimming and flight. Terrestrial environments exhibit a very high degree of unpredictability; hence it is not surprising that CPGs underlying walking and stepping are even more strongly controlled by sensory inputs.

Compensation for morphological alterations Further requirements for sensory feedback arise from alterations in an animal's form through feeding, accident, or predation. A particularly telling example comes from walking locomotion in insects, which modify their gait immediately when a leg is experimentally amputated. Other examples include seasonal size and weight alterations that require a reprogramming of the motor system but cannot be expected to alter the CPG. Although hormones can reprogram the nervous system to match an animal's activity to its overall condition, only sensory feedback can provide cycle-by-cycle feedback from the environment.

Components of Motor Systems

Motor systems, whether generating the neuronal substrates of locomotion or other rhythmic movements, comprise several elements. Central to these systems are one or more oscillator circuits that generate the rudiments, in period and phase, of the expressed motor activity. Excitatory inputs from higher centers, from sensory input, or from within the circuits themselves stimulate CPG output to pass from a 'resting' stable state, that is, without oscillations, to one that is unstable and hence oscillates with a frequency that may or may not match that observed in the intact animal. Most CPGs are formed entirely, or nearly so, of interneurons. However, motor neurons may constitute most of the CPG, as in the stomatogastric system of crustacea; they may be weakly involved in pattern generation, as in the leech swim CPG; or they may merely serve as followers to drive muscle contractions, as in the lamprey swim circuits. Sensory feedback arises from stretch receptors in muscles, proprioceptors, sensory hairs as in crustacean swimmerets, cuticle receptors that signal load in insects, and stretch receptors in the CNS itself, as in lamprey. These receptors may be spiking or nonspiking, but their function is to provide position, load, velocity, and angle information to the CPG – afferent information that informs the CPG whether the movement commanded is appropriately executed. Alternatively, sensory input modifies CPG function more drastically, as during animal walking, in which sensory processes control phase relationships among limbs and the intensity of motor neuron output and may advance, retard, initiate, or prevent phase transitions.

Experimental Approaches: Techniques and Animal Preparations

Experiments to determine the nature of the sensory receptors and their role in CPG modulation have

encompassed a wide range of animal preparations and experimental approaches.

Experimental Approaches and Techniques

Comparison of CPG output and movements of intact animals One methodology employed nearly universally to assess the relative importance of CPG circuits and sensory feedback in the control of animal movements is to compare the neuronal activity patterns expressed in reduced preparations with those of intact, behaving animals. Such comparisons reveal four major aspects of rhythmic activity that are modified by sensory feedback: cycle period, activity amplitude, phase relationships among local outputs, and intersegmental phase relationship. There is a wide range in the relative strength of sensory feedback effects, as illustrated in Figure 2, which shows that cycle periods of fictive (isolated CNS) swimming activity in both leech and lamprey are significantly greater than in the intact animal. However, phase relationships remain unchanged by removal of the periphery in the lamprey whereas intersegmental phase lags are reduced by nearly 50% when sensory feedback is eliminated in leeches.

Sensory entrainment A second widely used technique for determining the nature and strength of sensory feedback is to perform entrainment experiments. With this approach, either the body itself (in semi-intact preparations) or sensory receptor membrane potential is modulated rhythmically by the experimenter while the CPG is generating rhythmic output. For many systems, movements or direct current injection into sensory neurons can force the CPG to generate cycle periods that are up to ±50% of the unperturbed values. Figure 3 illustrates the entrainment technique as it is applied to the swimming rhythm in lamprey. Here physical movements of the rostral or caudal ends of a spinal cord/notochord preparation entrain the CPGs as the movement frequency is set to values both below and above those detected when movements are absent. Such experiments demonstrate that sensory structures, in this case edge cells, have access to the CPG and can modify its properties. Related, alternative approaches are to impede limb or body movements; place a limb into a particular, fixed position; or assess the effects of brief current injection into sensory neurons. Like the entrainment procedure, these alternative methods provide useful information about both the nature and the strength of sensory input in the expression of rhythmic movements.

Animal Preparations

Six preparations and behaviors are described here to illustrate current procedures of, and results from, studies on the relationships between CPG-generated rhythms and sensory inputs during the expression of rhythmic movements. These behaviors are flying in locusts, swimming in leeches and lamprey, swimmeret beating in crayfish, and walking in stick insects and crustacea.

Figure 2 Activity patterns during swimming locomotion: patterns generated by CPGs compared with those expressed by nearly intact animals. (a) Leech swimming. The upper traces (*in vitro*) were obtained from a preparation consisting of the isolated leech ventral nerve cord with electrodes attached to the dorsal posterior (DP) nerves of segments 4 and 10. The lower traces (intact) were obtained from electrodes implanted onto the DP nerves of segments 4 and 10 during swimming in a nearly intact leech. The bursts in these records are axon impulses of cell DE-3, a motor neuron that innervates dorsal longitudinal muscles. P is the cycle period, and d is the intersegmental delay. (b) Lamprey swimming. The upper traces (*in vitro*) depict ventral root activity during fictive swimming. The lower traces (intact) show electromyograph records obtained from an intact swimming lamprey. Letters R and numerals indicate that recordings are from the right side at the segments indicated. Fictive swimming was elicited by bath application of 0.5 mmol l^{-1} D-glutamate. Note the different time calibrations. (a) Reproduced from Pearce RA and Friesen WO (1984) Intersegmental coordination of leech swimming: Comparison of *in situ* and isolated nerve cord activity with body wall movement. *Brain Research* 299: 363–366, with permission from Elsevier. (b) Reprinted from Wallén P and Williams TL (1984) Fictive locomotion in the lamprey spinal cord *in vitro* compared with swimming in the intact and spinal animal. *Journal of Physiology* 347: 225–239, with permission from Blackwell Publishing.

Figure 3 Schematic diagram for entrainment experiments in lamprey. (a) Diagram of the *in vitro* notochord/spinal cord preparation. The caudal (right (RT.)) end of the preparation was rhythmically deflected with a pen motor while the preparation was immobilized to the left (LT.) of the arrowheads. (b) Step inputs. Brief movements (300 ms) of the caudal end at selected phases in the swim cycle were used to determine phase changes (as a fraction of the cycle period) to generate phase response curves (not shown). (c) Entrainment methodology. Sinusoidal movements with a range of cycle periods (T) were applied to the preparation; cycle period and the phase relationship (d/T) between the imposed signal and the fictive motor output were measured. Reprinted from McClellan AD and Jang W (1993) Mechanosensory inputs to the central pattern generators for locomotion in the lamprey spinal cord: Resetting, entrainment, and computer modeling. *Journal of Neurophysiology* 70: 2442–2454; used with permission.

Locust flight Locust flight was the first behavior for which the central role of a CPG was widely accepted. Ironically, locust flight is also among the first clear examples of sensory feedback coordinating animal movements in a well-defined system. Comparisons of flying in nearly intact but tethered animals with the output of the flight CPG in the absence of sensory input reveal the following differences. Wingbeat frequency in tethered flying locust is approximately 15–20 Hz, whereas deafferented preparations exhibit frequencies about half of those values. Moreover, nearly intact tethered locusts stimulated with air currents in a wind tunnel fly continuously, whereas reduced preparations lacking sensory feedback soon terminate the CPG-generated pattern. Stimulation of forewing stretch receptors alters the expressed

rhythm in several ways. First, repeated stimulation phase-locked to the flight pattern increases wingbeat frequency. Second, such stimulation prolongs the expression of the motor pattern. These effects are phase-dependent, indicating that they function on a cycle-by-cycle basis rather than through general excitation. Third, stimulation of both forewing stretch receptors at frequencies near the wingbeat frequency entrains the flight rhythm, provided that the frequency of the entraining signal is within 20% of the natural frequency. Single stimuli applied to the stretch receptors can, if appropriately timed, reset the phase of the flight rhythm. The rhythm can also be entrained by sinusoidal depression and elevation of a forewing while the locust is flying in a wind tunnel. The entrainment range for this more natural stimulation is somewhat smaller, with stable entrainment only when the entraining frequency is within 15% of control.

More than modifying the CPG rhythm, forewing stretch receptors appear to be important components of the flight oscillator in locusts. Intracellular recordings from flight CPG interneurons reveal short-latency excitatory input from forewing stretch receptors. Because these receptors are phasically active during flight, can entrain and reset the flight rhythm, and appear to have monosynaptic inputs to CPG interneurons, they are considered to be important elements in the system generating the normal flight rhythm during wing elevation (Figure 4). Effects of these receptors and of the tegulae also increase the precision of coordination among the wings. The conclusion is that the forewing stretch receptors and the tegulae (activated by wing depression) are peripheral elements of a complex oscillator system that comprises the CPG and peripheral sensory feedback loops.

Figure 4 Diagram illustrating identified interactions between sensory afferents and the locust flight central pattern generator (CPG). EIN, elevator interneurons; DIN, depressor interneurons; 566 identified interneurons that participate in the generation of the flight rhythm only when they receive phasic input from tegulae during flight. Elev, elevator motor neurons; Dep, depressor motor neurons; d, delayed excitation; D, long delay, with input arriving at the depressor neurons one cycle subsequent to one that generated the sensory signal. Leech swimming Medicinal leeches are elongated, segmental worms 5–15 cm in length when fully extended. During the prologue to swimming, the leech body flattens and extends in length and width, providing a nearly uniform, flattened profile that is efficient for swimming locomotion. Leeches swim by whole-body undulations that are seen in side-view as a traveling rostrocaudal sinusoidal wave with a cycle period range of 0.3–1 s. The most efficient waveform for this whole-body mode of swimming is a quasi-sinusoidal body wave comprising one wavelength. Commensurate with this theoretical expectation, at any instant, about a single wave length is expressed by swimming leeches. The rhythmic movements of the body are generated by locally antiphasic shortening–lengthening cycles in dorsal and ventral longitudinal muscles. These contraction rhythms, which act against the elevated internal body pressure generated by activity of the flattener muscles, exhibit rostrocaudal phase delays and thereby generate the observed traveling body wave. With some 18–20 body segments actively participating in generating the swim undulations, the intersegmental phase lags in swimming animals are about 20° per segment.

Like other rhythmic movements, the activity cycles, cycle period, and intersegmental phase lags expressed by swimming leeches find a rudimentary origin in a set of interneurons that constitute the CPG. The unit elements of the CPG are found in each midbody ganglion of the leech ventral cord. Although single ganglia are capable of brief, weak swim oscillations when exposed to 50 μmol l^{-1} serotonin, at least two segments are required to generate strong oscillations and intersegmental phase delays. The leech swim CPG comprises more than 13 interneurons per segment, with some participation by sets of dorsal and ventral inhibitory motor neurons. The central oscillator network does not, however, generate the full

rhythm expressed in the intact animal. The cycle period generated by the CPG ranges from 0.6 to 2 s, barely overlapping the period range observed in intact animal (0.3–1 s), and intersegmental phase lags expressed by the CPG (about 10° per segment) are only 50% of these of intact animals (Figure 2(a)). Thus the isolated CPG does not produce neuronal activity patterns for fast, efficient locomotion.

The sensory inputs that, together with CPG circuits, generate neuronal activity patterns appropriate for efficient swimming arise, at least in part, from segmental stretch receptors, whose somata are associated with dorsal and ventral longitudinal muscles. Stretching the leech body wall induces a hyperpolarization in these receptors, which have peripherally located somata and dendrites and whose giant axons conduct this signal to the CNS electronically.

The importance of sensory mechanisms in leech swimming locomotion was recognized from the beginning of systematic studies of this behavior. For example, leeches were found to swim at a lower frequency in high viscosity media. Moreover, leeches whose movement was restricted mechanically so that they were unable to execute the normal swim undulation altered their movements or aborted ongoing traveling waves. More recently, several types of experiments demonstrated that the stretch receptors can modify the basic activity patterns generated by the CPG. First, in nerve cord–body wall preparations, these receptors encode muscle tension information via membrane potential oscillations, with amplitudes up to 10 mV recorded as the axons enter the ganglia. Second, rhythmic current injection into these receptors can alter intersegmental phase lags by ±5° in a phase-dependent manner. Third, experimentally induced stretch receptor membrane potential oscillations entrain the CPG rhythm if the imposed rhythm is within about 50% of the free-running CPG rhythm. Fourth, brief (several seconds long) current pulses injected into a stretch receptor shift the phase of the ventral nerve cord swim oscillations. Finally, there is direct electrical coupling between at least one of the stretch receptors and a CPG interneuron (Figure 5). Hence, as for locust flight, the circuits that generate the swimming rhythm in the leech comprise both the CPG and the peripheral stretch.

Figure 5 Interactions between stretch receptors and swim-related neurons in leeches. Only a subset of central pattern generator (CPG) neurons (cells 115, 208, 28, and 33) and the phasically active motor neurons are depicted. The ventral stretch receptor (VSR) conveys tension information from the ventral longitudinal muscle (VLM) directly to at least one CPG interneuron, cell 33. IN, interneurons. Motor neuron (MN) designations: DE, dorsal excitor; DI, dorsal inhibitor; VI, ventral inhibitor; VE, ventral excitor; interaction symbols: filled circle, chemical inhibition; 'T,' excitation; resistor, nonrectifying electrical interaction. Dashed interactions appear to be indirect. Interactions between the DSR and the CPG remain unexplored. Reprinted from Cang J, Yu X, and Friesen WO (2001) Sensory modification of leech swimming: Interactions between ventral stretch receptors and swim-related neurons. *Journal of Comparative Physiology* 187: 569–579, figure 1(b), © 2001 Springer-Verlag, publisher. With kind permission of Springer Science and Business Media.

Lamprey swimming Lampreys are primitive fish that swim via anguilliform (eellike) undulations, that, as in leeches, comprise about one wavelength at any moment. The traveling wave results from antiphasic contraction of segmental muscles and from rostra-caudal delays of 1% of the cycle period per segment for a 100-segment animal. Intact lampreys swim with cycle periods ranging from about 0.13 s to more than 0.6 s. The spinal cord of lampreys includes a series of local CPGs. Comparisons of swimming movements in intact animals and motor neuron activity patterns generated within the stationary spinal cord (fictive swimming) show similar patterns (Figure 2(b)). Although the range of cycle periods obtained by altering the concentration of the swim-inducing excitatory amino acids (0.7–2 s) in fictive swimming overlaps that observed in the intact animal, the CPG-generated period is normally about twice that of the intact animal. Unlike results from leeches, the intersegmental phase lags in lampreys do not differ markedly in isolated preparations compared with those of intact animals (Figure 2(b)). Thus sensory feedback appears to be essential for setting the cycle period but not for phase control during undisturbed swimming in the lamprey.

Sensory feedback during the side-to-side undulations of the swimming lamprey arises, in part, from segmental 'edge cells' within the spinal cord. These cells make synaptic contacts with CPG neurons and with motor neurons. Interactions between the CPG and the edge receptors in the intact animal may, like the CPG itself, comprise a functional oscillator. Experiments on spinal cord–notochord preparations demonstrated that the CPG rhythm can be entrained

by mechanical movement of either the rostral or the caudal ends. That is, sensory input arising from these movements could alter the 0.7 Hz 'natural' frequency by a maximum of 50% above and no more than 25% below this control frequency. The range of entrainment depended on the length of the preparation. Short preparations (25 segments) yielded an entrainment range that was nearly twice the range for longer preparations (50 segments). Relative entrainment was also observed with input-to-expressed frequency ratios of 1:2 and 2:1.

Brief movement pulses applied to the spinal cord, as well as current injection into edge cells, can reset the phase of the swimming rhythm of lampreys. Movement pulses, used to generate phase response curves for the spinal cord–notochord preparations, showed phase advances during two-thirds of the cycle, with the largest phase shifts near mid-cycle. Again, it seems likely that, as for locusts and leeches, normal locomotion in lamprey arises both from segmental CPGs and from sensory feedback circuits (Figure 6).

Figure 6 Circuits underlying swimming movements in lampreys. A population of reticulospinal neurons (RS) excites the spinal interneurons and motor neurons. Excitatory interneurons (E), in turn, excite other spinal neurons, including inhibitory interneurons (I) that cross the midline to inhibit neurons on the contralateral side, and lateral interneurons (L) that inhibit ipsilateral interneurons and the motor neurons (M). Spinal stretch receptor neurons (edge cells) include two types; excitatory neurons (SR-E) that excite ipsilateral neurons and inhibitory neurons (SR-I) that inhibit contralateral neurons. Symbols denote populations of cells, not single neurons. Additional control of this system appears to arise from the ventral thalamus (VTH), the trigeminal nuclei (Trigem.), and the mesencephalic locomotor region (MLR). Reproduced from Grillner S and Wallén P (2002) Cellular bases of a vertebrate locomotor system: Steering, intersegmental and segmental co-ordination and sensory control. *Brain Research Reviews* 40: 92–106, with permission from Elsevier.

Crustacean swimmeret beating Crayfish, lobsters, and other decapod crustaceans have abdominal appendages, swimmerets, that beat with metachronal rhythms. The paired segmental CPGs in this system, unlike those described above, provide a basic rhythm that is nearly identical in both cycle period and intersegmental phase lag, about a quarter of the cycle period, to those observed in the intact animal. Although the need for sensory feedback in undisturbed beating is not obvious, execution of swimmeret movements is nonetheless monitored via a set of sensory receptors, including proprioceptors that provide phasic feedback. When, for example, the movement of a swimmeret is experimentally impeded, by fixing the limb at either the retracted or protracted phase in its movement cycle, the central rhythm sometimes stops, sometimes decelerates. In addition to the proprioceptors, lobsters have hairs whose deflection in response to water movements engendered by swimmeret beating can provide rhythmic afferent information. Also, there are two types of hypodermal mechanoreceptors that are likely to be activated when swimmerets beat rhythmically. It appears that swimmeret mechanoreceptor activity, although not required for generating an appropriate activity pattern for swimmeret movement, contributes to the movement of these appendages when normal movement is somehow impeded.

Insect and crayfish walking The neuronal activity patterns that underlie animal walking movements are considerably more complex than the neuronal patterns that underlie flying, swimming, or swimmeret beating. Most animals that utilize walking locomotion have multiple limbs, with each limb comprising multiple segments. Added to those factors is the daunting task of generating effective limb placement on a highly unpredictable substrate. It is therefore not surprising that sensory receptors are closely tied to CPG elements associated with this form of locomotion.

Many forms of animal locomotion can be viewed as the rhythmic alteration of two phases, a power stroke, in which the animal exerts forces on its environment that propel it forward, and a return stroke that returns the limb to the original position for the next power stroke. A major focus for studies of sensory input to the CPG circuits that underlie the walking cycle is the control of transitions between two phases in walking locomotion, the stance and

the swing phases. Two additional foci are the control of intra- and interjoint phase angles.

One of the best-studied walking behaviors is that of the stick insect. Each leg in the stick insect has three main joints that are responsible for movements in the horizontal and vertical planes. Muscles associated with the thoracocoxal (TC-) joint drive the leg back and forth, whereas the coxatrochanteral (CTr-) and femur–tibia (FTi-) joints (Figure 7(a)) are involved in placing the tarsal segment firmly onto the substrate (during the stance phase) or raising it into the air (during the swing phase). With appropriate stimulation, deafferented thoracic ganglia can be induced to generate the antagonistic motor neuron activity patterns that cause rhythmic joint movements. Because there is little or no coordination among groups of motor neurons associated with different joints in such a preparation, it appears that a unit CPG drives muscles at each joint. The specific neuronal circuits constituting these CPGs remain largely unidentified; however, it is clear that activity in these CPGs is closely coordinated by sensory signals arising from leg proprioceptors and cuticular strain receptors. Coordination of the movements of individual joints occurs by a cascade of sensory information whereby signals from one joint in a leg reset the phase of the CPG that drives a second joint in that leg. These signals include two temporally related sensory modalities: leg weight load and joint position. The effects of such sensory signals are weighted within the CNS to generate locomotory movements.

Figure 7 Schematic of sensory influences on the movements of the middle leg of the stick insect. (a) Cartoon of the stick insect leg showing the three main leg joints. (b) Extension position signals (ext. signals) from the FTi-joint switch the phase of the central pattern generator (CPG; Lev to Dep) in the adjacent joint (CTr-joint). The CPGs are denoted by boxes with two interacting neurons, with the active phase indicated by a filled circle. Arrows indicate interactions, but not specific synapses, between hypothesized CPG elements and the antagonistic sets of motor neurons (MNs; rectangles; filled elements are active) they control. (c) Load signals (load increase (incr.)) from the CTr-joint switch the state of the TC-joint CPG (Pro to Ret). TC-joint, –thoracocoxal joint; CTr-joint, –coxatrochanteral joint; FTi-joint, femur–tibia joint; Ret, retraction/retractor; Pro, protraction/protractor; Dep, depression/depressor; Lev, levation/levator; Flx, flexion/flexor; Ext, extension/extensor. Reprinted from Büschges A (2005) Sensory control and organization of neural networks mediating coordination of multisegmental organs for locomotion. *Journal of Neurophysiology* 93: 1127–1135, used with permission.

The specific roles of sensory influences on the CPGs that control the main joints in the stick insect are now known for the phase transitions that occur during step cycles. Two such transitions are illustrated in Figures 7(b) and 7(c). In Figures 7(b), movement-induced signals from FTi-joint receptors (extension signals, lower left) cause a transition from swing to stance phase. This occurs because this sensory input switches the CPG of the CTr-joint leg to the depressor phase, activating the depressor motor neuron, thereby lowering the leg to begin the stance phase. Next, in Figure 7(c), load receptor activation in the CTr-joint (load increase, left) induced by initiation of the stance phase forces a phase transition from protraction to retraction onto the TC-joint CPG, thereby activating retractor motor neurons that act at the TC-joint and begin the forward propulsion phase of the leg step cycle. Sensory receptor input often has two effects, such as when an increased load increases the activity in flexor motor neurons and hence to muscles that support the animal's weight while simultaneously inhibiting the antagonistic extensors. There appear to be two general coordinating systems: one that initiates transitions between phases of the walking cycle, and one that determines its direction. Computer simulations have demonstrated that the known sensory inputs to control limb motions can, when implemented in a simulated neuronal controller, generate leg stepping movements. Here again, rhythmic locomotory movements arise from combined CPG and sensory interactions. For the stick insect, the role of sensory input influences not only period and phase but the very transitions of the CPG between phases of the activity cycle.

