Implicit versus Explicit Sequence Learning

When considering the learning of sequential tasks, one needs to distinguish between explicit and implicit learning. Explicit learning is frequently assumed to be similar to the processes operating during conscious problem solving and includes conscious attempts to construct a representation of the task, a directed search of memory for similar or analogous task-relevant information, and conscious attempts to derive and test hypotheses related to the structure of the task. This type of learning has been distinguished from alternative models of learning, termed 'implicit' learning. The term 'implicit' learning denotes learning phenomena in which more- or less-complex structures are reflected in the overt behavior although the learners are unable to verbally describe these structures. Numerous studies have examined implicit learning of serial-order information using the serial reaction time (SRT) task established by Nissen and Bullemer. In this task, participants see a target stimulus, typically an asterisk, appearing at one of four locations on a computer display and are required to indicate its location by making a key press. Participants are initially trained on repeating a given sequence. However, learning is assessed by presenting participants with a block of experimental trials (e.g., a block of random trials) and then examining differences in reaction time (RT) existing between sequence and random blocks of trials. It was shown that the RTs in trials in which an overpracticed sequence was presented were significantly shorter than for random sequences, suggesting that participants have unconsciously learned the sequence and anticipated the next element (Figure 1).

There is a vast literature debating what is really learned in the implicit sequence paradigm in general and in the SRT task in particular. From a theoretical point of view, the description of a given sequence structure is not trivial because a given structure typically has several different structural components, such as frequency-based statistical structure (i.e., the redundancy of a specific element appearance in the pattern), relational structures (the occurrence of a specific element after or before a different element), and spatial structure (the position of the different elements in space, as in the case of fluent finger spelling). A literature review shows that all these components have an influence on the rate in which a sequence is learned.

Stages in Motor Learning: Transferability and Effector Specificity

A study conducted in monkeys, in which a sequence of 10 button presses is learned by trial and error, has shown that the time course of improvement of two performance measures, key press errors and RT, was different (Figure 2). The key press errors reached an asymptote within a shorter period of training compared with the RTs, which continued to decrease throughout a longer time. This finding suggested that the acquisition of sequence knowledge (as measured

Figure 1 Implicit acquisition of a practiced sequence. Participants see an asterisk appearing at one of four locations on a computer display and are required to indicate its location by making a key press. After a training period on repeating a given sequence, the participants are presented with a block of random trials. The differences in reaction time (RT) existing between the trained sequences and the random blocks of trails are shown by depicting the mean of median reaction times in milliseconds in each block. Filled circles, repeating sequence; x's, random sequence. Bars represent standard errors. From Nissen MJ and Bullemer PT (1987) Attentional requirements for learning: Evidence from performance measures. *Cognitive Psychology* 19:1–32.

by key press errors) may take place quickly, but long-term motor sequence learning (as measured by RT) may take longer to become established. Thus, different aspects of the task are learned in different timescales. It was shown that the learned procedure is effector-dependent: when monkeys were asked to use the hand that has not been used for long-term practice of the given sequence, their performance became very poor. However, this was not true for a newly learned sequence. These results suggest that the memory for a visuomotor sequence, which is accessible for both the trained hand and the untrained hand in the early stage of learning, becomes largely inaccessible to the untrained hand in the late stage of training, that is, the performance gain is not transferred to the untrained hand. It was further demonstrated that the whole sequence, rather than the individual elements, is learned: When the order of the component elements of a well-learned sequence was reversed, the performance became very poor, as if the monkeys were performing completely new sequences. The results suggested that the monkeys acquired the memories for individual elements separately. This was not true in the early learning stages. Further studies in monkeys and in humans demonstrated that although effector-dependent and -independent learning occur simultaneously,

Figure 2 Long-term retention test of motor skill in monkeys. (a) A procedure of the 2 × 5 sequence task. A monkey has to press the two illuminated buttons in the correct order to proceed to the next set until completing five sets (called a 'hyperset'). Each hyperset is presented repeatedly in a block until the monkey performs the whole hyperset for a total of 20 trials. A different hyperset is then used for the next block. (b) The learning curves of monkey PI for four hypersets during the initial practice period of 20 days are shown as the number of errors before completing 20 trials successfully (top) and the mean performance time for the successful trials (bottom).

effector-dependent representation might take longer to establish than effector-independent representation does and that they are mediated by different neural substrates.

It is reasonable to assume that a gain in performance reflects a change in brain processing triggered by practice. Many skills, while acquired, are retained over long time intervals, suggesting that training can induce long-lasting neural changes. Previous results from neuroimaging studies in which performance is modified over time have shown that many different stages can occur. As an effect of repetition or practice, several studies report that activations in particular brain areas decreased. In other studies, specific brain areas showed increase in the magnitude or extent of activation. In some reports, a shift in activated areas was observed between unskilled and more skilled performance of a task. Thus, decreases, increases, and shifts in activations are reported as an effect of practice. The differences in activations might be related, in part, to the amount of practice or repetition a participant has had with a task. A study conducted by Karni et al. demonstrated that motor skill learning (sequential finger opposition task) requires time and has two distinct phases, analogous to those subserving perceptual skill learning. An initial, fast improvement phase ('fast learning'), when the extent of activation in primary motor cortex (M1) decreases (habituation-like response), is followed by slowly evolving, posttraining incremental performance gains ('slow learning'), when the activation in M1 increases compared with control conditions. Figure 3 depicts the differential evoked responses in M1 in the trained versus the untrained (control) sequence. Overall, this study showed that limited training experience can be sufficient to trigger performance gains that require time to become evident. It was proposed that skilled motor performance is acquired in several stages: fast learning, an initial, within-session improvement phase, followed by a period of consolidation of several hours duration, and then slow learning, consisting of delayed, incremental gains in performance emerging after continued practice. This time course may reflect basic mechanisms of neuronal plasticity in the adult brain that subserve the acquisition and retention of many different skills. Later, using a simple single finger opposition task, Tracy et al. showed that even during a brief practice, there was a vast difference in activation in the corpus striatum, thalamus, and cingulate gyrus so that the neural circuit implementing this simple task varied over a brief window of practice.

A Schematic View of the Neural Representations of Motor Sequence Learning

Out of numerous views and results, sometimes controversial, that can be found in the literature on neural representation of learning motor sequences, this article discusses two major approaches, one claiming that there exist two parallel systems for neural coding of sequences and the other differentiating between the explicit and implicit learning processes. This approach bridges different observations and notions concerning sequence learning.

Two Parallel Systems of Coding

When people learn to perform a novel motor task, a corresponding memory trace is generated in the

(c) General schedule of the long-term retention test. After retention periods of 6–18 months, the monkey was instructed to perform the previously learned hypersets (O1–O6) and new hypersets (N1–N6) in a 1-day session. Reproduced from Hikosaka O, Rand MK, Nakamura K, et al. (2002) Long term retention of motor skill in macaque monkeys and humans. *Experimental Brain Research* 147: 494–504, with kind Permission of Springer Science and Business Media.

brain. This type of memory encodes procedural aspects of the task rather than facts and is termed 'procedural memory.' In the early stages of learning, a sequential motor procedure is composed of a series of sensorimotor processes, executed in a discrete manner (Figure 4(a)). However, the amount of computation needed to generate a novel sequential task is highly demanding. Such computations include the need to perform a series of coordinate transformations (e.g., from allocentric to egocentric or from eye-centered to hand-centered coordinate frames) and to deal with ordinal and temporal aspects of sequence generation, such as concatenating among sequential elements within the sequence. In order to address the question of how the system simplifies such complex computations and in order to relate to the finding that different learning stages are characterized by ability/inability to transfer the performance gain to the untrained hand, a hypothetical scheme for sequence learning has been suggested. This scheme, which attempted to suggest a plausible organization of motor sequence learning in the brain, proposed that a motor procedure is acquired and encoded independently by two cortical systems: one system encoding the sequence in spatial, extrinsic coordinates and the other one encoding the sequence in motor, intrinsic coordinates (Figures 4(b) and 4(c)). In the suggested scheme, each of these two parallel processes operates using a single type of coordinate system (either spatial or motor coordinates), hence providing a more parsimonious mode of representation. Based on a number of empirical studies conducted in monkeys and humans, the model proposes that (1) the procedural sequence is acquired in spatial, visual coordinates (green connections in Figure 4) before it is acquired in motor, intrinsic coordinates (blue connections in Figure 4); (2) the motor coordinate representation persists permanently, whereas the spatial representation is only temporary; and (3) the motor coordinate representation is effector specific and the spatial coordinate representation is not effector specific. The scheme may also be valid for the paradigms in which procedural memory is acquired implicitly, such as the SRT task.

As discussed earlier, the acquisition of a motor sequence in the brain is subserved by two distinct types of processes: implicit and explicit. An important question is whether the neural substrates of the two learning processes overlap and whether the acquisition of one learning type interacts or interferes with the other. Some studies reported that the neural substrates of implicit and explicit learning overlap at the levels of the prefrontal cortex and basal ganglia and that explicit learning of sequences, which exerts

Figure 4 A hypothetical scheme for information processing during sequence learning. (a) The pre-learning stage, in which the participant performs three actions (Acts 1–3) step by step by relying on sensorimotor transformations for each action (vertical connection). (b), (c) By performing the actions in the same order, sequential processes are formed across the actions (horizontal connections). This occurs at each of the two stages of the sensorimotor transformation so that a given sequence is learned independently but from different perspectives: as a sequence in visual coordinates (spatial sequence, shown in green) and as a sequence in motor coordinates (motor sequence, shown in blue). The spatial sequence mechanism acquires the sequence quickly and flexibly by relying on attention and working memory (b), whereas the motor sequence mechanism acquires the sequence slowly and steadily through long-term practice (c). The thicker arrows indicate the dominant process occurring in the early (b) and late (c) stages and also the corresponding coordinates, that is, spatial in (b) and motor in (c). From Hikosaka O, Nakahara H, Rand M, et al. (1999) Parallel neural networks for learning sequential procedures. *Trends in Neurosciences* 22: 464–471.

Figure 5 The association cortices (particularly prefrontal cortex) and the anterior part of the basal ganglia in monkeys constitute a loop circuit that operates as a spatial sequence mechanism (shown in green); the motor cortices (including primary motor cortex (M1) and supplementary motor area (SMA)) and the middle part of the basal ganglia constitute a loop circuit that operates in terms of motor coordinates (shown in blue). In addition, the anterior and posterior parts of the cerebellum contribute to the motor and spatial aspects of sequence generation by forming loop circuits with the motor and association cortices; their functions in the control of timing (indicated in the figure) are still speculative. The spatial and motor loops are capable of operating independently, acquiring and reproducing a given sequence in different coordinates. In addition, they have their own input and output: visual and auditory inputs and oculomotor outputs for the association cortices; somatosensory inputs and skeletomotor outputs for the motor cortices. The interaction between the two learning mechanisms is made possible in two ways: (1) by translation from spatial into motor coordinates by the premotor area and (2) by coordination or switching by the pre-SMA. From Hikosaka O, Nakahara H, Rand M, et al. (1999) Parallel neural networks for learning sequential procedures. *Trends in Neurosciences* 22: 464–471.

functional changes in the basal ganglia, directly inhibits implicit learning.

Figure 5 presents an anatomically supported model that describes the coordination between different brain areas mediating motor sequence learning, either in spatial or in motor coordinates, whereas Figure 6 depicts a scheme highlighting the hierarchy of the cortical structures based on their involvement in explicit/implicit representation. The organization of the cortical areas within the hierarchies depicted in both schemes is similar, and basically the two schemes supplement each other. Taken together, they suggest that the cortical structures that are strongly involved with explicit or implicit processes are mostly engaged with representing a new acquired sequence in spatial or motor coordinates, respectively. Hence, the interference between implicit and explicit sequence learning may be related to the functional and anatomical overlap among the brain structures mediating the spatial and motor learning mechanisms.

The Role of Different Brain Areas in Sequence Acquisition, Representation, and Implementation

The prefrontal cortex is located at the top of both schemes describing learning of motor sequences (Figures 5 and 6). Compelling evidence exists in favor of the prefrontal cortex involvement in the process of explicit sequence learning and the acquisition and representation of the spatial aspects of a newly acquired sequence. Furthermore, it is considered to be related to several functions relevant to sequence leaning, such as working memory, rehearsal,

Figure 6 A set of cortical structures subserve the control of motor sequences. Depending on the instructional set, a participant's intentions, and the development of awareness, implicit or explicit processes predominate or interact during sequence learning, triggering specific mechanisms and leading to the formation of different types of representations of the learned sequence. For instance, when the intention to learn the sequence is explicit, either as a consequence of awareness or as an instructional set, explicit processes will originate in prefrontal cortex and will propagate to premotor areas. In this case learning will be based on mechanisms such as rehearsal and chunking. When learning is implicit, as a result of simply performing sequential movements without intention to learn or awareness of the sequence, implicit processes originate in motor cortex and propagate to the premotor areas. In such instances learning might be based on element-to-element associations or temporal coding. Of course, in most cases, these two types of processes will interact with each other and will change in importance depending on the stage of the learning process. From Ashe J, Lungu O, Basford A, and Lu X (2006) Cortical control of motor sequences. *Current Opinion in Neurobiology* 16: 213–221.

and executive control. Lately, it has been shown that the prefrontal cortex is strongly activated during explicit learning in the SRT task, a standard visuomotor RT paradigm, and that single dorsolateral prefrontal neurons encode the temporal order of a sequence of actions.

Based on the hierarchy depicted in Figure 6, the medial premotor cortex is situated a step below the prefrontal cortex. A large body of work, including lesion studies, suggests that the medial premotor cortex has an important role in the temporal organization of sequences, including the chunking together over time of multiple, separately performed movements.

While the functional properties of the supplementary motor area (SMA) and pre-SMA overlap, it is still generally accepted that the repetition of earlier acquired sequences is more strongly manifested in the activity of SMA neurons and that there is a greater tendency of the activity of pre-SMA neurons to reflect representation of new sequences. Pre-SMA and premotor areas (including SMA) may be involved in coordinating between the spatial and motor sequence mechanisms (Figure 5). A specific feature of the pre-SMA with respect to learning is that its neurons tend to become active during acquisition of novel explicit sequences, and their inactivation causes deficits in learning of novel sequences.

M1 is strongly related to the execution of movements, so establishing its role in the acquisition of a novel movement sequence is difficult. However, experiments designed to differentiate between the two contexts (instantaneous encoding of movements and encoding of motor sequences), such as generating different sequences composed of the same elements but in different temporal order, implied that the neural activity in M1 and dorsal premotor cortex also encodes sequential attributes of motor tasks and that its role in sequence production is independent of its

role in basic control of movements. Moreover, M1 is engaged at the early stage of motor consolidation. Thus, in contrast to the commonly held view of the motor cortex solely as being important for motor execution, it may also be fully equipped for the planning and production of sequential behavior.

The function of the cerebellum in sequence learning is controversial. The cerebellum is suggested to be involved in the coordination of the movements of different body parts and in the acquisition of timing or rhythm. Coherent changes of activity in the cerebellum and M1 were found during learning of timed motor sequences. In particular, during the initial stages of learning (when performance is poor), the activity in the cerebellum was greater than the cerebellar activity at the advanced learning stage. In M1, conversely, greater activity corresponded to better performance at the advanced learning stage.

Neuropsychological research suggests that implicit sequence learning in the SRT task is spared in patients with organic amnesia, so implicit SRT learning does not appear to depend on the medial temporal and diencephalic brain regions that are critical for explicit memory. Conversely, patients with Huntington's or Parkinson's disease have consistently shown SRT impairments, so the basal ganglia seem to be critically involved in SRT learning. Recent studies indicate that the anterior striatum affects learning of new sequences whereas the posterior striatum is engaged in recalling a well-learned sequence. It is important to note that the hypothetical parallel learning mechanisms (motor vs. spatial) provide advantages in parsimony, robustness, and adaptability of the system. The basal ganglia may have a key role in motivating procedural learning. Reinforcement (via dopaminergic neurons) might take place separately for the spatial (via the anterior striatum) and motor (via the middle striatum) sequence mechanism (Figure 5).

Movement Planning and Anticipation: Submovements and Coarticulation

The stereotyped kinematic patterns of planar reaching movements are not the expression of a prewired or an inborn motor pattern but the result of learning during ontogenesis. When infants start to reach, their reaching is characterized by multiple accelerations and decelerations of the hand, whereas experienced infants reach with much straighter hand paths and with a single bell-shaped hand velocity profile. It has been shown that it is possible to decompose a large proportion of infant reaches into an underlying sequence of submovements that resemble simple adult reaching movements. Based on several studies with adult participants, it has been suggested that the CNS uses elementary simple movements, primitives, which are smoothly combined in order to compose more complicated trajectories.

Other evidence for the existence of primitive submovements has come from work on hemiplegic stroke patients, which shows that their first movements are clearly segmented and exhibit a remarkably invariant speed profile. The idea that curved and obstacle avoidance movements result from the superposition of more elementary movements was modeled by Burdet, who suggested a mathematical model for the learning of accurate human arm movements. Its main features are that the overall movement results from the superposition of smooth smaller submovements (primitives). A similar notion was also elaborated by Henis and Flash, who formulated the 'superposition' model for target switching experiments. It was found that arm trajectory modification in a double target displacement paradigm might involve the vectorial summation of two independent plans, each coding for a smooth point-to-point trajectory. The first plan is the initial unmodified plan for moving between the initial hand position and the first target location. The second plan is a time-shifted trajectory plan that starts and ends at rest and has the same amplitude and kinematic form as a simple point-to-point movement between the first and second target locations.

After extensively practicing a particular sequence, most of the participants undergo implicit or explicit anticipation, which results in a coarticulation – the emergence of both spatial and temporal overlap among adjacent articulatory units. It is well known that as humans learn to speak, the speech becomes smoother and more fluent. Coarticulation in speech production is a phenomenon in which the articulatory movements for a given speech sound vary systematically with the surrounding sounds and their associated movements. Coarticulation was also studied in hand motor sequence generation. It was shown that pianists could anticipate a couple of notes before they are being played, which resulted in hand and finger kinematic divergence; that is, the spatial configuration of the fingers was different according to the context in which a specific note was played. Such a divergence implies an anticipatory modification of sequential movements of the hand, akin to the phenomenon of coarticulation in speech. Moreover, a study of fluent finger spelling has shown that rather than simply an interaction whereby a preceding movement affects the consecutive one; the anticipated movement in a sequence can systematically affect the one preceding it (Figure 7).

Figure 7 Cartoon images of hand shapes representing letters of interest in the American Sign Language manuscript alphabet, rendered with POV-Ray software. The layout illustrates the experimental design for a study of coarticulation: two fixed-letter strings (I-S-C and N-T-R) were followed by one of the five vowels (A, E, I, O, or U). Reproduced from Jerde TE, Soechting JF, and Flanders M (2003) Coarticulation in fluent finger spelling. *Journal of Neuroscience* 23(6): 2383–2393, with permission from Society for Neuroscience.

A recent study conducted by Sosnik et al. has shown that extensive training on writing like sequence movements, whereby participants have to connect four target points "as rapidly and as accurately as possible," results in the coarticulation of consecutive segments of a given sequence of planar movements generated between a series of target points and that the outcome of prolonged training can be a novel, curved trajectory, which although corresponding to a longer path, affords smooth and rapid performance with no loss in accuracy (Figure 8). With accumulated experience, a qualitative change occurs in motor planning: from the generation of a sequence of individually planned component movements to the generation of globally planned, maximally smooth movement units, providing a highly effective solution to the challenge imposed by the double requirement to move "as rapidly and as accurately as possible." These findings suggested that a profound hierarchical change can occur in motor planning: from syntax-dependent performance to unitary (modular), globally planned movement (coarticulation).

Consolidation and Sleep in Sequence Learning

So far in this discussion, only a distinction between an early versus a late stage of sequence learning has been made. However, as was recently summarized in a review by Doyon et al., sequence learning actually occurs over several stages. The first stage is an early and fast one in which considerable improvements in performance occur very rapidly within a single training session. This stage is followed by a slow stage, during which further gains in performance are achieved over several practice sessions. Third, there is a consolidation stage, in which off-line, spontaneous increases in performance are achieved provided that another task is administered only beyond a critical period of 4–6 h; otherwise interference caused by the administration of the new sequence learning task can occur. The fourth automatic stage is one during which the skilled behavior requires minimal cognitive resources and is resistant to interference and to the effects of the passage of time. Finally, there is a fifth retention period in which the motor skill can be performed after long delays without further practice of the learned task.

An important mechanism for the retention of learned sequences in memory is consolidation. The term consolidation, which was coined more than a century ago, describes the reduction of the fragility of declarative memory – memory for facts and events after it has been acquired and encoded. Through consolidation, an initially fragile memory is transformed into a more robust and stable one. Consolidation has been exhaustively investigated with respect to declarative memory, but more recently it has been

Figure 8 The evolution of coarticulated trajectories throughout training. Participants have to connect four target points "as rapidly and as accurately as possible," resulting in the coarticulation of consecutive segments of a given sequence of planar movements generated between the series of points. There was a relatively high spatial alignment (obtuse angle) between the lines connencting target pairs *AB* and *BC* or *CD* and *DA*. For each training day, upper and lower plots denote trajectories and velocity profiles, respectively. Note the novel, curved trajectory that results. Reproduced from Sosnik R, Hanptmann B, Karni A, and Flash T (2004) When practice leads to co-articulation: The evolution of geometrically defined movement primitives. *Experimental Brain Research* 156(4): 422–438, with kind permission of Springer Science and Business Media.

extended to other memory systems, including procedural memory. Beyond the reduction in the fragility of the memory trace that occurs following the acquisition of a new skill, consolidation refers also to another phenomenon, namely, the off-line improvement in performance that can occur either between practice sessions or after the practice period has ended. There is evidence for both types of consolidation processes. This evidence will be discussed especially in the context of sequence learning.

Off-line improvements in the performance of a skill occur over time without practice and often depend on sleep. Overnight improvements are seen in the performance of short finger sequences. Only a negligible amount of improvement in performance is seen when the interval between sessions is spent awake. Learning another sequence before sleep can block this overnight improvement, showing that this learning requires an active and sequence-dependent mechanism. Moreover, the improvement depends on the time spent in a particular component of sleep or in the combination of several sleep components. Depriving the participant of the critical sleep component or of any sleep at all greatly reduces off-line improvements. Fatigue or circadian factors cannot account for this phenomenon. Instead, off-line improvements in sequence performance seem to reflect marked changes in the brain areas subserving the mechanisms involved in memory storage, retrieval, and sequence generation. There is evidence to suggest that overnight skill improvements are supported by replay of the previously learned task and involve both enhancement of neuroplastic mechanisms and reorganization of the learned information. Overnight reorganization of information and of the memory trace might lead to changes in the representations of motor sequences that previously have been attributed only to practice. Moreover, the dependence of off-line improvement on sleep holds for the learning of sequential tasks (e.g., sequential finger movements) only when the skill is acquired intently and involves explicit learning. In the case of implicit learning, off-line learning is not sleep dependent but develops equally well during the day and overnight. It takes then 4–6 h for such off-line improvements to appear.

Historically, consolidation was described as the reduction in the fragility of memory for a new task. The capability to perform a new acquired skill is interfered with when the participant practices another new skill immediately after the first one. The amount of interference depends on the time that passes between the learning of the two skills. In particular, in the case of dynamic adaptation, learning a second task disrupts the memory trace for the first task, a phenomenon called retroactive interference. As the time between the two learning sessions increases, the memory trace of the first skill becomes more stable, and the interference of learning a second skill becomes weaker. There is some evidence to suggest that retention in memory of learned sequences might also be susceptible to disruption. Doyon et al. have suggested an integrated view of the plasticity that motor memory traces can undergo across learning stages. In the first learning stage, both motor adaptation and sequence learning recruit the corticostriatal and corticocerebellar systems, depending on the cognitive processes required for the task.