As in stick insects, walking locomotion in the crayfish also arises from CPGs strongly influenced by sensory input. However, unlike the nearly independent joint CPGs of the stick insect, walking CPGs express a coordinated walking rhythm in deafferented preparations. That is, the crayfish CPGs

include effective interactions within the CNS while still requiring sensory input to ensure appropriate cycle periods and stable phase relationships. Although the CPGs associated with the eight walking legs in crayfish remain unidentified, at least one sensory structure, the thoracocoxal muscle receptor organ (TCMRO), is known to interact with the CPGs. Rhythmic stretching and releasing of the TCMRO can entrain the CPG, not only locally, but across other legs. The data show that the interactions between sensory input and the CPGs are strong, for the phase relationship between an imposed stimulus rhythm, and the entrained walking cycles is nearly constant. The suggestion is that the walking rhythm is not entrained but actually driven by sensory input. Relative coordination also occurs, with stimulus–response periods of 2:1 or 1:2 when the stimulus frequency lies outside the entrainment range. Direct current injection into the TCMRO afferents also was effective. Overall, sensory input, as in the stick insect, appears to trigger transitions between phases of the movement cycle, and hence sensory input provides essential information to the locomotory CPG in crayfish.

Conclusion: Beyond Sensory Modulation

Just as motor neurons sometimes are integral members of CPGs, even if they are not strictly limited to the CNS, so sensory neurons and muscles may be essential components of circuits that generate rhythmic movements. Sensory input varies in importance among the highly diverse circuits that generate wing movements in locust flight, swimming undulations in the medicinal leech and lampreys, and swimmeret beating and walking locomotion in insects and crayfish. For understanding the physiological bases of rhythmic movements, it appears to be unhelpful to construct artificial divisions between CPGs, motor neurons, muscles, and sensory feedback. A more useful approach is to identify oscillatory subcircuits wherever they occur, whether within the CNS or not; and whether comprising interneurons, motor neurons, effector structures, or sensory receptors. Such subcircuits, together with their mutual interconnections, generate the highly variable and adaptive oscillating patterns that underlie rhythmic animal movement.

Cerebellar Deep Nuclei

T W Thach

© 2009 Elsevier Ltd. All rights reserved.

Anatomic pathway tracing in the macaque clarifies the connections and topographic organization of the deep cerebellar nuclei. The output of the cerebellum is generated by the deep cerebellar nuclei (along with vestibular and reticular nuclei in the brain stem, which also receive direct Purkinje cell inputs). These project to and excite a target area within the thalamus that is sufficiently free of other inputs as to be called the 'cerebellar thalamus' (Figure 1). The target area includes VLc, VLps, VPLo, VLo, and X. The basal ganglia input to thalamus arrives more anterior in VLo and VA, and the lemniscal arrives more posterior in VPL. This cerebello-thalamic target area projects to cerebral cortical areas including the motor, premotor, supplementary motor, oculomotor, prefrontal, cingulated, and parietal regions.

Dentate, interposed, and probably fastigial and vestibular nuclei each project in overlapping fashion to the whole width (coronal) of the contralateral thalamic receiving area. The fastigius projection is sparse, bilateral, and restricted and appears not to project to X or VLo. This itself suggests that at the level of cerebellar outflow, control of the thalamic target is multiple and is repeated across each nucleus. (The projections of the three nuclei arrive in register at a macrolevel only; at the cellular level, they appear to interdigitate in patches (interpositus) and rostrocaudal rods (dentate)).

From the known somatotopic mapping in cerebellar thalamus, and from the topographic projection of each nucleus onto the common thalamic target, somatotopic mapping may be inferred within each of the cerebellar nuclei. In cerebellar thalamus, head is medial, tail lateral, trunk dorsal, and extremities ventral. In cerebellar nuclei, head is then caudal, tail rostral, trunk lateral, and extremities medial. This scheme has been supported by neural recording and inactivation studies during movement and is consistent with the electroanatomical input mapping studies in anesthetized macaques.

This is not to say that the cerebellar output is exclusively or even mainly directed to thalamus and cerebral cortex. Dentate projects to parvocellular red nucleus, the reticular nucleus of the pontine tegmentum, and the inferior olive (principal olive (PO)); interpositus projects to the magnocellular red nucleus, the reticular nucleus of the pontine tegmentum, to the inferior olive (dorsal accessory olive (DAO)), and to the spinal cord intermediate gray; and fastigius projects to lateral and descending vestibular nuclei, to n. reticularis tegmenti pontis and prepositus hypoglossi, to the reticular gray of the midbrain, to the inferior olive (medial accessory olive (MAO)), and to contralateral motor neurons in the spinal cord.

Lesion Studies: What Do the Multiple Maps in the Cerebellum Control?

If there is a separate body representation within each nucleus, it seems likely that each should control some different aspect of bodily function. In one study, unit activity was recorded within the cerebellar nuclei as the monkeys performed five different trained movements of the wrist. The hypotheses to be tested were the following: (1) each nucleus controls some parameter, within or across tasks; (2) each nucleus simply modulates to provide gain control in downstream target structures; and (3) each nucleus controls some type or 'mode' of movement and not others. The job of the animal was to flex or extend the wrist to line up the cursor within target window on an oscilloscope (Figure 2(a)) and to maintain the alignment as the window moved. The animals performed five tasks designed to dissociate hypothetical functions of the nuclei: (1) 'jerk', a prompt, visual-triggered move away from hold position; (2) 'jump', identical to the preceding, except requiring a stop within a visual target area; (3) 'pert', a return to the hold position after perturbation by torque step; (4) 'ramp', tracking of a slowly moving visual target; and (5) 'RAM', self-paced rapidly alternating movements. All tasks were performed in two directions, under two loads.

The earliest changes were seen in dentate on the jerk and jump tasks. Interpositus showed the earliest changes on the pert task, and alone showed modulation in relation to tremor on the ramp tracking. Interpositus and dentate showed equal modulation on the RAM task. Dentate and interposed discharge only occasionally related to the direction of movement and load (position was not dissociated from direction). Fastigial neurons occasionally showed modulations, but without the trial by trial or temporal consistency seen for the other two nuclei. Both dentate and interpositus seemed to contribute to all tasks, but at different times and intensities. The lack of consistent movement correlations in fastigius raised questions about whether it was taking any part in these movements.

To see whether the parameters of movement or movement stability depended on the neural discharge with which they were correlated, the different nuclei were inactivated with muscimol (temporary) or

Figure 1 Projection of cerebellar nuclear somatotopic maps onto a common map in cerebellar thalamus and then to motor cortex.

kainic acid (permanent) while the proficiency of performance was monitored. Any impairment was documented by comparing the pre- and postinjection movement traces. Several variables were examined, including onset and termination times, movement time, direction, velocity, amplitude, tremor, and EMG patterns.

For dentate, there was a slight (47 ms) delay in reaction time on jerks and jumps only. There was no overshoot of final target position. There was a tremor during ramps. Tremor was transient, even after permanent kainate ablation. Perts and RAMs (except for superimposition of tremor) were normal. For interpositus, there was a slight (10–20 ms) delay in the reaction time on perts after one muscimol injection. There was a tremor at the end of jumps and perts and during ramps. The tremor persisted. There was no consistent change in frequency, amplitude, or regularity of RAMs, except the superimposition of tremor. For fastigius there was no detectable abnormality in the performance of any of the five trained wrist movements. Similar small delays and irregularities of velocity and force in single joint tracking and in isometric force have been seen in studies in cerebellum-damaged patients.

To summarize: in no instance did inactivation abolish the task performance. The seemingly contradictory set of findings of (1) a good correlation of discharge with the behavior under study and (2) little or no deficit in that behavior after ablation again raises the perplexing question of what it is that the cerebellum does.

The question of whether the cerebellum independently controls the muscles that operate each joint, or

Figure 2 Cerebellar lesion impairs compound movements more than single-joint movement. Fastigial: falls to side of lesion; wide base. Interposed: antagonist delay; action tremor. Dentate: reach overshoot; x-y error; and finger incoordination. From Thach WT, Goodkin HP, and Keating JG (1992) The cerebellum and the adaptive coordination of movement. *Annual Review of Neuroscience* 15: 403–442.

whether it has a specific role and mechanism for combining the many muscles that operate many joints in a multijoint movement has previously been raised.

The preceding study was of the effect of nuclear inactivation across nuclei on the performance of five trained single-joint tasks. In the same animals in the same sessions, the performance of five untrained tasks was also observed. The tasks consisted of sitting, standing, walking, reaching out for bits of food, and picking small bits of food out of deep narrow food wells with a precision pinch of the fingers. Stance, sitting, and walking were evaluated immediately after the animal was released from the primate chair after the injections. Reaching involved coordinated movement of shoulder and elbow; reaching was performed while sitting and standing on the floor and while sitting in the primate chair. The chair reduced the requirements for active postural adjustments of trunk and other limbs and permitted easier assessment of the relative contributions of shoulder and elbow. The precision pinch task required coordinated movements of the hand and fingers, including the pinch *per se* of thumb and forefinger, and 'tea-cup' posturings of the other digits to keep them out of the way of the edges of the food well.

In sum, each nuclear inactivation produced an incapacitating impairment of bodily movement, but for each nucleus, the type of deficit was unique (Figure 2(b)). Fastigial inactivation prevented sitting, standing, and walking, with frequent falls to the side of the lesion. Interposed inactivation caused a severe action tremor of 3–5 Hz during reaching, but not during sitting, standing, or walking. Dentate inactivation caused excess angulation of shoulder and elbow in reaching, which resulted in overshoot of the target, and an increased use of single-digit strategies in attempting to pinch and pick up food morsels, from which an incoordination of compound finger movements was inferred. These tests showed differences across the three nuclei, and indicated task and movement mode specificity for each. They were qualitatively more severe than any deficits seen in the simple, single-jointed wrist movements.

Parallel Fibers and Purkinje Cell Beams Link Deep Nuclear Cells as a Mechanism of Coordination

The relationship between cerebellar somatotopic maps and parallel fiber morphology is consistent with a cerebellar role in movement coordination (Figure 3). In each body representation within the deep nuclei, the rostrocaudal axis of the body is mapped onto the sagittal axis of the nucleus. The hindlimbs are represented anteriorly, the head posteriorly, distal parts medially, and proximal parts laterally. This orientation suggests that the myotomes, which are arranged orthogonal to the rostrocaudal axis of the body, are represented primarily in the coronal dimension of the cerebellum and thus roughly parallel to the trajectory of the parallel fibers. Because the parallel fibers are connected to the deep nuclear cells by Purkinje cells, a coronal 'beam' of parallel fibers would control the nuclear cells that influence the synergistic muscles in a myotome. In this way, the parallel fiber would be a single neural element spanning and coordinating the activities of multiple synergistic muscles and joints.

Parallel fibers in the monkey are about 6 mm long, spanning a stretch of cerebellar cortex that projects

Figure 3 Parallel fiber beams: a mechanism for coordination. Parallel fibers are long enough to link together Purkinje cells projecting to different body parts within one nuclear body map, and to connect the different modalities of maps in adjacent nuclei. Within a parallel fiber beam, Purkinje cell discharge is synchronized. Cutting a beam prevents coordination of movements controlled by maps in adjacent nuclei.

across the width of one deep nucleus. Thus, a strip of Purkinje cells under the influence of a set of parallel fibers of the same origin and length control a strip of nuclear cells across an entire nucleus. Depending on which portion of the somatotopic map is involved, that nuclear strip may influence synergistic muscles across several joints in a limb or the muscles of the eyes, head, neck, and arm, for example.

A study in trained reaching rats supports this hypothesis. Simple spikes of pairs of Purkinje cells were recorded that, with respect to each other, were either aligned on a beam of shared parallel fibers or were located off beam. Firing rates of simple spikes firing in both on-beam and off-beam Purkinje cell pairs commonly showed large variations during reaching behavior. But with respect to timing, on-beam Purkinje cell pairs had simple spikes that were tightly time-locked to each other and to movement, despite the variability in rate. By contrast, off-beam Purkinje cell pairs had simple spikes that were not time-locked to each other.

What might be the consequence of the on-beam synchronicity? Since parallel fibers in the cerebellar cortex run roughly parallel to the myotomes of the body maps in the deep nuclei, the on-beam parallel fiber activity could thus recruit Purkinje cell inhibition to modulate coordination and timing of the natural myomeric synergists mapped within the deep nuclei. In addition, parallel fibers would be long enough to span (via Purkinje cell projections) two or more adjacent nuclei, fastigius controlling stance and gait, interpositus agonist/antagonist coordination at a single joint, and dentate eye–limb coordination in reaching and of digits in multidigit movements.

The role of the parallel fiber in movement coordination has been further supported in a human study. Five children who had surgical midline division of the posterior cerebellar vermis to remove fourth ventrical tumors could subsequently walk with little impairment. Further, they could hop in place on one leg as well as normal controls. Yet these same individuals could not do tandem heel-to-toe walking along a straight line without falling to one side or the other. These observations suggested that vestibular information could be used to control one leg, but that the two legs could not be thus coordinated. The division of parallel fibers crossing the midline seemed best able to explain this dissociation.

What Does the Cerebellum Contribute to Cognitive Processes?

There is now little question that the cerebellum projects to many areas of cerebral cortex outside of primary motor cortex, and that many of these areas have cognitive as well as motor functions. Does the cerebellum then control cognition?

Human brain imaging studies indicate that the cerebellum participates in some cognitive functions. One study revealed cerebellar activation when subjects imagined themselves moving or passively observed movement without moving themselves. In another study, the lateral cerebellum was activated in a language task in which subjects were asked to generate appropriate verbs for visually presented nouns. Interestingly, once the verb generation task had been well practiced, cerebellar activation diminished, suggesting a cerebellar role primarily in the learning of the noun–verb association. The cerebellum was not activated when the nouns were simply read, nor when nouns were matched with nonmotor adjectives. A third study showed that the dentate was activated bilaterally when subjects worked to solve a pegboard puzzle, and this activation was three to four times greater in magnitude than during simple peg movements. Overall, these findings indicate that the lateral cerebellum and dentate are activated in ways that would not be expected to account for movement alone.

Behavioral observations of humans with cerebellar damage have also provided evidence that the cerebellum participates in nonmotor aspects of cognition. In one case study, a cerebellar patient was unable to detect errors in a verb-generating task and did not exhibit normal practice-related learning, although the patient performed normally on standard intelligence and memory tests. In another study, cerebellar patients were deficient in both the production and the perception of a timing task. Lateral cerebellar lesions interfered with the perception of time intervals, while

medial cerebellar lesions affected the timing of implemented responses.

Some clinical studies have proposed even greater cerebellar control of mental activities. One such study has proposed a 'cognitive affective cerebellar syndrome'; however, the variety of mental deficits and the varied locations of the cerebellar lesions raised questions about the consistency of the suggested correlation. Other studies of infantile autism document attention deficits as well as the focal cerebellar atrophy. However, subjects with autism have abnormalities of movement in addition to abnormalities of mentation, while focal cerebellar lesions in previously normal individuals have not produced such a syndrome. This is also true for work on schizophrenia, which has documented a common association of focal cerebellar atrophy, yet schizophrenic patients also have disorders of movement, and focal cerebellar lesion in a previously normal individual has not been observed to cause a schizophrenic syndrome.

Cerebellar Motor Disorders

The most striking and debilitating effect of damage to the cerebellum is ataxia, which comes from the Greek and translates literally to 'without order.' Ataxia is typically used to mean incoordination of movement. Cerebellar ataxia can result from damage to the cerebellum itself or the pathways to and from it. Damage is typically caused by stroke, degenerative disease, or tumor. Alcoholism is known to cause atrophy especially of the anterior lobe of the cerebellum. Multiple sclerosis often affects the cerebellum as well. Many other neurodegenerative diseases, such as multisystem atrophy and the family of spinocerebellar ataxias, can damage the cerebellum. If there is damage to only one side of the cerebellum, the resultant symptoms manifest on the same side of the body as the damage.

There are many signs of ataxia, and different individuals can have some or all of them, depending on the location of damage. Since ataxia is a very general term, it is often used in reference to movement of a specific body part (e.g., arm ataxia) or type of movement (e.g., gait ataxia). There are many common manifestations of ataxia, including dysmetria (poor distance scaling), dysdiadochokinesia (incoordination between agonist–antagonist muscle pairs during rapid alternating movements), hypotonia (reduced muscle tone), dyssynergia (poor control of multijoint movements), and action tremor (oscillating limb movements about a joint during active movement).

One notable feature of the cerebellum is its distinct functional longitudinal 'zones.' Each cerebellar zone consists of a region of cerebellar cortex and its own set of deep cerebellar nuclei. Each zone has projections to and from different areas of the brain and spinal cord. Thus, each is uniquely positioned to control certain aspects of movement but not others. The middle zone consists of the midline structure, the vermis, and the fastigial nuclei. Patients with damage to the midline zone typically present with some (possibly transient) loss of postural tone, impaired upright posture and balance, gait ataxia, and eye movement deficits. The intermediate zone is made up of the intermediate hemispheres and the globose and emboliform nuclei. Damage to this region often results in action tremor, dysdiadochokinesia, and dysmetria of the limbs. The largest region of the cerebellum is the lateral zone, which contains the two lateral hemispheres and the dentate nuclei. Patients with damage in this region have dyssynergia, dysmetria, and difficulty planning complex limb movements, especially those that are visually guided. Because each of the cerebellar arteries supplies multiple longitudinal zones and most degenerative disorders are pancerebellar, patients typically have cerebellar lesions that span multiple longitudinal zones. Patients therefore usually show a variety of cerebellar signs.

Limb Control

One of the most obvious signs of cerebellar damage is limb ataxia. Unlike the smooth and accurate movements healthy people make, individuals with cerebellar lesions have arm and leg movements that are characteristically choppy, segmented, slow, and inaccurate. The impairments become more pronounced the faster the movements are made.

Several studies have shown that cerebellar patients are often hypermetric when they are asked to make rapid step-tracking movements of a single joint. Some abnormalities commonly observed are reduced but prolonged agonist muscle activity and delayed antagonist activity. When cerebellar patients are asked to make rapid reversals of movement (e.g., test for dysdiadochokinesia), they frequently have difficulty ceasing antagonist activity so that the agonist can begin the second phase of the movement. If a mass is added to the hand (e.g., carrying a load), the hypermetria increases. This is thought to be due to an inability to increase antagonist muscle activity to decelerate and stop the movement appropriately. Other specific deficits in muscle activation patterns differ with changing movement contexts. Nevertheless, it can be said that cerebellar damage results in inappropriate amplitude scaling and timing of the onset and cessation of agonist and antagonist muscles during single joint movements.

Though there are deficits in single joint movements, the motor abnormalities in more natural multijoint movements are much greater. From a mechanical perspective, the task of controlling a multijoint movement is much more complex than that of controlling each of the elemental single joint movements alone.

Figure 1 Finger endpoint locations for a group of healthy (left) and cerebellar participants (right) performing upward arm reaches (see experimental setup, far left) that are multijoint (top, labeled 'shoulder free') or single joint (bottom, labeled 'shoulder fixed'). Several trials from participants in each group are plotted (note: participants are given different numbers). Healthy participants are highly accurate in both conditions. Cerebellar patients are markedly inaccurate in the multijoint condition but show accuracy similar to that of healthy participants in the single-joint condition. Reproduced from Bastian AJ, Zackowski KM, and Thach WT (2000) Cerebellar ataxia: Torque deficiency or torque mismatch between joints? *Journal of Neurophysiology* 83: 3019–3030, used with permission from the American Physiological Society.

Figure 2 Wrist paths and finger endpoint locations for a typical healthy participant (top) and a cerebellar patient (bottom) performing forward arm reaches either as fast as possible (left, labeled 'fast') or slow and accurate (right, labeled 'slow'). Single reaching trials are overlaid for each type of reach for each participant. The target location is indicated by the large open circle; reach paths begin at the lower left and move upward and rightward. The healthy participant is nearly as accurate in the fast condition as in the slow (see finger endpoints) and shows very straight trajectories throughout (see wrist paths). The cerebellar patient is inaccurate during both types of movements, but noticeably worse in the fast than in the slow condition. During fast movements, hypermetria is predominant; during slow movements, hypometria predominates. Reproduced from Bastian AJ, Martin TA, Keating JG, and Thach WT (1996) Cerebellar ataxia: Abnormal control of interaction torques across multiple joints. *Journal of Neurophysiology* 76: 492–509, used with permission from the American Physiological Society.

Movements of one joint cause passive intersegmental interaction torques to occur at the other linked joints. For example, when the arm reaches forward, the active movement of the forearm will produce interaction torques that cause passive movement of the upper arm and vice versa. These torques are velocity and acceleration dependent and will therefore increase in magnitude with faster movements. Healthy individuals exploit interaction torques that assist with the intended movement and counter them when they oppose the intended movement. Because the muscle activity needs to be produced at the same time as the interaction torques, the descending commands must be generated before the movement occurs. Therefore, the nervous system must have some mechanism for predicting (rather than simply reacting to) these intersegmental dynamics (see Figure 1).

Studies of individuals with cerebellar lesions now indicate that limb ataxia may result from an inability to account for (either exploit or counter) intersegmental interaction torques normally. When cerebellar patients move their limbs fast, the torque produced by their muscles often does not counter the interaction torque appropriately, and the interaction torque contributes excessively to the generation of the movement. This results in an incoordinated reaching pattern, with the elbow and shoulder joints moving at inappropriate rates relative to one another, and movement hypermetria. On the other hand, when cerebellar patients move slowly, they tend to use a decomposition strategy. That is, they reach in a series of shoulder and then elbow movements individually, and the resulting movement is often hypometric (i.e., they undershoot the target; see Figure 2).

Balance and Posture

Patients with cerebellar damage frequently show abnormalities of posture and balance. The typical standing posture of a person with cerebellar damage is wide-based, often with the legs outwardly rotated to maximize the base of support. Also commonly seen is titubation, which is an abnormal bobbing-type motion especially involving the head, neck, and trunk. Standing postural sway is generally increased and can worsen under conditions of reduced or no vision. Specific patterns of postural sway vary depending on the location of the cerebellar lesion. If the anterior lobe is the primary

structure affected, sway is typically increased mostly in the anterior–posterior dimension, whereas with midline (the vermis and fastigial nuclei) cerebellar damage, postural sway is increased in all directions. Lateral cerebellar lesions tend to result in very minimal postural instability (see Figure 3).

Another characteristic balance deficit caused by cerebellar damage is abnormal responses to external perturbations. When the standing surface is quickly and unexpectedly displaced backward, cerebellar patients show excessive surface reactive extensor torque responses and an increased duration of the muscle activity. The behavior produced is one of reduced forward sway (caused by the movement of the support surface), followed by severely hypermetric reactive backward sway (caused by the muscle response to the perturbation).

Similarly, cerebellar patients also show impaired balance in response to perturbations generated by movements of their own body parts. Normally, when the arm is moved rapidly, muscles in the trunk and legs become active concurrently and even before the arm movement, to counter the inertial effects of the arm and maintain upright stance while minimizing postural sway and disequilibrium. Patients with cerebellar damage produce abnormally timed sequences of preparatory and concurrent postural muscle activity relative to the arm raise. Specifically, they often generate leg and trunk muscle activity that occurs too early to be effective in countering the inertial effects of the arm movement.

One idea that may explain the postural instability seen during self-generated movements is that cerebellar damage disrupts the ability to predict the intersegmental dynamics of the limbs and how the limb movements will produce torques at the trunk and other body segments that are not moving.

Figure 3 Sway position (center of pressure) histograms (bin width 10° polar; sampling frequency 30 ms; time 60 s) from a typical healthy participant (left), a cerebellar patient with anterior lobe cortical atrophy (middle), and a cerebellar patient with a vestibulocerebellar medulloblastoma (right). Note the scale changes across plots. The cerebellar patient with anterior lobe atrophy shows moderate instability in the anterior–posterior dimension. The cerebellar patient with vestibulocerebellar damage shows severe instability that is omnidirectional. From Dichgans J and Mauritz KH (1983) Patterns and mechanisms of postural instability in patients with cerebellar lesions. *Advances in Neurology* 39: 633–643.

Gait

Gait ataxia is probably the most common manifestation of cerebellar damage; it is often the first clinical sign of damage to the cerebellum and is also one of the most troublesome symptoms for patients. Cerebellar gait ataxia is characterized by a wide base of support and a walking path that does not follow a straight line but instead veers in different directions, giving the appearance of stumbling or drunkenness.

Quantitative studies of cerebellar gait have shown that coordination across the joints of the leg (intralimb coordination) and across the two legs (interlimb coordination) is impaired. Movements of each of the individual leg segments are timed incorrectly relative to one another and the magnitude scaled inappropriately, resulting in poor intralimb coordination. This sometimes manifests in a high-steppage gait pattern, where the foot elevation during swing phase is much higher than required to clear the foot. Inappropriate timing and scaling deficits also affect the position of one leg relative to the other, causing impaired interlimb coordination. The steps become irregular (excessively variable) in terms of the placement and timing of footfalls on one side relative to the other.

Another common feature of cerebellar gait is decomposition of movement. Decomposition is thought to reflect a compensatory strategy (rather than a primary motor deficit) to reduce the number of degrees of freedom and thereby minimize the complexity of the task. It is accomplished by breaking down a multijoint movement into a sequence of single joint movements. A common form of decomposition seen in patients with gait ataxia is a stiffening of the knee joint, probably produced through cocontraction of the muscles around that joint. In that way, the interaction torques that would be produced at other joints by virtue of knee motions are reduced.

Some aspects of intralimb leg incoordination during walking are due to deficits in dealing with interaction torques (e.g., stepping over obstacles). However, most of the observed deficits in walking relates closely to dynamic balance impairments, that is, deficits in coordinating the trunk and the two legs to maintain the body's center of mass over the feet. It has been shown that cerebellar patients with relatively minor balance impairments but relatively severe leg coordination impairments do not exhibit many of the features of gait ataxia. However, cerebellar patients with fairly minor leg coordination impairments but significant balance impairments show nearly all the signs of gait ataxia (see Figure 4).

Figure 4 Joint angles plotted against time for the ankle, knee, and hip during level walking. Examples are shown from a typical healthy participant (left), a cerebellar patient with predominantly ataxia of the limbs and minimal balance impairments (middle), and a cerebellar patient with predominantly balance impairments and minimal limb ataxia. Several single strides are overlaid for each participant, and a stride is from foot contact to the next foot contact on that leg. Note the timescale changes across plots. The limb movement-impaired cerebellar patient (who has no balance deficit) walks similarly to the healthy participant. The balance-impaired cerebellar patient (who has no voluntary leg coordination deficit) shows many features of gait ataxia, including reduced angular excursions, joint–joint decomposition, increased stride-to-stride variability, and reduced speed (see arrows). Reproduced from Morton SM and Bastian AJ (2003) Relative contributions of balance and voluntary leg-coordination deficits to cerebellar gait ataxia. *Journal of Neurophysiology* 89: 1844–1856, used with permission from the American Physiological Society.

Motor Learning

The cerebellum is also essential for motor adaptation, which is an error-driven learning process used to adjust movements to new sensory and/or motor demands through practice. Adaptation occurs relatively quickly, over minutes to hours, rather than days or weeks. Changes clearly occur in the earliest component of the movement, indicating that the adaptation affects feed-forward or predictive commands to the body. The new sensorimotor calibrations are stored, causing aftereffects that persist when the new demands are removed. Adaptation is important for keeping motor commands appropriately adjusted for changes in the environment or physical aspects of the body (e.g., growth, strength). Without it, an individual's ability to move smoothly and accurately suffers.

People with cerebellar damage show impairments in or loss of adaptation of movements to altered situations or novel demands. An example of this occurs when wearing laterally deviating prism glasses, which bend light and shift viewed objects to the right or the left. Movements toward the object are initially misdirected in the same direction as the prism shift. Healthy participants can adapt with practice to regain accuracy, and they show aftereffects in the opposite direction when the prisms are removed. People with cerebellar damage are slow or unable to adapt their movements to the prism shift and show reduced or absent aftereffects. Similar adaptation deficits occur during walking and reaching under altered dynamic or visual demands. This form of learning is therefore thought to be cerebellum dependent. Such deficits in adaptation raise the important question of whether rehabilitation treatments aimed at altering movement patterns can be learned by people with cerebellar dysfunction. Longer-term training studies have not been tested and might provide important insights into whether the cerebellum is needed for very slow motor learning processes (see Figure 5).

A Common Mechanism?

The fundamental cerebellar operation is still not understood. It has been proposed to be a movement combiner, an internal model of limb dynamics, a timer, a prediction mechanism, and/or a learning machine. Several of these ideas are based on descriptions of the deficits in one or a few movement types following cerebellar damage. Some theories are more clearly formalized, others less so, and none are mutually exclusive.

One idea is that the cerebellum helps combine simple movement elements together to produce a new, single, coordinated motion. This idea is consistent with the fact that patients have more difficulty

Figure 5 Maximal lateral deviations of the walking trajectory for a typical healthy participant (left) and a patient with cerebellar atrophy (right) plotted for each walking trial before (baseline), during (adaptation), and after (postadaptation) prism exposure while walking. The cerebellar patient adapts more slowly and to a lesser extent and shows a diminished aftereffect in the postadaptation phase. The adaptation rate (in numbers of trials) for the two participants is indicated on each plot. Adapt, adaptation; postadapt, postadaptation. Reproduced from Morton SM and Bastian AJ (2004) Prism adaptation during walking generalizes to reaching and requires the cerebellum. *Journal of Neurophysiology* 92: 2497–2509, used with permission from the American Physiological Society.

controlling multijoint than single joint movements and compensate by decomposing or breaking motions down into elemental components. One way that the cerebellum could contribute to this process is by computing the necessary adjustments to a motor command to account for mechanical interactions between body segments. This type of internal model would be critical for coordinated control of many parts of the body.

Another theory is that the cerebellum acts as a general timing mechanism, clocking short intervals in the millisecond to second range. This theory is consistent with the fact that cerebellar damage can cause abnormal timing of muscle activity and that patients can even have difficulty with timing perception. Precise timing control would be important for computing appropriate movement commands, regardless of how many joints or body parts were being controlled. An open question is whether timing deficits can explain the finding that more complex movements are so much more impaired than simple ones.

The cerebellum may also function as a prediction mechanism. It may function by helping to estimate the optimal motor commands, upcoming body states (i.e., position, velocity), or both. The prediction hypothesis is supported by work showing that cerebellar damage produces greater impairment of movements requiring predictive as opposed to reactive control in many different types of movement. Predictive control is critical for fast and ballistic movements, but impaired prediction can also affect slower movements, due to increased reliance on time-delayed feedback signals.

These three ideas are inherently interrelated, making it difficult to distinguish them behaviorally. Whether the cerebellum acts as a combiner, a timer, and/or a predictor, it is clear that cerebellar control must be learned and maintained through error-dependent learning mechanisms.

Summary

The cerebellum is a subcortical structure that is important for controlling and learning movement. Damage to the cerebellum results in incoordination, or ataxia, but not loss of movement, or paralysis. Different longitudinal cerebellar zones are used for control of different types of movement based on their connectivity with other brain areas. There are distinct signs of limb, balance, and gait ataxia, which are exacerbated by moving multiple joints together and by moving quickly. Thus, some cerebellar deficits seem to result from a failure of motor commands to account for mechanical interactions between moving body parts. Cerebellar patients also show deficits in timing control and in generating feed-forward or predictive motor commands. The fundamental cerebellar operation is not known, but it may act as a movement combiner, a timer, and/or a prediction mechanism. These types of computations are inherently different but could conceivably result in similar-looking deficits. More work is required to clarify the cerebellar operation. What is clear is that optimal cerebellar control is maintained through adaptive learning processes. These processes appear to operate on relatively short timescales to keep movement well calibrated for varying environmental demands.

Neuronal Elements Constituting Cerebellar Microcircuits

The cortical sheet covering the cerebellar surface has a laminar structure composed of the most superficial, molecular layer; the intermediate Purkinje cell layer; and the deepest, granular layer. These layers contain seven major neuronal types, namely, granule cells, Purkinje cells, basket cells, stellate cells, Golgi cells, Lugaro cells, and unipolar brush cells, as illustrated in Figure 1. In addition, the cerebellar cortex receives mossy fiber afferents, climbing fiber afferents, and the third type of afferent through the white matter underlying the granular layer. Purkinje cell axons provide the sole output of the cerebellar cortex and project through the white matter toward the cerebellar and vestibular nuclei. The following sections provide brief descriptions of neuronal elements of cerebellar microcircuits.

Mossy Fiber Afferents

These arise from the brain stem and spinal cord. Some of them arise directly from peripheral nerves, but most are relayed by various precerebellar nuclei. A mossy fiber afferent terminates in the granular layer, forming a rosette that is the core of the characteristic glomerulus structure. Branches of one mossy fiber supply excitatory synapses to 400–600 granule cells.

Granule Cells

These are individually the smallest (5–8 μm in diameter) but the most numerous neurons (2–3 million mm^{-3}, for a total of 10^{10}–10^{11} in humans) in the brain. Each granule cell extends four to five short dendrites, each of which receives an excitatory synapse from a mossy fiber terminal. Granule cell axons ascend through the Purkinje cell layer and molecular layer perpendicularly to the cortical surface and bifurcate to parallel fibers that extend 4–6 mm across the T-junction in the molecular layer. Granule cell axons supply excitatory synapses to other neurons in the cerebellar cortex.

Purkinje Cells

They are large inhibitory neurons lying in one layer at a density of 300–500 mm^{-2}. The human cerebellum contains 15 million Purkinje cells. Each Purkinje cell extends planar dendrites, through which numerous parallel fibers pass. Parallel fibers supply a Purkinje cell with as many as 175 000 excitatory synapses. The ascending segments of granule cell axons supply about 20% of the excitatory synapses that dendrites of each Purkinje cell receive from granule cells. Purkinje cells also receive excitatory synapses from climbing fibers and the third type of afferent, and inhibitory synapses from basket and stellate cells. Purkinje cell axons extend through the white matter to subcortical structures.

Basket Cells

Basket cells are located in the molecular layer near Purkinje cells at a density sixfold that of Purkinje cells. Basket cells receive excitatory synapses from parallel fibers and in turn supply γ-aminobutyric acid (GABA)-mediated inhibitory synapses to the bottleneck of a Purkinje cell soma, forming a unique complex structure called a 'pinceau.' One basket cell may inhibit 50 Purkinje cells, whereas one Purkinje cell may receive synapses from 20–30 basket cells. Basket cells also receive excitatory synapses from collaterals of climbing fibers.

Stellate Cells

Stellate cells are located in the superficial two-thirds of the molecular layer. There are 16–17.5 fold more stellate cells than Purkinje cells. Distinct from basket cells, stellate cells supply GABA-mediated inhibitory synapses only to dendrites of Purkinje cells.

Golgi Cells

In the granular layer, there is one Golgi cell for every 15 Purkinje cells. Each Golgi cell receives ~4788 excitatory synapses from parallel fibers on its apical dendrites extending to the molecular layer and also 228 mossy fiber terminals on their descending dendrites. A Golgi cell in turn extends a broadly branching axon to as many as 5700 granule cells and supplies GABA-mediated inhibitory synapses.

Lugaro Cells

Lugaro cells are located in or slightly below the Purkinje cell layer. Their axons supply GABA-mediated inhibitory synapses to apical dendrites of Golgi cells. The cerebellar cortex contains one Lugaro cell per Golgi cell. Ten Lugaro cells converge onto only one Golgi cell, whereas the axon of one Lugaro cell diverges onto 150 Golgi cells. Lugaro cells receive serotonergic synapses, and in the presence of serotonin, they discharge spikes regularly at 5–15 Hz.

From Ito M (2006) Cerebellar circuitry as a neuronal machine. *Progress in Neurobiology* 78(3–5): 272–303.

Unipolar Brush Cells

Unipolar brush cells are located primarily in the granular layer of the vestibulocerebellum, which is the portion of the cerebellum receiving primary vestibular afferents. A unipolar brush cell receives an excitatory synapse on its dendritic brush from a single mossy fiber terminal, thus forming a giant excitatory synapse. Axons of unipolar brush cells branch and give rise to large terminals that, within gromeruli, synapse with both granule cell and unipolar brush cell dendrites. In this sense, unipolar brush cells are the intracortical source of mossy fibers.

Climbing Fibers

Climbing fibers are a unique structure of the cerebellum with no homologs elsewhere in the central nervous system. They originate from the inferior olive in the medulla oblongata. Each Purkinje cell is innervated by one climbing fiber, which forms numerous synaptic contacts (e.g., 26 000 in rat) with dendrites of a single Purkinje cell. This arrangement provides particularly large excitatory postsynaptic potentials superimposed with Ca^{2+} spikes.

Climbing fibers are now considered to convey error signals instrumental to synaptic plasticity and learning in the cerebellar cortex (see the section titled 'Synaptic plasticity'). Climbing fiber signals are triggered in many cases by sensory stimuli, but whether climbing fibers convey sensory or motor information (motor information may be converted from sensory information) remains controversial.

Third Type of Afferent

Afferents of the third type contain various amines (e.g., serotonin, dopamine, acetylcholine, norepinephrine, and histamine) or peptides (e.g., orexin, angiotensin II, and corticotropin-releasing factor). This third type of afferent generally extends fine varicose fibers sparsely throughout the granular and molecular layers and forms direct contacts with Purkinje cells and other cerebellar neurons. Serotonin-containing fibers arise from raphe nuclei, whereas norepinephrine-containing fibers originate from the nucleus locus coeruleus. Histamine-containing fibers and many neuropeptide-containing fibers arise from the hypothalamus. It has long been suggested, but with scarce evidence, that the third type of afferent plays roles in emotion and behavior.

Cerebellar Nuclear Neurons

A major group of neurons in cerebellar nuclei are the target of GABA-mediated inhibitory synapses supplied by Purkinje cells. Purkinje cells provide 73% of the total synapses to nuclear neurons, including almost all the somatic synapses of nuclear neurons. Cerebellar nuclear neurons also receive excitatory synapses from collaterals of mossy fiber and climbing fiber afferents. Cerebellar nuclear neurons send their axons to extracerebellar structures, but their collaterals pass through the cerebellar cortex as mossy fibers. Cerebellar nuclei also contain small neurons whose axons supply GABA-mediated inhibitory synapses to inferior olive neurons. Some neurons in the vestibular nuclei (e.g., Deiters neurons and vestibuloocular relay neurons) also receive inhibitory synapses from Purkinje cells.

Parvicellular Red Nucleus Neurons

Neurons of the parvicellular red nucleus project to the inferior olive, in contrast to neurons of the magnocellular red nucleus, which project to the spinal cord. The parvicellular red nucleus–inferior olive pathway develops in association with phylogenetically newer parts of the cerebellum. Neurons in the parvicellular red nucleus receive excitatory synapses from cerebellar nuclear neurons and in turn supply excitatory synapses to inferior olive neurons that extend climbing fiber afferents.

Local Microcircuit Mechanisms

The above-introduced neuronal elements are interconnected to form various prototypes of local microcircuit.

Two-Stepped Divergence and Convergence

The major pathway across the cerebellar cortex consists of mossy fiber afferents, granule cells, and Purkinje cells, which are connected forwardly by the repetition of divergence and convergence. This is the fundamental substrate of the multilayered computational networks of the cerebellum as hypothesized by David Marr and James Albus around the end of the 1960s. Information received by the first layer, composed of mossy fibers, is spread in the 'hyperspace' formed by a large number of granule cells in the second layer. Purkinje cells in the third layer then receive signals from selected granule cells.

Synaptic Plasticity

About 200 000 parallel fibers and one climbing fiber converge onto one Purkinje cell. Around 1970, theorists speculated the meaning of this unusually asymmetric convergence of two inputs. Because climbing fiber signals inevitably activate Purkinje cells through the close contact between a climbing fiber and Purkinje cell dendrites, the conjunctive activation of parallel fibers and the climbing fiber leads to the Hebbian condition for synaptic plasticity. That is, the potentiation of synaptic transmission occurs when presynaptic and postsynaptic elements are conjointly activated. Because the actually discovered synaptic plasticity is long-term depression (LTD) and because climbing fibers convey error signals, it has been postulated that climbing fiber signals eliminate those parallel fiber synapses involved in an erroneous performance of a cerebellar circuit, in the manner of error-driven learning.

Cerebellar microcircuits involve also other types of synaptic plasticity. For example, long-term potentiation (LTP) occurs in parallel fiber–Purkinje cell synapses stimulated without conjunctive climbing fiber activation. This LTP balances LTD evoked by conjunction. Inversely, the conjunctive stimulation of a parallel fiber and a climbing fiber induces LTP in parallel fiber synapses with basket or stellate cells, and LTD is induced in them when only parallel fibers are activated. The synaptic plasticity in basket and stellate cells therefore operates oppositely to that in Purkinje cells and would have a synergistic effect on the latter. LTP occurs in the mossy fiber extending to granule cell synapses and would have the effect of adjusting the size of the granule cell hyperspace. A weak LTD occurs in tetanized climbing fiber–Purkinje cell synapses.

Feed-Forward Inhibition

Parallel fiber impulses are transmitted to basket and stellate cells, whose inhibitory signals are further transmitted to Purkinje cells. This pathway provides a feed-forward inhibition that parallels the excitatory pathway from granule cells to Purkinje cells. When the cerebellar surface is viewed from above, basket and stellate cells extend axons perpendicularly to parallel fibers. Hence, excitation propagating along a parallel fiber bundle will be flanked by inhibition mediated by basket or stellate cells. This is a spatial pattern of lateral inhibition. However, because such a pattern has not been observed to arise spontaneously, it could be a result of the electrical stimulation of a parallel fiber bundle.

Another potentially important function of feed-forward inhibition is to curtail sharply the parallel fiber-mediated excitatory synaptic effect by a slightly (1–4 ms) delayed inhibitory synaptic effect. By this mechanism, feed-forward inhibition could increase temporal precision and thereby minimize the randomness of circuit operation. This temporal fidelity justifies the use of a network model, with its binary input and output, for modeling the operation of the cerebellar cortex.

Feedback Inhibition

The loop through which granule cells excite Golgi cells that, in turn, inhibit granule cells represents a typical microcircuit for feedback inhibition. Computer simulation predicts that this feedback inhibition from Golgi to granule cells induces 10–50 Hz oscillations in spike discharges from the latter. Another possibility is that the circuit involving mossy fibers, granule cells, parallel fibers, and Golgi cells constitutes a phase converter, whose function is to generate a set of multiphase versions of a mossy fiber input. This phase converter (an 'alike' device) is essential in Masahiko Fujita's adaptive filter model of the cerebellum. Recently, another unique model has been proposed. It features a randomly connected granule cell–Golgi cell loop pathway, which operates as a clock for generating granule cell discharge in an ever changing ensemble of patterns. The patterns do not repeat unless reset by a large mossy fiber input to the pathway.

Reciprocal Inhibition

Basket and stellate cells in the molecular layer are reciprocally connected via inhibitory synapses. They are also linked to each other through electrical synapses. A computer simulation suggests that reciprocal inhibition causes an oscillation of the activity of basket and stellate cells at 100–250 Hz. This is a substantially higher rate of oscillation than that induced by Lugaro cells (5–15 Hz). Reciprocal inhibition also occurs among Purkinje cells via their recurrent collaterals that extend to neighboring Purkinje

cells within 300 μm of the parent cell. Mutual inhibition also occurs between Purkinje cells and basket cells, suggesting a possibility that Purkinje cells are involved in a mixed reciprocally inhibitory network containing Purkinje cells and basket cells.

Noise Generator

Spontaneous discharges of Purkinje cells are characteristically irregular. These irregular discharges are not caused by excitatory synaptic drives but, unexpectedly, by tonic influences from basket or stellate cells. The pharmacological blockade of ionotropic and metabotropic glutamate receptors does not affect spontaneous Purkinje cell discharges, whereas the blockade of $GABA_A$ receptors increases the rate of such discharges and makes the discharges regular. Similar irregular discharges and their dependence on tonic inhibition were also observed in basket and stellate cells that receive tonic inhibition from themselves. How noise is generated in basket and stellate cells has not been clarified. A modeling study suggests that noise helps Purkinje cells and basket and stellate cells respond rapidly, sensitively, and linearly to external inputs.

Modular Structure: Microzone and Microcomplex

The microcircuit structure is uniform throughout the cerebellum. However, the cerebellum is divided by transverse grooves into ten lobules (I–X) and also by various markers into seven longitudinal bands (A, B, C1, C2, C3, D1, and D2). Each division of the cerebellar cortex is further divided into microzones. A microzone combines with a set of subcortical structures including small groups of neurons in (1) a cerebellar or vestibular nucleus, (2) the inferior olive, and (3) the parvicellular red nucleus in phylogenetically newer parts of the cerebellum. These conjointly constitute a corticonuclear microcomplex.