When the skill has been learned well, the neural representation of this motor behavior is thought to be distributed in a network of structures involving only one of these circuits. The corticostriatal and corticocerebellar systems are crucial for consolidation and for maintaining in long-term memory a new motor sequence or a new motor adaptation skill, respectively. Thus in the case of sequence learning, Doyon and Ungerleider have shown that the cerebellum is no longer essential, and long-lasting retention of the skill involves representational changes only in the striatum and in the associated cortical areas.

Motor Skill Learning

Published by Elsevier Ltd.

Introduction

The vertebrate brain evolved to control movements and thereby achieve biological goals, including procreation, harm avoidance, ingestion of essentials, exploration, and energy economics. To cope with changing conditions, early vertebrates developed – and their descendants inherited – the ability to expand their innate repertoire of motor capabilities. This facility, called motor skill learning, increased their ability to attain biological goals through interaction with the environment. What motor skill learning did for our ancestors 500 Ma, it does for us today.

Some motor skills involve a single movement; others require movement sequences. These two types of motor skills are described in the following sections.

Skilled Single Movements

Single skilled movements can involve any skeletal muscles, but most research centers on reaching, pointing, or throwing with the arm and hand. The target of movement might come from memory, but often it arises from sensory receptors. In that case, the motor system must transform sensory information about the target's location into the motor commands necessary to bring to a target either the hand, tools held in the hand, or objects thrown from the hand. The motor system learns these computations, called perceptual–motor or sensorimotor mappings, by adjusting them from movement to movement based on errors and uses these mappings and feedback to adjust ongoing movements.

Types of Perceptual–Motor Mappings

Perceptual–motor learning includes both standard and nonstandard mappings. Because vision dominates the sensory life of primates, including humans, most research deals with visuomotor mappings. In standard mapping, visible objects serve as the targets of movement. In nonstandard mapping, visual inputs provide information about targets, but movements are aimed elsewhere. One type of nonstandard mapping, called transformational mapping, requires an algorithm to transform a cue's location into that of the target. For example, a ball should be aimed at a moving target's projected location, not its current one. In another type of nonstandard mapping, called arbitrary mapping, a symbolic cue specifies the goal. Learning to stop at a red light is an example of arbitrary mapping. Figure 1 (pink shading) illustrates these three kinds of perceptual–motor mappings, along with some of the brain regions thought to play key roles in computing them.

Motor Plans

Reaching, pointing, and throwing require changes in the hand's location relative to the rest of the body, mostly because of movements around the shoulder, elbow, and wrist joints. Figure 1(b) illustrates someone ready to reach for a coffee cup. He might be able to see his hand, as illustrated, but vision of the hand's starting location is not necessary to compute its initial position. Typically, people fixate on the target (dashed lines), not on the hand, so proprioceptors provide the best signals for estimating the hand's initial position (Figure 1(a), green shading). This estimate depends on motor learning: the experience gained by relating viewed hand position to proprioceptive inputs over many movements. Prisms can perturb these relationships, which leads to misalignments of viewed and proprioceptively sensed hand position. These misalignments, in turn, lead to reaching errors. The estimated initial hand position can then be brought back into alignment by the practice gained in several reaches, which eliminates the errors. Once the prisms are removed, the misalignment returns and an error of opposite sign, called an aftereffect, appears. This error, too, diminishes with practice.

Once the motor system has computed the target's location and the hand's starting position, it can develop a plan for moving the limb. The difference between initial hand position and target location defines a vector, called the difference vector, which has distance and direction as its dimensions. A net movement of the hand by that distance in that direction will bring it to the target. Neurophysiological research in monkeys indicates that parts of the posterior parietal cortex (PPC) play the largest role in computing target location, initial hand position, and the difference vector.

The difference vector is an important aspect of motor planning, but not the only one. Much of the literature on perceptual–motor learning explores the principles that guide the generation of motor

Before feedback arrives: computation of motor plan based on previous experience

Figure 1 (a) Model of skilled reaching. Each parallelogram represents a neural network, with some of their brain regions indicated nearby. One network (pink parallelogram) aligns proprioceptive input with the viewed position of the hand. A second network (white parallelogram) computes the difference between the current hand position and that of the target, called the difference vector. The next-state planner (black parallelogram) produces the next incremental change in hand position needed to reach the target in accord with a control policy, such as minimizing endpoint error. A kinematics map (orange parallelogram) is an internal model that learns to transform this next-state vector into the desired joint-angle changes. Finally, the dynamics map transforms the desired joint-angle changes into the required torques and forces. Abbreviations: BG, basal ganglia; CB, cerebellum; CMAs, cingulate motor areas; dv, difference vector; IT, inferior temporal cortex; PFv+o, ventral and orbital prefrontal cortex; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; PPC, posterior parietal cortex; pSMA, pre-supplementary motor area; SMA, supplementary motor area; SSC, somatosensory cortex. (b) A person planning to grasp a coffee cup. The arm's configuration after the reaching movement appears in white. Dashed line: orientation of gaze. commands for a given difference vector. These ideas focus on constraining redundant means of reaching a target or minimizing the jerkiness of movements, coactivation of antagonist muscles, endpoint or intermediate-point errors, or curvature in visual coordinates. The dominant factors appear to be the last two. Indeed, among the others, some properties said to be 'invariant' often vary dramatically depending on a person's intentions. Furthermore, according to Fitts' law, the motor system must trade-off speed and accuracy. So the coffee drinker in Figure 1 cannot move his hand as fast as possible to get the coffee. Variations in motor commands for a given difference vector, called control policies, compose crucial aspects of motor skills.

Motor Commands

The difference vector represents the desired displacement of the hand. Neural networks must convert this information into command signals that cause the joint-angle changes and forces necessary to reach the target. The former computation is called inverse kinematics, the latter, inverse dynamics (Figure 1). The neural networks that compute these transforms implement the kinematics and dynamics maps that underlie, respectively, inverse kinematics and inverse dynamics. Inverse models of this kind are one kind of internal model: a neural representation of how the body interacts with the world and itself. Another kind, called a forward model, is taken up below. An inverse model uses desired movements to compute motor commands; a forward model uses motor commands to compute predicted movements.

The mappings computed by internal models must be learned. For example, prisms perturb kinematics maps, as noted above for proprioceptively sensed hand position. They cause reaching errors by altering the visual consequences of movements. Likewise, dynamics maps can be perturbed by imposing forces on the limb during movement. These networks adapt

their mappings on a movement-to-movement basis to reduce errors. Indeed, every movement teaches the motor system something about the motor commands needed for future movements.

Neuronal Mechanisms

Neurophysiological and neuroimaging research indicates that in addition to the cerebellum, the PPC and certain nonprimary motor areas, such as the dorsal and ventral premotor cortex, compute kinematics maps, while the primary motor area (M1) and the supplementary motor area (SMA) compute dynamics maps.

Neurons in all of these structures have tuning curves, which peak at a preferred direction (PD) of movement. A population of neurons with different PDs can serve as the motor primitives for representing motor parameters. These computational components are also known as basis functions. The neuronal mechanisms of motor skill learning involve changes in both the PDs of the tuning curves, which encode a parametric value, and their width, which reflects encoding sensitivity. The encoding sensitivity affects how errors generalize from one kind of movement to another.

A common perturbation of the kinematics map, called the 'rotation' task, involves the use of a mouse or joystick to control a cursor on a computer screen. Initially, when the mouse moves left, the cursor also moves left, when the mouse moves away from the body, the cursor moves up, and likewise for all directions. After a perturbation of 90°, for example, when the mouse moves left, the cursor moves up. Therefore, to use the mouse–cursor tool to reach an upward target, subjects must learn to move the mouse to the left rather than away from the body. Training on the 'rotation' task can be for one direction or for several. After training on one direction of movement, humans and monkeys show limited generalization of learning. They generalize to other directions as a function of angular distance from the training direction, with a fall-off similar to the width of M1 tuning curves (and those elsewhere). As noted above, computational models suggest that the width of these tuning curves – their encoding sensitivity – could account for this pattern of generalization. Furthermore, changes in tuning-curve width might contribute to skill learning. After training, changes in M1 activity, which consist of narrowing the width of its tuning curves, occur only in neurons with PDs close to the training direction. By virtue of this increase in encoding sensitivity, M1 neurons contain more information about movement direction after learning, and this greater information might enhance motor skill.

The activity of M1 neurons also changes during the learning of new dynamics maps (**Figure 2**). About one-fifth of M1 neurons change their PDs during adaptation to a force field (shaded area), but return to their baseline properties after removal of those forces, called the null field. For another fifth of the cells, their PD changes during the force-adaptation period, but they maintain those changes after monkeys readapt to the null field (**Figure 2(c)**). Finally, another fifth of the cells change their PD after a return to the null field, not during force adaptation (**Figure 2(d)**). Because, as a population, the changes depicted in **Figures 2(c) and 2(d)** balance, the population shows no net change in PD. Nevertheless, over 40% of M1 neurons have changes in PD that outlast the adaptation period. Thus, the sum of M1 output remains unchanged, which supports the computation of movement direction in the null field, yet the network as a whole retains an influence of monkey's adaptation to the force field.

In addition to M1, the cerebellum plays a central role in learning dynamics maps. Studies of force-field adaptation suggest a reliance on motor primitives that resemble the tuning curves of cerebellar Purkinje cells. These neurons have two peaks in their tuning curves, one for hand velocity in the cell's PD, and a smaller peak for the opposite direction. This tuning property could account for the transfer of learning from a practiced movement direction to the opposite direction. Furthermore, patients with cerebellar disease adapt poorly, if at all, to forces imposed on the limb during a movement. Unlike healthy subjects (**Figures 3(a) and 3(c)**, blue), who decrease their reaching errors as they gain experience in counteracting imposed forces, cerebellar patients continue to make errors without noticeable improvement (**Figures 3(a) and 3(b)**, green). Cerebellar diseases also affect the learning of other motor skills, including mirror writing and learning to copy shapes rapidly.

It seems likely that sometimes the motor system uses multiple controllers that can be selected and switched according to task context. Adapting to two force fields based on contextual cues, such as color, may be impossible under certain circumstances, but when random and frequent switching of context occurs, people can learn multiple, parallel skills, based on mappings cued by context. Learning a prism skill is also possible. Given a contextual cue, people can immediately call up the kinematic mappings needed for a given prism-induced displacement of the visual field.

Adjusting Ongoing Movements

In addition to adjusting motor commands from movement to movement, the motor system can adjust

Figure 2 Perturbation of the dynamics map: (a) The monkey grasps a handle, and motors in that handle exert variable forces during a reaching movement. The monkey reaches one of eight directions from center to a visible target. In a baseline period, the motors do not apply forces, a condition called the 'null field.' (b) After practice in the force field, the monkey makes straighter movements, demonstrating the learning of a new dynamics map (see **Figure 1**). When the force disappears, aftereffects occur, which also decrement with practice (early washout vs. late washout). (c, d) The activity of two neurons in the primary motor cortex (M1). Activity for each of the eight movement directions is depicted in polar coordinates (blue), with the cell's PD in red. (c) As the monkey adapts to the clockwise force, the PD of one M1 cell shifts by approximately 30° clockwise. As a population, PDs in M1 cells shift by 16°. After a return to the null field (washout), the monkey readapts as the kinematics and dynamics return to baseline conditions. If M1 neurons processed only movement dynamics, all PDs should return to baseline in the washout condition, and many do. But in this and other M1 neurons, the changes in PD outlast the perturbation. (d) In a different M1 cell, a shift in PD occurs during readaptation to the null field. Overall, 41% of M1 cells exhibit the properties shown in (c, d), in equal proportions. (a, c, d) Adapted from Li CS, Padoa-Schioppa C, and Bizzi E (2001) Neuronal correlates of motor performance and motor learning in the primary motor cortex of monkeys adapting to an external force field. *Neuron* 30: 593–607, with permission from Elsevier. (b) Adapted from Padoa-Schioppa C, Li CS, and Bizzi E (2004) Neuronal activity in the supplementary motor area of monkeys adapting to a new dynamic environment. *Journal of Neurophysiology* 91: 449–473, with permission from American Physiology Society.

ongoing movements. Adjustments become necessary if movements begin inaccurately, if the target moves during a reach, or if some force perturbs the limb, among other reasons. If the pencil in **Figure 4** rolls away during the movement, an updated computation of the difference vector will restore a trajectory toward the target.

Much like some of the sequence learning discussed below, this kind of online correction can occur without conscious awareness. For instance, when people reach to a target that jumps to a new location during a movement, they often deny that it jumped at all. When told to suppress a movement to a target if it jumps, they cannot do so. It appears that a mechanism like that shown in **Figure 4** functions something like the automatic pilot of an airplane, adjusting to perturbations of the limb or unexpected movements of the target with fast, corrective actions. Patients with PPC lesions lack these autopilot adjustments, as do healthy people when transcranial magnetic stimulation disrupts PPC activity.

According to the model illustrated in **Figure 4**, the ability to adjust ongoing movements depends on a forward model, which predicts proprioceptively sensed hand movements based on ongoing motor commands, called efference copy. In essence, they predict where the hand should be at a given time after a motor command, taking feedback delays into account. Why should the motor system predict the sensory consequences of motor commands? First, a

Figure 3 Effects of cerebellar disease on motor learning: (a) Learning index for movement-to-movement learning of force fields. Prior to imposing a complex pattern of forces, participants make straight movements to visible targets in a null field (N). The participants then learn to make straight movements in one force field, of pattern A, which is the same as used in **Figure 2**. Subjects practice in field A for three blocks of trials. HD (red) and control (blue) participants learn to counteract the imposed forces and return to making relatively straight movements, indicated by the relatively high learning index. This learning does not transfer to the opposite pattern of forces, pattern B. Patients with cerebellar damage (green) show very little movement-to-movement learning. (b) Data leading to B for cerebellar patients. After four blocks of movements in the null field, the patients practiced for three blocks in the A field. Once every seven movements, a catch trial (dashed line) occurred in which the null field was presented. The lack of change in error and the lack of aftereffects in catch trials indicates a severe learning deficit. (c) HD (red) patients and asymptomatic carriers of gene for HD (orange) learn as effectively as control subjects, as indicated by the decrease in error for the second and third blocks in the A field and the aftereffects on the corresponding catch trials. Reprinted from Smith MA and Shadmehr R (2005) Intact ability to learn internal models of arm dynamics in Huntington's disease but not cerebellar degeneration. *Journal of Neurophysiology* 93: 2809–2821, with permission from the American Physiological Society.

forward model allows the motor system to monitor motor output and predict the sensory state of the limb ahead of the actual sensory feedback. If neural noise, for example, causes the motor system to generate erroneous motor commands, they can be corrected before sensory feedback arrives. Second, once feedback arrives, the motor system has two sources of information to guide action: the predicted state of the limb and the sensed state. By combining them, it acquires a more accurate (less noisy) estimate of limb state than it can from either source alone.

Research on Huntington's disease (HD) suggests that parts of the basal ganglia contribute crucially to these computations. Although HD involves more than the basal ganglia, it is most involved in the disease, especially in its early phases. Even earlier, asymptomatic carriers of the HD gene have a subtle reaching abnormality that worsens once symptoms appear. Unlike cerebellar patients (**Figures 3(a) and 3(b)**, green), HD gene carriers (**Figures 3(a) and 3(c)**, orange) and symptomatic HD patients (**Figures 3(a) and 3(c)**, red) learn to correct reaching errors in a force field as well as controls (**Figures 3(a) and 3(c)**, blue). Instead, they have problems adjusting ongoing movements based on error feedback, and make jerky movements as they approach the target.

In summary, neural networks involving the cerebellum, motor cortex, and PPC adjust perceptual–motor mappings for the next movement based on the errors encountered on previous ones, whereas networks involving the basal ganglia and cortex adjust ongoing movements.

Sequential Movements

Although it takes considerable skill to make a single movement with spatial and temporal accuracy, the epitome of skilled behavior – exemplified by writing, speaking, typing, and dancing – entails learning a limited set of movements and then combining them into new sequences. It might seem that generating a sequence of movements need not differ fundamentally from generating a single movement – the motor system could simply select a series of movement targets, in turn. But the motor system does not plan sequences in this manner. If it did, then it would complete the first movement in a sequence before planning and completing the next. Skilled movements occur much too fast for this sort of planning. A skilled typist initiates the second keystroke of a sequence long before the motor system receives any proprioceptive feedback about the first. The fact that

Figure 4 Forward models predict feedback and learn to correct ongoing movements. Format as in **Figure 1**, but incorporating feedback and the prediction of feedback. Forward models compute the movement that should occur given a motor command. the time to make the first movement in a sequence increases with sequence length further demonstrates that the motor system plans sequences coherently, not piecemeal.

Perhaps the most fundamental problem to be solved in sequencing lies at its heart: the ability to combine a limited set of elements into a limitless set of motor acts. But how then can the motor system distinguish sequences? For example, how can it plan to type 'pig' and 'gap' and do both efficiently? In one case, 'g' follows 'p,' and in the other, 'p' follows 'g.' Simple associations chained together will not suffice: the motor system needs some mechanism for sequence planning, and this mechanism makes sequencing powerful.

Control of Sequencing

There is a considerable overlap in the neural machinery that supports moment-to-moment control of motor sequencing and that which supports sequence learning. **Figure 5** shows a heuristic representation of a linear organization of cortical areas that contribute to motor sequencing. Sequencing is initiated by the dorsolateral prefrontal cortex (DLPFC), and perhaps other prefrontal areas, which may be considered to employ more cognitive representations, meaning that they are flexible in terms of how sequencing behavior may be expressed. The hierarchy of cortical areas culminates in M1, which employs the least flexible representation, meaning that sequencing is closely tied to motor expression in terms of force production.

Figure 5 A schematic of cortical structures that underlie sequence learning. The darker regions are not available to awareness, but lighter regions are. Explicit learning originates in the DLPFC, and is expressed via the supplementary motor area (SMA), the pre-SMA, and the motor cortex. The red arrows show that, with practice, motor areas show learning consistent with the explicit sequence – that is, automaticity is developed. Implicit motor sequence learning progresses in the opposite direction, beginning in motor areas. According to this model, with sufficient practice this information propagates to prefrontal cortex and so becomes accessible to awareness. Reprinted from Ashe J, Lungu OV, Basford AT, and Lu X (2006) Cortical control of motor sequences. *Current Opinion in Neurobiology* 16: 213–221, with permission from Elsevier.

Among the areas illustrated in Figure 5, DLPFC has long been implicated in temporal order, dating to neurological observations of sequencing deficits in patients with frontal lesions. Neurophysiological studies show that these symptoms cannot be accounted for solely on the basis of dysfunction of an executive planner or deficits in working memory: some DLPFC neurons code temporal order, others code object identity, and yet others integrate object and order information. The pre-supplementary motor area (pre-SMA) receives prominent projections from DLPFC and sends projections to the SMA. There is overlap in the functionality of the pre-SMA and SMA; both contain neurons that code ordinal information (e.g., the second movement in the sequence, irrespective of the specific movement), neurons that code sequence initiation or the transition from one movement to another, and neurons that code a specific movement, but only for a particular sequence. For example, some cells become active when a monkey will push a lever, but only when it follows a pulling movement (Figure 6). Pre-SMA shows a higher proportion of neurons for order, initiation and transition, and the SMA for specific movement pairs, such as pull–push. Striatal neurons show similar properties, as might be expected due to the substantial projections from SMA and pre-SMA to the striatum, and projections that loop back to these cortical areas from striatum, via other basal ganglia structures and the thalamus. The SMA also projects to M1, which has recently been shown to be sensitive to sequencing. Activity patterns for simple movements change in M1 depending on the sequence context, and reversible blockade affects sequence production while having little impact on single movements.

Sequence Learning Tasks

Most of the work on motor sequencing has examined sequencing of spatial responses, and much of it has used a model task: the serial reaction time task (SRTT). The subject sits before a computer monitor, with the middle and index finger of each hand resting lightly on four response buttons. On each trial, a stimulus appears in one of four possible locations, and the subject presses the button directly below the stimulus. The stimulus disappears, and after a brief

Figure 6 A SMA neuron that is active before a push movement, but only if the monkey has just completed a pull movement. In the raster display, each row shows the neuron's activity for one trial, the plus represents movement initiation, and each dot represents one discharge of the neuron. The histogram indicates the activity average. Reprinted from Shima K and Tanji J (2000) Neuronal activity in the supplementary and presupplementary motor areas for temporal organization of multiple movements. *Journal of Neurophysiology* 84: 2148–2160, with permission from the American Physiological Society.

delay a new stimulus appears. This procedure continues for several hundred trials. For some trials the stimuli appear randomly, and for others they appear in a repeating sequence, typically 12 units long. This task has been used in hundreds of sequencing experiments because of its simplicity, and because it can, with little modification, be used to test two types of sequence learning: implicit or explicit. In implicit sequence learning, the subject remains unaware that he or she is learning anything. If subjects are not informed about the presence of the sequence, they often remain unaware of it. Nevertheless, their response times to individual stimuli decrease with practice, and increase if the sequence changes. Despite this implicit learning, subjects perform at chance on a recall or recognition test of the sequence. Hence, subjects show behavioral evidence of learning, despite their unawareness of the sequence.

The same task may be used to measure explicit sequence learning, in which the subject is aware of learning the sequence. In this version, the experimenter simply informs the subject that the stimuli appear in a sequence, and encourages the subject to learn it, as a way of responding more quickly. With these instructions, subjects will exhibit sequence learning through faster response times to the sequenced stimuli than to the random stimuli, and will also successfully produce the sequence during a later recall or recognition task.

Tracking tasks have also proven useful in studies of sequencing. In a standard pursuit tracking task, the subject uses a manipulandum to control a cursor, which is to be kept as close as possible to a moving target on a screen. The target appears to move randomly, but a repeating sequence is embedded in the otherwise random movement, as shown in Figure 7. Learning is assessed by comparing tracking error in the sequenced and random segments. Such learning is virtually always implicit and, in this respect, resembles the force adaptation learning illustrated in Figure 2(b).

Implicit Sequence Learning

Behavioral studies indicate that when subjects learn a sequence implicitly, they learn a sequence of targets for the movements. That is, they do not learn the sequence of stimulus locations, nor a sequence of specific motor responses in terms of joint-angle changes or forces. Instead, they learn the sequence of targets to which movements will be made. After

Figure 7 A continuous tracking task: (a) The subject sits before a computer screen with the forearm resting on a lever, capable of movement via shoulder rotation through a 90° arc. Lever movement manipulates a screen cursor, which the subject uses to track a moving target. The target moves in one dimension, from the subject's left to right. (b) Example of target movement on three different trials. Note that the segments for the first and last (third) trials differ (and are random) but the intervening segment repeats for each trial. Reprinted from Boyd LA and Winstein CJ (2004) Cerebellar stroke impairs temporal but not spatial accuracy during implicit motor learning. *Neurorehabilitation and Neural Repair* 18: 134–143, with permission from Sage Publications.

training, the stimulus locations can be changed, or the effectors used to respond can change, without any cost to learning, as long as the sequence of target locations remains the same.

These behavioral data aid in interpreting neuroimaging and neurophysiological studies of implicit sequence learning. Neuroimaging studies of the SRTT and of the tracking task (Figure 7) show consistent activation in four brain regions: the SMA and pre-SMA, striatum, PPC, and cingulate cortex. The PPC represents the sequence of targets in an abstract spatial code (Figure 1, pink shading), and the striatum and SMA represent it in a motor code, consistent with neurophysiological data implicating these structures in motor sequencing. Cingulate cortex may monitor the success of motor prediction, as indicated by the findings that it is especially active during sequence violations and that its activity decreases as the skill develops and errors decrease. Consistent with this interpretation, lesions to SMA or PPC devastate implicit sequence learning. Striatal dysfunction caused by HD or Parkinson's disease also leads to deficits in sequence learning, although only partially, likely because patients in a testable stage of the disease have only incomplete striatal damage.

Cerebellar activation is observed in some neuroimaging studies, and cerebellar patients show drastically impaired implicit sequence learning. But behavioral paradigms that separate learning and the behavioral expression of learning in the SRTT show cerebellar activation associated with the latter, not the former. This interpretation is consistent with the putative role of the cerebellum in timing; it may calculate when the next position in the sequence will appear, which facilitates motor preparation, but not the identity of the next sequence element for which to prepare. Also relevant are data from the tracking task. Cerebellar patients are impaired on this task, but only on the timing component; the spatial response profile shows normal learning of the sequence, but their responses lag behind the target and the timing of responses is variable. Thus, the cerebellum appears to support the behavioral expression of implicit sequence learning, but does not appear to be the site of learning the specific motor commands.

Explicit Sequence Learning

Explicit sequence learning has been examined in the SRTT, and in conceptually similar studies in which subjects repeatedly perform a simple sequence of finger-thumb opposition movements. Behavioral studies show that learning in these explicit sequencing tasks is based on knowledge of the stimulus locations, in contrast to implicit sequences, which are learned as sequences of target locations.

Neuroimaging studies show consistent activation in PPC and in DLFPC. These two regions are associated with spatial working memory, attention, and goal selection, consistent with the interpretation that explicit sequence learning is not tied to the motor system, at least early in training. Explicit learning is open to flexible expression, for example through verbal responses or through motor responses different than those used in training. Structures linked to explicit learning, such as the hippocampus and other parts of the medial temporal lobe, are also active. Furthermore, amnesic patients, who often have damage somewhere in the white or gray matter of the medial temporal lobe, are profoundly impaired in explicit sequence learning, although they learn implicit sequences normally.

As expected from the discussion above, the SMA and pre-SMA are also consistently active in neuroimaging studies of explicit sequence learning. Although

no one knows whether monkeys learn these tasks explicitly or implicitly, neurophysiological studies in monkeys show that the pre-SMA is especially active during the learning of new sequences, and that once the sequence is well learned, some pre-SMA neurons discharge only at the initiation of the sequence. Furthermore, functional blockade of pre-SMA impairs the learning of new sequences by trial and error. Thus, pre-SMA activity in monkeys has some of the properties to be expected for explicit sequence learning.

Practice-Related Changes

A salient behavioral consequence of practicing an explicit skill is the decreasing role of attention, and eventual automaticity of behavior. Characterizing the neural changes associated with long-term practice has been difficult because of variation in experimental designs and because behavior changes with training – skills are performed more quickly and with fewer errors – and those changes must be accounted for when interpreting physiological changes. Figure 5, based on neuroimaging studies of long-term sequence learning in humans, depicts a rough summary of the pattern that has emerged. The red arrows represent the progression of explicit learning, which DLPFC and other prefrontal areas are thought to underlie. With sufficient training, motor areas become tuned to the specifics of the explicitly learned sequence, and then the contribution of prefrontal cortex diminishes. The blue arrows represent changes in implicit learning, which begins in motor areas, and with sufficient practice may propagate to prefrontal cortex, which presumably contributes to awareness of the sequence.

As skilled performance becomes more automatic, attentional resources can be directed to other matters, such as perceptual decisions and the choice of future actions. Although the implicit nature of highly practiced skills has led some to consider them as a 'lower' form of learning, the early-twentieth-century mathematician, Alfred North Whitehead (1911), put the matter in its proper perspective when he noted that it was mistaken to "cultivate the habit of thinking of what we are doing. The precise opposite is the case. Civilization advances by extending the number of important operations which we can perform without thinking about them."

Issues

Accurate timing of movements is a key element of most motor skills and includes the ability to coordinate separate elements of an action and to synchronize the action with external cues. For instance, in tennis, good relative timing of stepping and swinging the racquet with the arm results in an accurately directed shot, but this must be synchronized with the approach of the ball. In a music duet, each player produces series of notes timed according to the score but must also maintain relative phase with the other player. In these examples the timed intervals fall in the tens and hundreds of milliseconds range. In the study of motor timing, the issues are defined by seeking answers to important questions: What brain mechanisms support motor timing? Is there evidence of hierarchical timing with more complex temporal patterns represented at higher, cortical levels? Are there different timing systems for paced and unpaced responding? Is there generality of timing across different movement systems or is timing modality specific? How are movements of separate limbs coordinated? How is timing integrated with other aspects of movement such as force?

Experimental Tasks

A common paradigm in the study of motor timing, providing control over interresponse interval, comprises an initial period of paced responding, in which movement events (e.g., tapping the finger on a response button that records the time of each response) are synchronized with a metronome, followed by unpaced tapping at the same rate (see Figure 1(a)). In the paced phase, synchronization error between each tap and corresponding metronome pulse is the main measure of interest. Synchronization error is typically found to exhibit a small lead (negative onset asynchrony). People are very sensitive to changes in synchronization error. For instance, an advance in metronome phase, produced by one metronome interval being longer than the rest, causes a reduction in negative onset asynchrony. This results in compensatory timing adjustment to produce an advance in response phase, even when the metronome phase shift is so small that it is not consciously detectable (Figure 1).

In the unpaced phase of tapping, measures of interest include the mean and variability of the intervals produced. A commonly observed characteristic is that the variability increases with the mean, with the ratio of the standard deviation to the mean (Weber fraction) approximately constant except for an increase as the interval goes to zero, partly due to the positive intercept at zero (see Figure 1(b)). The form of the variability in unpaced responding is also of interest, with successive interresponse intervals commonly exhibiting a short–long pattern (negative lag-one autocorrelation), while, over the longer term, there is often a tendency for drift, producing positive autocorrelation at long lags. In some studies the pacing sequence comprises a rhythmic pattern, rather than all equal intervals (isochronous sequence). In such cases it is found that the longer intervals in the rhythm are more variable than the shorter ones and the overall level of variability is higher than when the same intervals are produced in an isochronous context.

Tapping the finger on a button introduces a clear event, or response, within what might otherwise be a smooth cycle of movement. A variant of the paced–unpaced tapping paradigm is one in which the movements are made with continuously smooth direction change, as in circle drawing or flexing and extending the finger without contact. In the unpaced phase, timing of continuously smooth circling or flex–extend movements are less variable than for discontinuous event-based movements. However, with continuous movements, the synchronization error in the paced phase is greater. Such differences suggest contrasts in the underlying nature of timing, with, for example, corrective adjustment in paced but not in unpaced tapping, but also emphasize the need to document the form of movement when reporting the accuracy of motor timing.

A contrast with timing involving just a single effector is provided by a paradigm focusing on bilateral interlimb coordination, with two effectors moving with specified relative phase. For instance, left and right index fingers might flex concurrently giving 0°, in-phase movements. Or flexion of one digit might be combined with extension of the other, resulting in 180° out-of-phase movements. A characteristic finding is that the stability of relative phase for in-phase movements is greater than for movements at other phases. Another important finding is that the stability of relative phase for out-of-phase movements decreases as frequency increases (the movements are typically paced by a metronome, the rate of which is progressively increased), even to the extent that relative phase undergoes a spontaneous transition to the more stable in-phase movement (see Figure 2).

Figure 1 (a) Response key with time line showing paced (with phase shift) and unpaced (interval) tapping phases. A metronome phase delay (at red pulse marker) results in rapid compensation in tapping. (b) Increase in interresponse interval (IRI) variability with the mean interval.

Figure 2 Isofrequency phase transition.

The form of movement in interlimb coordination studies is usually smoothly continuous (e.g., making circles in the air). It is possible that synchronization between two effectors is difficult and control of phase is unstable, because there are no discrete events in the two effectors that can be used to monitor produced phase. If event structure is introduced (for instance, by requiring tapping on a surface), relative phase becomes more stable. This effect, which is referred to as anchoring, presumably relates to improved synchronization seen with discontinuous, event-based tapping, compared to circling. A variant of the interlimb coordination task is one in which the two limbs move at different frequencies. In this case certain frequency combinations are found to be more stable than others (e.g., 2 against 3 is more stable than 4 against 5). Increasing the rate of responding tends to result in transitions from less stable to more stable frequency combinations.

Models

A widely cited theoretical account of the variability of unpaced interresponse intervals in single-effector timing assumes dissociable sources of variance due to central timing and the implementation of successive responses (see Figure 3). This two-level account separates out the variance contributions of timer intervals and delays in motor implementation, and predicts the negative lag-one autocorrelation generally seen in unpaced interresponse interval data, although this may be partly masked by drift in central timing.

A second focus of motor timing models has been the nature of the coupling, which maintains relative phase between motor events and the metronome in the paced tapping task, or between movement trajectories produced by each of the two limbs in the interlimb coordination task. In the former, linear first-order correction gives a good account of the data while nonlinear coupled oscillator models provide important insights into the latter (see Figures 3(b) and 3(c)). In the coupled oscillator models a contrast is made between instantaneous and delayed linkage between effector states. Instantaneous linkage is suggestive of central origin of the coupling – for instance, due to motor command interactions. Coupling that includes a delay between effector states, which might be identified with feedback delays, is consistent with placing the origin of coupling effects at the level of motor consequences rather than at the motor command level.

The form of the central timer or oscillator has been a matter of debate. In one perspective, a neural pulse source is assumed and motor timing depends on comparing an accumulated count with a remembered standard (see Figure 4(a)). If the neural event source is modeled by a Poisson process (random times between events), the variance of the interval being timed increases linearly with the mean. However, in motor timing it is usually found that standard deviation, rather than variance, increases with the mean (recall Figure 1(b)), and this suggests an additional source of variance that is rate dependent. For instance, the counter mechanism might be error-prone in proportion to the total count, perhaps due to inattention. Consistent with a role for attention in the central timer is the finding that performance of a secondary task

Figure 3 (a) Wing and Kristofferson model of timing: interresponse intervals in unpaced responding. (b) Linear phase correction model. (c) Coupled (two-level) oscillator model (including implementation delay to account for negative lag-one autocorrelation). The Haken–Kelso–Bunz (HKB) equation expresses the dynamics of interlimb rhythmic coordination. (b) From Vorberg D and Wing AM (1996) Modelling variability and dependence in timing. In: Heuer H and Keele S (eds.) *Handbook of Perception and Action*, vol. 2, pp. 181–262. New York: Academic Press.

(e.g., solving anagrams) reduces timer accuracy, but not motor implementation variability, during tapping. Other alternatives to accumulative counter-based timing have been proposed, including models involving sets of oscillators in which a combination of oscillators approximates the target interval or timing based on the spatial spread of activation, with longer intervals represented by greater neural distance.

Lesion Studies

Given various models of motor timing, a key question concerns how their component functions map onto brain structures. In this section and the next, we consider neural bases for timing from two perspectives, lesion and brain activation studies. In both cases we examine the extent to which motor timing functions can be localized to individual brain regions or networks of regions. Unpaced tapping is more variable in various neurological disorders, including Parkinson's disease (PD), cerebellar disorders, and hemiparetic stroke. Comparison of these three groups has indicated that the central timer is more variable in cerebellar disease, whereas motor implementation is more variable in PD and stroke (see Figure 5(a)). Another study revealed a double dissociation in timing deficits exhibited by cerebellar patients with medial versus lateral lesions, the former having elevated implementation variability and the latter having increased timer variability (Figure 5(b)). However, the reliability of cerebellar timing deficits is a matter of current debate, and not all classes of timing are affected by cerebellar disease. Patients with cerebellar lesions are selectively impaired on motor timing tasks with discontinuous movements such as tapping, but are not affected in circling movements that lack definite event structure. Other studies have demonstrated elevated timer variability, and no evidence of increased variability of motor implementation, in impaired basal ganglia function associated with PD and in right frontal cortical stroke. Thus, the suggestion that there is a clear mapping of clock timer variability and motor variability onto different brain structures remains contentious.

Figure 4 (a) Counter model of the timer. (b) Compared to baseline, concurrent secondary task increases timer, not motor implementation variance. (a) From Treisman and Gibbon. (b) From Sergent et al. (1993).

Figure 5 (a) Increased timer variability in study participants with cerebellar damage, compared to those with Parkinson's disease (PD) and stroke. (b) Medial vs. lateral cerebellar differences. (c) Phase correction in Parkinson's disease vs. cerebellar impairment. (a, b) From Ivry and Keele (1989). (c) After Diedrichsen et al.

So far we have focused on deficits in motor timing in unpaced responding. Maintenance of phase in paced tapping has also been investigated in cases of neurological disorders. Cerebellar patients exhibit larger clock variability, whereas PD patients show weaker error correction together with larger negative onset asynchrony (see Figure 5(c)). In an interesting single case study, a musician with impaired expressive and receptive music abilities following right temporoparietal stroke showed more variable timing but normal motor implementation. There was evidence of stronger correction of phase errors between responses and metronome pulses. This might have been due to strategic adaptation to impaired memory for temporal interval, or it may have reflected compensation for loss of tempo, evidenced as an increased tendency to drift in unpaced timing.

Transcranial magnetic stimulation (TMS) affords a means of introducing temporary disruption in cortical processing. In studies of motor timing this has been used, both in single-pulse TMS mode, delivered at various phases with respect to the tapping movements, and with repetitive stimulation (rTMS), using tests before and after to determine temporary disruptive effects on motor timing. rTMS over primary motor cortex reduces the phase lead (negative-onset asynchrony) in paced responding but, surprisingly, has no effect on the response to phase shift (see Figure 6). This suggests that these two aspects of paced responding reflect different underlying mechanisms. One possible interpretation of the changed asynchrony is that the interval being produced by the central timer is lengthened. Single-pulse TMS over motor cortex during unpaced tapping causes selective effects

Figure 6 (a) Baseline, but not correction, affected by repetitive transcranial magnetic stimulation. (b) Motor implementation affected by single-pulse transcranial magnetic stimulation (TMS); timer variance not affected. (a) From Doumas. (b) From Verstynen.

on motor implementation but not timer variability (see Figure 6(b)).

Motor impairments in neurological disorders are often lateralized to a marked degree. For example, a patient with a left cortical stroke will show impairment of movement of the right (contralesional) limbs, whereas the deficit following a cerebellar stroke is on the same (ipsilesional) side. The motor symptoms of PD are typically quite lateralized, particularly in the early to moderate stages of disease that are most commonly studied. This has a methodological benefit for studies of motor timing in that each participant can serve as her own control. Thus, the affected side can be compared with the unaffected (or less affected) side. More importantly, such lateralization of motor timing function leads to the conclusion that there are two separate timing systems, one for either side of the body. It is then interesting to note that, in patients with lateralized lesions, bilaterally simultaneous movements result in timing that is intermediate between each side alone. This indicates that multilimb integrative processes operate in motor timing. Multisegment integrative effects have also been reported in normal participants, with two limbs showing less variable timing compared to either limb alone, an effect attributed to statistical benefits arising from cumulating the output of separate timers.

Patients with missing or incomplete corpus callosal connections between the two cerebral hemispheres also show a reduction in variance with bilateral movements, suggesting that subcortical, rather than cortically interconnected, structures support integration of the timers. Interestingly, this bilateral timing advantage depends on the movements having an event structure and disappears if the movements are continuous, again suggesting two distinct classes of motor timing behavior. From this one may infer that discrete movements are coupled at a subcortical level, whereas corticocortical connections underpin the coupling of continuous movements. In this context it is of interest that patients with left parietal lesions show marked difficulty in synchronizing their hands in making antiphase circling movements, which may rely on corticocortical connections.

As noted earlier, patients with PD may show impairment in timing actions with a single limb. The administration of drugs that enhance or depress dopaminergic neural transmission affects timing functions in healthy volunteers. For example, the dopamine antagonist haloperidol impairs perception of timing intervals of 500 ms or less. The most prominent deficit in PD is in dopaminergic innervation of the striatum by the substantia nigra. The striatum is that part of the basal ganglia that receives the largest input from the cerebral cortex. Therefore it is of interest to review studies of bilateral coordination in PD. There is general agreement that patients have great difficulty in maintaining antiphase movements of the arms, whereas there may be little or no impairment of in-phase movements, thus PD patients may be considered to show pathologically strong coupling between the sources of control for movements of each side.

It is interesting to compare the performance of PD patients with that of patients with Huntington's disease (HD). In the latter, the major pathology falls in the striatum rather than in the substantia nigra, and the dopaminergic innervation of the striatum from the substantia nigra is intact. Patients with HD produce bimanual cyclical movements with lower accuracy and greater variability than do controls. They are unable to produce antiphase movements, generating in-phase movements instead. Interestingly, the same study reveals a similar pattern in PD patients; however, the performance of PD, but not HD, patients during in-phase movements improves with an external auditory

pacing signal. One might speculate that the dopaminergic nigrostriatal system plays a specific role in conveying external timing signals to the striatum.

A lesion affecting one hemisphere of the cerebellum causes ipsilateral limb ataxia. Phase relationships between pairs of limbs during cyclical in-phase and antiphase movements have been investigated in a cerebellar patient with left arm and leg ataxia (see Figure 7). The phase relationships between the unaffected right arm and leg were normal, as expected. When one unaffected and one affected limb were moved together (the 'diagonal' conditions), the phase relationships were close to normal. However, the mean relative phase and its variability were very high when moving the left arm and left leg together. One possible explanation for these findings is that because the patient was unable to generate accurate timing signals for the left side, then maintenance of an accurate and stable phase relation between the left limbs was impossible, whereas in the diagonal conditions the right-sided timing signal was able to support both sides.

In summary, the human lesion literature suggests that a widespread network of cortical and, critically, subcortical areas is involved in motor timing. One controversial claim is that the cerebellum has an important role as a central timer, for both paced and unpaced actions. This may only be true for discontinuous movements, in which there are discrete motor events. In contrast, impaired performance following cortical and basal ganglia damage has been attributed to variability in motor implementation. There is evidence for largely independent timers for the two sides of the body; integration between the two sides may rely more on subcortical interconnections for discrete movements, and callosal connections for continuous movements. One interesting idea is that damage to the basal ganglia may result in pathologically strong coupling between the two sides. Comparison of PD and HD raises the possibility that the dopaminergic nigrostriatal pathway may be important in paced movements. With the marked exception of cerebellar studies, there has been little patient work contrasting discontinuous and continuous movements, which may well rely on different timing mechanisms.

Brain Activation Studies

One of the earliest brain activation (functional magnetic resonance imaging) study of motor timing involved paced followed by unpaced responding. The results indicated that the two modes of tapping draw on partially separate networks in the brain, with the network for continuation including that for synchronization as a subset. Increased activation when tapping at 300 or 600 ms with the right hand, compared to rest, involved right cerebellum, left sensorimotor cortex, and right superior temporal gyrus in both paced and unpaced phases of the task (see Figure 8). In addition, during unpaced, but not during paced, responding, activation was observed in the right inferior frontal gyrus, supplementary motor area (SMA), putamen, and ventrolateral (motor) thalamus. These results lead to the suggestion of a contrast between 'implicit' timing, in keeping pace with the metronome, and 'explicit' timing, in continuation. The latter was assumed to involve processes to sustain an auditory working memory representation of the target interval, based on right inferior frontal gyrus

linked to right superior temporal gyrus, plus explicit timing control based on SMA, putamen, and ventrolateral thalamus.

A recent imaging study of motor timing emphasized similarities rather than differences between paced and unpaced tapping. Participants were asked to tap in phase (synchronize) or in antiphase (syncopate) with a metronome and then to continue with unpaced tapping after the metronome stopped. The results showed that activation was more widespread for syncopation than for synchronization, including increased activity in SMA, left premotor area (PMA), right thalamus, bilateral inferior frontal gyri, and cerebellum. Interestingly, there were no differences between the paced and unpaced phases, with the exception that auditory temporal cortex was not active in the absence of the metronome. That is, the difference between synchronized and syncopate tasks persisted into the unpaced phase, even though in this phase the movements were indistinguishable. It is intriguing that the brain state in unpaced responding should so closely reflect those in the paced phase, and it suggests that mental structures that are set up during pacing are preserved in unpaced responding. This might correspond to a subjective feel of swing that, set up by the offbeat syncopate task, is preserved even when the metronome stops.

Several imaging studies have sought to determine the neural underpinnings of sequential information in combination with motor timing. One important dimension of sequential complexity is rhythm, in which grouping of motor events derives from patterning of intervals. Given that rhythmic sequences are more complex than are equal-interval sequences, it is interesting to note that the cerebellum, already implicated in equal-interval timing, shows decreasing contribution with advancing skill level in rhythm production. Thus, in a study which tracked activation over several days of learning a temporal pattern, cerebellar activation progressively declined. In another study the temporal patterns were learned prior to the brain imaging in order to identify parametric dependence of activity on complexity of the rhythm. Participants tapped six different temporal patterns that varied in complexity but were matched in overall frequency of responding. Activations in several regions, including bilateral SMA and PMA, and right dorsolateral prefrontal and motor cortices, were observed to be correlated with rhythm complexity in the paced phase (and in a preparatory phase before that), but no areas of correlated activation were observed in unpaced tapping. This difference may have reflected preparatory processes in retrieval and setting up of the correct time program in the initial phases of paced responding, which then ran with lower attention demands during unpaced tapping.

A rhythm conveys a sense of grouping among responses in an otherwise undifferentiated event series. Such grouping can be defined by patterning of the force used in responding (e.g., low and high) as well as by patterning of the time intervals (e.g., short and long). In a study evaluating the effect of alternation of force and time, participants produced squeeze responses at equal (600 ms) or alternating (400 and 800 ms) intervals with either equal (12 N) or alternating (8 and 16 N) force (see Figure 9).

Figure 9 Functional magnetic resonance imaging study of alternation of force but not time, showing basal ganglia activation. From Pope.

Analysis of the unpaced phase compared to rest showed activation of M1, SMA, basal ganglia, thalamus, and cerebellum during the production of sequences marked by equal interval and force. Although there was no reliable main effect of alternating interval, these regions exhibited greater activity with the extra demands of responding with alternating force pulses. These data are important in identifying a significant role of the basal ganglia in the control of force and also point to the need to control force in activation studies when the focus is on basal ganglia function in timing (since patterning of force alone is sufficient to activate these structures). Interestingly, one region, right posterior parietal cortex, showed significant activation related to the effect of alternation of force and time, compared to alternation of either force or time.

As noted earlier, the motor timing literature is replete with studies of contrasting in-phase and antiphase bilateral movements, which generally reveal, at higher frequencies, greater variability with antiphase movements and a tendency to switch spontaneously from antiphase to in-phase movements. People can be trained to produce polyrhythms, in which there is a noninteger relationship between the two limbs (e.g., 2:3). In a study that compared in-phase, antiphase, and polyrhythm production during functional magnetic resonance imaging (fMRI), it was shown that the latter two coordination modes activate a much larger network than do in-phase movements. This network included SMA, pre-SMA, inferior parietal gyri, PMA, and the superior temporal gyri, whereas in-phase movement activated the cingulate motor area (CMA) and anterior cerebellum. In addition, polyrhythms activated the posterior cerebellum and part of the CMA. These imaging data are largely in agreement with those derived from lesion studies, in suggesting an extensive frontoparietotemporal network, with strong cerebellar involvement. The imaging studies tend not to emphasize basal ganglia activation, although many of the active cortical areas are strongly interconnected with the basal ganglia.