A microcomplex represents a unitary neuronal machine of the cerebellum devoted to a specific function. The presence of a microcomplex in the intermediate part of the cerebellar hemisphere has been confirmed by a combination of zebrin immunohistochemical analysis and tracer techniques. A typical microcomplex structure including the flocculus and vestibular nuclei has been dissected in detail in association with horizontal, vertical, and rotatory canal–ocular reflexes. A microcomplex involved in the horizontal canal–ocular reflex was systematically labeled by retrograde transneuronal tracing with the rabies virus from a medial rectus muscle of guinea pigs. The microzonal structure was studied in detail in the C3 zone of the anterior lobe, which receives mossy fiber and climbing fiber inputs from receptive fields in the forelimb skin. This area contains 30–40 longitudinal microzones lying side by side, each of which is 50–150 mm wide. In each microzone, Purkinje cells and basket or stellate cells receive climbing fiber inputs from the same cutaneous receptive field. Climbing fibers in adjacent microzones are activated by stimulation of adjacent skin areas. Adjacent microzones in turn innervate adjacent cell groups in the anterior interpositus nucleus, which controls movement components that have specific relationships with the location of climbing fiber receptive fields. Assuming that a microzone is 10 mm wide, it may be calculated that the human cerebellum contains on the order of 5000 microcomplexes, each of which plays a specific role via its connections with functional systems in the spinal cord, brain stem, and cerebral cortex.

Each microcomplex receives mossy fiber inputs and sends out outputs of cerebellar or vestibular nuclear neurons. Learning can modify the input–output relationship of a microcomplex with reference to error signals conveyed by climbing fiber inputs. The roles of the third type of afferent have not been clarified, but it is probable that these afferents set the functional status of a microcomplex at different levels or in different modes. A microcomplex thus appears to be a unit machine representing a multipurpose adaptive computer chip.

Incorporation of Microcomplex into Segmental Circuits

Cerebellar microcomplexes are interconnected with various reflex centers in the spinal cord and brain stem. For example, the vestibuloocular reflex, optokinetic eye movement response, ocular following response, eyeblink conditioning, and baroreceptor reflex for arterial blood pressure have been studied as simple motor or autonomic systems representing functions of the cerebellum. The cerebellum is also connected to segmental circuits for saccadic eye movement, interlimb coordination during locomotion, and the operant conditioning of the H-reflex.

These microcomplexes interconnected with segmental microcircuits subserve adaptive mechanisms required for acquiring and maintaining precise motor or autonomic control. When a microcomplex changes its dynamic characteristics according to error signals conveyed by climbing fibers, this learning will lead to the optimal tuning of dynamic characteristics of the segmental motor or autonomic centers. This tuning should minimize error signals of climbing fibers.

Incorporation of Microcomplex in Cerebral Cortical Circuits: Internal Model for Voluntary Movements

The involvement of the cerebellum in voluntary movements has been studied using various experimental paradigms since Tom Thach's pioneering work that started in the 1960s: for example, wrist flexion in response to a sudden load perturbation, the operant conditioning of wrist movements to lift a lever in response to visual stimuli, throwing while looking through prisms, reaching, the hand manipulation of a computer mouse, and finger gripping. The smooth pursuit eye movement is also a type of voluntary movement.

A characteristic circuit arrangement for the cerebellar control of voluntary movements is the cerebrocerebellar communication loop. In this loop, the motor cortex projects mossy fiber afferents to the intermediate part of the cerebellar hemisphere via the pontine nucleus, and cerebellar outputs from the interpositus nucleus pass back to the motor cortex via the thalamus. A recent study using the transneuronal transport of neurotropic viruses by Peter Strick's group confirmed that neurons in the arm area of the motor cortex receive inputs from Purkinje cells located primarily in lobules IV–VI of the cerebellar cortex. In turn, neurons in the arm area project back via the pons to granule cells primarily in the same three cerebellar lobules.

It has been hypothesized that, through this communication loop, the cerebellum provides an internal feedback that may replace the external feedback via a sensory system. If the cerebellum contains an accurate model of the lower motor system including a motor apparatus, the internal feedback through the model should enable us to perform a precise movement even without the external feedback. This hypothesis explains how one can move correctly even with the eyes closed and how dysmetria characterizes patients with an impaired cerebellum. The internal model subserving the internal feedback is called the forward model. Motor learning can be considered to be a process by which the forward model is formed and reformed in the cerebellum through LTD-based error-driven learning.

Another important circuit connects the cerebral cortex and cerebellum in parallel. For example, neurons in the supplementary motor cortex and premotor cortex project to the motor cortex, and at the same time, they project to the cerebellum via the pontine nucleus. A cerebellar microcomplex can then be incorporated parallel to the motor cortex. When the cerebellar cortex operates in parallel with the motor cortex, it forms another type of internal model that bears a transfer function reciprocally equal to the dynamics of the controlled object. The inverse model proposed by Mitsuo Kawato's group acts as a feed-forward controller that replaces the motor cortex serving as a feedback controller. The forward and inverse models and their combination have been applied successfully to the construction of a robot that is able to learn movement skills.

Incorporation of Microcomplex in Cerebral Cortical Circuits: Internal Model for Mental Functions

The most lateral part of the human cerebellum evolved in parallel to the expansion of cerebral association cortices. Recent virus mapping in monkeys has revealed that the projections to the motor and premotor cortices originate from the dorsal portions of the dentate nucleus, whereas projections to the prefrontal and posterior parietal areas of the cortex originate from the ventral portions of the dentate nucleus. The anterior intraparietal area of the posterior parietal cortex also receives projections from a broad area of the dentate nucleus. On the other hand, Purkinje cells located primarily in crus II of the ansiform lobule receive inputs from prefrontal area 46 and project to the same area 46. Therefore, a closed cerebrocerebellar communication loop is also formed between the prefrontal cortex and cerebellar hemisphere.

The presence of the cerebrocerebellar communication loop between the prefrontal cortex and cerebellar hemisphere supports the extension of the above-mentioned forward model hypothesis for voluntary movements to mental functions of the cerebral cortex. The internal model hypothesis has been extended conceptually to apply to mental functions such as thought. To do this, it is essential to assume that thought is the manipulation of mental models that are small-scale models of reality used by the mind to anticipate events requiring reason and an explanation. One may suppose that, in thought, a mental model of an image, idea, or concept is formed in the temporoparietal association cortex. The prefrontal cortex as the controller manipulates the mental model as the controlled object, just as the motor cortex controls the voluntary movements of body parts. Then, the cerebellum copies a mental model to form an internal model. Thus, thought proceeds with the internal models of the mental models as the controlled objects.

Because processes occurring in the cerebellum do not reach the level of awareness, the internal model hypothesis explains how we become able to conduct movements and thoughts unconsciously after

repeated exercises. For example, an idea pops out even without an obvious conscious effort to think it out! This hypothesis also explains diverse psychological and pathological mental experiences such as delusion, hallucination in schizophrenia, and the lack of sympathy for other persons as being caused by an impairment of a cerebellar internal model.

The inverse model postulated above for voluntary movements may also apply to thought. In this hypothesis, an inverse model substitutes the executive function of the prefrontal cortex. If both the forward and inverse models are formed, the entire process of thought could be performed within the cerebellum; the thought could then proceed in complete unconsciousness. This possibility may be relevant to the current intriguing question of whether the mental force we feel in initiating a voluntary movement is illusory. It has been argued that the conscious self feels the mental force as an experience of a movement initiated by unconscious processes, which could proceed within the cerebellum.

Conclusion

The elaborate structure of cerebellar microcircuits and their organization in a microcomplex as a unit machine have been well analyzed. The mechanism by which cerebellar microcircuits subserve various types of neural control has been clarified in terms of adaptive control and internal models. However, dynamic mechanisms operating in cerebellar microcircuits have to be investigated further, and in this respect, a realistic modeling of cerebellar microcircuits becomes increasingly important. A special interest in the field of neuroscience is the mechanism by which information not only of a physical nature in movements but also of a cognitive nature in mental activities is processed and stored in cerebellar microcircuits.

Cerebellum and Oculomotor Control

D S Zee and M Walker, The Johns Hopkins Hospital, Baltimore, MD, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The cerebellum plays a pivotal role in the control of all types of eye movements. Its essential function is to optimize ocular motor performance so that images of objects of interest are brought to the fovea – where visual acuity is best – and then kept there quietly to give the brain time to analyze and interpret the visual scene, and so decide what to do next. The cerebellum has both immediate, on-line functions (as reflected in immediate appearance of abnormalities when the cerebellum is damaged), and long-term, adaptive functions that ensure that the ocular motor responses are calibrated correctly to the stimuli that drive them.

Anatomical Approach to the Cerebellum and Ocular Motor Control

The approach here will be based upon structural–functional correlations: cerebellar influences on eye movements will be discussed by anatomical regions (see Table 1 and Figure 1). Since the cerebellum has an important role in motor learning that permits adaptation and compensation for lesions, a rigid compartmentalization of function inferred from enduring effects of lesions within the cerebellum may not strictly apply to the contribution of the cerebellum to the control of eye movements in intact subjects. With this caveat, the ocular motor functions of the cerebellum will be interpreted using the combination of the effects of acute and of chronic lesions, and the results from physiological studies. Here, the emphasis will be on the areas within the cerebellum about which most is known: the flocculus/paraflocculus, the nodulus/ventral uvula (lobules IX and X of the cerebellar vermis), and the dorsal oculomotor vermis (OMV) (lobules V–VII) and its target in the posterior portion of the underlying fastigial nucleus called the fastigial oculomotor region (FOR).

The cerebellum has a distinctive anatomical organization. Purkinje cells of the cerebellar cortex primarily project to and inhibit cells within the underlying deep cerebellar nuclei; the vestibulocerebellum (flocculus, paraflocculus, nodulus, and uvula) also projects to the vestibular nuclei some of which can be thought of as 'displaced' deep cerebellar nuclei. There is a rich innervation to the cerebellar cortex from the inferior olive, as climbing fibers directly to Purkinje cells, and from all the premotor brain stem nuclei concerned with eye movements (and from the vestibular nerve), as mossy fibers to cerebellar granule cells, and then onto Purkinje cells via parallel fibers. There are also direct climbing fiber and mossy fiber inputs to the underlying cerebellar nuclei, so that the cerebellar cortex can be thought of as a parallel pathway that can influence (via the projections of its Purkinje cells) the direct flow of information to and from the brain stem through the deep cerebellar nuclei.

Vestibulocerebellum: The Flocculus/Paraflocculus

The flocculus and paraflocculus together with the caudal portions of the cerebellar vermis (nodulus and uvula) are part of the oldest portion of the cerebellum – the archicerebellum, also called the vestibulocerebellum (Figure 1). Neurons within the flocculus/paraflocculus discharge in relation to various features of the stimulus (e.g., head motion or visual target motion), to the position of the eye in the orbit during fixation, and to the movements of the eye during smooth pursuit, vergence, and vestibular response to head motion (the vestibulo-ocular reflex or VOR).

Pursuit With lesions of the flocculus/paraflocculus smooth tracking of a moving target is impaired, either when the head is still (smooth pursuit) or moving (VOR cancellation). Both the initiation of pursuit and the response during sustained tracking can be affected. Complete lesions of the flocculus/paraflocculus lead to a considerably decreased steady-state gain (eye velocity/target velocity) of pursuit. There is considerable recovery of pursuit function, even with relatively complete floccular/paraflocular lesions. This is likely mediated by other parts of the cerebellum though other parts of the brain might also be involved.

Gaze holding A second cardinal feature of lesions of the flocculus/paraflocculus is impaired gaze holding: after eccentric horizontal eye movements, the eyes drift centripetally (Figure 2). This finding indicates that the flocculus/paraflocculus functions under the control of the brain stem circuits that convert (integrate) velocity into position commands for all types of conjugate eye movements, and so permits steady fixation.

Spontaneous nystagmus A third distinctive feature of lesions in the flocculus/paraflocculus is downbeat nystagmus, in which the eyes drift up (slow phase) and are brought back to the fixation target by a

Table 1 Anatomical localization of ocular motor functions within the cerebellum

Structure	*Function*
Flocculus/paraflocculus	Gaze holding Smooth pursuit and VOR cancellation Control amplitude and direction of rotational VOR Match pulse step to prevent postsaccadic drift
Nodulus/ventral uvula	Modulate velocity-storage mechanism within vestibular nuclei to influence low-frequency rotational VOR • Amplitude and direction (relative to gravity) of rotational VOR • Habituation of rotational VOR • Tilt suppression of postrotatory VOR
Dorsal vermis/fastigial oculomotor region (FOR)	Saccade amplitude and direction Pursuit initiation (open-loop acceleration) Horizontal eye alignment

Figure 1 Cerebellar structures important for eye movement control. Modified from Leigh RJ and Zee DS (2006) *The Neurology of Eye Movements*, 4th edn. New York: Oxford University.

corrective downward saccade (quick phase). This nystagmus likely arises from a loss of inhibition of Purkinje cells in the flocculus/paraflocculus upon pathways within the brain stem that mediate upward slow phases. This effect could be upon pathways the mediate the rotational VOR, the translational VOR, pursuit, or at some point where these signals are already combined, for example, in the brain stem circuits that mediate neural integration for gaze holding. An important feature of the upward drift is that it can have either a decreasing or an increasing slow-phase velocity waveform. These different velocity profiles suggest differences in the effect of the lesion on the vertical neural integrator. If the integrator is 'leaky' (its discharge decays with time), the velocity of the slow phase will be decreasing. If the integrator is 'unstable' (its discharge increases with time), the velocity of the slow phase will be increasing. Some monkeys with experimental floccular and parafloccular lesions show downbeat nystagmus with a decreasing velocity waveform, others an increasing velocity waveform.

Figure 2 A simple hypothesis to explain how the cerebellar flocculus might influence gaze-holding. An inherently poor gaze-holding network resides in the brain stem. By virtue of positive feedback, the flocculus can modulate the ability of the brain stem neural integrator to generate a steady tonic eye position command. If feedback is inadequate, gaze holding is impaired. If feedback is excessive, gaze is unstable. Modified from Zee DS, Yamazaki A, Butler PH and Gucer G (1981) Effects of ablation of flocculus and paraflocculus of eye movements in primate. *Journal of Neurophysiology* 46: 878–899.

A simple hypothesis to explain the effects of lesions of the flocculus/paraflocculus on gaze holding is based upon the idea that there is an inherently poor, 'leaky' ocular motor integrator within the brain stem that sustains the discharge of neurons in the absence of an ongoing external input (Figure 2). The neurons in the paramedian tracts (PMTs) and in the medial vestibular nucleus and the nucleus prepositus hypoglossi are probably important constituents of this integrator network, and the superior vestibular nucleus and the interstitial nucleus of Cajal in the midbrain may also play a role in vertical neural integration. In this scheme, the cerebellum improves the performance of this brain stem neural integrator by acting upon a positive feedback loop around it. The flocculus/paraflocculus would then modulate the gain of this feedback loop. For the horizontal system, monkeys with floccular/paraflocculus lesions always develop a gaze-evoked nystagmus with a velocity-decaying waveform, indicating that the flocculus/paraflocculus is critical for improving the performance of the inherently 'leaky' horizontal brain stem neural integrator. The variable effect on the waveform of upward slow phases suggests that for the vertical integrator the flocculus/paraflocculus has a more subtle, modulatory role that is based upon an individual animal's inherent capabilities, which in turn depends upon its genetic makeup and its own ocular motor history (e.g., trauma or disease).

Postsaccadic drift Another feature of the floccular/paraflocculus syndrome is a brief drift of the eyes, lasting several hundreds of milliseconds, following each saccade. This postsaccadic drift reflects a mismatch between the pulse (phasic) and the step (tonic) of innervation for saccades and is due to abnormal amplitude of the step output of the neural integrator relative to its velocity input, the pulse. Normally, these two premotor signals are matched precisely, so the eye abruptly stops at the end of the saccade. In monkeys with lesions of the flocculus/paraflocculus, the direction of the postsaccadic drift, onward or backward, is variable from animal to animal, again in keeping with a modulatory role of the cerebellum upon the premotor brain stem circuits generating eye movements.

Vestibular–ocular reflexes The flocculus and paraflocculus are not critical for the VOR response to head rotations (r-VOR) in the sense that the r-VOR is still present in animals with lesions of the flocculus/paraflocculus or even after complete ablation of the cerebellum. The amplitude, however, may be normal, increased or decreased, and it may be misdirected, that is, the axes of eye rotation and head rotation become misaligned.

During rotation of the head around an earth-vertical axis, patients with diffuse cerebellar lesions may show a dynamic upward bias so that the eyes move up as well as horizontally, producing a 'cross-coupled' VOR. There are also inappropriate torsional components and the responses in the two eyes are disconjugate, with relatively more torsion in one eye and more vertical rotation in the other. A release of inhibition upon anterior semicircular circuits within the brain stem (which produce upward slow phases)

is a plausible explanation. These results implicate the cerebellum, and likely the flocculus/paraflocculus, in generating movements of each eye that have the correct amplitude and direction for perfect VOR compensation.

The cerebellum also plays a role in the translational VOR (t-VOR), and the flocculus/paraflocculus may be involved in its generation though this is not yet proven. The t-VOR can be measured alone (e.g., pure side-to-side, fore-and-aft, or up–down linear motion), or with a rotation of the head when the axis is in front of or behind the labyrinths, which leads to a combined rotation and translation. Patients with cerebellar lesions can have a profoundly impaired t-VOR even when the r-VOR is intact. They also have defects in adjusting the r-VOR for the distance of the target of interest and for the displacement of the orbits away from the axis of head rotation. These are necessary requirements for adequate gaze stabilization during head rotation, since virtually all head rotations are accompanied by some translation of the orbits. The flocculus/paraflocculus have neurons that discharge in relation to vergence and it is possible that this information is used to adjust the VOR for target distance, a necessary requirement whenever translation is a component of head motion. Other parts of the cerebellum including the nodulus and ventral uvula, the dorsal (oculomotor) vermis, and the underlying fastigial nuclei may also play a role in the t-VOR.

Vestibulocerebellum: The Nodulus/Ventral Uvula

The nodulus and adjacent ventral uvula are the most caudal aspects of the cerebellar vermis (Figure 1). The nodulus/ventral uvula acts upon the 'low-frequency' components of the VOR via its projections to a 'velocity-storage' mechanism within the vestibular nuclei. With a constant-velocity rotation of the head, the velocity-storage mechanism extends the duration of the VOR response beyond that expected from the mechanical properties of the cupula–endolymph system within the semicircular canals. This perseverating action slows the decay of nystagmus during a constant-velocity rotation in the dark and improves the performance of the VOR at low frequencies of rotation. During sustained 'off-vertical axis' rotation of the head, when there is an imposed change in linear acceleration due to the continuous reorientation of the head relative to the pull of gravity, the velocity-storage mechanism modulates the direction of compensatory slow phases, reorienting the axis of eye rotation relative to the axis of head rotation.

Lesions of the nodulus result in an increase in the duration of vestibular responses to a constant-velocity input (the VOR time constant is increased). There is also a loss of habituation to repetitive stimulation (the VOR time constant no longer decreases with repetitive stimulation). Tilt suppression of postrotary nystagmus, a phenomenon by which the decay of postrotary nystagmus is hastened by pitching the head down immediately following the end of a constant-velocity rotation, no longer occurs. With nodulus lesions, the VOR no longer shows the reorientation of the axis of eye rotation that normally occurs with an imposed linear acceleration. Patients with diffuse cerebellar disease may show abnormally directed slow phases, or 'cross-coupling' during low-frequency head rotation around an earth-vertical axis, during sustained optokinetic stimulation with the head upright, and after horizontal head shaking. These abnormalities of the direction of the VOR in response to low-frequency stimuli likely reflect dysfunction of the nodulus/ventral uvula. The nodulus/uvula also may play a role in other aspects of otolith–canal interaction and in enabling the brain to distinguish tilt from translation, since the otoliths signal linear acceleration regardless of its source, and in themselves cannot distinguish between a dynamic translation of the head and a static reorientation of the head with respect to gravity.

Periodic alternating nystagmus (PAN), a horizontal jerk nystagmus that changes direction every few minutes, may appear following lesions of the nodulus. PAN reflects the combined actions of a (1) disinhibited brain stem vestibular velocity-storage mechanism (due to loss of inhibition from Purkinje cells in the nodulus that project to vestibular nuclei) and (2) an intact adaptive mechanism that acts to null any sustained unidirectional nystagmus, thus allowing PAN to change direction. Because Purkinje cell inhibition is mediated through $GABA_B$ receptors, treatment with baclofen (a $GABA_B$ agonist) disengages the velocity-storage mechanism and stops PAN (gamma-aminobutyric acid, GABA).

The nodulus and uvula may have other ocular motor functions; lesions there also alter smooth pursuit and optokinetic nystagmus, but their exact contribution to these visual-following reflexes is unclear.

Functional Differences between the Flocculus/Paraflocculus and the Nodulus/Uvula

The vestibulocerebellum has many functions and lesions produce a variety of abnormalities. Are there overriding principles about the functions of these two areas of the cerebellum? One simple hypothesis is that the flocculus and paraflocculus are more concerned with relatively immediate and fast-acting, ocular motor functions that relate to the needs of the fovea, for example, smooth pursuit, the t-VOR and steady gaze following saccades, all of which relate to holding images steady on the fovea. The nodulus and ventral

uvula would be more concerned with generating eye movements that determine the duration and axis of eye rotation in response to low-frequency vestibular stimuli and so determine the orientation of images on the entire retina. This idea remains speculative, and even within the flocculus/paraflocculus and nodulus/uvula a further segregation of function is likely.

Dorsal Cerebellar Vermis and the Posterior Fastigial Nucleus

The dorsal vermis (lobules V–VII, called the oculomotor vermis (OMV)) and the underlying posterior fastigial nucleus (called the fastigial oculomotor region, FOR) are important in the control of saccades and pursuit (Figure 1).