Magnetoencephalography (MEG) offers greater temporal resolution than does fMRI in assessing changes in cortical activity accompanying polyrhythm production. A recent study reported MEG signal changes suggestive of cross-hemispheric inhibition of coupling during polyrhythm production. A picture is emerging of bilateral coupling of independent timers, for the two sides of the body, which occurs mainly at a subcortical level. The tendency for the two sides to produce similar, in-phase actions most readily must be overcome by intercortical inhibition (mediated by the corpus callosum) in order to produce independent continuous movements of the two arms (for example, fast antiphase movements, or polyrhythms). Participants find making antiphase movements of intermediate difficulty, between the level of difficulty of making in-phase movements and polyrhythms. Patients with PD reliably show difficulty in antiphase movements. These results suggest that the basal ganglia might form part of the subcortical network that supports bimanual coupling. Many of the cortical areas that show activity in antiphase movements project to the basal ganglia. 'Descending' commands from these cortical areas might modulate basal ganglia activity to 'allow' decoupling of the limbs during antiphase and polyrhythm production.

Conclusion

Several themes have emerged in this review of motor timing studies. We have stressed the importance of models to help formalize our approach to motor timing. For example, a general framework in which to approach unpaced timing is the two-level model that allows the experimenter to distinguish variability due to central timer functions (which encompasses a number of processes, including motor programming) from that due to motor implementation variability. Working in this framework, lesions of the (lateral) cerebellum have been implicated in central timing difficulties, whereas motor implementation errors have been associated not only with medial cerebellar damage, but also with cortical and basal ganglia dysfunction. However, the allocation of specific functions to individual brain regions on the basis of human lesion studies remains contentious, and functional imaging studies strongly suggest that networks of cortical and subcortical structures are crucial in timing functions.

It is important to consider in greater detail the type of movement made. One can study paced movements, typically involving synchronization with an external cue (such as a metronome), or unpaced movements in which the participant attempts to continue the movement in the absence of an ongoing cue. An extension of this approach is to compare movements made in synchrony with an external pacer with movements made to syncopate with the beat. Another distinction is that between continuous and discontinuous movements. In each case wide but generally overlapping underlying networks have been demonstrated.

We have also seen evidence of separate timing systems for the two sides of the body. Synchronization of the two may depend on subcortical connections, particularly for discrete movements. Patients with diseases of the basal ganglia (PD being the most extensively studied) show deficits in interlimb coordination when required to make antiphase movements. This may reflect inflexibility in the coupling of the two sides. In contrast, patients with corpus callosal lesions show greater ease than do persons with healthy brains in making independent movements of the two limbs. The corpus callosum may be crucial for inhibiting these interactions to allow the generation of complex patterns such as fast antiphase movements and polyrhythms.

Progress in motor timing will come from a multifaceted approach. Behavioral studies in healthy volunteers and patients with well-defined neurological deficits should be informed by models, and should in turn inform these theoretical accounts. A range of different types of single and multilimb movements should be studied. These same tasks should be used during imaging (with both fMRI and MEG) and with carefully timed application of TMS to disrupt cortical function. In general, imaging studies show extended networks involved in a given task; it is, however, often difficult to determine the precise role or roles of an area by the traditional subtraction techniques (what is active in task B but not A?). Lesion studies can be complementary, but the same set of tasks needs to be used in a range of patient groups in order to make sense of these data.

MPTP Parkinsonism Model

T Wichmann and M R DeLong, Emory University School of Medicine, Atlanta, GA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Recent progress in neuroscience research has led to major insights into the pathophysiologic basis of Parkinson's disease (PD). The availability of suitable animal models, in particular the primate treated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), has been crucial in this progress. This article reviews some of the essential pathologic changes found in PD, gives an overview of the mechanism by which MPTP induces parkinsonism, and summarizes, from a systems perspective, the pathophysiologic concepts that have arisen from the studies carried out in MPTP-treated primates.

Pathologic Substrate in PD

Idiopathic PD is characterized by the cardinal signs of akinesia (impaired movement initiation and poverty of movement), bradykinesia (slowness of movement), muscular rigidity, and tremor at rest. The etiology of PD is most likely multifactorial, with both genetic and environmental factors playing a role. Multiple genetic forms of PD have now been identified, and epidemiologic studies have identified a number of environmental risk factors, such as rural living, consumption of well water, and head injury. The motor features of PD result from degeneration of dopaminergic neurons in the substantia nigra pars compacta (SNc), which project to the striatum and, to a lesser extent, to other basal ganglia nuclei such as the external and internal segments of the globus pallidus (GPe and GPi, respectively), the subthalamic nucleus (STN), and the substantia nigra pars reticulata (SNr). At the time of onset of clinical signs, dopamine loss affects particularly the sensorimotor portion of the striatum, the putamen, resulting in the appearance of motor disturbances early in the disease. In later stages, more-widespread dopamine loss, affecting other regions of the basal ganglia (such as the caudate nucleus and the pallidum) and extrabasal ganglia areas, such as cortex, hypothalamus, and thalamus, may contribute to the clinical manifestations of the disease.

Although dopamine loss is the defining pathologic feature of PD, it is now clear that other brain systems are also affected, even early in the disease. Indeed, recent studies indicate that the earliest pathologic changes occur in the mesenteric plexus of the gut and in the olfactory bulb. The disease appears then to involve brain stem neurons in an ascending fashion, involving the dorsal motor nucleus of the vagus, the nucleus gigantocellularis, the locus coeruleus, and the raphe nuclei before reaching the SNc. Subsequent steps in the progression of the disease involve the amygdala, thalamus, and cerebral cortex. Damage to these extranigral areas may significantly contribute to the nondopaminergic manifestations of the disease, in particular the accompanying anxiety and depression, sleep disturbances, dementia, and autonomic disturbances resulting in orthostatic hypotension, constipation, and urinary problems.

Animal Models of PD

None of the available animal models for parkinsonism faithfully reproduce the progressive pathology and clinical phenotype of human PD. Instead, animal models for PD can be grouped into genetic models and toxin-based models. Genetic models, such as α-synuclein overexpression mice, model the process of neurodegeneration, often without resulting in a convincing clinical phenotype. By contrast, toxin or drug models mimic the consequences of dopamine depletion but generally employ toxins unlikely to be etiologically relevant for human so-called sporadic PD. The MPTP model falls into the latter category of models and is described in detail below. It is one of a family of compounds that can be employed to disturb dopaminergic functions in the brain. Other members of this group are selective dopamine receptor blockers and nonselective catecholamine-depleting agents such as reserpine or tetrabenazine. These agents are used primarily for acute *in vitro* experiments or for studies requiring a reversible dopaminergic deficit. Models produced by toxins that permanently destroy dopaminergic cells more faithfully reproduce the pathology of the human disorder and are often used for *in vivo* studies. In rodents, injections of 6-hydroxydopamine into the SNc or treatment with mitochondrial complex I inhibitors such as rotenone or MPTP can produce oxidative damage to dopaminergic neurons.

Historical Aspects and Clinical Findings

MPTP was first synthesized and described in 1947 by Hoffman LaRoche chemist Albert Ziering as a by-product of the synthesis of the opioid analgesic meperidine

analog 1-methyl 4-phenyl 4-propionoxypiperidine. Starting in the 1950s, MPTP was evaluated in pharmaceutical trials in animals and humans for possible anticholinergic, antihypertensive, and even antiparkinsonian effects. The realization that exposure to MPTP can result in almost instantaneous parkinsonism came after drug addicts became parkinsonian in the early 1980s after having injected themselves with a meperidine analog which was contaminated by MPTP. Acutely after MPTP injections, such individuals experienced euphoria, sometimes associated with disorientation, transient visual illusions, or hallucinations followed by intermittent appendicular jerking movements. Over the next few weeks, this reaction was followed by the gradual development of more-typical parkinsonian features, including slowness of movement, dysarthria, dysphagia, and tremor (which may be asymmetric). In the ensuing chronic parkinsonian phase, patients showed all the cardinal motor features of idiopathic PD, as well as freezing, paradoxical kinesia, dystonic posturing of trunk or limbs, and flexed posture. MPTP-induced parkinsonism in humans is a chronic but nonprogressive condition. The symptoms of the disease respond to commonly used antiparkinsonian medications, such as levodopa and dopamine receptor agonists. It is interesting that patients exposed to MPTP also develop cognitive abnormalities comparable to those seen in moderately advanced idiopathic PD, but they do not develop some of the other nonmotor abnormalities seen in PD (such as olfactory dysfunction).

In 1983, it was first reported that MPTP treatment in primates induces movement abnormalities similar to those seen in PD. The MPTP-treated monkey has since been used in numerous investigations into the pathophysiology and pharmacology of PD. In addition, MPTP was shown to produce dopamine depletion in mice. The phenotype of the parkinsonian syndrome resulting from dopamine loss in these animals is not as convincing as the MPTP-induced phenotype in primates. However, the use of the toxin in mice has greatly helped clarify its mechanism of action, and MPTP is often used for pharmacologic and molecular or genetic experiments.

MPTP: Mechanism of Action

After systemic administration, MPTP rapidly crosses the blood–brain barrier and is taken up by glia and serotonergic cells. The compound is metabolized by monoamine oxidase B into an unstable intermediate product (MPDP), which undergoes spontaneous conversion to a more stable metabolite, 1-methyl-4-phenylpyridium, MPP^+ (see Figure 1). MPP^+ is released into the extracellular space and taken up via the plasma membrane dopamine transporter into dopaminergic cells. Following the transmembrane mitochondrial potential gradient, MPP^+ then accumulates within mitochondria. It has long been known that the toxin is an inhibitor of the mitochondrial complex I and inhibits adenosine triphosphate production. Failure of energy production is the direct cause of the dying back of nigrostriatal axon terminals and the eventual death of some dopaminergic neurons. In addition, mitochondrial inhibition also results in overproduction of reactive oxygen species, which in turn triggers apoptotic signaling and cell death.

Figure 1 Metabolism of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). MPTP is a protoxin which is converted to 1-methyl-4-phenylpyridium (MPP^+), the actual toxin in glia cells. MPP^+ is a substrate for the dopamine transporter, which is found in dopaminergic neurons. Once taken up by the dopaminergic cell, MPP^+ acts to inhibit the mitochondrial complex I and may also enhance apoptotic cell death via an increase in oxidative stress. MAO-B, monoamine oxidase B; MPDP, 1-methyl-4-phenyl-2,3-dihydropyridinium.

Pathologic Changes Seen in MPTP-Induced Parkinsonism

MPTP administration in primates results in pathologic and biochemical changes in the basal ganglia that are similar to those seen in human idiopathic PD. Immunohistochemical and other studies have revealed a marked cell loss in the SNc, particularly affecting the ventrolateral portion of the SNc, similar to pathology found in humans. Additional, although less pronounced, damage has been found in the ventral tegmental area, locus coeruleus, raphe nuclei, hypothalamus, retina, and cerebral cortex. The loss of dopaminergic cells in the SNc has been demonstrated to be associated with iron accumulation and an increased astrocytic reaction. The most prominent biochemical changes are loss of dopamine in putamen and caudate nucleus (often reaching more than 90% in symptomatic animals), associated with an increase in the turnover rate of dopamine. The pattern of

striatal dopamine loss is similar to that seen in PD. However, while dopamine loss in the putamen is greater than that in the caudate nucleus in MPTP-treated primates, the difference is not as striking between these regions as it is in human PD. Other neurotransmitter systems, such as the norepinephrine system, and serotonin systems may also be affected.

Two primary areas have been identified in which the pathology of MPTP-induced parkinsonism in monkeys differs from that of idiopathic PD in humans. One is the fact that MPTP treatment results in an acute parkinsonian syndrome rather than a slowly progressive disease, although attempts have been made to generate a chronic model through the use of small amounts of MPTP administered daily over months. The second difference is that MPTP-treated monkeys lack clearly defined intracytoplasmic eosinophilic inclusion bodies, the so-called Lewy bodies. Lewy bodies are one of the pathologic hallmarks of idiopathic PD in humans and contain aggregates of α-synuclein, as well as other proteins. Lewy bodies are found in many brain regions, most notably the SNc and cortex. Levels of α-synuclein in the SNc are known to be upregulated in MPTP-treated monkeys, and α-synuclein aggregates may occur. Eosinophilic inclusion bodies have also been described, particularly in aged monkeys treated with MPTP. However, the inclusion bodies do not resemble the ultrastructure and composition of Lewy bodies as they are found in parkinsonian patients. In contrast to idiopathic PD, MPTP does not cause the formation of cortical Lewy bodies.

In nonprimate species, MPTP has somewhat different effects. While causing little pathologic or biochemical damage in rats, it induces prominent dopamine depletion in mice, albeit at much higher doses than those required in monkeys. Acutely, the toxin has been shown to lead to vacuolation and nuclear condensation of dopaminergic cells in the SNc, associated with perivascular edema and astrocytic and microglial activation. As in monkeys, MPTP administration eventually results in degeneration of DA neurons in the SNc, VTA, and retrorubral field, as well as lesser degeneration in regions outside the basal ganglia, such as the midline and intralaminar thalamic nuclei.

The relationship between the MPTP-induced changes and the expression of α-synuclein has been closely scrutinized in these animals. MPTP treatment results in an increase in the number of neurons expressing α-synuclein in the SNc. In some studies, animals overexpressing α-synuclein have been more susceptible to MPTP, while α-synuclein knockout animals are partly protected from the effects of MPTP. Some authors have reported cytoplasmic inclusion bodies in surviving dopaminergic neurons in MPTP-treated mice, particularly with chronic MPTP exposure, although they lack the typical Lewy body morphology.

Basal Ganglia Circuits Affected by Treatment with MPTP

The use of MPTP in animals has led to important discoveries regarding the pathophysiology and potential environmental mechanisms involved in the degeneration of dopaminergic cells in PD. All the research that has been done with this toxin is beyond the scope of this article; it focuses instead on a description of the use of the MPTP model of PD in one specific area of research, that is, research into the pathophysiology of parkinsonism from a 'systems' perspective. This field has been revolutionized by the availability of the MPTP model, and the knowledge gained from experiments in MPTP-treated primates has been translated into new therapies of this disorder.

The loss of dopamine impacts basal ganglia function. The basal ganglia are a group of functionally related subcortical nuclei that include the neostriatum (comprised of the caudate nucleus and the putamen), ventral striatum, GPe, STN, GPi, SNr, and SNc. They are anatomically related to large portions of the cerebral cortex, thalamus, and brain stem. The cortex–basal ganglia–thalamocortex circuits appear to be organized in an orderly arrangement of segregated reentrant circuits. Of these circuits, the 'motor circuit' has been particularly studied because of its likely involvement in the pathophysiology of movement disorders. In primates, it involves projections from the somatosensory, motor, and premotor cortices, which terminate in the postcommissural putamen. Cortical inputs also terminate in the STN. A second major group of inputs to striatum and STN arises from the intralaminar thalamic nuclei, the centromedian, and parafascicular nucleus. In primates, the centromedian projects to the motor portions of putamen and STN. Brain stem projections to the STN, GPi, and SNr also arise from the pedunculopontine nucleus (PPN), which receives major output from the GPi/SNr.

Cortical information is conveyed from the striatum to the output nuclei of the basal ganglia (GPi and SNr) via the the so-called direct and indirect pathways. The direct pathway arises from striatal neurons that project monosynaptically to neurons in GPi and SNr, whereas the indirect pathway arises from a separate set of neurons that projects to GPe. GPe conveys the information it receives either directly to GPi/SNr, or via the STN. Anatomically, some striatofugal neurons appear to collateralize more extensively,

reaching GPe, GPi, and SNr. Dopamine modulates the activity of the basal ganglia output neurons in GPi and SNr by facilitation of transmission over the direct pathway and inhibition of transmission over the indirect pathway. The net effect of striatal dopamine release appears to be to reduce basal ganglia output, whereas a reduction of dopamine release, as occurs in PD, results in a net increase in basal ganglia output.

Basal ganglia output arises from both GPi and SNr. The motor territory of GPi projects almost exclusively to the posterior part of the ventrolateral nucleus, which in turn sends projections toward the supplementary motor area, the primary motor cortex, and premotor cortical areas. GPi and SNr also project to the noncholinergic neurons of the PPN and to the intralaminar thalamic nuclei (centromedian and parafascicular nuclei).

Movement-Related Basal Ganglia Activity in Normal Animals

Since the majority of neurons in GPi exhibit a spontaneous high-frequency (inhibitory) discharge and increase their firing rate with movement, it has been speculated that a major role of the basal ganglia is to inhibit the activity of the thalamocortical network. Voluntary movements are initiated at the cortical level of the motor circuit with output to brain stem and spinal cord and to multiple subcortical targets, including the thalamus, putamen, and STN. Cortical activation of putaminous direct pathway neurons leads to a reduction of the inhibitory basal ganglia output and subsequent disinhibition of related thalamocortical neurons and facilitation of the movement. In contrast, activation of striatal neurons that give rise to the indirect pathway will lead to increased basal ganglia output and a suppression of movement. The basal ganglia may play a role in the control of specific kinematic parameters, such as amplitude, velocity, or direction, allowing intended movements to proceed and suppressing unintended movement. They may also be involved in self-initiated (internally generated) movements, in motor (procedural) learning, and in movement sequencing.

The functions of the nonmotor portions of the basal ganglia may be analogous to the motor functions, that is, participating in the respective roles of the anatomically related cortical areas, but they are less explored.

Parkinsonism

Early studies using the MPTP model of parkinsonism suggested that metabolic activity (as measured with the 2-deoxyglucose technique) is increased in both pallidal segments but decreased in the STN. This was interpreted as evidence for increased activity of the striatum–GPe connection and the STN–GPi pathway or, alternatively, as evidence for increased activity via the projections from the STN to both pallidal segments. It was then shown with microelectrode recordings of neuronal activity, that MPTP-induced parkinsonism in primates is associated with reduced tonic neuronal discharge in GPe and increased discharge in STN, GPi, and SNr, compared with normal controls. In parkinsonian patients undergoing pallidotomy, it has also been shown that the average discharge rate in GPe is significantly lower than that in GPi.

The changes in discharge rates in the basal ganglia nuclei have been interpreted as indicating that striatal dopamine depletion leads to increased activity of striatal neurons of the indirect pathway, resulting in inhibition of GPe and subsequent disinhibition of STN and GPi/SNr. In addition, loss of dopamine in the striatum may lead to reduced activity via the direct pathway. Increased basal ganglia output to the thalamus and increased inhibition of thalamocortical neurons have been corroborated by 2-deoxyglucose studies in which increased (synaptic) activity in the ventral anterior and ventrolateral nucleus of thalamus was demonstrated. Positron emission tomography studies have shown that the activation of motor and premotor areas in parkinsonian patients is reduced although no changes have been seen in the thalamus. Alterations of cortical activity in motor cortex and supplementary motor areas have also been demonstrated with single-cell recording in hemiparkinsonian primates.

Increased inhibition of thalamocortical neurons by excessive output from GPi/SNr may reduce the responsiveness of cortical mechanisms involved in motor control or in the initiation of movement or may interfere with 'set' functions that have been shown to be highly dependent on the integrity of basal ganglia pathways. Because parkinsonism is a circuit disorder, surgical or pharmacologic interventions at a variety of targets within the network could be successful. This can indeed be appreciated when considering the results of lesion studies in parkinsonian primates. One of the most important and dramatic in this regard was the demonstration that lesions of the STN in MPTP-treated primates reverse all the cardinal signs of parkinsonism, presumably by reducing GPi activity. Similarly, GPi and SNr inactivation have been shown to be effective against at least some parkinsonian signs in MPTP-treated primates. These results have rekindled interest in functional neurosurgical approaches to the treatment of medically intractable PD. This was first employed in the form of GPi lesions (pallidotomy) and, more recently, with STN lesions. In addition, high-frequency deep brain

stimulation (DBS) of both the STN and the GPi have been shown to reverse parkinsonian signs, probably by multiple modes of action, for instance by inhibition of STN neurons through 'depolarization block' or activation of inhibitory afferents or by true activation of STN efferents to the pallidum.

Although the simple rate-based circuit models were consistent with many aspects of PD, several findings in patients are not compatible with the rate-based model. For instance, the model would predict that thalamic lesions would worsen parkinsonism, but such lesions are, in fact, beneficial in the treatment of tremor and rigidity. Similarly, the fact that lesions of GPi are effective against drug-induced dyskinesias contradicts the rate-based model. Dyskinesias were initially thought to arise from pathologic reduction in basal ganglia output and thus should not respond positively to further reduction of pallidal outflow. These and other findings suggest that factors other than changes in the discharge rates are important in the development of PD. It has now been extensively documented that not only rates but also discharge patterns and the level of synchronization between neighboring neurons undergo substantial changes in MPTP-treated monkeys and patients. For instance, the proportion of cells in STN, GPi, and SNr with discharge in oscillatory or nonoscillatory bursts is greatly increased in the parkinsonian state. There is also a marked increase in the synchronization of discharge between neurons in the basal ganglia, and the intensity and prevalence of neuronal responses to passive limb manipulations in STN, GPi, and thalamus increase after treatment with MPTP.

At least some of these abnormal discharge patterns may be caused by intrinsic membrane properties of neurons in the dopamine-depleted basal ganglia. Local circuit interactions may also contribute to bursts and oscillations in the basal ganglia. Oscillations and other firing abnormalities throughout the entire basal ganglia–thalamocortical network may be tightly related to each other so that in most cases, no single generator of such abnormalities may be identifiable.

Conclusions

The discovery that a relatively selective dopaminergic neurotoxin, MPTP, produces a typical parkinsonian syndrome in humans and monkeys is one of the major breakthroughs in neuroscientific research. The use of this toxin in monkeys has resulted in the formulation of a highly valuable model of the disease. More importantly, the work in MPTP-treated primates and other species has contributed to the development of new insights into the pathophysiologic basis of PD and to the application of surgical interventions that can be used to help patients with PD and has provided researchers with a tool for examining the properties of new antiparkinsonian drug treatments.

Müller Cells

A Bringmann and A Reichenbach, University of Leipzig, Leipzig, Germany

© 2009 Elsevier Ltd. All rights reserved.

The retina of all vertebrates contains specialized radial glial cells even in the adult stage. They were discovered in 1851 by Heinrich Müller and were later termed radial fibers of Müller or Müller cells. It is interesting to note that Müller observed the cells, together with some adhering photoreceptor cells, in dissociated retina preparations (Figure 1(d)). In many lower vertebrates, Müller cells are the only retinal glia; in mammals, they constitute the vast majority of glial cells together with the minorities of astrocytes and microglial cells, which latter are both confined to the innermost retinal layers (nerve fiber, ganglion cell, and inner plexiform layers).

Basic Properties of Müller Cells

Morphology

Müller cells display a characteristic bipolar morphology. Their soma is located in the inner nuclear layer; it gives rise to two main stem processes which pass through the tissue in opposite directions, together spanning the entire thickness of the retinal tissue (Figures 1–3). The inner stem process terminates at the inner (i.e., vitread) retinal surface with an endfoot which contributes, together with a basal lamina, to the inner limiting membrane. The inner stem process contains bundles of intermediate filaments, consisting mainly of vimentin in the healthy retina but also of increasing amounts of glial fibrillary acidic protein (GFAP) in virtually all forms of retinal injury. The endfoot is densely packed with smooth endoplasmic reticulum (Figure 2); its vitread surface membrane contains many orthogonal arrays of membrane particles, most likely representing ion and water channels, and other transport proteins. Similar *en-passant* endfeet are formed by Müller cell processes where they contact retinal blood vessels in species with vascularized retinae (i.e., in most mammals including humans). The outer stem process, arising from the opposite pole of the soma, contains microtubules and ends up at the outer limiting membrane, formed by zonulae adherentes between these Müller cell processes and the inner segments of the photoreceptors. From there, this process extends many microvilli into the subretinal space. Within both synaptic (plexiform) layers, many side branches originate from the two stem processes which form complex, filigrane sheaths around the synapses. Furthermore, thin velate sheaths arise from the Müller cell in all nuclear layers, enveloping the neuronal somata. This is particularly evident in the outer nuclear layer where the outer Müller cell process forms honeycomb-like structures (Figures 1–3).

Whereas this general description applies to Müller cells in all vertebrate retinae, there is considerable adaptive variation in cell morphology (Figure 3). For instance, in the Müller cells of reptiles and birds the inner stem process is usually split into sheaves of thin processes, each with its own small vitread endfoot. Moreover, in the thick central retina (where the retinal cells are densely packed) the Müller cells are longer and thinner than in the retinal periphery. In the retinae of most lower vertebrates and of mammals with avascular retinae (such as rabbits and guinea pigs), the Müller cells have only few mitochondria, located at the sclerad end of the outer stem process (i.e., close to the choroid as the only source of oxygen; cf. Figure 2), whereas in vascularized retinae mitochondria are distributed along the entire length of both Müller cell processes.

As a rule, Müller cells occupy approximately 10% of the total retinal volume (up to >70% in the nerve fiber layer of the retinal periphery where the adjacent Müller cell endfeet form a continuous cobblestone pattern and only a few nerve fiber bundles pass through). The surface-to-volume ratio of the Müller cell processes is high, particularly within the two plexiform layers (14–18 μm^{-1}), in the outer nuclear layer (approximately 20 μm^{-1}), and at the subretinal microvilli (up to 50 μm^{-1}). Thus, virtually all neuronal elements are contacted by Müller cell processes separated only by narrow extracellular clefts. As a whole, the Müller cell population forms a regular pattern (Figure 1(c), middle and bottom rows) with strikingly similar cell densities among the various vertebrate retinae (some 5000 Müller cells mm^{-2} in the retinal periphery, up to 15 000 mm^{-2} in the retinal center; only in the perifoveal retina of primates are higher densities of more than 25 000 mm^{-2} found). Each of these cells can be considered the core of a columnar micro-unit of retinal neurons, in mammals constituted by approximately one cone photoreceptor, three to six interneurons of the inner nuclear layer, less than one retinal ganglion cell, and a varying number of rod photoreceptor cells (approximately two in diurnal squirrels; approximately ten in average mammals such as human, rabbit, horse, and others; and slightly more than 20 in nocturnal rodents and carnivores).

Figure 1 Müller cell morphology and its activity-dependent changes: (a) semi-schematic drawing of a Müller cell (green) together with the retinal neurons ensheathed by it (red) and retinal capillaries (violet) contacted by en-passant-endfeet; (b), Müller cells (in vital retinal slice) selectively stained by the vital dye, Mitotracker Orange (green); (c) confocal views on to the GCL (top) and the IPL (middle and bottom) of retinal wholemounts, revealing cross sections through the Müller cell endfeet and inner processes (green) and neuronal structures (red; reflexion mode of the microscope); (d) enzymatically dissociated vital Müller cell from a guinea pig retina, together with some adhering photoreceptor cells (bottom); Nomarski optics. In (c), the acute application of the excitatory neurotransmitter, L-glutamate (1 mM for 10 min) causes a swelling of the ganglion cell bodies in the GCL and of the synapses in the IPL. The swelling of neuronal elements is partly compensated by a decrease in the thickness of the Müller cell processes (which is also observed after retinal ischemia; bottom). These dynamic changes in glial cell shape prevent dramatic changes in the volume of the extracellular spaces. In (d), adhering photoreceptor cells can be used for electrophysiological (patch-clamp) and fluorimetric studies. Functions

Müller cells constitute an anatomical and functional link between the retinal neurons (of their column) and the compartments with which these need to exchange molecules (i.e., the retinal blood vessels, the vitreous body, and the subretinal space). Müller cells thus play a wealth of roles in supporting neuronal information processing that is carried out by astrocytes, oligodendrocytes, and ependymal cells in other regions of the central nervous system (Figure 4). Müller cells are essential in the ontogenetic creation and the adult maintenance of the neuroretinal architecture; they also (1) support neuronal survival, (2) provide retinal neurons with nutrients such as lactate and pyruvate for their oxidative metabolism, and (3) remove the metabolic waste of the neurons. In this context, Müller cells maintain the homeostasis of the retinal extracellular milieu, including ion, water, and pH homeostasis. Moreover, Müller cells regulate the retinal blood flow, contribute to the formation and maintenance of the blood–retina barrier, and act as modulators of immune and inflammatory responses and as phagocytes of fragments of degenerating retinal cells and foreign substances. They contribute to neuronal signaling processes, particularly by fast uptake and recycling of neurotransmitters, by providing precursors of neurotransmitters to neurons, and by the release of factors (e.g., D-serine and glutamate) which control the excitability of neurons. Moreover, Müller cells are probably involved in the recycling of photopigments. Any impairment of the supportive functions of Müller cells must therefore cause or aggravate retinal dysfunction and loss of retinal neurons by increasing the susceptibility of neurons to stressful stimuli.

Retinal Development

In the vertebrate retina, there are no glia- or neuron-specific progenitor cells; even the final division of a late progenitor cell typically generates one rod photoreceptor or bipolar cell and one Müller cell. Before this last division, each of the late progenitor cells undergoes a species-specific varying number of cell divisions, eventually generating a columnar aligned group of neurons together with one Müller cell in its core. Thus, most of the cells in a given columnar micro-unit which is constituted by one Müller cell and surrounding neurons (Figure 1(a)) are clonally as well as functionally related.

To take on the multitude of supportive functions for retinal neurons, the young Müller cell must undergo a radical differentiation. In rodents, this differentiation occurs during the first 2–3 postnatal weeks (Figure 5). This period includes the cessation of cell proliferation (during the first postnatal days) and the establishment of the mature synaptic wiring of retinal neurons (end of the first week) as well as the

Figure 3 Adaptations of Müller cell morphology in various vertebrates. Most cells were drawn from Golgi-stained preparations, some are camera-lucida drawings of dye-filled cells. As far as possible, all cells are shown at the same magnification. Adapted from Reichenbach A and Wolburg H (2004) Astrocytes and ependymal glia. full development of photoreceptor outer segments (the second week). Accordingly, the retinal glia differentiates from a progenitor-like state, via a stage of immature radial glia, to mature Müller cells. This differentiation involves morphological, biochemical, and (electro-)physiological changes; the cells extend side branches between the neuronal somata and synaptic processes, accumulate glia-specific enzymes such as glutamine synthetase, and dramatically change the expression pattern of membrane proteins such as ion channels. In differentiating Müller cells, a dramatic increase of the transmembranous K^+ conductance occurs (Figure 5), accompanied by a hyperpolarization of the plasma membrane toward the adult levels of approximately −80 mV. This is apparently due to the insertion of K^+ channels into the Müller cell membrane during the second week of life and provides the essential precondition for most of the neuron-supportive functions of mature Müller cells. For example, in neurotransmitter recycling,

Figure 4 Summary of Müller cell functions, exemplified in a semi-schematic drawing of the mammalian retina. Spatial buffering of K^+ ions and water from extracellular clefts around active neurons into the vitreous body, the blood vessels, and the subretinal space (left). Transmitter recycling; the amino acid transmitters, GABA and glutamate, are taken up by the Müller cells and are converted into the nonactive metabolite glutamine, which is then released for neuronal resynthesis of the transmitters (middle). Metabolic symbiosis; the glycolytic metabolism of Müller cells generates lactate/pyruvate, which is delivered to the neurons as a substrate of their Krebs cycle (right). The neurons then release CO_2, which is either used by the Müller cells for their lipid synthesis or disposed of via the glial enzyme carbonic anhydrase. CA, carbonic anhydrase; GABA, γ-aminobutyric acid; gln, glutamine; glut, glutamate; GS, glutamine synthetase; LDH, lactate dehydrogenase; PK, pyruvate kinase. after the neural synapses are established at the early second week of life, the Müller cells (1) send side branches toward the synapses and ensheath them, (2) express glutamate uptake transporter molecules in the membrane of these perisynaptic sheaths, (3) hyperpolarize their resting membrane potential to provide the necessary driving force for the transporters, and (4) express the enzyme glutamine synthetase to convert the internalized glutamate molecules into glutamine. In parallel, the young Müller cells are involved in the control of retinal vascularization including the induction of the blood–retina barrier.

Postmitotic Müller cells retain a remarkable plasticity even in adult retinas; they are capable of dedifferentiation and proliferation. As important steps of this dedifferentiation, the cells reduce the K^+ conductance of their membrane (Figure 5) and increase their intracellular Ca^{2+} signaling (Figure 5(a)). The reduction of the K^+ conductance must cause a severe loss of functions involved in normal neuron–glia interaction, most of which require a hyperpolarized membrane potential. Moreover, a subpopulation of Müller cells expresses markers for neural progenitor (stem) cells even in the adult tissue (Müller stem cells). Transient Müller cell proliferation induced by *N*-methyl-D-aspartate (NMDA) excitotoxicity in postnatal chicken retinas causes a dedifferentiation of Müller cells into retinal progenitor-like cells. These cells may remain undifferentiated for longer time periods, may generate new Müller cells, or may transdifferentiate into retinal neurons. Similarly, Müller cells may be stimulated to transdifferentiate into neurons and photoreceptor cells in the adult rat retina after toxic injury produced with NMDA. These observations suggest that Müller cells are a potential source of neural regeneration in the postnatal retina.

Metabolic Symbiosis

As in many types of glial cells, the energy metabolism of Müller cells relies mainly on anaerobic glycolysis, even in the presence of sufficient oxygen supply. Therefore, Müller cells display a low rate of oxygen consumption and may withstand even long-lasting

Figure 5 Differentiation and dedifferentiation of Müller cells: (a) in rabbit retina; (b) in rat retina. During the early postnatal differentiation of Müller cells from immature radial glial/progenitor cells, there occurs an increased expression of inwardly rectifying K^+ channels (mainly, Kir4.1), which results in increased inward current densities (top row, original traces; and blue bars) as well as in more negative membrane potentials (not shown). In parallel, the percentage of Müller cells which respond to adenosine 5′-triphosphate (ATP) application with an intracellular Ca^{2+} rise (dark violet/red bars in (a)) decreases, and the Müller cell swelling in response to hypotonic stress gradually disappears (dark violet/red bars in (b)). In many cases of retinal injury, such as retinal detachment (a) and ischemia/reperfusion (b), a de-differentiation of the cells occurs. The density of K^+ inward currents decreases dramatically (top row, original traces; and blue bars), accompanied by a depolarization of the mean membrane potentials (not shown), and the majority of Müller cells again display intracellular Ca^{2+} rises upon ATP-stimulation (bright-violet bars in (a)) and swell on hypotonic challenge (bright-violet columns in (b)).

anoxia. As long as oxygen is available, Müller cells are also resistant to the absence of glucose because other substrates such as lactate, pyruvate, glutamate, or glutamine may be used as energy substrates for their (although normally nondominant) Krebs cycle. Short periods of glucose deficiency and even ischemia (associated with a complete lack of glucose and oxygen) may be compensated by the glycogen deposits in Müller cells. Müller cells are abundantly endowed with the brain-specific glycogenolytic isoenzyme, brain-specific isozyme (BB) glycogen phosphorylase. The elevation of the extracellular K^+ concentration causes rapid glycogenolysis in Müller cells, indicating that the amount of glial glycogenolysis depends on the momentary neuronal activity in the retina.

The glycolytic metabolism of glial cells results in the generation of lactate, which is converted into pyruvate. Pyruvate is then released from the cells, probably via their monocarboxylate transporter MCT2, and is taken up by the neurons which use it as a substrate for their Krebs cycle (Figure 4, right). This interaction has beneficial consequences for both neurons (which are being fed by the substrate of their metabolism, without the necessity of their own unefficient but costly glycolytic pathway) and glial cells (which are getting rid of the unwarranted acidic end product of their metabolism). A mirror image of this mutual benefit arises at the end of the aerobic pathway when CO_2 and water are generated by the neurons. By means of the glia-specific enzyme carboanhydrase, the Müller cells transfer CO_2 to HCO_3^- and either transport it via a H^+/ HCO_3^- exchanger into the vitreous body and the blood vessels or use it for their lipid synthesis. Again, the neurons (which cannot get rid of CO_2 on their own) are liberated from a potentially dangerous end product, and the Müller cells (which do not generate enough CO_2 in their own glycolytic metabolism) receive a substrate for their metabolism (Figure 4, right).

Homeostasis of the Extracellular Space Milieu

Neurotransmitter Recycling

For the fast clearance of the neurotransmitters from synaptic spaces, the Müller cell membranes contain uptake systems for various amino-acid transmitters such as glutamate, γ-aminobutyric acid (GABA), and glycine. The clearance of synaptic glutamate by Müller cells is required for the normal function of excitatory synapses and for the prevention of neurotoxicity. After experimental inhibition of glutamate uptake by Müller cells, even low concentrations of

extracellular glutamate become neurotoxic. The main glutamate transporter expressed by Müller cells is the glutamate/aspartate transporter (GLAST) (excitatory amino acid transporter 1 (EAAT1)). GLAST is the predominant transporter for the removal of glutamate within the retina, also mediating the rapid termination of the postsynaptic action of glutamate. The Na^+-dependent glutamate uptake of Müller cells is electrogenic and, therefore, energy dependent; a very negative membrane potential is necessary for efficient uptake. Cell depolarization (e.g., by activation of glial ionotropic receptors or by elevated extracellular K^+) decreases the uptake rate. After its uptake, glutamate is intracellularly converted into glutamine by the enzyme glutamine synthetase, which is expressed only by Müller cells. Likewise, after the uptake of GABA into Müller cells, it is converted to glutamate, which then is fed into the glutamine synthetase pathway. Glutamine is transported back to neurons as a precursor for their synthesis of glutamate and GABA (glutamate–glutamine cycle of the retina). Due to the efficiency of the glutamine synthetase, demonstrable levels of glutamate within Müller cells are present only when the enzyme is experimentally inhibited or downregulated under pathological conditions. When the glutamine synthetase activity is experimentally blocked in Müller cells, retinal neurons lose their glutamate and the animals become rapidly (within 2 min) functionally blind.

The uptake of glutamate by Müller cells is also important for the retinal defense against free radicals and toxic factors. Müller cells synthesize the tripeptide glutathione from glutamate, cysteine, and glycine. Reduced glutathione is provided to neurons and acts as a scavenger of free radicals and reactive oxygen compounds. As the glutamine synthetase of Müller cells is the only enzyme available for ammonia detoxification in the retina, this is an important sideways function of neurotransmitter recycling.

K^+ Homeostasis

Müller cells are crucially involved in retinal K^+ homeostasis by mediating transcellular spatial buffering K^+ currents, which counteract the changes in extracellular K^+ concentration associated with neuronal activity. A dysregulation of the K^+ homeostasis causes K^+-evoked neuronal hyperexcitation and glutamate toxicity. Active neurons release K^+ ions predominantly into the extracellular clefts of the plexiform (synaptic) layers. This causes a local driving force for K^+ inward currents into Müller cells; thus, Müller cells take up the neuron-derived excess K^+ from the plexiform layers and release a similar amount of K^+ into fluid-filled spaces outside of the neural retina (blood, vitreous, and subretinal space) (Figures 4 and 6). Passive K^+ currents through inwardly rectifying K^+ (Kir) channels play a major role in counteracting fast extracellular K^+ increases.

The plasma membranes of Müller cells are highly permeable to K^+ as a consequence of the high density of specialized K^+ channels. The high K^+ permeability causes a very negative membrane potential of the cells close to the equilibrium potential of K^+ ions (approximately -80 mV), which is an essential precondition for virtually all neuron-supportive functions of the cells. A block or downregulation of the K^+ channels depolarizes the membranes. In addition to Kir channels, which are active at the resting membrane potential, Müller cells express various other types of K^+ channels that are activated on membrane depolarization, including voltage-gated, outwardly rectifying K^+ (Kv) channels, tandem-pore (TASK) channels, and Ca^{2+}-activated, big conductance K^+ (BK_{Ca}) channels. Among the various subtypes of K^+ channels expressed by Müller cells, two subtypes of Kir channels have been mainly implicated in mediating the K^+ buffering currents: Kir4.1 and Kir2.1. The proteins of both channels are expressed in a polarized fashion in the plasma membrane of Müller cells. The Kir4.1 protein shows a strong enrichment in such membrane domains across which the cells release excess K^+ during neuronal activity (i.e., in perivascular membrane sheets and at the inner and outer limiting membranes) (Figures 6(b) and 6(c)). Kir4.1 channels are weakly rectifying; that is, they mediate outward and inward K^+ currents with similar amplitudes (Figure 6(a)). The Kir2.1 channel is strongly rectifying and, thus, predominantly mediates inward K^+ currents. The Kir2.1 channel protein is expressed by Müller cells in such membrane domains which abut neurons of the inner retina and within both plexiform layers (Figures 6(b) and 6(c)). The differential expression of Kir4.1 and Kir2.1 channels (together with the local transmembranous K^+ gradients) determines the direction of the transglial K^+ currents; excess K^+ is absorbed by Müller cells from extracellular spaces around neurons and is distributed into spaces outside the neuroretina.

Water Homeostasis

Water accumulates in the retinal tissue due to (1) the metabolic production of water associated with the oxidative synthesis of adenosine 5′-triphosphate (ATP), (2) the influx of water from the blood coupled to the uptake of metabolic substrates such as glucose, and (3) the forcing of water into the retina by the intraocular pressure. The accumulated water is continuously redistributed out of the neuroretina by the pigment epithelium, which dehydrates the subretinal space, and by Müller cells, which dehydrate the inner retina. Both the pigment epithelium and Müller

Figure 6 Müller cell physiology and K^+ (Kir) channels: (a) weakly rectifying Kir4.1 channel and strongly inward-rectifying Kir2.1 channel; (b) the differential expression of Kir channels causing a directional flow of K^+ ions through the Müller cells during neuronal activation, that is, Müller cells take up the neuron-derived excess K^+ ions and release them into extraretinal spaces; (c) after transient ischemia of the rat retina, the expression of the Kir4.1 channels strongly decreases while the Kir2.1 channels remain expressed in Müller cells, impairing K^+ homeostasis in the injured retina. Müller cells express different subtypes of inwardly rectifying Kir channels. The weakly rectifying Kir4.1 channel (cf. the current–voltage relation of the currents in (a)) is expressed at the contacts of Müller cells to extraretinal spaces, that is, at both limiting membranes (arrowheads in (c)) and around the blood vessels (arrows in (c)). The strongly inward-rectifying Kir2.1 channel is expressed in Müller cell membranes which contact neurons. This differential expression of Kir channels causes a directional flow of K^+ ions through the Müller cells during neuronal activation. This clearance mechanism is called spatial buffering or potassium siphoning. GCL, ganglion cell layer; ILM, inner limiting membrane; INL, inner nuclear layer; IPL, inner plexiform layer; ONL, outer nuclear layer; OLM, outer limiting membrane; OPL, outer plexiform layer. Scale bar = 20 μm. Adapted from Bringmann A, Pannicke T, Grosche J, et al. (2006) Müller cells in the healthy and diseased retina. *Progress in Retinal and Eye Research* 25: 397–424.

cells mediate transcellular water fluxes that are coupled to the fluxes of osmolytes (mostly ions) and which are facilitated by the polarized expression of water-transporting proteins, the aquaporins. The co-expression of Kir4.1 and aquaporin-4 water channels in Müller cell membranes at interfaces to extraretinal spaces (Figure 7) has led to the suggestion that the water transport through Müller cells is tightly coupled to the spatial buffering K^+ currents mediated by the cells. In addition, aquaporin-4 water channels are also expressed in the plexiform layers; thus, aquaporin-4 is expressed in all membrane domains through which Müller cells take up and release excess K^+. The coupling of water and K^+ transport through Müller cells is also suggested by the observation that in aquaporin-4 knockout mice the b-wave potential of the electroretinogram is reduced, indicating a reduced or disturbed excitability of second-order neurons after indirect inhibition of the transglial K^+ clearance. The aquaporin-4 water channels expressed by Müller cells may facilitate the constitutive redistribution of metabolic water from the retinal parenchyma into the blood as well as the activity-dependent rapid water fluxes necessary for regular neuronal activation and synaptic transmission.

pH Homeostasis

Neuronal activity leads to substantial variations in the concentration of H^+ in the extracellular space; these may affect synaptic transmission. Müller cells play an essential role in regulating the extracellular H^+ concentration by the expression of carbonic anhydrase (which converts CO_2 into HCO_3^-) and of the electrogenic Na^+/HCO_3^- cotransporter and by other acid/base transport systems or pumps. Light stimulation causes an extracellular alkalinization generated by synaptic activity, as well as a reduced metabolic activity of photoreceptor cells. Activation of the Na^+/HCO_3^- cotransporter system of Müller cells by increasing the extracellular K^+ concentration results in acid efflux and an acidification of the extracellular

Figure 7 Water channels and Müller cell swelling in the normal and in the diabetic rat retina. In (a), aquaporin-4-expressing Müller cell membranes abut the superficial vessels in the ganglion cell layer (red immunostaining in the upper photograph, retinal wholemount; blue immunostaining in the middle photograph, retinal slice) and the deep vessels in the inner nuclear layer and in the outer plexiform layer (red staining in the lower photograph). The co-expression of aquaporin-4 and Kir4.1 (shown exemplary for the deep vessels in the lower photograph) makes sure that, osmotically coupled to the transglial K^+ currents (see **Figure 6**), water is absorbed from the retinal tissue and released into the blood (schematic drawing). Astrocyted (green immunoreactivity in the middle photograph) in the vicinity of superficial vessels do not contact the vessels. In (b), the superficial vessels are surrounded by astrocytes which express aquaporin-1 (green immunoreactivity in the upper photograph), whereas the immunoreactivity for aquaporin-4 is less pronounced. The middle photograph shows an astrocyte (green immunoreactivity for GFAP) surrounding a vessel in the ganglion cell layer. Müller cells decrease their expression of Kir4.1 around the vessels (lacking blue immunostaining in the lower photograph) and at the limiting membranes. Because the Müller cells may take up neuron-derived K^+ through other subtypes of K^+ channels (e.g., Kir2.1; cf. **Figure 6**), K^+ may accumulate within the cells, which causes an increase of the intracellular osmotic pressure. The alteration in the osmotic gradient at the glio-vascular interface results in inflow of water from the vessels into the Müller cells, which subsequently swell (schematic drawing). Therefore, Müller cell swelling may contribute to cytotoxic edema in the diabetic (and ischemic) retina. AQP, aquaporin; GCL, ganglion cell layer; INL, inner nuclear layer; Kir4.1, inwardly rectifying potassium channels; OPL, outer plexiform layer. All scale bars = 20 μm. space. The acidification may counterbalance the alkalinization generated by neuronal activity.

Homeostasis of the Müller Cell Volume

Neuronal activity in the retina is associated with volume changes of the neuronal cells and, particularly, their synapses. This occurs because the activation of ionotropic receptors causes an influx of Na^+ and Cl^- ions into the synapses, which is associated with a water influx and, therefore, with swelling of neuronal structures (**Figure 1(b)**). For the maintenance of the extracellular space volume, which is necessary to avoid excessive increases in the concentration of ions such as K^+ (which would disturb regular neuronal activity), Müller cells display compensatory changes of their cell shape, with a decrease in the thickness (and an elongation) of their stem processes (**Figure 1(b)**).