Saccades Lesions in the OMV lead to changes in the accuracy, latency, and dynamic properties of saccades, as well the ability to undergo saccade adaptation. Physiological studies in monkeys reveal that Purkinje cells in the OMV discharge before saccades, and stimulation of this same area can elicit saccades. In humans, too, artificial stimulation using transcranial magnetic stimulation (TCM) and functional magnetic resonance imaging (fMRI) scanning, while subjects make saccades, confirms the participation of the OMV in the generation of saccades (Figure 3). Neurons in the FOR also discharge in relation to saccades. They supply a presaccadic burst for contraversive saccades (i.e., the right FOR bursts before leftward saccades) and a 'braking' discharge, late during the saccade, for ipsiversive saccades. Thus, each FOR acts to facilitate contraversive saccades and contributes to the termination of ipsiversive saccades. Purkinje cells in the OMV behave in a similar way to those of the FOR, though, as predicted from their inhibitory nature, their 'sign' is opposite. Thus, each side of the vermis acts to facilitate ipsiversive saccades and contributes to the termination of the contralateral saccades. Consequently, lesions in the FOR cause ipsiversive saccadic hypermetria (overshoot) and contraversive hypometria (undershoot). Bilateral FOR lesions cause bilateral hypermetria. Since Purkinje cells of the OMV inhibit the ipsilateral FOR, the effects of OMV lesions are opposite to those of FOR lesions: hypometric ipsiversive and hypermetric contraversive saccades. Bilateral lesions in OMV cause hypometric saccades in both horizontal directions. The role of the cerebellum in generation of vertical saccades is not as well localized, and other areas, such as the interposed nucleus and paraflocculus, may also be important.

Figure 3 fMRI of the cerebellum during voluntary saccades made in darkness, showing relative activation in the regions of the dorsal vermis and also the lateral cerebellar hemispheres. How does the cerebellum influence the circuits within the brain stem that generate saccades? There are a number of possible targets by which the FOR could influence saccades. The early influence of the FOR on the initiation of saccades could be mediated through the excitatory burst neurons (EBN) within the brain stem reticular formation. The late influence of the FOR on stopping saccades could be through the inhibitory burst neurons (IBNs) in the brain stem reticular formation. These neurons could act to 'choke' or 'brake' the saccade by strongly inhibiting the abducens nucleus that had been driving the agonist muscles during the saccade. Projections of the FOR to omnipause neurons (OPNs), which inhibit premotor saccadic EBN – either directly or via projections to OPN from the fixation zone of the rostral pole of the superior colliculus – are other routes by which the FOR could help bring the saccade to an end. Modulation of the trajectories of saccades, 'on-line', has also been suggested as a function of the FOR, with the OMV receiving information about performance during saccades and adjusting its inhibition upon the FOR to assure saccade accuracy. In this scheme, the OMV would also recognize contexts (e.g., the position of the eye in the orbit) and adjust the output of the FOR to fit the particular circumstances in which the saccade must be generated. Though attractive, these speculations about cerebellar function in the control of saccades await experimental confirmation.

Pursuit Like saccades, there is considerable evidence that the OMV and FOR participate in the generation of pursuit eye movements. Lesions in the OMV lead to changes in the smooth pursuit as well the ability to undergo pursuit adaptation. Electrical

stimulation of the OMV can enhance contraversive or impair ipsiversive pursuit in monkeys, and TCM of the posterior cerebellum in humans can also evoke pursuit eye movements in the same pattern. There are neurons in both the OMV and the FOR that discharge in relation to pursuit. In the case of the FOR, neurons discharge early during contraversive pursuit and late for ipsilateral pursuit, analogous to activity associated with saccades. Thus, each FOR can facilitate contraversive pursuit and can contribute to the termination of ipsiversive pursuit. Purkinje cells in the OMV probably behave in a similar way to those of the FOR, though, as predicted from their inhibitory nature, their 'sign' is opposite. Each side of the vermis would act to facilitate ipsiversive pursuit and contribute to the termination of contralateral pursuit.

The pursuit deficits that have been reported after lesions in the OMV and the FOR are largely in accord with the physiological findings. As expected, with a lesion in the FOR, contralateral pursuit is impaired. Bilateral FOR lesions would be expected to produce reasonably symmetrical and relatively intact pursuit and this appears to be the case, though a detailed analysis of the open-loop behavior (i.e., the first 100 ms during which pursuit is initiated) of such animals is not yet available. On the other hand, bilateral lesions of the OMV produce bilateral pursuit deficits.

One other remarkable finding after OMV lesions in monkeys is that there are quantitative similarities in the effects of the lesions on saccade amplitude, and on pursuit velocity at the end of the 'open-loop' initial period of pursuit tracking (the first 100 ms of tracking after a target has started moving or has changed its speed). This similarity suggests that the OMV functions in the control of the preprogrammed, 'open-loop' component of eye movements, and furthermore that saccades and the 'open-loop' portion of pursuit share neural circuitry, not only in the cerebellum but also in the brain stem and superior colliculus. Compatible with this idea is the finding of neurons within the OMV that discharge for both pursuit and saccades, and that stimulation of the OMV can alter ongoing saccades or pursuit, depending upon the parameters of the stimulus.

Before leaving the FOR and OMV, one must ask why there are multiple areas within the cerebellum that seem related to pursuit and saccades. For example, the uvula and the interposed nucleus, the flocculus/parafloccus, and the FOR/OMV complexes, all have neurons that discharge with pursuit eye movements. Lesions in the uvula and within the lateral cerebellar hemispheres also have been associated with pursuit deficits. One dichotomy to consider is that the OMV/FOR is more concerned with the initiation and termination of the preprogrammed, open-loop, initial portion of pursuit, and the flocculus/paraflocculus is more concerned with pursuit during sustained tracking. Such a strict segregation of function, however, is not yet proven. Furthermore, after partial lesions in the cerebellar cortex, there is a considerable recovery of function, suggesting a capability for one part of the cerebellum to take over for another though other parts of the brain, too, may be involved in this recovery.

For saccades, too, there are neurons in areas of the cerebellum apart from the FOR/OMV that show saccade-related activity. They include the posterior portion of the interposed nucleus, the basal interstitial nucleus, and the lateral cerebellar hemispheres. Both pursuit and saccades are commonly associated with other motor behaviors, head movements, arm movements, and walking or running, for example, and also occur in different contexts (e.g., reflexive or self-generated). Thus, one can envision a number of areas within the cerebellum associated with different motor behaviors that might want to 'know' or use information about associated eye movements to help optimize their own performance.

Other Abnormalities of Ocular Motor Control Associated with Cerebellar Dysfunction

Abnormalities of eye torsion The torsional orientation of the eye during fixation is precisely controlled and is described by Donders' and Listing's laws. Donders' law states that during steady fixation, the torsional orientation of the eyes is fixed for a given eccentric (horizontal and vertical) eye position. Listing's law describes the way in which Donders' law is implemented; it defines the kinematic features of eye rotations that fix the torsional orientation of the globe for a given horizontal and vertical position of the eyes in the orbit. Listing's law is not perfectly obeyed in patients with cerebellar lesions. Which part of the cerebellum serves this function is not yet known.

The Cerebellum and Binocular Ocular Motor Control

Most of the findings relating the cerebellum to ocular motor control have dealt with conjugate eye movements. Less is known about the role of the cerebellum in disconjugate ocular motor control when the eyes must rotate by different amounts, either to alter the relative positions of the eyes during fixation (static alignment), or to readjust alignment during movement (dynamic alignment or yoking of the eyes).

Disorders of alignment with cerebellar lesions Patients with cerebellar damage sometimes show a

skew deviation, a vertical misalignment of the eyes that cannot be attributed to oculomotor or trochlear nerve palsy. The misalignment often changes its sense with horizontal eye position; most commonly, the abducting eye is higher. Patients with cerebellar abnormalities also may have an esotropia (a convergent squint in which the eyes turn inward), sometimes attributed to a divergence paralysis since the esodeviation is usually greater at distance. Patients with caudal cerebellar lesions may also have a divergence-beating nystagmus (convergent slow phases with divergent quick phases). Experimentally, lesions of the FOR produce convergence failure while lesions in the OMV produce an inward turning of the eyes. These types of abnormalities hint at an excess of convergence tone with some cerebellar lesions.

The VOR must be able to produce disconjugate compensatory responses, especially those associated with translation of the head. Patients with diffuse cerebellar atrophy produce disconjugate vestibular responses and also show disconjugate saccades in which the movements of the two eyes during and immediately after saccades are not yoked. Taken together with anatomical and physiological studies, there is compelling evidence for a role for the cerebellum in the disconjugate control of eye movements, though much needs to be learned about these particular aspects of cerebellar function.

Ocular Motor Learning and the Cerebellum

Perhaps the most intriguing aspect of cerebellar function is its role in motor learning. The flocculus/paraflocculus has a clear role in ocular motor learning including the amplitude (gain) and the direction (relative to head motion) of the r-VOR, the pulse-step ratio for saccades, and the gain of smooth pursuit. The OMV, too, has a role in ocular motor learning, especially in modification of the initial acceleration of pursuit and of the amplitude of saccades. As expected, the FOR also plays a role in saccade (and presumably pursuit) adaptive control. Disconjugate ocular motor control is also subject to motor learning and under cerebellar influence.

The effect of experimental lesions within the cerebellum on ocular motor function often varies from animal to animal. While differences in the extent of lesions may explain some of this variability, another interpretation relates to the central role of the cerebellum in long-term ocular motor learning. In this formulation, the cerebellum acts to compensate for differences in motor performance that are idiosyncratic from animal to animal, depending upon the particular genetic makeup of each animal, its 'life history' of disease and trauma, and the interaction between inherent capabilities and environmental influences during development and aging.

The exact mechanisms of ocular motor learning are unclear, and their elucidation is a major focus of contemporary neuroscience. Just to point out a few of the more topical issues: What are the error signals that trigger motor learning? What are the relative roles of the cerebellar cortex, and of the deep cerebellar nuclei (or in the case of adaptation of the VOR, the vestibular nuclei) in acquisition versus maintenance of motor learning? What is the role of the cerebellum in short (minutes to hours) versus long-term (days to weeks) motor learning? What are the differences in mechanisms between relatively simple motor learning (e.g., adjustment of the amplitude of the VOR for all head movements) and relatively complex, context-specific motor learning (e.g., adjustment of the amplitude of the horizontal VOR as a function of eye position or viewing distance)? What is the role of the cerebellum in developing the internal models of the effectors of movements themselves (e.g., the oculomotor muscles and orbital structures, the 'plant') that are required for the brain to calibrate motor responses in the long term? Perhaps the most challenging questions relate to the molecular bases for learning within the cerebellum, be it in alterations of synaptic transmission, changes in connectivity with neural circuits, or changes in the properties of neuronal membranes themselves. And finally, can learning be promoted with medications or therapy?

Cerebellum: Clinical Pathology

M Molinari, Santa Lucia Foundation, Rome, Italy
M G Leggio, University of Rome 'La Sapienza,' Rome, Italy

Published by Elsevier Ltd.

Introduction

When clinicians examine a patient for signs of cerebellar disease, they follow a procedure that developed from the observations of Luigi Luciani (1840–1919), Joseph Babinski (1857–1932), Andre Thomas (1867–1961), and Gordon Holmes (1876–1965). The notion of the pivotal function of the cerebellum in motor coordination and fine-tuning of movements originated from their pioneering work. The motor aspects of cerebellar functioning dominated cerebellar studies almost completely until the 1980s, when the importance of nonmotor cerebellar functions was recognized. As the spectrum of cerebellar functions enlarged, classical theories of cerebellar functioning were questioned so thoroughly that now there is little consensus over the basic rules controlling cerebellar physiology and the influence of this cerebral structure on other circuits in the central nervous system (CNS). To complicate matters even more, cerebellar symptoms, although similar independently of the etiology, may differ in their pattern of onset and recovery. Differences have been evidenced between focal acute and chronic degenerative pathologies as well as between developmental and adult lesions. Namely, acute vascular lesions have an abrupt, even dramatic, onset often followed over weeks or months by a progressive lessening of symptoms and even to quite complete clinical recovery. Degenerative pathologies behave in the opposite way, with rather slow onset and progressive development into a disabled state. Cerebellitis and cerebellar localization of more diffuse CNS pathologies, such as multiple sclerosis, tend to present acute onset and little if any recovery, even after stabilization of the primary pathology. During development, a very different clinical picture emerges from lack of development of the cerebellum or from acquired damage. Given this complex framework, our comprehension of the pathophysiology of cerebellar motor symptoms is still poor. However, cerebellar signs and symptoms are remarkably similar no matter what the disease process and, at least for the motor domain, are well defined and substantially the same as those listed by Holmes in 1939. In the present article, motor symptoms and related clinical signs, together with cognitive and behavioral impairments related to cerebellar diseases, are presented.

Common symptoms in the case of acute onset include headache, vertigo, nausea, and vomiting. However, these symptoms can depend on an increase in intracranial pressure resulting from expanding mass lesions or on secondary hydrocephalus due to a block of cerebrospinal fluid (CSF) flux in the aqueduct. Therefore, they cannot be considered specific to damage of the cerebellum *per se*. Since signs and symptoms related to cerebellar damage are remarkably the same no matter what the disease process, in this article they are not related to differences in pathological processes affecting the cerebellum. Different clinical scales have been developed to provide reliable and valid measures of the severity of cerebellar symptoms. Diseases specifically involving the cerebellum are listed in Table 1.

Motor Symptoms

In the motor domain, cerebellar symptoms are ipsilateral to the side of the cerebellar lesion and can be grouped as follows: (1) modified muscle tone, (2) impaired motor coordination, (3) tremor, (4) oculomotor disturbances, (5) stance and gait disturbances, and (6) speech disorders.

Muscle Tone

Some researchers believe that a reduction in muscle tone is linked to direct cerebellar influence on the spinal gamma loop; however, this interpretation has been questioned. More recently, the absence of facilitatory cerebellar influence over the contralateral motor cortex has been cited to explain cerebellar hypotonia. Although hypotonia is often intense in children, in adults it is usually associated with severe cerebellar damage or occurs in the acute stage of the disease. The following clinical tests are used diagnostically.

Gordon Holmes sign Patients place their elbows on a table and keep their forearms and hands extended upward. If hypotonia is present the hands slowly close, drooping down toward the arms, because the patients are unable to hold the antigravity posture.

Pendulousness When an extremity is displaced passively, so that it swings freely, there is a regular, precise pendulous motion that diminishes in a steady, even manner. Upper extremities are tested by moving the standing patient's shoulders back and forth. Lower extremities are tested with the patient sitting on the edge of a bed with their legs hanging freely. The examiner briskly flips one leg and lets it swing.

Table 1 The most common examples of cerebellar pathology

Pathology	*Description*
Developmental	Complete or partial absence of the cerebellum (agenesis), Dandy–Walker syndrome
Degenerative	Genetic disorders including spinocerebellar atrophies, Friedreich ataxia, ataxia telangiectasia, Refsum syndrome, amaurotic familial idiocy, multiple sclerosis, Wilson's disease, tuberous sclerosis, carcinomatous diffuse corticocerebellar degeneration
Infectious	Bacterial (abscesses, tuberculosis, syphilis, whooping cough), fungal infections, parasitic infestations (cysticercosis, malaria), viral infections (mumps, viral encephalitis, poliomyelitis, kuru, Creutzfeldt–Jakob disease, looping ill)
Toxic and metabolic	Ethanol, dilantin, carbon tetrachloride, anoxia, hypoglycemia, vitamin deficiencies (B_1, B_{12}), hypothyroidism, heat stroke
Vascular diseases	Thrombosis, embolism of superior cerebellar, anterior inferior cerebellar, or posterior inferior cerebellar branches of the basilar or vertebral arteries, transient ischemic episodes in these arterial territories, hemorrhage
Trauma	Restricted to the cerebellum; usually results from penetrating wounds and typically involves vessels and parenchyma
Tumors	Metastatic from primary sites elsewhere in the body; astrocytoma (slow growing, cystic, common in children); medulla blastoma (invasive, rapidly growing, most commonly occurs in children); ependymomas, vascular malformations, and hemangioblastoma; acoustic neuroma

Modified from Dow RS (1987) Cerebellum, pathology: Symptoms and signs. In: Adelman G (ed.) *Encyclopedia of Neuroscience*, pp. 203–206. Boston: Birkhäuser.

In patients with cerebellar disease, pendulousness is increased.

Postural asymmetries In unilateral lesions, side differences in muscle tone can induce postural asymmetries.

Pendular tendon reflexes Especially for patellar and triceps reflexes, reflex responses are characterized by limb oscillation around the position at rest.

Impairment of Motor Coordination

Impaired synchrony of agonist and antagonist muscle interplay is considered to be the neurophysiological basis of the motor coordination deficits observed in cerebellar pathologies classically grouped under the term 'ataxia.' Ataxia, from the Greek ατάξια (i.e., lack of order), refers to a lack of motor coordination and can be evidenced by several clinical tests that explore limb functions.

Heel–knee–shin/toe square-drawing tests The patient, lying supine on a bed or sitting on a chair, flexes one leg at the hip, knee, and ankle so that the heel traces a path lightly along the top of the opposite shin and then extends to all joints to retrace the line. In normal persons the path is straight and the motion continuous, with smooth and accurate termination and reversal at the endpoint. In patients with ipsilateral damage of the cerebellum the moving limb commonly overshoots the endpoint (knee, ankle) and the path oscillates from side to side. The oscillation is rough, as if several rhythms were intermixed; the turnarounds look distinctly like 'bounces.' Although lateral deviations are the most conspicuous variations, to-and-fro variations also occur; up-and-down variations are damped by contact with the shin. In drawing a square, the patient is asked to follow the examiner's finger and/or to trace an imaginary square in the air with the big toe. Here again, in cerebellar disease one sees overshooting of the endpoint, with side-to-side oscillation that characteristically increases as the target is approached.

Finger–nose–finger test The patient reaches out and uses his extended forefinger to touch the examiner's forefinger and then touches his own nose, repeating the process. The abnormalities to be looked for are (1) tremor at 3–6 Hz, which is primarily side to side and up and down, (2) overshooting the target position, which may then be corrected by a movement, and (3) in chronic cases, a tendency to 'decompose' the movement (moving first one joint then another seriatim).

Rebound The examiner holds the cerebellar patient's wrists and asks her to pull against the resistance. Without warning the examiner suddenly releases his hold. The patient is unable to cease agonist and initiate antagonist muscle actions rapidly enough, and the patient's arms fly toward her and may even hit her in the face. In a similar test, the cerebellar patient is asked to hold outstretched a leg or an arm. The examiner then briskly taps a distal spot on the limb from a variety of different directions. The normal response is to deviate minimally from the initial position and return to it promptly, using a rapid increase first in agonist and then in antagonist muscle activity, to return to and hold the position without overshooting

or oscillation. In cerebellar patients, a greater displacement occurs; the return overshoots the initial position, followed by one or more beats of oscillation.

Finger-to-finger and finger-to-thumb tests The patient is asked to tap the pad of his thumb on the pads of each of the digits from 2 to 5 and then return from 5 to 2 in rapid succession. Cerebellar disease is characterized by slowing down, a lack of fixed rhythm and imprecise placing of the thumb on the fingertips. Actually, it is rare that these signs are greatly affected by cerebellar disease, possibly due to the surviving ability of the motor cortex to control single digits normally (the thumb may be held fixed while the fingers move at the metacarpophalangeal (MCP) joint only). A more sensitive test was devised by C M Fisher in which the nail of the index finger is tapped rapidly and repeatedly on the skin-crease at the top joint of the thumb. What is observed in cerebellar disease is slowing, irregularity in the amplitude of the excursion and the rhythm of subsequent excursions, and great variation in the position of the index 'hits' to either side of the thumb-crease target. The first test uses the stereotyped mechanisms of single-digit movement built into the motor cortex. The endpoint is primarily controlled by digit length. This test is more specific for lesions of the motor cortex than for lesions of the cerebellum. The second test requires coordinated action across proximal interphalangeal (PIP) and MCP joints (and lumbricals and long flexors) to an arbitrary endpoint and tests the integrity of the dentate nucleus in the lateral cerebellum.

Rapid, alternating movements The capacity to develop alternating movements is tested by pronation–supination movements. The patient is asked to keep his forearms vertical and to perform pronation–supination movements with his hands. This function can also be tested by asking the patient to slap the palm and the back of one hand alternately on the palm of the other hand or on the thigh. Irregular rhythm and amplitude of excursion with slowing and frequent repeated 'wrong moves' are looked for, especially since the task performance is prolonged.

Tremor

Although the pathophysiology of cerebellar tremor has been addressed by numerous experimental and clinical studies, it is still a matter of debate. In general, it is thought to be generated within central motor loops.

Intention or kinetic tremor This type of tremor is tested using the finger–nose and heel–knee test. It may be present throughout the entire movement or only at the beginning, but it is particularly evident at the end of the movement. Intention tremor tends to worsen in the days or weeks after acute cerebellar lesion.

Postural tremor This type of tremor, defined also as 'action tremor,' appears during performance of postural tasks that require precision. It is tested by asking the patient either to keep her arm outstretched or, in a supine position, her legs held fixed against gravity.

Palatal tremor This type of tremor is characterized by short, rhythmic, involuntary movements of the soft palate often associated with hypertrophy of the contralateral inferior olive.

Oculomotor Disturbances

In cerebellar pathologies, oculomotor deficits are usually related to involvement of the dorsal vermis or the fastigial nucleus, the folliculus and paraflocculus, and/or the uvula and the nodulus in the pathological process. Disorders of fixation, pursuit, and saccades, together with the development of nystagmus and skew deviation, are often observed. During fixation, brief oscillations (flutter), usually horizontally conjugated and present in both the light and the dark, can be observed. Nonsmooth pursuit, characterized by a stepwise decomposition of movement, is frequently observed in cerebellar diseases, but with low specificity. Also, in saccadic movements, the characteristic overshooting observed in limb movements (i.e., ocular hypermetria) can be present.

Equilibrium and Stance

The patient is in a standing position with his eyes first open and then shut. This test was originally devised by Moritz Romberg (1795–1873) to distinguish diseases of peripheral nerves or spinal afferent somatosensory pathways from diseases of the cerebellum. Patients with somatosensory disturbances can stand well with their eyes open but may fall when their eyes are closed. Patients with cerebellar disease may be unstable with their eyes open as well as closed; unlike normal persons, they cannot use somesthesis, vestibular information, or vision for equilibrium and stance. With acute unilateral cerebellar damage, the patient falls toward the side of the lesion. Equilibrium has been clinically tested in patients with cerebellar lesions by measuring postural sway on a force-sensing platform. Lesions of the flocculo-nodular lobe and posterior vermis (which projects heavily to the lateral vestibular nucleus) cause an irregular course sway (back and forth and side to side), as does damage to the membranous labyrinths, which is indistinguishable

from 'vestibular ataxia.' Damage to the anterior lobe cortex (alcoholic cerebellar degeneration; late-life atrophy) causes back-and-forth oscillation of the trunk.