In addition to the synaptic structures which undergo a volume increase on activation of ionotropic receptors, the blood vessels show volume alterations during neuronal activity. Müller cells are crucially implicated in the activity-dependent regulation of the local blood flow. Light-evoked dilation and constriction of arterioles is mediated by a purinergic neuron-to-glia signaling in the retina, probably via ATP released from activated neurons, suggesting that Müller cells contribute to neurovascular coupling. It has been suggested that the release of K^+ ions from perivascular endfeet plays a role in the local dilation of arterioles. To avoid changes in the extracellular space volume around the vessels when they dilate during neuronal activation, Müller cells should decrease the volume of their perivascular processes, despite an increase of the intracellular osmotic pressure due to the uptake of neuron-derived osmolytes such as K^+ and Na^+-glutamate. It has been suggested that glutamate, released by retinal neurons on activation, causes the activation of a purinergic volume regulatory mechanism in Müller cells via the activation of metabotropic glutamate receptors and

subsequent stimulation of autocrine ATP- and adenosine-mediated signaling. The activation of adenosine A1 receptors results in an opening of additional K^+ and Cl^- channels in the Müller cell membrane; these allow for an ion extrusion, which is coupled with a water outflow and thus inhibits swelling of the cells. This mechanism may mediate the homeostasis of the extracellular space volume during neuronal activation. It remains to be determined whether long-range Ca^{2+} waves, which propagate through the network of retinal astrocytes and Müller cells during strong neuronal activation and which proceed by autocrine ATP signaling, transmit volume regulatory signals over a wide area within the retina and therefore mediate ascending vasodilation.

Modulation of Synaptic Transmission

It has recently become obvious that in the retina there is a two-way communication between neurons and glial cells, with a significant contribution of the glial cells to neuronal information processing. Light-evoked activity in retinal neurons results in an increase in the frequency of Ca^{2+} transients in Müller cells, probably evoked by release of ATP from neurons and the subsequent activation of purinergic receptors on glial cells. Conversely, the light-evoked activity of retinal ganglion cells is modulated by retinal astrocytes and Müller cells. Ca^{2+} waves in retinal glial cells are associated with the enhancement or depression of light-evoked spiking and excitatory postsynaptic currents of retinal ganglion cells. Enhancement of ganglion cell activity is probably mediated by Ca^{2+}-dependent release of glutamate from Müller cells, whereas ganglion cell hyperpolarization is mediated by the release of ATP from Müller cells, extracellular conversion of ATP into adenosine, and activation of neuronal adenosine A1 receptors, which finally inhibits the neurons by increasing K^+ conductance. Müller cells may also stimulate neuronal activity by the release of the neuromodulator D-serine. In the retina, Müller cells appear to be the primary source of D-serine. D-Serine plays a role as an endogenous co-agonist of the NMDA receptor and is therefore involved in setting the sensitivity of ganglion and amacrine cells.

Support of Neuronal Survival

Neurotrophic factors such as basic fibroblast growth factor (bFGF), brain-derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF), and glial cell line-derived neurotrophic factor (GDNF) promote the survival of retinal neurons and photoreceptor cells. Müller cells play an active role in the survival of retinal neurons and photoreceptor cells, in particular by releasing such neurotrophic factors and/or by mediating the effects of these factors. The protective effects of neurotrophic factors on photoreceptor cells may be mediated directly (in the case of bFGF) or indirectly (in the cases of BDNF and CNTF, whose receptors are not present on photoreceptor cells) via the activation of the Müller cells. Factors secreted by activated microglial cells, or extracellular glutamate, boost the production of trophic factors by Müller cells, thus increasing the survival of photoreceptor cells. Neurotrophic factors such as CNTF may cause a shift of Müller cells toward a more neuroprotective phenotype, which is characterized by, for example, a more efficient buffering of high concentrations of glutamate. Additional (previous) retinal injuries, such as mechanical stress, or preconditioning with bright light may protect the photoreceptors from degeneration because these stimuli cause an upregulation of bFGF and CNTF expression by Müller cells.

Blood–Retina Barrier

Müller cells are communicators between vessels and neurons, responsible for the uptake of glucose from the circulation, the glycolytic metabolism of glucose, and the transfer of substrates such as lactate and pyruvate to neurons. Retinal capillaries consist of endothelial cells and pericytes which are covered by a basement membrane and are ensheathed by membranes of astrocytes and Müller cells. Müller cells participate in the establishment of the blood–retina barrier, which is constituted by the tight junctions between the vascular endothelial cells. *In vitro*, Müller cells enhance the endothelial cell barrier function under normoxic conditions and impair the barrier function under hypoxic conditions. Müller cells produce factors that increase (GDNF, neurturin, pigment epithelium-derived growth factor (PEDF)) and others that decrease (tumor necrosis factor, vascular endothelial growth factor, etc.) the tightness of the endothelial barrier. Under normal conditions, Müller cells provide a permanent antiproliferative condition for vascular endothelial cells by the release of anti-angiogenic factors such as PEDF and thrombospondin-1.

Multimodal Signaling in Animals

P Otovic, University of South Florida, Tampa, FL, USA

Animals communicate using their entire bodies and faculties. The scientific study of animal communication has progressed from early ethologists' observations of display behavior, which included detailed descriptions of elaborate combinations of visual, vocal, and chemical signals, to the current focus on experiments conducted to discover the meaning of the signals in a more controlled format. The gains in controlling variables through experimentation came at the cost of decreased complexity, however; in order to isolate a signal of interest, experimenters typically had to simplify the situation by examining one component of the display at a time. Advances in experimental techniques now allow for simultaneous manipulation of multiple facets of a display, allowing for a more complete understanding of an animal's display behavior. This renewed interest in multimodal communication (communication using signals in multiple sensory channels) has spurred new research on the topic, which is summarized here. This article discusses terminology, methods for studying multimodal communication, and the classification of multimodal and multicomponent signals and hypotheses. It also discusses the incidence of multimodal signals and channels used, and theory concerning the evolution and function of multimodal signaling. In addition, it briefly discusses the neural integration of multimodal stimuli.

Terminology of Multimodal Signals

A communication signal is defined here as any aspect of an organism that modifies the behavior of the signal recipient. This definition is broad and includes static or enduring components such as body color and size, along with dynamic or transient components such as vocal or chemical emissions. Although much attention has been focused on communication signals that contain only one component, signals that contain more than one component (composite signals) have attracted increased interest in recent years. There are two types of composite signals: multicomponent and multimodal. Multicomponent signals contain components that are transmitted in the same sensory channel. For example, male jungle fowl (*Gallus gallus*) court females with brightly colored combs, long tails, and display movements all in the visual modality (Figure 1(a)). Multimodal (or multisensory) signals contain components that are transmitted via multiple sensory channels. Many animals communicate by simultaneously producing signals from different sensory channels or modalities during courtship, aggressive, or antipredator displays. For example, arctiid moths (*Rhodogastria leucoptera*) emit an odor from their thoracic glands while moving their wings to reveal red coloration on their abdomen in an attempt to ward off potential predators (Figure 1(b)).

Methods for Studying Multimodal Signals

There are many ways to study the meaning of multimodal signals. Observational methods provide invaluable baseline data concerning the incidence of multimodal signal usage in the field. It is imperative that fieldwork be conducted to understand how these signals are used under natural conditions. Experimental methods allow the control of extraneous variables while signals of interest are manipulated. With experimental techniques, we can classify and assess the function of multimodal signals.

Video and audio playback is an experimental method that has gained popularity in recent years. This method has the potential to provide adequate control conditions and to manipulate the signal content in each condition, which allows one to posit a plausible cause-and-effect relationship between signal and response. For example, playback methods have been used to assess the function of each component in the multimodal courtship display of wolf spiders, which consists of visual foreleg waving and vibration of the substrate. These methods allow one to present each unimodal component to an organism in isolation as well as simultaneously in order to assess and compare the elicited responses. Playback methods can also be used for presenting conflicting cues to an organism. A visual component from a conspecific signal can be presented along with an auditory component from, for instance, a heterospecific signal. This is especially useful for determining the relative importance of each signal channel.

However, video playback has several limitations that may be circumvented by an alternative method – mechanical modeling of a live conspecific. First, video stimuli may be perceived differently by humans than by nonhuman animals, with problems arising from differences in critical flicker fusion frequency or spectral sensitivity. Second, a mechanical model has three dimensions, which makes it more lifelike by adding cues for depth perception and allowing active perception by the recipient (in which the recipient can get multiple views by moving its head).

Figure 1 (a) Multicomponent visual display: Red jungle fowl use their long tail feathers and brightly colored combs in courtship. Reproduced from Hogle Zoo. (b) Multimodal visual/chemical display: An arctiid moth exposes its red abdomen while emitting a thoracic odor to deter predators. Adapted from a drawing by Jane Carlson, Louisiana State University, with permission.

Third, mechanical modeling allows the live animals to interact with the model in real time and space. Robotic models have successfully elicited species-specific behavior in animals, including frogs, bowerbirds, honeybees, and lizards. This method is ideal for examining multimodal signals since models can perform visual movements, mechanical vibrations, or emit sounds via speakers.

Classification of Multimodal Signals

In order to understand the plethora, variety, and complexity of animal signals, researchers have devised categorization systems for classifying them within or across taxonomic boundaries. Communication signals have traditionally been classified within species according to behavioral context (aggression or courtship, etc.) or channel (auditory or visual, etc.). Researchers have devised new classification schemes specifically for composite, multicomponent signals. These new approaches to categorizing composite signals are discussed in the following sections along with a classification scheme created specifically for multimodal (as opposed to multicomponent) signals.

Categorization by Receiver Fitness

Multicomponent communication signals have been classified by hypotheses proposed to explain how they affect the survival, growth, and reproductive success of a signal receiver; these fitness effects can be positive, negative, or neutral (Table 1). For example, signals that are assumed to enhance receiver fitness comprise one group, such as feather color in greenfinches (*Carduelis chloris*). In these birds, the brightness of color patches on the tail reflects an individual's ability to resist parasites and the brightness of color patches on the wing conveys age information, so these multiple visual signals facilitate accurate mate assessment. Signals that have a negative impact on receiver fitness constitute a second group. Signals evolving via intersexual conflict, such as deceptive signals used by males to overcome mating resistance on the part of females, are classified in this group. Signals that are assumed to have negligible or only indirect effects on receiver fitness encompass a third group. For instance, some signal components may be remnants of past selection for sexually selected traits and may in fact be useful in the present only as attractants to ensure that a male meets the threshold level of attraction for a female.

Categorization by Other Selective Pressures

Signals have also been grouped according to other selection pressures affecting their evolution (Table 2). One category includes composite signals that are thought to have evolved due to changes in the environment. For instance, yellow and green colors are most salient in green-colored forest shade, whereas blue colors are most salient in blue-colored open woodland shade, so one would expect composite visual displays of animals in each of these habitats to emphasize these respective colors. Signals that have been shaped primarily by a receiver's sensory apparati, such as Fisherian runaway traits, or by individual variability in the perceptual abilities of receivers form another group. Individuals of the same species vary in their capacity to perceive signals from different modalities. For example, human children who are musically inclined process verbal stimuli more effectively than those inclined to the visual arts, whereas the artistically inclined recognize visual stimuli faster than the musically inclined children.

Categorization by Meaning

If signal meaning can be determined, for example, by correlating a feature such as redness of neck feathers with nutrient quality, then composite signals can be classified by their intrinsic meaning or information content (Table 3). Hence, signal components that

Table 1 Categorization of signals by how they affect receiver fitness

Adaptiveness of preferences	*Form of cues*	*Proposed hypotheses*	*Purpose of different cues*	*Proximate benefit gained by the receiver*
Adaptive, increase fitness through less errors or lower costs	Informative cues	Multiple messages	Indicator traits that reflect different qualities	
			Sensitive to different environmental or intrinsic factors	Evaluated together, traits reflect overall quality
			Develop at different times	Individuals can emphasize cue most relevant for them
		Backup cues	Indicator traits that reflect the same quality	Increased accuracy of assessment
		Species recognition	Different cues for species recognition and mate assessment	Avoidance of costly matings with other species
		Fisherian cues	Indicate heritable attractiveness	Offspring inherit the attractive trait
	Uninformative cues	Unreliable cues	Exploitation of sensory biases in the receiver	Facilitates detection of the signaler
		Receiver psychology	Additional cues enhance detectability, discriminability, or memorability of the signal	Facilitates mate assessment
	Informative or uninformative cues	Multiple sensory environments	Indicator or unreliable cues that are used	Facilitates mate assessment or increases the amount of information gained
			At different distances	
			At different stages of the courtship ritual	
			In different signal transmission habitats	
Nonadaptive, no effect on fitness	Uninformative cues	Unreliable cues, threshold cues	Exploitation of sensory biases in the receiver	
			Remnants from past selection	
Maladaptive, reduce fitness	Uninformative, manipulating cues	Intersexual conflict	Manipulation of mating resistance by exploitation of preexisting sensory biases	

Adapted from Candolin U (2003) The use of multiple cues in mate choice. *Biological Reviews* 78: 575–595.

Table 2 Categorization of signals by other selection pressures

Multiple sensory environments	Signal transmission and reception are influenced by environmental conditions. Efficacy backup: each signal acts as a backup to the other in the presence of environmental variability. Efficacy trade-off: the transmission characteristics of each signal vary; each one is specialized to overcome a particular transmission impediment.
Sensory constraints	The receiver's sensory system influences the detection and processing of signals. Parallel processing: multiple bits of information can be processed simultaneously, potentially reducing the latency to receiver response. Sensory bias for multisensory integration: given the existence of multisensory neurons, a multimodal signal enhances the neuronal response, thereby increasing the salience of the event. Sensory overload: a signaler can 'jam' a receiver's reception and/or processing system by providing more information than can be handled by the receiver's sensory system. Perceptual variability: each signal acts as a backup to the other in the presence of perceptual variability among receivers.

Adapted from Hebets EA and Papaj DR (2005) Complex signal function: Developing a framework of testable hypotheses. *Behavioral Ecology and Sociobiology* 57: 197–214, with permission.

Table 3 Categorization of signals by content

Multiple messages	Different signals provide different information: either different types of information or information about different aspects of signaler quality. Quality: both signals convey different aspects of signaler quality; referred to in the literature as 'multiple messages.' Static vs. dynamic: one signal conveys more static properties (i.e., genetic indicators) while a second conveys more dynamic properties (i.e., current condition). Species recognition: one signal conveys species identity while another conveys a different type of information, such as signaler quality. Quality plus: one signal conveys signaler quality while another provides a different type of information such as signaler location. Receiver variability: different signals are directed at different receivers due to variable receiver preferences.
Redundant signal	Different signals provide the same information, allowing for increased accuracy of receiver response.

Adapted from Hebets EA and Papaj DR (2005) Complex signal function: Developing a framework of testable hypotheses. *Behavioral Ecology and Sociobiology* 57: 197–214, with permission.

transmit the same information may be classified in one group, such as the red-orange bill color and redundant red feathers under the wing of female northern cardinals (*Cardinalis cardinalis*), which are both correlated with body condition. Composite signal components that each convey different information may be classified in another group, such as multiple visual signals of size and color pattern in male pygmy swordtails (*Xiphophorus pygmaeus*). In this case, size indicates mate quality, whereas black bars on the body are likely used for species identification.

It is important to note that practitioners must be careful in their conclusions regarding signal meaning. It may be possible for two components to carry the same general message, such as that the individual is in good condition, yet the specific meanings or literal translations can differ. For example, in zebra finches (*Taeniopygia guttata*), higher song rate and redder beak color are both preferred by females, suggesting that they may be redundant signals of male quality. Nevertheless, song rate ostensibly indicates a mate's present condition, whereas beak color indicates past condition, because after controlled nutrition and exercise the finches' song rate changed much faster than their beak color. Therefore, two signal components may both function in mate choice but have slightly different meanings or act on different time courses.

Categorization by Signal Interaction

Composite signals may be demarcated by how the components influence one another (Table 4). Composite signals in which one component facilitates learning or memory for the other component could be grouped together. For instance, when learning to avoid water with an aversive taste, rats (*Rattus norvegicus*) learn

Table 4 Categorization of signals by their interactions

Multitasking	A signaler's ability to generate one signal is constrained by, and thus negatively correlated with, his or her ability to generate another signal.
Increased detection and discrimination	The presence of one signal either increases the probability and/or speed of detection of a second signal or increases the accuracy with which a receiver responds to a second signal. Amplifier: one signal increases the probability of detection of the second signal and/or decreases the detection threshold, making it more conspicuous. Alerting and attention altering: one signal either alerts a receiver to a second signal, thereby decreasing the reaction time, or influences the information-filtering mechanism of the receiver such that the receiver's attention is focused on another signal. Context: the presence of one signal provides a context in which a receiver can interpret and respond to a second signal. Emergence: a receiver is better able to discriminate among signalers due to the emergent properties of combining multiple signals in such a way that a new, unique signal is formed.
Increased learning and memory	The presence of one signal increases a receiver's ability to learn and/or remember another signal or the entire display.
Increased deception	The presence of one signal decreases the accuracy with which a receiver responds to another signal.

much faster when an aversive odor is also perceived. Signals in which the production of one component limits the capacity to produce another component could form another group. Male brown-headed cowbirds (*Molothrus ater*) use visual and vocal signals in their communication displays; however, they often remain still while vocalizing in order to prevent any detrimental effects to the sound quality of their vocalizations. Composite signals in which one component affects the ability to accurately perceive the other component could comprise another group, such as when a male stickleback (*Culaea inconstans*) releases a chemical signal in order to attract a female's attention toward his visual signal components of courtship, such as his red ventral patch and zigzag movements.

Categorization by Receiver Response

One classification system has been set up to categorize specifically multimodal signals (Figure 2). It is based on receiver response to both the multimodal signal and the individual signal components. Signals are then categorized based on the relationship between their components. Multimodal signals can be divided into those that are redundant and those that are nonredundant. In order to determine which applies, the receiver's response to each unimodal component as well as to the composite signal must be analyzed. This classification system is discussed in more detail because it is meant to be used specifically for multimodal signals.

Response to redundant multimodal signals

A redundant multimodal signal occurs when a receiver's response to a composite signal is qualitatively identical to its response to each of the unimodal components. Therefore, a redundant composite signal contains components with the same general meaning, sometimes referred to as backup signals. For example, when begging for food from their parents, young magpies (*Pica pica*) use a multimodal display that consists of a gaping beak (visual component) and begging vocalizations (auditory component), both of which elicit parental feeding behavior.

Redundant signal components can be parsed into two subcategories according to the quantitative nature of the receiver's response: equivalence and enhancement (Figure 2). Equivalent signals refer to those in which the receiver's response to the composite signal and each signal component is qualitatively and quantitatively homogeneous. For example, male moths (*Cyncia tenera*) emit acoustic clicks and chemical pheromones during courtship displays. Females are equally willing to copulate with the males no matter whether acoustic, chemical, or both channels of information are available, suggesting that this composite signal would be classified in the equivalence subcategory.

Enhancement, a heightened response to the composite signal relative to the response to either single component, is more common than equivalence. For example, female fruit flies (*Drosophila melanogaster*) are much more likely to mate if simultaneously presented with auditory (wing vibration song) and chemical (hydrocarbons from male cuticle) components of the male's courtship display than if they are presented with either unimodal component alone. Female pigeons (*Columba livia*) respond with more courtship behavior after being exposed to the male's multimodal bow and coo display than after being exposed to only the bow or the coo.

Figure 2 Classification of communication signals by receiver response. First, the responses to each signal component alone must be compared in order to classify the signal as redundant or nonredundant. Then, to classify into subcategories, the responses to the signal components must be compared to the response to the whole composite signal. Different shapes indicate qualitatively different responses, whereas different sizes represent quantitatively different responses. Reproduced with permission from Partan SR and Marler P (1999) Communication goes multimodal. *Science* 283: 1272–1273. Copyright (1999) American Association for the Advancement of Science.

Technically, enhancement may be parsed into three further subcategories: minor enhancement, summation, and multiplicative enhancement (Figure 3). Minor enhancement occurs when the response to the composite, multimodal signal is greater than the response to each isolated component but less than the sum of the responses to each component. Summation occurs when the response to the multimodal composite signal is equal to the sum of the responses to each unimodal component. Seitz's law of heterogeneous summation is an example of this subcategory; he found that the aggressive response of cichlids (*Haplochromis* spp.) to models that consisted of various visual components was equal to the sum of the aggressive responses to each of the components presented in isolation. Finally, multiplicative enhancement occurs when the response to the composite, multimodal signal is greater than the sum of the responses to each unimodal component. The three subcategories of enhancement can be difficult to accurately distinguish when strictly studying behavior; this type of distinction is easier to measure when observing neuronal response to multiple stimuli.

Response to nonredundant multimodal signals Nonredundant multimodal signals refer to composite signals in which the response to each unimodal component is qualitatively different, or when the response to the composite signal is qualitatively different than the response to at least one of the unimodal components. For example, rhesus macaques (*Macaca mulatta*) are likely to respond to a silent threat (e.g., an open-mouthed gesture (**submissive**)) with fearful and submissive responses. However, when this visual threat is combined with an aggressive vocalization (e.g., a bark), the monkeys are as likely to respond with aggressive responses as they are with submissive responses. Nonredundant signals may be divided into four subcategories: independence, dominance, modulation, and emergence.

Independence indicates that the response to the composite, multimodal signal consists of both responses to each of the unimodal components. Hence, the response to the multimodal signal is merely a combination of the (qualitatively different) responses to each unimodal component. For example, in the tropical wandering spider (*Cupiennius salei*), males display undirected courtship behavior in the presence of female pheromones alone. After being exposed to tactile cues on the web due to movement of the abdomen and legs, the males move in the female's direction. When both chemical and tactile cues are present, the males direct courtship behavior in the female's direction; the response to the composite signal is simply the combination of the responses to each unimodal component.

Dominance refers to a situation in which the response to the composite, multimodal signal is equivalent to the response to only one of the unimodal components. When soliciting play, domestic dogs (*Canis familiaris*) may combine a paw lift gesture with a growl. Growls generally indicate aggression in dogs, and paw lifts generally indicate playfulness; when the two signals are combined, play behavior is

Figure 3 Redundant signals: equivalence and enhancement. Vertical axis indicates a measure of response to the signals. Equivalence occurs when the response to each component is qualitatively similar to the response to the composite signal. Minor enhancement, summation, and multiplicative enhancement occur when the response to the composite signal is less than, equal to, or greater than the sum of the responses to each signal component, respectively. Reproduced from Partan SR (2004) Multisensory animal communication. In: Calvert GA, Spence C, and Stein BE (eds.) *The Handbook of Multisensory Processes*, pp. 225–240. Cambridge, MA: MIT Press, with permission.

elicited. Therefore, the play component is thought to dominate the aggressive component when the two are combined to create a multimodal signal.

Modulation occurs when the response to the composite signal is qualitatively similar to the response to one of the components but quantitatively dissimilar. Dart-poison frogs (*Epipedobates femoralis*) use a multimodal display during territory defense that consists of vocal sac pulsations and vocalizations. The frogs do not display any noticeable responses to the pulsating vocal sac alone, but some frogs move in the direction of the sound source after hearing vocalizations without a visual component. When the multimodal signal is presented, nearly all males approach the displaying frog. Hence, the response to the multimodal signal is an amplified version of the response to the auditory signal component. In fact, the term 'amplifier' has been used to describe this situation when it occurs solely in the visual modality.

Modulatory multimodal signals can also reduce the response that is elicited from one of the unimodal components. Male snapping shrimp (*Alpheus heterochaelis*) respond aggressively after viewing a female conspecific's open chela, or claw, but do not respond aggressively when only female chemical cues are detected. When the males have access to the chemical and the visual components, their aggressive response diminishes considerably relative to their response to the visual-only component.

Finally, emergence refers to a situation in which the composite signal elicits a response that is new, in that it is qualitatively different from the responses elicited to either unimodal component in isolation. For instance, young chickens (*Gallus domesticus*) display a robust aversive response to stimuli with a combination of pyrazine odor and red or yellow coloration (aposematic warning signals). However, they do not avoid stimuli that contain only the visual or the chemical component. Therefore, a novel response is elicited from the multimodal signal.

Incidence of Multimodal Signaling and Channels Commonly Combined

It is likely that all animals (including humans) communicate via multiple sensory channels simultaneously. Surveys of the literature show that multimodal signals have been observed in both invertebrates and vertebrates. Depending on their sensory acuity and on habitat features, different taxa rely on different combinations of channels. Insects commonly combine chemical with visual or vibrational signal components, for example, whereas birds usually combine auditory and visual signals. In a survey of 30 species whose multimodal signaling behavior has been examined in

detail, invertebrates employed only those multimodal signals that included chemical or vibrational components; vertebrates strongly preferred auditory/visual composites (Table 5). Almost all (26 of 30) examples include at least one short-distance communication channel (visual, tactile, or vibratory). Therefore, it appears that one component of a multimodal signal often serves to relay information to nearby receivers.

Out of a subset of 18 examples from the same survey that were definitively classified into one of the categories shown in Figure 2, most fell into the redundant enhancement or the nonredundant modulation groups (Table 6). Interestingly, auditory components were more common in those signals classified as redundant (six of the seven redundant examples contained an auditory component compared to 3 of 11 nonredundant ones), whereas visual and chemical components were more common in the nonredundant group (9 of 11 nonredundant examples contained visual components compared to three of seven redundant ones; 7 of 11 nonredundant examples contained chemical components compared to three of seven redundant ones). This suggests that auditory signals may more often be merely repetitive, whereas visual and chemical signals carry unique information.

Function and Evolution of Multimodal Communication

Function of Redundant and Nonredundant Signals

Redundant signal components provide insurance that the signal will be received. This is especially useful in environments with biotic or abiotic impediments to signal transmission. For instance, if there is an abundance of auditory noise in a particular environment, incorporating a visual component to the signal will increase the chances of it being detected. Examples of abiotic impediments include dense habitats that impede visual displays or broken substrate unfavorable for seismic signaling. In these cases, the incorporation of an additional signal channel will improve transmission. Given the assumption that each signal is perceived by a receiver with a certain

Table 5 Survey of sensory channels used by 30 species whose multimodal signaling has been examined in detail[a]

Sensory channels used	*Invertebrates (n = 11)*	*Vertebrates (n = 19)*
Auditory/visual ($n = 11$)	0	11
Chemical/visual ($n = 9$)	5	4
Auditory/chemical ($n = 4$)	2	2
Chemical/tactile ($n = 2$)	0	2
Chemical/vibrational ($n = 2$)	2	0
Visual/vibrational ($n = 1$)	1	0
Auditory/vibrational ($n = 1$)	1	0

[a]Species names and signals used in these examples are listed in Partan SR and Marler P (2005) Issues in the classification of multimodal communication signals. *American Naturalist* 166(2): 231–245, tables 2 and A1. This is neither an exhaustive nor necessarily representative list of species that use multimodal signals; rather, it is a survey of species that have been studied by biologists who explicitly examined the use of each signal component in multimodal communication.

Table 6 Sensory channels used, by signal category, for all 18 signals from the survey that were able to be categorized according to Figure 2[a]

Redundant			*Nonredundant*			
Sensory channels	*Redundant Equivalence*	*Enhancement*	*Nonredundant Independence*	*Dominance*	*Modulation*	*Emergence*
Auditory/chemical	1	1				
Auditory/vibrational	1					
Auditory/visual		3		1	2	
Chemical/vibrational		1	1			
Chemical/visual					4	1
Chemical/tactile					1	
Visual/vibrational					1	

[a]Species names and signals used in these examples are listed in Partan SR and Marler P (2005) Issues in the classification of multimodal communication signals. *American Naturalist* 166(2): 231–245.

amount of error, redundant signals may also increase the probability that a signal is detected accurately. In addition, redundant signals may increase the salience of a display. Hence, redundant signals have the potential to increase stimulus intensity, such as when sex pheromones increase the visual attractiveness of a human of the opposite sex. In other cases, they also may have the potential to jam a receiver's sensory apparati in order to diminish or prevent a response (Table 2). Finally, redundant signals may facilitate stimulus recognition; humans utilize redundant visual and vocal components when speaking, and their combination enhances the recognition of the spoken word.

Nonredundant signal components have the potential to increase the amount of information sent per unit time. It is likely that the 'coo' component of the male Barbary dove (*Streptopelia risoria*) courtship display indicates individual identity, whereas the 'bow' component indicates sex. Male jumping spiders (Salticidae) likely signal different aspects of mate quality in their multimodal display that includes visual and seismic signals. Although there are fewer examples of nonredundant than of redundant multimodal signals, many animals perform multicomponent, rather than multimodal, displays in which each component represents a different aspect of mate quality. For example, the black cap of the American goldfinch (*Carduelis tristis*) is likely influenced by dominance rank, whereas the color of the plumage and bill indicate intestinal health.

There are a number of other potential functions that apply to both redundant and nonredundant multimodal signals. Multimodal stimuli are generally detected faster and elicit a shorter reaction time than their unimodal components. In addition, the detection threshold is lower and discriminability is facilitated for multimodal versus unimodal stimuli. For example, cats (*Felis cattus*) are more accurate in perceiving the intensity of light when it is presented with an auditory stimulus than when the auditory component is missing. Multimodal signals can also facilitate learning and memory relative to their unimodal counterparts. For instance, male nightingales (*Luscinia megarhynchos*) learn more songs and repeat them more accurately if they are accompanied by a pulsating strobe light during acquisition. Finally, a component from one modality can often provide the context for a second signal. Pheromones from the snapping shrimp (*Alpheus heterochaelis*) ostensibly indicate sex, as implied previously, and these chemical cues modify the response to the open chela. If female pheromones are detected, a male conspecific's response depends on chela size. In contrast, responses are independent of chela size when male pheromones are detected. Therefore, the chemical cue appears to provide a context in which to interpret the visual chela cue.

Game Theory and Sexual Selection

Game theoretical models have been proposed to explain the evolution of multicomponent and multimodal communication signals, particularly as used in mate choice. Some models have predicted that signals with multiple components will only be stable over evolutionary time if each signal component plays an equal role in indicating the quality of a mate. The backup signal hypothesis states that each component within a composite signal is indicative of the same quality. Hence, backup signals serve to reduce the probability of a receiver assessing a quality inaccurately. However, individuals may vary in the traits they find important in mate choice. In addition, a composite display may be directed at multiple receivers. Consequently, other hypotheses, such as the multiple messages hypothesis, have been posited to explain the evolution of signal components that reveal different types of information about an organism.

Particular attention has been paid to signals that have evolved via sexual selection. Two common theories to explain this process are exploitation of a mate's preexisting sensory biases and Fisherian runaway selection. Exploitation of sensory biases occurs when animals produce signals that are sent via specific channels or ranges that take advantage of a conspecific's preexisting sensory receptors for stimuli within those channels or ranges. For example, courting male water mites (*Neumannia papillator*) produce vibrations that mimic prey items in order to attract females. It is thought that this courtship display evolved subsequent to female sensory systems becoming attuned to detecting the vibratory stimuli produced from nearby copepods. Fisherian runaway selection, in which male traits evolve due to arbitrary female preferences, may explain the evolution of traits such as the costly, elaborate tail feathers of male peacocks that do not facilitate their owners' survival. Males most likely produce these feathers for the sole purpose of increasing their attractiveness to females.

Another theory proposed to explain the evolution of composite signals involves amplifiers or modifiers. These are signal components that may have no intrinsic meaning but instead can function to alter the perception of another component. For example, the feathers of many birds are outlined in dark colors. Although the outline coloration may not convey any information alone, it may attract more attention

toward the feathers or make it easier to accurately perceive feather condition; the outline is a modifier to feather condition in this multicomponent visual signal. Similarly, male blue-black grassquits (*Volatinia jacarina*) combine a visual leaping display with a vocalization in order to facilitate localization of the acoustic signal by the receiver. The amplifier theory can also apply to signals that are not involved in

Figure 4 (Top) Response enhancement in the cat brain: the neural response to the multimodal stimulus (visual plus auditory) is greater than the response to either the audio or the visual stimuli presented in isolation. (Bottom) Response depression: the neural response to the multimodal stimulus is less than the response to the unimodal stimulus (visual only). Copyright (1983) American Association for the Advancement of Science.

sexual selection. For instance, one component can help to clarify an ambiguous signal from another channel, such as when female red-winged blackbirds add a vocalization to their visual displays in order to indicate either aggression or courtship.

Neural Factors (Multisensory Integration)

The neural integration of multisensory information has traditionally been tested using lights and tones as stimuli. Current research, however, uses recordings of actual communication signals as stimuli to test biologically relevant multisensory input. For example, monkey neural responses to auditory/visual input are tested using video of monkey faces combined with audio recordings of monkey vocalizations.

Multisensory integration can be the result of higher-level neural integration of information from primary sensory areas or of single neurons that preferentially respond to multimodal stimuli. Techniques such as functional magnetic resonance imaging can reveal whether a particular brain area in general responds to multimodal stimuli, but single cell recordings are necessary to assess the presence of multimodal neurons. Multimodal neurons can show any of the same responses that were described previously for behavior: response enhancement, depression, modulation, and even emergence (Figures 2 and 4). This provides a mechanism for the behavioral reactions.

Evidence of a neural substrate for multisensory integration does not necessarily imply that this mechanism is used for purposes of communication. For example, some organisms that have neural connections between different sensory areas, such as rattlesnake (*Crotalus viridus*) visual and infrared modalities, are not known to use multimodal signals that combine these two sensory channels for communication purposes. It is plausible that this sort of preexisting connection between different sensory modalities initially subserved other behaviors, such as predation, and may later facilitate the evolution of multimodal communication.

Multiple Memory Systems

N M White, McGill University, Montreal, QC, Canada

© 2009 Elsevier Ltd. All rights reserved.

The term multiple memory systems (MMSs) refers to the idea that different types of information are processed and stored in different parts of the brain. It is an application of the concept of localization of function, based on the premise that processing and storing particular types of information are unique functions. Each of several series of connected brain structures forms parallel pathways or systems. Each system contains microstructure specialized to process a different type of information, represented by patterns of neural activity. As these activity patterns move through the systems, they are altered (processed) in various ways. The outputs of the systems influence thought and behavior. These ideas are illustrated and expanded in Figure 1.

In its weakest form the MMS concept is a convenient way to organize information about the localization of memory functions in the brain. In its strongest version MMS theory postulates that information is processed and memories of that information are stored in several parallel, independently functioning systems. In some part of each system, neuroplastic properties of the microstructure may allow information being processed to alter synaptic relationships. These changes constitute memories. Because of them, processing similar information on subsequent occasions results in altered output of the system, generating new (learned) thoughts and behaviors.

Although direct interactions among the systems are possible, the idea that they function independently implies that their outputs converge to influence behavior and thought. The most common form of interaction among the outputs is probably cooperation, when the information processed by each system makes a unique contribution to a complex memory or performance of a complicated task. The systems can also process information leading to different outcomes resulting in competition for control of behavior. These situations, which can be created in the laboratory, provide valuable insights into the operation and interaction of the systems.

Origin of the MMS Idea

The MMS idea was originally suggested by the study of individuals in whom damage to a particular part of the brain impairs one type of memory but not others. The most common case is damage to the medial temporal lobes, variously including parts of the hippocampus and the overlying parahippocampal cortex. These people are unable to remember most personal experiences that occurred prior to their brain damage or current events a few minutes after they occur. They are unable to find their way around even in familiar environments. However, the same people can learn new skills and procedures, and acquire and retain new emotional responses. An example is the patient HM, described by Milner, Penfield, and Scoville. Most of HM's medial temporal lobes had been surgically removed to relieve otherwise intractable epilepsy. After repeated practice HM became proficient at solving a short maze by moving a stylus on a tablet through a series of left and right turns. However, when asked to demonstrate this ability he invariably replied that he was willing to try but doubted he would be very good at it because he had never seen the task before. He then proceeded to solve the maze easily. This behavior pattern demonstrated HM's inability to recall his previous experience with the maze (memory normally dependent on the medial temporal lobe) and his simultaneous ability to remember the sequence of moves required to solve the maze. The memory for this sequence must have depended on some part of the brain other than the medial temporal lobes.

Types of Information/Memory

Declarative and Procedural Memory

The kind of information HM was unable to recall is usually called declarative memory because it can be described verbally. His intact memory for solving the maze is a type of skill, often called procedural memory.

Sherry and Schacter have suggested that procedural and declarative memories consist of functionally incompatible information. Procedural memories represent constant relationships among the elements of a situation. They are acquired by repeated exposure to such constancies, usually in situations where a specific stimulus comes to evoke a specific behavior pattern or response. These characteristics led Mishkin to suggest the term habit memory as a synonym for procedural memory. Procedural memory is prescriptive (e.g., the sight of a particular door invariably elicits the response of opening it). In contrast, most declarative memories are acquired as the result of a single experience and are descriptive in nature (the sight of the door elicits a memory of what to expect when it is opened). Descriptive information about the door can be combined with other information in a flexible way that could result in a decision to open or not to open the door. No such flexibility is possible

Figure 1 Diagram of MMSs concept: (1) Information enters the brain from various external and internal sources and is represented by patterns of neural activity. As the individual's situation changes, the activity patterns change. (2) The changing patterns converge on various brain areas and move, or flow, through several parallel series of interconnected structures (circles in the figure), known as systems. (3) Due to differences in internal microstructure each system is specialized to represent activity patterns consisting of different kinds of information. In this way, each system can represent different information about the same situation. When an activity pattern corresponds to the microstructure of a system the system responds in a coherent manner – indicated by the dark brown circles in the figure. As the activity patterns change the system responding most coherently may change. (4) The outputs of the system converge on brain structures that result in behavior and thought. The outputs may promote similar behaviors or parts of complex behaviors and thoughts (cooperation), or they may promote different behaviors (competition). The output of the system responding most coherently at any time exerts the strongest influence on thought and behavior.

in the procedural system where a specific stimulus always evokes the same specific response.

Because it is purely descriptive, declarative memory can be described as a series of associations among stimuli (S–S associations). Procedural memory has been described as consisting of a series of unique stimulus–response (S–R) associations.

Emotional Memory

Emotions and internal motivational states result from patterns of activity in the autonomic nervous and endocrine systems, and in certain brain structures. These activity patterns are innate, unconditioned responses (URs) to specific kinds of stimuli – an approaching speeding car or the smell of certain foods (even if they have not previously been tasted) – called unconditioned stimuli (US) or reinforcers. A neutral stimulus present at the same time as a US becomes a conditioned stimulus (CS) which can, in the absence of the US, elicit a conditioned response (CR) that is similar to the UR. This is Pavlovian conditioning, also described as stimulus–reinforcer (S–Rf) learning.

Although emotional states can be described and act to influence thought and behavior, no declarative memory of the relationship between a CS and the conditioned emotional state it elicits is required for this form of memory. Emotional memories are limited to USs and the URs they elicit innately, and do not require the performance of any other response. In contrast, procedural memories can be formed from associations between any stimulus that can be perceived and any response that can be performed.

Anatomical Basis of Memory Types

The preponderance of evidence is that damage to the medial temporal lobes (including either the hippocampus or the fimbria-fornix, a major input–output pathway of the hippocampus) or the medial thalamus impairs declarative memories but leaves procedural and emotional memory functions intact. Procedural memories are impaired by damage to the basal ganglia (including the caudate nucleus), which does not impair declarative or emotional memories. Damage to the amygdala impairs emotional memories with no effect on procedural or declarative memory.

These dissociations are strong evidence for localized processing of different information types. In this experimental design (illustrated in Figure 2) the effects of damage to different brain structures (usually two) on an equal number of memory tasks are compared. A dissociation is demonstrated when performance on each task is impaired by damage to a different structure and damage to each structure affects only one of the tasks.

Each of the structures implicated in one of the three types of memory has extensive efferent and afferent connections that allow information to flow through it. Each structure, together with its efferents and afferents constitutes a system. Evidence dissociating the information types processed in each system form the basis of the MMS idea.

Dissociations in Human Memory Functions

Declarative versus Procedural Memory

Especially in their early stages, certain pathologies selectively affect specific brain structures. Alzheimer's disease primarily impairs hippocampal function; Korsakoff's syndrome affects the medial thalamus. Patients with either of these pathologies suffer severe declarative memory loss and are referred to as amnesic. Parkinson's and Huntington's diseases primarily affect the function of the basal ganglia, including the caudate nucleus.

Figure 2 Dissociation paradigm. In this experimental paradigm, subjects are given several different behavioral tests (1–3 in the diagram) for their ability to learn and recall specific types of information. Different subjects or groups of subjects have impairments of specific brain areas (A–C in the diagram) due to accidental trauma, disease, or surgery in humans or experimental manipulations in animals. Each of the brain lesions impairs performance on one of the tasks but leaves the others intact. Demonstrations of this type are evidence that the brain area required to process the information necessary for performing each of the tasks is not required for the other tasks. This shows that the information processing functions for each of the tasks occur in different parts of the brain. The conclusion is that A, B, and C are parts of systems that function independently to process different kinds of information. Most dissociations involve two tasks and two brain areas (double dissociation), but McDonald and White have described a triple dissociation of this kind among memory types and brain systems.

Mirror reading Cohen and Squire found that with practice, amnesic patients could learn to read fluently complex words seen in a mirror (a skill or procedural memory) but were subsequently unable to recall any of the words they had read (declarative memory). This pattern of deficits was replicated in Korsakoff's patients by Heindel, Butters and colleagues. They also showed that Huntington's patients were unable to improve their mirror reading skill but could remember the words they had read. This double dissociation localizes declarative (S–S) memory to the hippocampus and medial thalamus, and procedural (S–R) memory to the basal ganglia. The dissociation also shows that both systems can process and store these types of information independently of the other system (although it remains possible that both structures could contribute to both behaviors in normal individuals).

Weather prediction task In the weather prediction task (Knowlton, Mangels, and Squire) subjects are shown displays of four cards at a time selected from a larger set, each printed with a unique pattern. The cards predict either of two outcomes, rain or shine, with a probability of less than 100%. Participants indicate their responses by pressing either of two buttons and receive feedback as to whether or not their response was correct. The probabilistic association between each stimulus and its correct response provides sufficient repetition to produce procedural (S–R) learning while retarding declarative (S–S) learning about the correct responses. Parkinson's patients are severely impaired on the weather prediction task while amnesiacs perform almost as well as normal controls. Notwithstanding their near normal weather prediction, amnesic patients are unable to answer questions about the testing experience (declarative memory); the Parkinson's patients' memory of the testing experience is normal. These findings are a double dissociation of declarative memory (in the amnesiacs with impaired function of medial temporal lobe and/or medial thalamus) and procedural memory (in the Parkinson's patients with impaired function of basal ganglia).

Brain imaging with functional magnetic resonance imaging (fMRI) while doing the weather prediction task (Poldrack and colleagues) revealed increased activity in the basal ganglia (caudate nucleus) and decreased activity in the medial temporal lobe. When the same information was learned by presenting the cards together with the outcome they predicted (a form of paired associate declarative learning known to depend on the medial temporal lobe), activity in the hippocampus increased while activity in the caudate nucleus decreased. This double dissociation is consistent with the evidence from brain-damaged patients.

Radial maze In another imaging study (Iaria, Bohbot, and colleagues) normal participants searched for virtual rewards at the ends of the arms of a computer-generated radial maze (a circular center area with eight arms radiating from it in a sunburst pattern). The maze was surrounded by a landscape with mountains, trees, and the sun. Since rewards obtained were not replaced, participants had to remember which maze arms they had visited to avoid reentries and obtain the rewards with the fewest possible errors. After performing the task, about half of the participants said they had used the landmarks to remember and avoid previously visited arms (a spatial strategy). Hippocampal activity was increased in these participants. The other half said they had arbitrarily labeled or counted the arms (a nonspatial strategy). These participants showed increased activity in the caudate nucleus. A subgroup that started out using a spatial strategy reported that they switched to a nonspatial strategy during training; their patterns of brain activation shifted from hippocampal to caudate activation in parallel with their reported strategy switch.

Declarative versus Emotional Memory

Bechara and Damasio compared a patient with Urbach–Wierthe disease, which produces brain damage confined to the amygdala complex, to a patient with hippocampal damage due to anoxia. The patients were shown slides of different colors, one of which (the CS) was followed by the sound of a very loud air horn (US). In addition to a startle response, the horn produced increased skin conductance (UR), a standard measure of aversive emotional state. When the CS slide was shown without the horn it elicited increased skin conductance (a CR) in normal participants, an instance of Pavlovian conditioning. The patient with amygdala damage did not exhibit this CR but was subsequently able to recall most details of the experimental experience (declarative memory). In contrast, the hippocampal patient showed normal conditioning, but was unable to recall most experimental details.

Johnsrude and colleagues compared surgical patients with unilateral amygdala resection to a group with unilateral frontal cortex resection. The patients were exposed to a series of patterns on a computer screen while performing a highly distracting counting task. The patterns were accompanied by a reward (a raisin or small candy) on either 90% or 10% of their appearances. After training, the participants were asked for the result of the counting task (declarative memory) and were then shown pairs of the patterns and asked which one they preferred (Pavlovian conditioning).

Normal participants performed the counting task accurately and preferred the patterns that had been paired with the reward 90% of the time over those that had been paired 10% of the time, a conditioned preference. Patients with amygdala damage performed the counting task accurately but did not exhibit the conditioned preference. In contrast, patients with frontal lobe damage were unable to perform the counting task but exhibited normal conditioned preferences.

These studies dissociate the processing of information required for amygdala-based aversive and appetitive Pavlovian conditioning (S–Rf memory) from the processing of declarative (S–S) information.

Summary of Dissociations in Humans

Figure 3 illustrates the anatomical dissociations of the different types of information processing described. Some of the justification for this way of organizing the data derives from experiments with rats, reviewed next.

Dissociations of Memory Systems in Rats

Although animals cannot verbalize recalled information, it is possible to show that they can learn and recall the same three types of information as is suggested by the human studies, and that these types are processed in neural systems consisting of the same or homologous brain structures.

Declarative (S–S) versus Procedural (S–R) Memory

Cross maze An experimental paradigm for dissociating declarative and procedural memory in rats, introduced by Tolman in 1946, makes use of a

Figure 3 Dissociations of information types and brain structures. The figure is based on evidence that performance on tasks requiring memory for three different kinds of information (S–S, S–R, and S–Rf) is impaired by lesions of the medial temporal lobes, basal ganglia, and amygdala, respectively, and that none of these lesions affects processing of the other information types. Imaging data also dissociate activity levels in hippocampus and caudate nucleus with processing declarative and procedural information, respectively. The figure presents this information in the context of the MMS concept: the idea that the three kinds of information are processed in different, parallel neural systems. The figure shows the systems interacting only when their outputs converge to influence behavior and thought.

cross-shaped maze, described in Figure 4. Using this paradigm, Packard and McGaugh found that when tested after 8 days of training, most rats ran to the correct spatial location of the food, even though this required them to make a turn opposite to the one which had been reinforced during training. This is an example of the flexible use of information by the declarative system. After 8 more days of training, most of the same rats made the same turn at the choice point that had been reinforced during training, even though this response led away from the food. This is an example of an inflexible S–R relationship of the kind mediated by the procedural system. This shift from the control of behavior by declarative information to control by procedural information is similar to the shift reported by humans on Iaria et al.'s virtual radial maze task, many of whom switched from using spatial information to nonspatial methods during the course of training.