Gait

Gait is tested by observing the patient walking in a straight line, in tandem, and backwards. Gait is impaired if ataxia is present. The latter produces irregular steps, often with a broad base, staggering with clumsy corrections, altered rhythm, and irregular, often reduced, speed. Locomotion increases the tendency to fall to the side of the cerebellar lesion, especially in tandem walking. When mild unilateral damage is present, patients start to fall to the side of the lesion, sense the impending fall (vestibular sense is intact), and voluntarily correct themselves with a wider step to that side. The spinal cord contains many of the mechanisms necessary for stance and locomotion; spinal cats can make rudimentary walking movements. Results of animal studies show that stance and gait are specifically controlled by vestibular and fastigial nuclei: cells fire during walking; lesions cause falls to that side. Neurophysiological data in patients suggest that the cerebellum intervenes to adjust movements related to many joints, especially to accommodate external constraints.

Speech

Cerebellar damage affects both motor and cognitive aspects of speech. Dysarthria, cerebellar mutism, agrammatism, and reduced verbal fluency are symptoms of impaired speech reported after cerebellar damage.

Dysarthria Patients with cerebellar disease can have what is called a scanning dysarthria. This impairment is characterized by difficulty in articulating sounds into words. The problem is not at the language level – that is, in choosing and saying words correctly or in making sentences and paragraphs out of them. The patient is asked to use lips (mi-mi-mi), tongue (la-la-la), pharynx (go-go-go), and larynx (kay-kay-kay) to make sounds involving relatively smaller groups of muscles, together with those moving the thorax and diaphragm. These utterances may sound normal or may be unevenly spaced across time. Saying a sample sentence is relatively more impaired. The utterance is monotonous, lacking normally modulated inflexion of volume, and is slow and slightly slurred. The impaired patient sounds illiterate, painfully and slowly reading from a text one word at a time (hence, scanning). The topography of cerebellar control over motor aspects of speech is not clear. Holmes found this symptom mostly with midline lesions. Working in the 1970s, Richard Lechtenberg and Sid Gilman also found local lesions to be very close to the midline, with a somewhat larger percentage in the left intermediate than in the right zone. This was somewhat surprising since language is located predominantly in the left cerebral hemisphere and thus one would expect its articulation to be located in the known crossed projection zone in the right cerebellar hemisphere. There are also recent reports of patients with lesions limited to the right cerebellar hemisphere.

Cerebellar mutism The term 'mutism' refers to the inability of an alert patient to produce verbal output. The cerebellar form of mutism has been attributed to lesions of the cerebellar vermis or the cerebellar hemispheres and refers to a complete but transient loss of speech followed by dysarthria, usually after surgery for posterior fossa tumors, cerebellar hemorrhage, or trauma, or in infectious or postinfectious cerebellar syndromes. Cerebellar mutism has often been reported in children and adolescents, but rarely in adults; although it is believed to be due to lost coordination of orofacial movements, the issue is still being debated.

Agrammatism Agrammatic deficits have been reported in patients with right cerebellar lesions, and the role of the cerebellum in grammar has been recently reviewed. In general, all authors report agrammatism in spontaneous speech with or without involvement of sentence comprehension. In agreement with current theories on agrammatism, it was previously found that cerebellar processing did not affect syntactic knowledge but rather affected sentence construction.

Verbal fluency Verbal fluency is the ability to generate lists of words according to a given rule. The latter can be either a letter of the alphabet (e.g., retrieval of words that begin with the letter F) or a semantic category (e.g., retrieval of words from the semantic category of 'animals'). There are consistent reports that verbal fluency is reduced after cerebellar damage; also, functional neuroimaging data demonstrate cerebellar activation during verbal fluency tasks. In particular, verbal fluency is impaired in a modality-specific manner, with reduced phonemic rule performance and spared semantic rule performance.

Cognition and Emotion

As early as the nineteenth century there were speculations that the cerebellum might play a role in higher mental processes. However, the notion that the cerebellum might have a nonmotor function only became influential about 50 years ago. Subsequently, the advent of functional neuroimaging techniques, demonstrating

cerebellar activation in a variety of cognitive, nonmotor tasks, and the discovery of reciprocal connections between the lateral cerebral hemispheres and the contralateral frontal and parietal cerebral association cortex provided strong support for clinical evidence of cognitive defects in cerebellar pathologies. Today, the number of studies addressing the cerebellar role in emotion and cognition has increased enormously and clinical data and neuroimaging evidence converge in supporting cerebellar influence on quite disparate functions, such as attention, cognitive flexibility, linguistic processing, mental imaging, sensory discrimination, visuospatial processing, timing, and verbal memory, as well as working memory.

Cerebellar Role in Motor Learning

Animal and human studies have shown that the cerebellum is involved in and needed for a variety of different motor tasks, including modification of vestibuloocular reflex gain, adaptation of saccade endpoint to target, associative conditioning of a blink reflex, and gaze–arm calibration in prism-adapted reaching and throwing. Neurophysiological and functional neuroimaging observations in humans indicate the importance of the cerebellum in implicit/procedural learning, and lesion studies indicate procedural learning impairment in cerebellar-lesioned subjects. Although these observation have not yet proved to be of any clinical relevance, knowledge of the characteristics of motor and procedural learning impairment is of clinical relevance, especially in rehabilitation settings.

Localization: Body Maps and Motor Modes

Holmes found little evidence for localization of functions in the cerebellum. Although clinical symptoms are not very useful for a lobular localization of cerebellar damage, there are general indications that medial lesions affect posture and gait while more lateral lesions affect voluntary limb movements. Animal studies have conclusively shown that the flocculus and the nodulus (vestibulocerebellum) control antigravity stance and eye and head movements in response to vestibular information; the vermis and fastigial nucleus control antigravity stance and saccadic eye movements; the intermediate zone cerebellar cortex and interposed nuclei control agonist–antagonist muscle coordination; and the lateral hemisphere cortex and dentate nuclei control combined activities of synergistic muscles in multijointed reaching toward and grasping of objects in space. Further, animal studies strongly support a scheme of localization of functions and of body parts. In macaques, a somatotopic map of muscle actions is seen within each of the fastigial, interposed, and dentate nuclei, with anterior lower extremity, posterior head, medial distal, and lateral proximal parts; the upper extremity is represented in the midportion. The advent of functional neuroimaging and the availability of a detailed atlas of human cerebellar folia have made it possible to collect localization data. Consequently, there is growing evidence of different maps in the cerebellum.

Sensorimotor Maps

Motor and kinesthetic tasks activate the rostral and caudal spinocerebellum with two distinct homuncular representations. One is located upside down in the superior cerebellum and the other, smaller one is in the inferior cerebellum. The somatotopic map closely resembles that observed in macaques. Correlations between clinical findings and magnetic resonance imaging (MRI)-based cerebellar lesions provide support for a localization data diagnosis based on clinical evidence.

Localization of Cognitive Functions

Activation studies consistently demonstrate cerebellar activation in different cognitive functions and provide support for the development of topographic maps of the cognitive cerebellum, which evidence the following findings: explicit memory retrieval in vermal lobules IV–VIIA and in the left hemisphere, mainly in Crus I; sequence learning bilaterally in Crus I and in vermal lobule VI; language and working memory functions in vermal lobules IV–VIIA and Crus I of the right hemisphere; and verbal working memory in HVIIB of the right hemisphere. This functional topography has not yet been confirmed by clinically relevant data coupling cerebellar damage with cognitive symptoms.

Introduction

This article discusses the structure and function of the mammalian cerebellum from an evolutionary point of view. This approach is only tentative since there are only a few clues from endocasts of fossil skulls; the fossil record can give only limited evidence about the evolution of soft tissues. Since there are few data on the relative size of the entire cerebellum or its parts that can be derived from fossil evidence, and there are no guaranteed living primitive forms, we focus on insights from comparative anatomy and development. Comparative anatomy reveals the relative size of the cerebellum and its subdivisions and the variations upon the common plan among vertebrates; hence, it may provide clues as to its evolution. Studies on the connectivity of the cerebellum give indications about its functions and may provide clues regarding adaptations in cerebellar structure during evolution. Cerebellar morphogenesis and its genetic control provides information on the crucial stages at which mutations make these adaptations possible. Unfortunately, the link between structure and function, so evident for many other parts of the central nervous system, is lacking for the cerebellum. This aspect, the missing link in cerebellar evolution, is discussed in the final section of this article.

The comparative anatomy of the vertebrate cerebellum was reviewed by Llinas, Larsell et al., and Nieuwenhuys et al. The evolution of the cerebellum was considered from a comparative anatomical and developmental perspective by Glickstein et al. Its developmental biology was reviewed by Sotelo. Most of the material and many of the illustrations in this article are drawn from these works.

The cerebellum, the 'small brain,' is located in the rostral roof of the fourth ventricle. Mammalian and avian cerebella are characterized by many transverse fissures, which divide it into lobes, lobules, and folia, but this lobular pattern is not present in all vertebrate cerebella. The cerebellum processes information from widely different sources, including the spinal cord, the brain stem, and the telencephalon, and projects to many different centers in the brain involved in postural adaptations and the generation of movements. The cerebellum is covered by a cortex which is typically three layered. A layer formed by the perikarya of the large Purkinje cells separates the superficial, cell-poor molecular layer from the deep layer of the granule cells. Purkinje cells form the main output element of the cerebellar cortex. The granular and molecular layers both contain several types of interneurons.

The cerebellum is characterized by a lattice structure of its cortex. The flattened dendritic trees of the Purkinje cells, which extend into the molecular layer, are oriented perpendicular to the parallel fibers, the axons of the granule cells (Figure 1). This configuration was discovered more than a century ago by Cajal in the avian cerebellum.

Histology of the Mammalian Cerebellar Cortex

We take the structure of the mammalian cerebellar cortex as our starting point (Figures 1(a)–1(c)). The cerebellar cortex has six major cell types. The dominant cell, first described by Purkinje, the nineteenth-century Czech physiologist/anatomist, is called the Purkinje cell. Purkinje cells extend as a single layer of neurons throughout the entire extent of the cerebellar cortex. Below the layer of Purkinje cells there is a dense concentration of small granule cells. In addition to the granule cells, this layer contains the Golgi cells and the unipolar brush cells. Above the layer of Purkinje cells there is a cell-sparse zone, the molecular layer, which contains two other cell types – the basket cell and the outer stellate cells.

The Purkinje cell has a large, pear-shaped cell body whose dendrites spread out broadly within the molecular layer in an orientation which is transverse to the cerebellar folia. When viewed in sections cut parallel to the fissures of the cerebellum, the dendritic tree of the Purkinje cell extends over a much narrower distance. The dendritic tree of the Purkinje cell can be divided into proximal smooth and distal spiny branches. In mammals, the Purkinje cell axon terminates in the cerebellar nuclei, which are located in the cerebellar white matter, and in the vestibular nuclei. Purkinje cells are inhibitory neurons using GABA as their transmitter.

Granule cells are small, measuring approximately 7 μm in diameter. The axons of granule cells ascend to the molecular layer where they bifurcate in a T junction. The two branches of the axon extend within the molecular layer parallel to the direction of the folium. Because of their orientation, granule cell axons are called parallel fibers. They terminate on the distal, spiny branchlets of the Purkinje cells,

which they meet on their way, and on dendrites of Golgi, basket, and stellate cells in the molecular layer. Granule cells are excitatory, glutamatergic neurons.

Golgi cells are found below the Purkinje cells, at the top of the granule cell layer. Golgi cell bodies are approximately the same size as those of the Purkinje cell, but there are only approximately one-tenth as many Golgi cells as there are Purkinje cells. The pattern of branching of the dendrites and axons of Golgi cells differs from the pattern of those of the Purkinje cells. Golgi cell dendrites branch in a cylindrical extent within the molecular layer, and their axons remain confined within the granular layer of the cerebellar cortex. Golgi cells are a heterogeneous population of glycinergic inhibitory neurons. Their axons terminate on granule cell dendrites in the granular layer.

Basket and outer stellate cell bodies are located in the molecular layer. Their axons extend in a direction perpendicular to the folia. Basket cell axons extend along a series of Purkinje cells giving off dense basket-like collaterals which surround the Purkinje cell body and terminate at its base. Outer stellate cells have their cell body more superficially located within the granular layer. They too connect to the Purkinje dendrites. Basket and outer stellate cells are inhibitory GABAergic neurons.

Unipolar brush cells are excitatory neurons with one sturdy dendrite, located in the granular layer. Their axons terminate as mossy fibers on granule cell dendrites. Unipolar brush cells are excitatory neurons.

Two extracerebellar afferent fiber systems, mossy and climbing fibers, connect to the cerebellar cortex. Mossy fibers constitute the vast majority of the afferents to the cerebellum. They arise from many sources, including spinal cord brain stem and pontine nuclei, and synapse on the dendrites of the granule cells, with

extensive synapses on the single dendrite of unipolar brush cells. The other class of afferent fibers, the climbing fibers, derive from only a single source, the contralateral inferior olivary nucleus. Unlike the mossy fibers, which are indirectly linked to Purkinje cells by way of granule cells, climbing fibers ascend through the molecular layer and twine directly around the proximal smooth dendrites of the Purkinje cells. Climbing fibers branch sparingly in the cerebellar cortex. Each climbing fiber innervates a single Purkinje cell. Both mossy and climbing fibers are glutamatergic and excitatory.

The principal circuit of the cerebellar cortex consists of mossy fiber afferents, which connect with granule cells in complex synapses (glomeruli). Granule cell axons, the parallel fibers, connect with Purkinje cells. These cells inhibit neurons of the cerebellar or vestibular nuclei, which receive excitatory input from mossy and climbing fiber collaterals. Unipolar brush cells function as boosters for the mossy fiber input. Golgi cells provide feedback inhibition at the level of the glomeruli; stellate and basket cells provide feed-forward inhibition of the Purkinje cells (Figure 1(c)).

One of the main properties of the cerebellar circuitry is its remarkable plasticity. Long-term depression (LTD) and long-term potentiation (LTP) of its synaptic connections are the processes involved. LTD at the parallel fiber–Purkinje cell synapse is the best studied example. Each Purkinje cell receives more than 100 000 synapses from the parallel fibers which traverse its dendritic tree. At any moment, however, only a small fraction of these synaptic connections are available. Most of these synaptic connections are totally or partially depressed by LTD, a process which affects the ionotropic glutamate receptors responsible for the transmission at the parallel fiber–Purkinje cell synapse. LTD depends on the simultaneous activation of climbing fiber and parallel fiber afferents of a Purkinje cell. LTD sculpts the cerebellar cortical network on the basis of previous experience and, most likely, forms the basis of the main function of the cerebellum (i.e., the optimalization of movements). The flattening of the Purkinje cell dendritic trees guarantees maximal access of parallel fibers to the Purkinje cells.

Cerebellar Cortex in Vertebrates

The principal circuit of the cerebellar cortex can be recognized in the cerebellum of all vertebrate classes (Figure 2), with the exception of amphioxus, the lampreys, and the myxinoids, which lack a cerebellum. Flattening of the Purkinje cell dendritic trees and the orthogonal orientation of granule cell axons, the parallel fibers, with respect to the Purkinje cells are general characteristics, although the precision of this arrangement may differ. Cortical interneurons have been identified. Climbing and mossy fibers and a homolog of the inferior olive are universally present. Differences concern the spatial position of Purkinje and granule cells; that is, the presence of a three-layered cortex, the shape of the Purkinje cell dendritic tree, the morphology of the climbing fibers, and the typology of the interneurons.

In cartilaginous fishes, teleosts, amphibians, and reptiles, the Purkinje cell dendritic tree is characterized by the presence of long and straight distal branches, which ascend to the meningeal surface. These distal branches are covered with spines and thus correspond to the spiny branchlets of the mammalian Purkinje cells. The proximal smooth dendrites are largely restricted to the Purkinje cell layer or the deepest part of the molecular layer. Climbing fibers terminate on these smooth dendrites. They do not climb into the dendritic tree but, rather, remain confined to the region of the Purkinje cell layer. The configuration in the avian cerebellum is intermediate between reptiles and mammals. Smooth dendritic branches ascend halfway up into the molecular layer, spiny branchlets reach up to the meningeal surface, and climbing fibers are found in the inner half of the molecular layer.

Golgi and stellate cells have been identified in most, if not all, vertebrate cerebella. However, basket cells, which can be considered as a differentiation of the stellate cells, appear to be absent in cartilaginous and teleost fishes and amphibians.

The position of the Purkinje cell as the sole output element of the cerebellar cortex is maintained in all vertebrates. In teleost fishes, however, the cerebellar nuclei, the main target of the Purkinje cell axons, are absent. Purkinje cell axons terminate on so-called eurydendroid cells, which are located within the Purkinje cell layer (Figures 1(d) and (2)). Unlike Purkinje cells, their dendrites lack spines. The axons of these cells, like those of the cerebellar nuclei, project outside the cerebellum to terminate in the brain stem. A similar configuration may be present in cartilaginous fishes. Projections of Purkinje cells to the vestibular nuclei have been identified in all vertebrates.

Gross Anatomy of the Vertebrate Cerebellum

Although cerebellar circuitry is stereotyped in all vertebrates, the gross morphology and the distribution of granule and Purkinje cells vary greatly in different vertebrate classes. In cartilaginous fishes (Figure 3), the cerebellum consists of an evaginated corpus

cerebelli that is smooth in small but foliated in large species. Laterally, two auricles are present; the auricles are continuous across the midline by the pars medialis (or lobus caudalis), which caudally adjoins the corpus cerebelli. Granule cells form ridges at the ventricular surface of the corpus cerebelli and occupy the auricles. Purkinje cells are scattered among the granule cells of the ridges and are located in an irregular layer in the lateral corpus cerebelli, where a molecular layer can be identified. Purkinje cells are absent from the auricles (Figure 3). The cerebellar nucleus, identified in some species, receives Purkinje cell axons. The corpus cerebelli receives information from somatosensory and visual centers. The auricles and the lobus caudalis are connected with the lateral line organs and the vestibular centers.

In teleost fish, an evaginated corpus cerebelli, an eminentia granularis (corresponding to the auricle), and a lobus caudalis can be identified. Rostrally, the valvula cerebelli is invaginated into the mesencephalic ventricle. An irregular layer of Purkinje cells and a molecular layer cover the corpus cerebelli and the valvula; scattered Purkinje cells are present in the eminentia granularis. Cerebellar nuclei are absent. The valvula attains enormous proportions in mormyrid fish, in which it pushes the tectum aside and covers the telencephalon (Figure 4). Mormyrids are actively electroreceptive teleosts with an electric organ and electroreceptors involved in electrocommunication and electrolocation. Electroreceptive centers provide the main afferent mossy fiber input to the valvula.

In chondrostean fish, the cerebellum is invaginated into the ventricle. A rostrally projecting valvula, covered by the anterior medullary velum and two auricles connected by the lobus caudalis, can be identified (Figures 5 and 6). Granule cells form multiple ridges in the corpus cerebelli and the auricles (Figures 6(b) and 6(d)). Purkinje cells are scattered among the granule cells and in central portions of the corpus cerebelli. A molecular layer is present in the auricles.

In amphibians, the cerebellum is small and leaflike (Figure 7). Laterally, the auricles are located in the wall of the lateral recess of the fourth ventricle. A multilayer of Purkinje cells and a molecular layer cover the cerebellum. Cerebellar nuclei are present.

The cerebellum in reptiles is larger and compact and covered by a three-layered cortex (Figure 8). Cerebellar nuclei are situated centrally in the cerebellum.

The avian cerebellum is foliated (Figure 9). Parallel cerebellar folia are arranged like the pages of an opened book. Larsell distinguished ten folia in the avian cerebellum, numbered from I to X. The caudal-most

folia laterally form the auricle, the homolog of the mammalian flocculus. The cerebellum is covered by a three-layered cortex; laterally, this cortex is unfoliated. Cerebellar nuclei occupy the central white matter.

The mammalian cerebellum is foliated and can be subdivided into a median vermis (Latin for 'worm') and two hemispheres (Figure 10). The mammalian cerebellum is divisible into three major lobes which

are bounded by two fissures. In all mammals, the primary fissure marks the dividing line between the anterior lobe and the posterior lobe of the cerebellum, and it is particularly deep. Near the caudal end of the cerebellum, the posterolateral fissure separates the posterior lobe from the flocculus and the nodulus (flocculonodular lobe). Early anatomists suggested that the mammalian vermis and the flocculus (the 'paleocerebellum') are identical to the entire avian cerebellum, and that the hemispheres are new acquisitions (the 'neocerebellum'). However, this proposition is probably mistaken. The lateral unfoliated

cortex of the avian cerebellum is the likely homolog of the mammalian hemisphere and the auricle represents the flocculus.

The Dutch anatomist Lodewijk Bolk made the fundamental observation that although the cerebellum appears to be complexly folded, there is a fundamental plan to its organization. The anterior lobe and the first lobule of the posterior lobe, which Bolk called lobulus simplex, constitute a single unbranched chain of cerebellar folia. Just behind the lobulus simplex, the hemispheres become separate from the midline, frequently bending outward and forming two successive loops. Bolk called the first of these loops the ansiform lobe (**Figure 10(c)**). The second of these loops constitutes the paraflocculus and flocculus. The folia first are directed away from the midline in crus I of the ansiform lobe and then return toward the midline as crus II. The chain of folia then continues along the vermis as the paramedian lobule before looping outward again as parafloculus and flocculus. Thus, there is a continuous chain of folia from the most anterior lobule of the anterior lobe to nodulus and flocculus.

Bolk speculated that the pattern of cortical organization reflects a functional division between a midline

Figure 10 The cerebellum of the cat (*Felis domestica*). (a) Dorsal, caudal, and ventral views of the cerebellum. The direction of the folial chains of vermis and hemispheres is indicated by open lines. The two main loops in the folial chain of the hemisphere are located in the ansiform lobule (1) and in the paraflocculus (2). (b) Tranverse section through the cerebellum. The molecular layer (m) is unlabeled, the granular layer (g) is shown in medium gray, the cerebellar nuclei in dark gray, and the white matter in light gray. P, Purkinje cells. (c) Bolk's wire diagram of the fundamental structure of the mammalian cerebellum. In the anterior cerebellum (i.e., the anterior lobe and the lobulus simplex (SI)), vermis and hemispheres are difficult to distinguish. More caudally, the cerebellum divides into the folial chain of the vermis (v) and the two folial chains of the hemispheres. Two loops in the folial chain of the hemisphere are indicated: one in the ansiform lobule (1) and the other in the paraflocculus (PFL; 2). The last section of the folial chain of the hemisphere turns back on itself (Bolk's terminal hook, or the flocculus (FLO)). ANS, ansiform lobule; ANT, anterior lobe; fPL, posterolateral fissure; fsHEM, folial chain of the hemisphere; fsVERM, folial chain of the vermis; NO, nodulusa; PFLd, dorsal paraflocculus; PFLv, ventral paraflocculus; PMD, lobulus paramedianus; UV, uvula; VII, lobule VII of Larsell; VIII, pyramis.

cerebellum, which is responsible for the regulation of structures whose muscles require collaboration across the midline for effective motor control. For example, consider the necessary collaboration between muscles of the neck that are required for smooth turning of the head. Bolk suggested that the hemispheres are responsible for the control of distal muscles which do not require as close a collaboration between the two sides of the body. Bolk also made the assumption that there is a single map of the body's muscles in the cerebellum. Although the suggestion of a single map is wrong, Bolk's insights on the differential role of midline and hemispheric cerebellum seem valid in light of clinical and experimental evidence.

Figure 11 shows flattened maps of cerebellar cortex of a number of species of mammals, with the relative surface areas preserved. The organization of the cerebellar cortex in all mammals is essentially similar and corresponds to Bolk's fundamental plan. The anterior lobe and lobulus simplex, the first lobule of the posterior lobe, are continuous across the cerebellum from its left to its right side. Behind the lobulus simplex, the cerebellar hemispheres are no longer continuous with the vermis. They extend lateral to the vermis and are often complexly folded.

Longitudinal Modular Organization of the Cerebellar Cortex and Its Efferent Connections

At first glance, the structure of the cortex is uniform and homogeneous over the entire cerebellum. However, electrophysiological, anatomical, developmental, and neurochemical studies have shown that the Purkinje cells of the mammalian and avian cerebellar cortex are arranged in a number of parasagittal, parallel, symmetrically disposed zones. This zonal pattern can be appreciated from a reconstruction of the cerebellum of the rat (Figure 12). The cerebellum was stained with a Purkinje cell-specific antibody, zebrin II. Zebrin-positive and zebrin-negative bands are distributed in alternating longitudinal bands. It has been shown that the zebrin pattern is correlated with the distribution of many different substances

Figure 11 Outlines of the shapes of the cerebellar cortices obtained by connecting the ends of the most prominent folia. The scale is the same in the laterolateral and anteroposterior direction. Note the division of posterior cerebellum in the folial chains of vermis and hemispheres and the relative widths and lengths of these chains in different species. 1, mouse; 2, bat; 3, flying fox; 4, guinea pig; 5, rabbit; 6, pigeon; 7, hare, 8, chinchilla; 9, squirrel; 10, dog; 11, cat; 12, macaque; 13, sheep; 14, human; 15, bovine. in Purkinje cells. The zebrin pattern can be identified in most mammals investigated as well as in the avian cerebellum. Moreover, Purkinje cells of different zebrin-positive and -negative bands receive their climbing fibers from different subnuclei of the inferior olive and project to particular cerebellar or vestibular nuclei. On the afferent side, mossy fibers terminate in similar longitudinal parcellations of mossy fiber terminals. This modular organization is fundamental to the structure of the cerebellum. It can be recognized in mammals and birds. In reptiles, the distribution of Purkinje cells follows a similar longitudinal organization (Figure 13). The cerebellar or vestibular target nuclei of the modules project to motor centers in the brain stem. In the mesencephalon, they terminate in the red nucleus and the tectum, whereas in the diencephalon they terminate in the motor thalamus. Caudally, they innervate the preoculomotor centers in the vestibular nuclei and the reticular formation and neurons giving rise to descending pathways to the spinal cord.

Variations of the zonal pattern among mammals concern specific lobules (lobule VII, the 'visual vermis,' the ansiform lobule and the paraflocculus) and certain zones (the C2 zone, or zebrin zone 5 (Figure 12), with its projection to the posterior interposed nucleus, and the lateral D1 and D2 zones, zebrin zones 6 and 7, with projections to the dentate nucleus). These variations are related to the evolution of the motor and premotor cortex and the cortical visuomotor system in primates.

Development of the Cerebellum

The cerebellum is derived from an embryonic territory at the junction of the developing midbrain and

Figure 13 Map of the Purkinje cells of the cerebellum of the turtle *Pseudemys scripta elegans*. Three longitudinal Purkinje cell zones can be distinguished on the basis of cell-poor ridges and differences in the packing of the cells. Figure 14 Diagram of the brain stem of a mammalian embryo. The rhombic lip borders on the fourth ventricle. Rostral and caudal parts of the rhombic lip can be distinguished. The rostral rhombic lip and the adjacent ventricular epithelium give rise to the cerebellum; the caudal rhombic lip gives rise to precerebellar nuclei such as the inferior olive and the pons.

hindbrain, the so-called mid-hindbrain boundary (MHB). Chick/quail transplantation experiments have revealed an organizing influence of a band of cells at the MHB. This region directs the formation of the midbrain, cerebellum, and anterior hindbrain, and it can induce midbrain and cerebellum tissue when placed ectopically. Genetic analysis in mice has shown that the position of the isthmic organizer is fixed at the boundary between the domains of expression of two homeodomain transcription factors, Otx2 and Gbx2. Otx2 is typically expressed throughout the embryonic forebrain and midbrain with a caudal border at the MHB; Gbx2 is expressed in the anterior hindbrain with a rostral limit at the MHB.

The cerebellum develops from the rostral rhombic lip and the adjacent ventricular epithelium. The rhombic lip is the dorsal rim of the alar plate which gives attachment to the thin roof plate of the fourth ventricle. The border between the rostral and caudal rhombic lip is located at the greatest width of the fourth ventricle (Figure 14). The caudal rhombic lip gives rise to neurons of precerebellar nuclei, such as the inferior olive and the pontine nuclei.

Both temporal and spatial factors appear to determine the fate of neurons produced by the rostral rhombic lip. Neurons of the cerebellar nuclei are the first cerebellar neurons to be produced (Figure 15), followed by the Purkinje cells. At a later stage, cells produced near the attachment of the roof of the fourth ventricle to the cerebellar anlage migrate rostrally over its meningeal surface. This superficial migration is known as the external granular layer (EGL). During the late prenatal and early postnatal period, the cells of the EGL proliferate and produce granule cells. These cells emit parallel fibers, and their cell bodies migrate through the Purkinje cell layer to take up a position in the internal granular layer. Interaction between parallel fibers and Purkinje cells results in flattening of their dendritic tree. Inhibitory interneurons of the cerebellar cortex arise from a separate population of cells in the ventricular epithelium. These cells migrate into the cerebellar white matter, where they proliferate and differentiate into different types of inhibitory interneurons during late prenatal stages.

An important refinement of this temporal sequence in the production of different cerebellar cell types was published by Hashimoto and Mikoshiba. They showed that Purkinje cells of the mouse cerebellum, born on different dates, settle in different longitudinal zones. However, the birth date of these cells is not the only factor which determines their zonal localization. The importance of positional information is evident from a study by Sgaier et al. Early in its development, the rostral rhombic lip changes in position from a mainly rostrocaudal orientation to a mediolateral one, a transformation illustrated by His in the nineteenth century. This change in position may be caused by mechanical factors and is related to the development of the pontine flexure and/or differential growth within the cerebellar primordium. Sgaier et al. drew attention to this change in position in their interpretations of their fate maps of the cerebellar anlage, and they suggested that the rostral rhombic lip ultimately

Figure 15 Diagram of the development of the cerebellum of the rat. The earliest neurons to be born in the ventricular matrix are those of the future cerebellar nuclei. They are followed by the Purkinje cells. Cells of the external granular layer (EGL) take their origin from the attachment of the thin roof of the fourth ventricle. These cells migrate rostrally to cover the entire meningeal surface of the cerebellar anlage. Later, the cells of the EGL produce the granule cells, which move inwards through the Purkinje cells, which form a monolayer to take up a position in the inner granular layer (IGL).

Figure 16 Orthogonal rotation of the anterior–posterior (A–P) axis of the rhombic lip gives rise to the mediolateral orientation of cerebellar zones. Growth of the brain and the cerebellar primordium in mouse between embryonic day (e) 9.5 and 12.5 results in a 90° rotation of the longitudinal axis of the rhombic lip. The darkly shaded region indicates a zone of cerebellar cell clones marked at e7.5 using an En2 promoter-based genetic fate mapping strategy. The open contour line indicates the rhombic lip and the cerebellar primordium. Note that the boundaries of the marked region change from a primarily A–P orientation to a mediolateral one. A and P, AP axis; CbP, cerebellar primordium; M and L, mediolateral axis; Mb, midbrain; Mes, mesencephalon; R and C, rostral and caudal, respectively. corresponds to the medial cerebellum, and posterior rhombic lip corresponds to the lateral cerebellum. They showed that Purkinje cells in the medial cerebellum originate from the rostral (late medial) rhombic lip and Purkinje cells of the hemisphere from its caudal (late lateral) part (Figure 16).

Many other factors determining cell adhesion, cell recognition, and the expression of their final neurochemical identity, reviewed by Sotelo, are responsible for the morphogenesis of the adult modular organization of the cerebellum. Studies suggest that the division of the cerebellum into zones occurs by mechanisms that are intrinsic to that tissue and genetically encoded. If this is the case, then it is likely that functional differences among the species could be added by slight modifications of the genetic program underlying this pattern, resulting in expansions or contractions of zonal dimensions and/or cell numbers as the need arises. Mutations in genes determining the position of the cerebellum and the production and differentiation of cells in the rostral and caudal rhombic lip, which are responsible for the setting up of the temporal and spatial gradients in the production of different cell types expressing specific recognition and repulsion molecules, which would subserve the future patterning in their connections, are a possible substrate for natural selection.

Motor Control and Motor Learning: The Link between Structure and Function

Preservation of structures during evolution implies that these structures serve a definite purpose. In the case of the cerebellum, it is the circuitry of the cerebellar cortex, with its remarkable degree of plasticity, which has been preserved. This circuitry is characterized by the perpendicular relationship between the parallel fibers and the Purkinje cells and its dual mossy fiber and climbing fiber afferent connectivity. This arrangement guarantees maximal access of mossy fiber–parallel fiber afferents to the Purkinje cell. Moreover, this arrangement is repeated in the longitudinal zonal structure of the cerebellar cortex in reptiles, birds, and mammals. Climbing fibers and cerebellar interneurons enable the selection of a relevant mossy fiber–parallel fiber input in this network. Climbing fibers are generally considered to carry information on errors in motor performance. When climbing fibers and parallel fibers are simultaneously active, the parallel fiber–Purkinje cell synapses are blocked by LTD. Purkinje cell inhibition of the

pertinent motor circuits subsequently corrects the error. Whether this type of motor learning is solely dependent on the cerebellum seems unlikely, but an essential role of the cerebellar circuitry is well established.

The cerebellum is required for direct control of certain classes of movement. Following loss of the cerebellum, monkeys and humans cannot make smooth pursuit eye movements. Saccadic eye movements may be preserved, but they become dysmetric. The role of the cerebellum in motor learning has been exemplified in long-term adaptation of the vestibulo-ocular reflex, the adaptation of saccades, and in the role of the cerebellum in eyelid conditioning.

In general, there are two classes of reflex – open and closed. A closed reflex is arranged so that the reflex acts directly on the part of the body receiving the stimulus. Tapping the knee elongates the tendons connected to the quadriceps muscle. The resultant stretch of the muscle activates the sensory fibers within the spindles of the same muscle. The output of the spindles is connected by way of a single synapse to the motor neurons of the same muscle. Similarly, a painful stimulus to the hand or the foot leads to a flexion and, hence, a withdrawal of the limb from the painful stimulus. Stretch and flexion are examples of closed loop reflexes. The vestibulo-ocular reflex (VOR) is a classic example of an open loop reflex in which the reflex is not fed back onto the input. If the head is turned to the left, there is a reflex tendency for the eyes to move in an equal and opposite direction to the right, thus stabilizing the gaze. Open loop reflexes such as the VOR must be continuously calibrated in order to remain precise and adaptive. The cerebellum is necessary for such calibration. Consider the problem if a person or monkey were to wear a pair of spectacles that magnified the visual image. If the head turned to the left, the VOR would be too small to stabilize the gaze. Similarly, if the image were made smaller, the VOR would be too large. There is clear evidence that if such spectacles are worn for a few days, the amplitude of the VOR changes in the appropriate direction, and that it is the cerebellum which regulates that change using an error signal on retinal slip carried by the climbing fibers and information on vestibular input, eye position, and movement carried by the mossy fibers.

In addition to the role of the cerebellum in the direct control of some movements and the calibration of open loop reflexes, there is also evidence of a role for the cerebellum in classical conditioning. If a rabbit or person is presented with a neutral stimulus such as a tone or a light and if the neutral stimulus is followed after a very brief interval by a puff of air to the cornea, over a series of such paired conditioning trials a conditioned response will develop to the previously neutral stimulus. The sound or light will now cause blinking. Lesions of a particular region of the cerebellum in rabbits or humans result in a deficit in acquiring or retaining a conditioned response. Information on the unconditional stimulus is carried by the climbing fibers. The cerebellar cortex offers the opportunity to pair it with various conditional stimuli, carried by the mossy fibers.

Cerebellar Learning Models

The cerebellum is one of the best- and earliest-studied parts of the brain. In the past 50 years, a number of conceptual models have proposed various functions, such as error correction, coordination, timing processing, and rhythm. Among these, cerebellar learning models have always been the most attractive, versatile, and influential. They are also the most explicit class of theory from the computational viewpoint. A large number of experiments and theoretical studies have been conducted to resolve the controversies and disputes surrounding them. The learning models are based on unique structures of the cerebellar cortex. The Purkinje cell, the only output neuron in the cerebellar cortex, receives two major excitatory inputs from climbing fibers and parallel fibers. A single climbing fiber axon makes multiple synapses on a single Purkinje cell and induces very strong excitatory postsynaptic potentials, which lead to complex spikes that consist of a few Ca^{2+} spikes. By contrast, 200 000 synapses from parallel fibers, which are the axons of 10^{10-11} granule cells, generate simple spikes, each of which is a single Na^{+} spike.

Brindley first proposed that parallel fiber–Purkinje cell synapses undergo plastic changes if the climbing fiber input is concomitantly activated. Around 1970, Marr, Albus, and Ito postulated the first learning theory of the cerebellar neural circuits. Albus correctly predicted that synaptic efficacy decreases if the parallel and climbing fibers are simultaneously activated, which was later physiologically demonstrated as long-term depression (LTD) by Ito and colleagues. Ito proposed that the climbing fiber input carries an error signal rather than a teacher (desired output) signal and explained adaptation of the vestibulo-ocular reflex by an LTD-based learning model.

A general model of cerebellar learning, which is an extension of the model proposed by Ito to explain general movements with many degrees of freedom and a simplification of the model proposed later by Kawato, is shown in Figure 1. Mossy fiber inputs carry information on the goal of a movement, sensory feedback about the current state of the body and the external world, and the efference copy of motor commands to granule cells. Purkinje cells, mainly activated by parallel fiber inputs from granule cells, project to cerebellar nuclei, which further transmit information to downstream motor systems such as the oculomotor system, spinal cord, red nucleus, and cerebral cortex via the thalamus (depicted together as the postcerebellar network in Figure 1). Motor commands generated by this network induce movements, which are measured by sensory organs. Subtracting this measured state feedback to the brain from the desired state gives the sensory error, which is further transformed into the appropriate coordinates for Purkinje cell outputs. The inferior olive neurons send this transformed error back to Purkinje cells via the climbing fibers.

Cerebellar Purkinje cell learning can be modeled by the following simple supervised learning based on the known synaptic plasticity of parallel fiber–Purkinje cell synapses, including LTD and long-term potentiation (LTP), and the rebound potentiation of inhibitory synapses on Purkinje cells, as well as LTP between parallel fibers and inhibitory interneurons. For simplicity, the firing rate $-y$ of a Purkinje cell is assumed to be the weighted summation of 200 000 parallel fiber inputs x_i:

$$-y = \sum_{i=1}^{200\,000} w_i x_i$$

Then, the inhibitory action on deep cerebellar nuclei is negative of the Purkinje output, y. If the desired output for the sign-inverted Purkinje cell's simple spike is denoted as y_d, then the objective function to be minimized for the supervised learning, in which the synaptic weight w_i is learned so that the actual output y best approximates the desired output y_d, is given as

$$E = 1/2(y_d - y)^2$$

The steepest descent direction of this error function can be obtained by the following partial derivative (called the Widrow–Hoff rule):

$$\Delta w_i, \propto -\frac{\partial E}{\partial w_i} = -\left(-\frac{\partial y}{\partial w_i}\right)(y_d - y) = -x_i(y_d - y)$$
$$= -x_i(C - \bar{C})$$

Here, $(C - \bar{C})$ is the difference between the climbing fiber firing rate and its temporal average (background firing activity), and it is assumed to encode the error signal in the last equation.

When both parallel and climbing fibers are activated, x_i and $(C - \bar{C})$ are positive, and thus Δw_i is negative (LTD). In contrast, when the parallel fiber is activated and the climbing fiber is not, then

Figure 1 A cerebellar learning model.

x_i is positive but $(C-\bar{C})$ is negative, and thus Δw_i is positive (LTP). When both the climbing fiber and the inhibitory interneuron synapse on a Purkinje cell are activated, x_i and $(C-\bar{C})$ are positive, and thus Δw_i is negative, leading to an increase in the amplitude of w_i, which is negative (LTP of inhibitory pathway).

Cerebellar learning theory predicts that a memory of learning is stored at parallel fiber–Purkinje cell synapses; that LTD is an elementary cellular process of cerebellar learning; and that climbing fibers carry an error signal with some precision in the output coordinates of Purkinje cells. These predictions have all stimulated a vast amount of experimental examination and controversy, but they have been quite well supported by recent data and modeling four decades after they were first proposed. These controversial issues are discussed below.

It is well established that when the cerebellum as a whole is lesioned, for some movements, learning capability is lost, stored memory of learning is destroyed, and movements are not well corrected or coordinated. Controversies have centered mainly on the question of whether the cerebellar cortex (Purkinje cell synapses) or the cerebellar nucleus is the major site of memory. Recent systematic lesion studies have shown that the cerebellar cortex is a memory site for several days at least and that the cerebellar nuclei can contain even longer memory. Interfering with LTD pharmacologically (e.g., by administration of hemoglobin, which is a scavenger of NO, essential for LTD) or by genetic manipulation (knockout mice and their pharmacological rescue) are more recent and sophisticated ways of resolving this controversy. Abolishment of LTD was shown to destroy various motor learning capabilities, such as adaptation of walking, vestibulo-ocular reflex, optokinetic eye movements, and precise timing in eyeblink conditioning.

Computational Models of Cerebellar LTD

If LTD of parallel fiber–Purkinje cell synapses is the elementary cellular process of supervised learning, as postulated in the cerebellar learning theory, it must satisfy the following three requirements. First, LTD should be associative. That is, LTD should be induced only when both parallel fiber inputs and climbing fiber inputs are conjunctively activated. Second, LTD should be maximally induced when climbing fiber activation is delayed 50–200 ms with respect to parallel fiber activation. This is because the time window of LTD should compensate for the delay of the reafferent climbing fiber inputs to feedback the consequences of the parallel fiber–simple spike-induced movements. Third, LTD should be synapse specific; only a parallel fiber synapse that is conjointly activated with a climbing fiber input should be depressed, but not other synapses. However, a considerable number of studies have reported violations of these three requirements under some experimental conditions; consequently, LTD has been questioned several times as the elementary process of cerebellar supervised learning and has been postulated for other functions, such as the

normalization of total synaptic efficacies on a single Purkinje cell. The kinetic simulation model of LTD signal transduction pathways in a Purkinje cell dendritic spine (Figure 2) provides a coherent perspective on these confusing experimental data and competing theoretical hypotheses, and it is described below.

Climbing fiber inputs activate α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors (AMPA-Rs) on dendritic shafts and induce depolarization, which opens the voltage-gated calcium channels (VGCCs), as indicated by the broken line in Figure 2, leading to Ca^{2+} influx from the extracellular space into the spine head, reaching a concentration of about $1\,\mu mol\,l^{-1}$. Parallel fiber inputs also induce AMPA-R activation on dendritic spines, just as a climbing fiber input does, but parallel fiber inputs produce smaller depolarization and Ca^{2+} influx. In addition, they simultaneously activate metabotropic glutamate receptors (mGluRs). Furthermore, they presynaptically synthesize nitric oxide (NO), which diffuses into the spine. In the metabotropic pathway, activated mGluRs induce production of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol via G-proteins and phospholipase Cβ at the postsynaptic density. IP_3 then diffuses into the cytosol and binds to IP_3 receptors (IP_3Rs), which are IP_3-gated Ca^{2+} channels on the intracellular Ca^{2+} stores, such as endoplasmic reticulum (ER). Cytosolic Ca^{2+} above some threshold triggers a regenerative cycle of IP_3-dependent Ca^{2+}-induced Ca^{2+} release (depicted as a positive feedback loop between Ca^{2+} and IP_3Rs in Figure 2) from the ER via IP_3Rs opened by binding of both IP_3 and Ca^{2+}. This means that the open probability of IP_3Rs increases with Ca^{2+} concentration, and the Ca^{2+} threshold of this regenerative cycle decreases with IP_3 concentration. An increase in cytosolic IP_3 concentration was simulated to be maximal at $3\,\mu mol\,l^{-1}$ about 100 ms after the parallel fiber input. This slow rate of increase in IP_3 concentration is due to the slow dynamics of the metabotropic pathway. Because Ca^{2+} influx via VGCCs due to climbing fiber activation is an immediate event, when the climbing fiber input is delayed about 100 ms with respect to the parallel fiber input, Ca^{2+} increase coincides with IP_3 increase, and they together trigger the Ca^{2+}-induced Ca^{2+} release of $10\,\mu mol\,l^{-1}$. If either climbing fiber input or parallel fiber input alone is activated, this large Ca^{2+} release does not occur because either IP_3 or Ca^{2+}, respectively, does not reach the threshold for the regenerative cycle. Consequently, the Ca^{2+} nonlinear excitable dynamics model by Doi (right third of Figure 2) reproduced the associative nature and the spike timing-dependent plasticity (STDP) of LTD.

In the model proposed by Kuroda, the large Ca^{2+} increase, which is caused by the conjunctive parallel fiber input and the delayed climbing fiber input, induces

the activation of linear cascades of phosphorylation of protein kinase C (PKC), followed by phosphorylation and then internalization of AMPA-R, which explains the early phase of LTD up to about 10 min. On the other hand, the intermediate phase of LTD, up to several times longer, is mediated by a mitogen-activated protein (MAP) kinase-dependent positive feedback loop, which consists of PKC, Raf, MAP/extracellular signal-regulated kinase (MEK), MAP kinase, cytosolic phospholipase A_2, arachidonic acid, and back to PKC (Figure 2). This positive feedback loop has two stable equilibrium points separated by a saddle point that determines the threshold of LTD. At the low equilibrium point, the MAP kinase positive feedback loop is not activated, but if strong and long Ca^{2+} elevation occurs, the state jumps to the higher equilibrium over the saddle point, and AMPA-Rs continue to be phosphorylated and internalized during this prolonged activation of the positive feedback loop. Consequently, this MAP kinase positive feedback model (middle third of Figure 2) explains the long-term nature of LTD and is supported by George Augustine, Keiko Tanaka, and collaborators.

In the Kuroda model (left third of Figure 2), NO activates soluble guanylyl cyclase (sGC), and the activated sGC catalyzes the conversion of guanosine triphosphate into cyclic guanosine monophosphate (cGMP), which activates cGMP-dependent protein kinase (PKG). PKG phosphorylates its substrate, G-substrate, and phosphorylated G-substrate preferentially inhibits protein phosphatase 2A (PP2A). Activated PP2A dephosphorylates MEK and AMPA-R. Inhibition of the dephosphorylation of MEK was required for the activation of the MAP kinase positive feedback loop. Therefore, by ultimately inhibiting PP2A and activating the positive feedback loop, NO plays a permissive role in the induction of LTD.

The Ca^{2+} dynamics model coherently reproduces both the associative and the nonassociative natures of LTD and the spike timing dependency of associative LTD as follows. Within the physiological ranges of input strength, the conjunctive stimulation of the parallel fiber input and the delayed climbing fiber input is essential to induce a large, regenerative Ca^{2+} increase, which is necessary for crossing the threshold of the MAP kinase positive feedback loop and inducing LTD. However, if stimulation of parallel fiber bundles is strong enough, or if uncaged Ca^{2+} or IP_3 is abundant enough, these stimuli alone can increase the Ca^{2+} concentration so that it crosses the Ca^{2+} dynamics threshold, resulting in a large enough Ca^{2+}-induced Ca^{2+} release from the ER to reproduce nonassociative LTD. In the hippocampal and cerebral pyramidal neurons, backpropagation of somatic action potentials releases the magnesium block on *N*-methyl-D-aspartate (NMDA) receptors and is the essential mechanism for millisecond-order STDP there. Backpropagation of somatic action potentials requires activity of postsynaptic cells, which is the essential condition of Hebbian learning. Neither backpropagation nor the NMDA receptors exist in Purkinje cells, suggesting cellular mechanisms for the clear distinction of Purkinje cell-supervised learning, with 100-ms STDP, from cerebral Hebbian learning, with STDP of tens of milliseconds.

The excitable dynamics of the Ca^{2+} model and bistable dynamics of the MAP kinase positive feedback loop model may provide a possible molecular mechanism to resolve the 'plasticity–stability' dilemma of memory stability with environmental sensitivity. Each spine is equipped with a surprisingly small number of molecules (e.g., only tens of AMPA-Rs). With a cascade of excitable and bistable dynamics starting from Ca^{2+} dynamics, followed by the MAP kinase positive feedback loop, internalization of AMPA receptors, a possible change in cytoskeleton and membrane proteins, and finally a morphological change in the spine, LTD can be induced by very delicate and low-energy inputs but acquired memory can be maintained over a prolonged period of days, even under stochasticity due to the small numbers of molecules.

The synapse specificity of LTD is also well explained by the NO model combined with an electrical cable model of Purkinje cell dendrite and spines, the Ca^{2+} dynamics model, and the MAP kinase positive feedback loop model. When no nearby parallel fiber is activated and NO is low, even a conjunction of the parallel fiber and climbing fiber inputs cannot induce LTD. If too many surrounding parallel fibers are stimulated and NO is very high, even the synapse, which is not stimulated, exhibits LTD only by climbing fiber stimulation. In this case, a spread of LTD occurs, and the synapse specificity of LTD is lost. Only when a modest number of parallel fibers are activated and NO is within an intermediate range can synapse-specific LTD occur; the contextual information for storing different motor skills might be conveyed by this gating mechanism. This strongly predicts the sparseness of parallel fiber coding *in vivo*, which has recently gained much experimental support.

Altogether, the LTD kinetic simulation models provide a comprehensive account of several seemingly diverse, conflicting, and unrelated experimental data within the framework of complicated nonlinear dynamics regulated by Ca^{2+}, IP_3, and NO concentrations. We must note that because of the nonlinear summation effects of these signaling molecules, nonphysiological stimuli *in vitro*, such as parallel fiber bundle stimulation, uncaging of Ca^{2+}, and IP_3, might induce characteristics qualitatively different

from those induced *in vivo* LTD in terms of its associative nature, spike timing dependency, and synapse specificity.

Rhythmic versus Chaotic Firing of Inferior Olive Neurons

The most influential model of the cerebellum other than the learning theory is probably the timing, rhythm, and synchronization hypothesis. The inferior olive nucleus, which sends out climbing fibers to Purkinje cells, possesses the highest density of gap junctions in the mammalian brain. Inferior olive neurons have several unique ion channels distributed on the somatic and dendritic membrane, as shown in Figure 3(a), and these exhibit rhythmic activities in slice preparation under some conditions, especially with harmaline. However, in awake monkeys at rest, no rhythmicity has been found for complex spikes. When the effective electrical conductance of gap junctions is increased by picrotoxin application to the inferior olive, which blocks inhibitory synapses on glomeruli of inferior olive neurons from cerebellar nuclei, the inferior olive neurons tend to be spatially synchronized in their firing.

None of these unique and well-studied anatomical and physiological characteristics of inferior olive

Figure 3 A network model of inferior olive (IO) neurons electrically connected by gap junctions. (a) Two-compartment biophysical model of an IO cell. The somatic ionic currents include a low-threshold calcium inward current (I_{Ca_l}), an anomalous inward rectifier current (I_h), the Hodgkin–Huxley type inward sodium (I_{Na}) and outward delayed rectifier potassium (I_{K_dr}) currents, and a leakage current (I_{ls}). The dendritic currents include a high-threshold inward calcium current (I_{Ca_h}), an outward calcium-dependent potassium current (I_{K_Ca}), and a leakage current (I_{ld}). As the dendritic potassium current I_{K_Ca} is calcium dependent, Ca^{2+} concentration dynamics is included in the model. g_{int} is the coupling conductance between the two compartments and I_{sd} is the current flowing through this conductance. The electronic coupling between this cell and multiple other cells is not shown. (b) Between 4 and 27 IO cells are connected on a lattice by electrical conductance via gap junctions; g_c, coupling strength. (c) Largest Lyapunov exponent as a function of g_c for different networks of nonidentical cells. Error bars are standard deviations obtained from 10 different simulations. When the largest exponent was large, the network exhibited marked chaotic behavior. When the largest exponent was close to zero, firing was almost rhythmic. (d) Network mutual information per spike as a function of g_c for different networks of nonidentical cells. Adapted from Schweighofer N, Doya K, Fukai H, Chiron JV, Furukawa T, and Kawato M (2004) Chaos may enhance information transmission in the inferior olive. *Proceedings of the National Academy of Sciences of the United States of America* 101: 4655–4660, with permission from National Academy of Sciences, USA.

neurons has been incorporated into or explained by the learning theory until recently. Schweighofer and colleagues developed a two-compartment model of an inferior olive neuron, as shown in Figure 3(a), with known spatial distribution of ion channels. These neurons are connected by gap junctions within a planar sheet, as shown in Figure 3(b), and the firing characteristics, as well as the input and output information transfer characteristics, have been examined. The network model reproduced rhythmic firing, as well as synchronized oscillation, when the coupling conductance was high. Figure 3(c) plots the largest Lyapunov exponent of the network dynamics as a function of the coupling conductance. The small Lyapunov exponent at large conductance indicates that the firing is synchronized and rhythmic when electrical coupling is strong, corresponding to picrotoxin application. With small conductance, each neuron periodically fires at its own frequency without much interaction; thus, the Lyapunov exponent is again close to zero, indicating an almost periodic solution. However, with medium conductance, the Lyapunov exponent is much higher than zero, indicating that neurons fire asynchronously and aperiodically. This is actually chaotic and desynchronized firing, and for this range of dynamics, input and output information transmission becomes the largest, as shown in Figure 3(d). These theoretical predictions were recently supported experimentally. Consequently, climbing fiber inputs can convey error signals most efficiently, even with their low firing frequency (typically 1 spike s^{-1}), when the conductance is medium and chaos is induced. Low-frequency firing usually implies poor representation of the error signal. Chaotic and desynchronized firing of inferior olive neurons might be a basic neural mechanism for insuring high-fidelity error-signal transmission even with a low firing rate.

The feedback error learning theory of the cerebellum explained in the next section theoretically requires low firing rates of climbing fiber inputs. This is because climbing fiber inputs convey time-delayed feedback motor commands, and if they were to be strongly manifested in Purkinje cell output, smooth and sophisticated feed-forward motor control would be ruined. Hirano and his colleagues provided experimental support for this prediction in AMPA-R delta 2 knockout mouse. Climbing fiber inputs occupy a much larger proportion of Purkinje cell output in this knockout mouse compared with a normal mouse, and optokinetic eye movements are much more delayed than is control performance.

Feedback Error Learning Model

Although early learning models proposed that the cerebellum conducts pattern recognition, probably influenced by a 'perceptron,' they are not consistent with physiological data showing that simple spike firing rates of Purkinje cells temporally change and encode dynamic and kinematic features of movements. Recent studies suggest that the human cerebellum is important for sensory and cognitive functions as well as for motor control. What general computation might be realized by the cerebellar cortex that would cover the sensory, cognitive, and motor domains; would be compatible with existing hypotheses, such as timing, coordination, and error correction; and could be learned by supervised learning such as that shown in Figure 1? Internal models seem to provide the most versatile and compatible computational entity satisfying all these requirements. Internal models are neural networks inside the brain ('internal') that can mimic ('model') the input–output characteristics of some dynamic process outside the brain. In a motor control context, a forward model of a body can predict sensory consequences of movement from the efference copy of a motor command. This is because the controlled objects in movements generate a trajectory from motor commands. By contrast, the inverse model of a body and the external world can compute the necessary motor commands from a desired movement pattern. Internal models are useful for predictive computations in sensory, cognitive, and motor functions. If an inverse dynamics model for a controlled object possessing dynamics and kinematics with multiple degrees of freedom is destroyed, the movement becomes clumsy, slow, and not well corrected, because neither feed-forward nor feedback control (both of which are dependent on the inverse model) is available. Thus, control must rely on poor and crude feedback control alone. Internal models can be learned based on supervised learning.

Around 1990, Kawato proposed that different parts of the cerebellum contain either forward or inverse models. He also proposed a computational scheme called feedback error learning to acquire an inverse model in the supervised learning scheme, as shown in Figure 4(a). If supervised learning takes place in the brain for motor control, the following difficult computational problem called 'distal teacher,' formulated by Jordan, should be resolved. As shown in Figure 1, the error between desired and actual movement patterns can be measured by sensory organs, but these movement errors could be very different in spatial coordinates as well as in temporal dynamics from the necessary error signal for the motor command. Furthermore, it should be emphasized that there exists no teaching signal for motor commands in supervised motor learning, because if it were to exist, it would be directly utilized for motor control, and there would be no need for learning. The distal teacher problem is

Figure 4 (a) The general feedback error learning model. (b) The cerebellar feedback error learning model. The 'controlled object' is a physical entity, such as the eyes, hands, legs, or torso, that needs to be controlled by the central nervous system. Different colors are for correspondence between (a) and (b).

almost absent in simple gain control with one degree of freedom, such as vestibulo-ocular reflex; thus, it motivated the following more recent models for general many-degrees-of-freedom movements with dynamics and kinematics. Several computational models have been proposed, such as direct inverse modeling, back-propagation through a forward model, or decorrelation learning, but the feedback error learning model, which transforms the sensory error into a motor error by a preexisting feedback controller in the central nervous system (Figure 4(a)), is probably the most biologically plausible and best supported.

The feedback error learning model depicted in Figure 4(a) is the same as the basic model shown in Figure 1 except for the following four points. First, the inverse model transforms a desired trajectory into a feed-forward motor command. Second, a crude feedback controller generates feedback motor command from the sensory error. Third, the summation of the feed-forward and feedback motor commands is sent to the controlled object. Finally, and most important, the feedback motor command is used as the error signal for motor commands in supervised learning for acquisition of the inverse model (cf. Figures 1 and 4(a)). Stability and convergence of the feedback error learning algorithm have been mathematically proved as well as successfully applied to several robotic demonstrations. Figure 4(b) adapts the basic feedback error learning model to the cerebellar neural circuit. Here, simple spikes represent feed-forward motor commands, and parallel fiber inputs represent the desired trajectory as well as the sensory feedback of the current status of the controlled object. A microzone of the cerebellar cortex constitutes (a part of) an inverse model of a specific controlled object such as the eye or arm. Most importantly, climbing fiber inputs are assumed to carry a copy of the feedback motor commands generated by the feedback control circuit. Thus, the complex spikes are predicted to be trajectory error signals already expressed in motor command coordinates. Although

Figure 5 Continued

climbing fiber inputs are delayed by 100 ms with respect to the responsible parallel fiber inputs that caused the movement and the resulting error, spike timing dependency of LTD (see the section titled 'Computational models of cerebellar LTD') selectively changes only the responsible parallel fiber synapses.

The Ventral Paraflocculus and Ocular Following Responses

Kawano and his colleagues supported the cerebellar feedback error learning model by neurophysiological studies in the ventral paraflocculus of monkey cerebellum during ocular following responses. Ocular following responses are tracking movements of the eyes, evoked by movements of a large visual scene, that are thought to be important for the visual stabilization of gaze. In the neural circuit controlling this response Figure 5(b), the phylogenetically older, crude feedback circuit comprises the retina, the accessory optic system, and the brain stem. The phylogenetically newer and more sophisticated feed-forward pathway and the inverse dynamics model correspond to the cerebral and cerebellar cortical pathway and the cerebellum, respectively. In Figure 5(b), the sensory error signal is computed as the image motion on the retina (retinal slip). This is different from the schemes of Figures 1 and 4 in which some neural mechanisms explicitly compute the difference (error) between the desired and actual states. However, in the case of eye movement control such as ocular following responses or vestibulo-ocular reflexes, the desired state is that the eye movement is made so that the retinal image does not move, and thus the optical computation (retinal slip detection) can replace subtraction of the desired and actual states. On the other hand, the desired trajectory information transmitted to the flocculus for the vestibulo-ocular reflex is the head motion signal detected by semicircular canals whereas for the ocular following responses, it is the image motion signal conveyed by the visual areas in the cerebral cortex.

During ocular following responses, the time courses of simple spike firing frequency show complicated patterns (Figure 5(c) top, thin line). However, they were quite accurately reconstructed by using an inverse dynamics representation of eye movement (thick line). The model fit was good for the majority of the neurons studied under a wide range of visual stimulus conditions, different eye movements, and different firing patterns. The same inverse dynamics analysis for the medial superior temporal area (MST) of the cerebral cortex and dorsolateral pontine nucleus, which provide visual mossy fiber inputs, revealed that their firing time courses were not well reconstructed from motor commands but rather that they were well reconstructed from visual retinal slip. Taken together, these data suggest that the ventral paraflocculus is the major site of the inverse dynamics model of the eye for ocular following responses.

Motor commands, conveyed by simple spikes, should be directly modified and acquired by LTD while guided by motor command errors, which are conveyed by climbing fiber inputs. For this to work, the climbing fiber inputs need to convey comparable details of temporal and spatial information to the motor commands, but the ultralow discharge rates of the latter would appear to rule out this possibility. This apparently discrete and sporadic nature of climbing fiber inputs was characterized as an unexpected event detector, which suggested a reinforcement learning type theory. However, if thousands of

trials are averaged, the firing rates actually conveyed very accurate and reliable time courses of motor command error within a few hundreds of milliseconds (Figure 5(c), bottom). More specifically, complex spike time courses are better reconstructed by retinal slip than by eye movements but in the motor command coordinates rather than in visual coordinates, as detailed below. Because LTD is a rather slow process, taking several tens of minutes, it can conduct the averaging over many trials. Consequently, the firing probability of climbing fiber inputs can convey high-frequency temporal information matching information of the dynamic command signal.

The preferred directions of MST and pontine neurons were evenly distributed over 360°, as shown in Figure 5(a)(3). Thus, the visual coordinates are uniformly distributed over all possible directions. On the other hand, projections of the three-dimensional spatial coordinates of the extraocular muscles were in either a horizontal or vertical direction, and they were entirely different from the visual coordinates. Preferred directions of simple spikes were either downward or ipsiversive (Figure 5(a)(3)), and at the site of each recording, electrical stimulation of a Purkinje cell elicited eye movement toward the preferred direction of the simple spike. These data indicate that the simple spike coordinate framework is already that of the motor commands. Thus, at the parallel fiber–Purkinje cell synapse, a drastic visuomotor coordinate transformation occurs. The neural representation dramatically changes from population coding in the MST and pontine nucleus to firing rate coding of Purkinje cells at the parallel fiber–Purkinje cell synapse (Figure 5(a)). What, then, is the origin of this drastic transformation? The theory proposes that the complex spikes, and ultimately the accessory optic system, are the source of this motor command spatial framework. The preferred directions of pretectum neurons are upward, and those of the contralateral nucleus of optic tract neurons are ipsiversive (thus contraversive for the cerebellum). Their signals are conveyed to the inferior olive and further to the cerebellum to produce the complex spikes. In summary, the coordinate frame of the climbing fibers was vertical and horizontal, forming the motor coordinates, not the visual coordinates of MST or pontine nucleus. All these experimental findings were successfully simulated by the network model shown in Figure 5(b). The coordinates of semicircular canals and the extraocular muscles are very similar, and it is rather difficult to evaluate coordinate transformation in the vestibulo-ocular reflex and flocculus compared with ocular following responses. However, recent physiological studies indicate that climbing fiber inputs encode motor error rather than sensory error. This argues against a class of model that assumes sensory–motor transformation downstream of Purkinje cells, including decorrelation models.

Toward a General Model of the Cerebellum

We have a very solid computational model (feedback error learning and inverse model) and a rich set of supporting experimental data for the ventral paraflocculus with ocular following responses. The model has also been well supported for other slow eye movements, such as vestibulo-ocular reflex, optokinetic eye movements, and smooth pursuit, for the flocculus and paraflocculus. Can we extend this to other parts of the cerebellum, other types of movements, and other computational models? Many theorists believe so since the neural circuit is generally uniform except for the newly found unipolar brush cells, found primarily in the flocculonodular lobe. Furthermore, Kitazawa and colleagues have demonstrated that complex spikes recorded from cerebellar hemispheres encode reaching errors at goal points during monkey whole-arm reaching, whereas simple spikes represent movement dynamics such as an electromyogram.

What can we generalize about cerebellar functions from previous studies on specific functions and specific areas? First, synaptic plasticity is unique and ubiquitous, and the learning is undoubtedly supervised learning and not Hebbian or reinforcement learning. Second, the cerebellar 100 ms STDP, in contrast to cerebral and hippocampal millisecond-order STDP, strongly suggests that the cerebellum is better suited for approximating some nonlinear dynamical system outside the cerebellum as 100 ms is exactly the time required for sensory signal feedback from the external world. Finally, the major computation is feed-forward, with less emphasis on recurrent feedback, because spatial resources are allocated more to neurons than to their connections in the cerebellum, as is evident from the number of neurons: more than that of the cerebrum in a volume only one-tenth that of the cerebrum. Consequently, internal models are the most promising computational functions of the cerebellum. Forward models have been theoretically postulated several times and supported by neuroimaging experiments. Cancellation of a self-generated electrical field by a forward model is the function of the electrosensory lobe (cerebellum-like structure) of the weakly electric fish and might be interpreted as another support. But it is actually a different story because NMDA receptors play the essential role in anti-Hebbian learning there. Thus, supporting evidence

for forward models is much more circumstantial than is the evidence for inverse models, and we need more-decisive data. Computational models for how multiple internal models are integrated and used for motor control and cognition have been proposed (e.g., the modular selection and identification for control model), but innovative experimental methodology to further explore these phylogenetically newer functions of the cerebellum seems necessary.

The mammalian cerebral cortex is an enormous sheet of cells covering in the human brain approximately 250 000 mm^2 and containing 1×10^9 or more nerve cells in a volume of about 300 cm^3. The human cerebral cortex is by no means the largest – it is exceeded in area by that of the whales – but it is probably the most highly differentiated. Differentiation, in this sense, means the subdivision of the cortex into the largest number of histologically distinct subareas each of which has a known or suspected function.

The fundamental divisions of the cerebral cortex in mammals are the hippocampal formation (or archicortex), the olfactory cortex and associated areas such as the entorhinal and periamygdaloid area in the piriform lobule (paleocortex), and the remainder (neocortex). The three parenthetical names indicate the phylogenetic assumptions of past generations of neuroscientists who regarded the neocortex as the hallmark of mammalian evolution. In nonmammalian brains, a hippocampal formation and an olfactory-related cortex can readily be identified, whereas a neocortex is probably absent or if present, is extremely small. The remainder of this article deals only with mammals and only with the neocortex.