In other groups of rats, Packard and McGaugh temporarily inactivated either the hippocampus or the caudate nucleus with lidocaine during the test trials. The results (explained in detail in Figure 5) revealed that the tendency to turn toward the food on the early test trial was due to hippocampus-based processing of spatial information, and the tendency to turn away from the food on the later trial was due to caudate-based processing of S–R information. These results illustrate several features of hippocampus-based declarative and caudate-based procedural memory and their interaction. (1) Declarative memory can be used flexibly, depending on the current context, to generate behavior leading to an outcome; procedural memory is inflexible: a stimulus (the choice point in the maze) always elicits the same response regardless of the outcome. (2) Declarative memory is acquired and stored relatively quickly; procedural memory requires more repeated trials for an S–R association to build up sufficient strength to influence behavior. (3) The outputs of the declarative and procedural memory systems compete with each other for control of behavior. Such evidence of competition between behaviors produced by different kinds of information mediated in different brain systems is evidence that the systems acquire and process information independently (see Figure 5).

Water maze Morris and colleagues described a task for studying spatial learning using a large circular pool of opaque water situated in a room with a variety of cues. Rats swim around until they encounter a small platform, invisible below the surface, which allows them to escape from the water. Over repeated trials, the rats quickly learn to swim directly to the platform even when they are placed into the pool at different points on the perimeter. Since no local cues indicate the platform location it must be learned in relation to the spatial cues in the pool environment. This instance of spatial learning can be contrasted with learning to swim to a platform that is visible above the surface of the water. The presence of a local cue makes this a form of S–R learning.

McDonald and White trained rats to find a platform that remained in a constant location on training trials when it was visible and when it was submerged. On a final test trial the visible platform was moved to a new location (Figure 6). Rats with fimbria-fornix lesions tended to swim directly to the visible platform;

Figure 4 The cross maze task. On training trials (left) rats are placed at the end of one of the arms. When they reach the choice point, the barrier forces them to turn either left or right. Food is always placed at the end of the arm on the right. After repeated training trials, during which rats learn to turn right, a test trial (right) is given: the rats are placed at the opposite end of the start arm which is again blocked, forcing them to turn left or right at the choice point. The direction of the turn reveals the nature of the processed and stored information that produced it. A right turn, the same response as the one made during training – but now leading away from the food – is due to procedural or S–R learning. A left turn – opposite to the one made during training but leading toward the food – is due to spatial learning, a subtype of declarative or S–S memory.

Figure 5 Results and explanation of cross maze experiment: Top row: normal rats. The graph shows the number of rats that turned in the direction of the food indicating use of spatial information, or away from the food indicating use of S–R information on the two test trials. After 8 days of training most rats turned toward the food due to hippocampus-based processing of spatial information (light green). At this time insufficient caudate-based S–R learning had occurred to influence the response (white). After 16 training days, S–R learning had become strong enough for the output of the caudate system (dark green) to compete with the hippocampus-based response and take control over the rats' behavior, causing them to make the response acquired during training, leading away from the food. Middle row: inactivation of the hippocampus during the test trials. After 8 days hippocampal inactivation (gray) produced random responding, as predicted by the hypothesis that turning toward the food was due to hippocampus-based spatial information processing. After 16 days hippocampal inactivation (gray) did not affect the tendency to turn away from the food, consistent with the hypothesis that the hippocampus was not involved in this S–R type behavior. Bottom row: inactivation of the caudate nucleus during the test trials. After 8 days caudate inactivation (gray) had no effect, as predicted by the idea that this structure was not involved in processing the spatial information that produced the turn toward the food. After 16 days caudate inactivation (gray) resulted in turning toward the food, reversing the behavior of normal rats, which turned away from the food at this point (top row). This is predicted by the hypothesis that the caudate nucleus mediated the S–R information that produced the turn away from the food in the normal rats. It also shows that the hippocampus-based spatial information was still present and able to influence behavior, but that it was prevented from doing so in normal rats by competition from the output of caudate-based S–R information. Eliminating the caudate output allowed the spatial information to resume its influence, allowing the rats to turn toward the food. Data from Packard MG and McGaugh JL (1996) Inactivation of hippocampus or caudate nucleus with lidocaine differentially affects expression of place and response learning. *Neurobiology of Learning and Memory* 65: 66.

rats with caudate lesions tended to swim to the former location of the invisible platform first; upon failing to find it there they then swam to the visible platform.

These results (explained in detail in Figure 6) show that two kinds of information competed for control of the rats' behavior on the test trial. Eliminating spatial information processing with a fimbria-fornix lesion resulted in expression of S–R memory (swimming directly to the visible platform without regard to its new location), and eliminating S–R processing with caudate lesions resulted in swimming to the previously learned platform location notwithstanding that the platform was visible in a different location.

Analysis of the behavior of the control rats (explained in Figure 7) showed that at the start of training half of them relied on spatial learning to find

Figure 6 Competition between visible and invisible platform in the water maze. The blue circles are top views of a circular swimming pool about 1.5 m in diameter. Rats were placed into the pool once at each of the four starting points on each training day. The platform was always in the same location; it was visible on some training days and submerged (invisible) on others. On the test trial the rats were placed into the pool with the visible platform in a new location. In this situation, spatial learning about the location of the platform competed with the S–R tendency to swim to the visible stimulus. As shown by the typical swim path (red line) of a rat with fimbria-fornix lesions on the bottom left, the inability to process spatial information resulted in a tendency to swim directly to the visible platform due to the expression of caudate-based processing of S–R information. The bottom right shows a typical swim path for a rat with caudate nucleus lesions that could not process S–R information. This rat swam directly to the old spatial location of the platform due to the expression of hippocampus-based spatial information. After failing to find the platform in the old location the rat swam to the visible platform. Adapted from McDonald RJ and White NM (1994) Parallel information processing in the water maze. *Behavioral and Neural Biology* 61: 260.

Figure 7 Performance of normal rats grouped according to behavior on the competition test in the water maze. Of eight normal control rats, four swam directly to the visible platform (like the rats with fimbria-fornix lesions and intact caudate nucleus) and four swam to the old platform location first (like the rats with caudate lesions and intact hippocampus system) on the competition test (**Figure 6**). This figure shows the mean time required to find the hidden platform after each of three successive 3-day blocks of training with a visible platform in the same location. Learning the location of a hidden platform requires spatial information processing. The group that used spatial information on the competition test learned the spatial location of the hidden platform during the first three visible platform trials, but the group that used S–R information on the competition test required considerably more training to learn its spatial location. Adapted from McDonald RJ and White NM (1994) Parallel information processing in the water maze. *Behavioral and Neural Biology* 61: 260.

the maze while the other half acquired an S–R association. This parallels the finding of Iaria et al. that about half of humans solving a virtual radial maze initially used each of the two kinds of information and suggests that there may be constitutional differences in the relative influence of the two kinds of information on individual behavior.

Radial maze The radial maze task was introduced by Olton and colleagues in 1975 as a measure of working memory for spatial information. The maze is illustrated in Figure 8. A food pellet is placed at the end of each arm. A hungry rat is placed on the center platform and allowed to forage freely for the available food. Since consumed pellets are not replaced, the rat should enter each arm only once (leading to the description of the behavior as win-shift).

This task has a number of features in common with declarative memory. Entering each arm only once requires a memory of which arms have been entered

Figure 8 Effects of lesions and attenuation of extra-maze cues on win-stay performance. The top part of the figure shows an eight-arm radial maze in a room with extra-maze cues. On each daily trial, four of the eight maze arms have lights at their entrances (yellow dots) and only those four arms contain food (red dots). These four arms change on each daily trial. When a rat obtains the food pellet from one of the arms it is replaced. When the rat obtains the second pellet from an arm the light at the entrance is extinguished and no further food is placed in that arm. The bottom left shows the number of lit arms entered as a percent of total arms entered while retrieving the eight pellets. The graph shows that caudate nucleus lesions impaired win-stay performance relative to the normal controls, but that rats with fimbria-fornix lesions learned the task faster and attained a higher level of performance than normal rats. The superior performance of the rats with fimbria-fornix lesions can be explained by assuming that the caudate and fimbria-fornix are parts of independent information processing systems that acquire different kinds of information while the rat performs the task. Since win-stay performance is impaired by lesions of the caudate nucleus, that structure is assumed to be part of a system that processes the S–R information required to perform the task correctly. At the same time, the medial temporal lobe system, of which the fimbria-fornix is a part, processes information about the spatial locations of the food in the maze environment. However, since the spatial locations of the food change on each trial, information about food location acquired on any given trial and recalled on a subsequent trial is likely to be wrong and result in errors. Eliminating this source of errors by impairing the function of the hippocampal system with fimbria-fornix lesions therefore improves performance. The top right of the figure shows the maze surrounded by a curtain which attenuates extra-maze cues, retarding spatial learning with respect to those cues. The graph on the bottom right shows that rats trained with attenuated extra-maze cues learn the win-stay task faster and perform better than rats tested with normal exposure to the cues. This demonstration is consistent with the explanation for the facilitation of win-stay learning by fimbria-fornix lesions. Both the curtain and the lesions impair spatial learning, eliminating its interference with correct responding based on S–R learning. Adapted from Packard (1987), unpublished Master's thesis, McGill University.

as the trial progresses. The rat must therefore be able to identify (discriminate among) the arms. With appropriate controls this can only be done by learning the locations of the visited arms in relation to the cues visible in the maze environment. The rat must use information about arms entered to label each visited location so it can be avoided for the remainder of the trial. This information about each entered arm is acquired in a single experience without repetition and is different on every trial. Note that consumption of the food at the ends of the arms does not function as a reinforcer, which would make reentries more, not less, likely. Instead, information about which arms no longer contain food may contribute to the tendency to avoid those arms as the trial progresses.

Packard, Hirsh, and White used this apparatus to compare declarative (win-shift) learning and S–R learning using the win-stay task (see Figure 8). Since the presence of food at the ends of the arms in the win-stay task is always indicated by lights at the arm entrances spatial learning is not required to discriminate among the arms or to remember which arms have been entered. Instead, the rats repeatedly enter lit arms and each entry into any such arm is followed by food functioning as a reinforcer by increasing the probability of entering lit arms.

Rats with lesions of the fimbria-fornix or hippocampus are impaired on the win-shift but not on the win-stay task. In contrast, rats with lesions of the caudate nucleus are impaired on win-stay, but not on win-shift. This double dissociation of the neural substrates of information processing required to perform these declarative and procedural tasks is consistent with the other human and animal evidence described.

Figure 8 shows the impaired win-stay performance of the rats with caudate lesions and also shows that the rats with fimbria-fornix lesions acquired this task more quickly and reached a higher level of performance than normal rats. This observation is another demonstration of competition between caudate-based S–R learning and hippocampus-based spatial learning, explained in detail in Figure 8.

These radial maze findings are further evidence for the idea that different parts of the brain process and may also store declarative and S–R information independently, and that outputs of these systems compete for control of behavior.

Declarative (S–S) versus Emotional (S–Rf) Memory

Radial maze White and McDonald used the radial maze to study Pavlovian conditioning of emotional memory with the conditioned cue preference (CCP) task, explained in Figure 9. Hungry rats are confined in one of the maze arms with a supply of food. Eating the food (US) elicits internal responses perceived as reward (UR). The neutral cues visible from the arm acquire CS properties by becoming associated with the UR. On the test trial the rats are given a choice between the food-paired and another arm, with no food in either arm. Normal rats spend more time in the food-paired arm than in the unpaired arm. This is due to conditioned reward elicited by the conditioned cues visible from the food-paired arm.

Figure 9 The CCP task. On the training trials (left) rats are confined on one arm of the maze with a supply of food, and on a nonadjacent arm with no food for 30 min, on alternate days. One or more of these 2-day training trials are given. On a subsequent test trial (right) the rats are allowed to forage for food on the maze with access to both arms, neither of which contains food. Normal rats spend more time in the food-paired arm than in the unpaired arm. With appropriate controls this preference can be attributed to the formation of an association between the extra-maze cues visible from the food-paired arm and the effects of consuming the food, an S–Rf association. Since the cues visible from the food-paired arm cannot be seen from the no-food arm during training this arm discrimination does not require spatial information. Since the rats consume the food while confined at the end of an arm no specific response is associated with the food-paired stimuli. It must therefore be attributed to Pavlovian conditioning: a rewarding internal response (UR) elicited by the food (US) is associated with the cues visible from the food-paired arm (CS). Elicitation of the CR on the test trial causes the rats to enter and remain in the empty food-paired arm.

The CCP is impaired by lesions of the amygdala, but unaffected by lesions of the caudate nucleus, fimbria-fornix, or hippocampus. In contrast, amygdala lesions do not affect win-stay or win-shift learning (a triple dissociation – see Figure 2). Accordingly the S–Rf information required for the CCP is processed in a different neural system from those that mediate the S–R and S–S information processing required for the win-stay and win-shift tasks.

Emotional (S–Rf) versus Procedural (S–R) Memory

Radial maze McDonald and Hong trained rats on the win-stay task and then gave them a preference test on the same maze with no food available. All eight

arms of the maze were open and four of them were lit. The rats spent more time in lit than in dark arms, showing that they acquired a CCP during win-stay training. When tested with the same procedure, rats with amygdala lesions were normal on win-shift learning but did not express CCPs; rats with dorsal striatum lesions were impaired on win-shift learning but expressed normal CCPs. This double dissociation of caudate-based S–R learning and amygdala-based S–Rf learning shows that the information leading to the two types of behavior is acquired and expressed independently by different neural substrates.

Summary

The data from both humans and rats show that, consistent with the concept of functional localization, processing each of three kinds of information is impaired by damage to a different neural structure. In humans, imaging reveals complimentary information relating the kinds of information being processed and activated brain structures. These relationships are summarized in Figure 10. The figure organizes the data by suggesting the existence of three independent neural systems, each of which is specialized to process a different kind of information. The outputs of these processes influence thought and behavior.

The dissociations that provide the evidence for these ideas are based on specific learning tasks that depend on information processing in single systems. Most normally occurring behaviors undoubtedly depend on information processing in more than one of the systems and on cooperation among them at the output level. Competition among systems may also occur normally, possibly accounting for phenomena of indecision, hesitation and 'mind changing.'

Although considerable evidence for the idea that different kinds of information are processed in different brain areas has been discussed, no direct evidence has been presented that the memories for these information types are actually stored in these systems. While it is possible that this is the case, it is also possible that memory storage for all types of information is stored in a single location (e.g., the cortex) and that the systems selectively utilize cortically stored information. Given evidence that short-term memories may be stored in subcortical systems but that memories retained for months or years may be stored in the cortex, both of these hypotheses remain possible.

Most of the evidence for the MMS idea comes from the study of just three central brain structures, the hippocampus (or fimbria-fornix), the amygdala, and the basal ganglia (caudate nucleus). In each case, these central structures together with their afferents and efferents must constitute systems. Further research will define the anatomical divergence and convergence of the neural pathways (known as memory systems) that process and store different types of information.

Figure 10 How multiple memory systems influence thought and behavior. (1) As shown in Figure 2, patterns of neural activity originate in exteroceptors and interoceptors. (2) These patterns converge on sensory thalamic and cortical areas where they are processed and combined into activity patters that represent the current external and internal environments. (3) These activity patterns are transmitted to subcortical areas, each of which is activated by a specific set of relationships among the elements represented: basal ganglia are activated by S–R relationships, the amygdala is activated by S–Rf relationships, and the medial-temporal lobe system is activated by stimulus–stimulus (S–S) relationships. Most situations activate each of the systems to a different degree. (4) The outputs of the systems converge in various ways on brain areas that mediate behavior and thought. Basal ganglia-mediated S–R output influences behavior in an inflexible manner. Amygdala-mediated S–Rf output can influence behavior directly by producing conditioned approach or withdrawal responses, and can produce conditioned emotional states whose perception can influence behavior by instrumental learning. Medial-temporal lobe mediated S–S learning results in knowledge which can be used flexibly in combination with current affective and sensory information to produce behavior.

Multisensory Convergence and Integration

B E Stein, B Rowland, P Laurienti, and T R Stanford, Wake Forest University School of Medicine, Winston-Salem, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

Interest in the neurobiology of multisensory integration extends well beyond the biomedical sciences. Engineers have long been interested in producing an effective sensor-fusion device based on biological principles for such purposes as air traffic control, detecting the presence of obstacles under the sea, searching the ocean floor for unexploded mines, and hundreds of other purposes that depend on the remote sensing of objects and/or events. This engineering interest was sparked by inherent problems in using single-sensor devices, which have been effectively minimized by biological organisms through the process of multisensory integration. Consider that the effectiveness of commonly used single-sensor devices such as radar or sonar is greatest when the event to be detected provides a clear signal whose signature is readily recognizable. If the signal is weak, ambiguous, and/or embedded in noise, it can be very difficult to detect and/or disambiguate. Simply lowering the threshold of the sensor in an attempt to detect weak signals is not a viable solution because it makes the systems increasingly vulnerable to false positives. However, this problem can be mitigated by coupling different sensors (e.g., for light and sound), each tuned to detect events with specific features of interest, to a central processor capable of signaling their synchronous activation. The probability that anything other than the event of interest would mimic its signature in multiple-sensor domains is comparatively low.

Fusing or, more accurately, integrating signals that are derived from different sensory systems is a ubiquitous phenomenon in extant biological organisms. Its utility is evident regardless of how elaborate and specialized individual senses become; pooling information from them enhances not only the likelihood of detecting a given environmental event but also of identifying it. Because each sense is tuned to a different type of environmental energy, events that cannot readily be unambiguously identified along any single sensory dimension (e.g., how they look, feel, or sound) may be identified through a combination of sensory dimensions.

Converging Channels of Sensory Information

There are many areas of the brain that receive inputs from multiple-sensory systems. Best known among these is a midbrain structure known as the superior colliculus (SC), as well as a host of higher-order areas of cortex, sometimes referred to as association cortices. These areas contain mixtures of unisensory neurons, representing each of the structure's input modalities and each of the possible modality convergence patterns. Most of these multisensory neurons are capable of synthesizing their convergent cross-modal information and of producing a signal that is quite different from those evoked by either of the individual inputs. The product signal can be enhanced or degraded. Signal enhancement is generally the result of the synthesis of input signals that are initiated by the same events because these inputs are closely linked in space and time and thus meet the neural specifications for enhancement (discussed later). From an operational perspective, these cues are coherent or meaningful and their enhancement makes them more salient. When the signals are not linked in space and/or time, as is often the case when they are derived from different events, they are either not integrated or are depressed, and thereby rendered less salient. The benefits of such integrated products are obvious in determining which events have the highest priority in gaining an animal's immediate attention and influencing behavior. The process also adds depth to our sensory experiences and provides nuanced perceptions that could not be achieved if the sensory channels always operated independently of one another.

Illusions Illustrate the Potency of the Multisensory Product

The potency of multisensory integration is particularly evident in circumstances in which small discrepancies disrupt the normal spatial and/or temporal relationships among cross-modal stimuli. A good example is the Ventriloquism Effect, in which we think we hear the entertainer's voice coming from the dummy's mouth. This effect is really a general phenomenon that we experience regularly when watching a movie: the sounds all come from the same place (the acoustical speakers) but seem to be linked to the location of specific events or characters on the screen. The illusion depends on the brain preferring visual over auditory information for the purpose of localization. There are many such illusions, all of which represent the brain's effort to properly match cross-modal cues with one another in order to best evaluate an event.

Multisensory Integration as a Statistically Optimal Inference

As already noted, sensory information is frequently ambiguous, and thus environmental events cannot

be detected and identified with complete certainty. Bayes's theory provides a model for how a statistically optimal inference about an environmental event (e.g., its location) can be made based on ambiguous sensory information and how multiple sensory streams can be combined to make the best possible use of all of the available information. Human performance on tasks requiring visual-auditory and visual-tactile (or haptic) integration is consistent with that predicted by a Bayesian model, giving credence to the idea that organisms integrate sensory information in a statistically optimal fashion. Furthermore, Bayesian models correctly predict the neurophysiological response properties of multisensory neurons in areas of the brain such as the SC. Thus, Bayesian models may offer more than a yardstick of statistically optimal integration. The computations internal to Bayesian models may provide insights into how information is actually integrated in the brain and point to likely underlying neural mechanisms.

The Superior Colliculus Neuron: A Model of Multisensory Integration

The SC neuron has been used most extensively as a model to understand the neural processes underlying multisensory integration. This structure is involved in orientation toward targets in contralateral space and uses incoming visual, auditory, and somatosensory information to do so. These inputs adhere to a similar maplike pattern to ensure that the different sensory inputs to a given SC neuron provide information from common areas of sensory space. As a result, the different receptive fields of an individual multisensory neuron overlap one another, as shown in Figure 1(d). This pattern of spatial register is found in multisensory neurons throughout the nervous system.

Although the SC's best-known role involves initiating and controlling gaze shifts (i.e., eye and head movement) to objects or events in contralateral sensory space, it is actually involved in coordinated orientation of the various sensory organs (e.g., eyes, head, ears, limbs, whiskers, and mouth) that best position the animal to both assess and react to the stimuli of interest. It plays a role in these orientation responses via its output projections to those areas in the brain stem and spinal cord that are in more direct contact with the muscles. Anatomically, the SC is situated in the midbrain (Figure 1(a)), where it receives visual, auditory, and somatosensory inputs from a variety of sources. Many of these inputs converge on the same neurons, thereby rendering them multisensory. Despite the variety of afferent sources and their ultimate convergence patterns, there is a characteristic constancy to these projections – they are topographically ordered. In each case, the different inputs to a common SC target neuron provide information from common areas of sensory space. This pattern of topographic fidelity is not unique to the SC but, rather, is characteristic of multisensory neurons throughout the nervous system.

A Multisensory Map of Sensory Space

Organizing the receptive fields throughout the SC into overlapping visual, auditory, and somatosensory maps creates a multisensory map of contralateral sensory space, with the central-peripheral axis (or head to rump) laid out from front to back in the SC and the superior–inferior axis laid out from medial to lateral in the structure. This multisensory map is in register with the motor representation used to orient the eyes, ears, and head. However, unlike the organization found in the primary sensory projection pathways, whose maps are referenced to the relevant peripheral sensory organ (eyes, ears, head, etc.) and which are more involved in processing sensory-specific information, the SC maps have been transformed from their individual modality-specific frame of reference to a common motor frame of reference. In primates and carnivores, for example, the coordinate frame in the SC is linked to the direction of gaze. By making such a transformation, the brain has made sure that, regardless of the positions of the peripheral sensory organs with respect to one another, the activity initiated by any sensory cue in the SC represents its position relative to the current line of sight. This ensures that the site of activity in the SC is always that which initiates a gaze shift to look at the target.

Multisensory Integration: The Physiology of Response Enhancement and Response Depression

The principal job of multisensory neurons, regardless of where in the brain they are located, is to pool and integrate information carried by the different senses. This is evident when two different sensory inputs, such as sound and touch, produce a response that is significantly greater or less than the response produced by either of these individual stimuli. Indeed, this is the definition of multisensory integration and is an effect often noted in individual SC neurons. As previously noted, one of the critical factors in this process is the positions of the cross-modal stimuli

Figure 1 Multisensory enhancement and depression depend on the locations of cross-modal stimuli relative to their overlapping receptive fields: (a) posterior cortex removed from the cat brain schematic to reveal the superior colliculus (SC) in the midbrain; (b) receptive fields (shading) of a visual-somatosensory neuron; (c) receptive fields (shading) of an auditory-somatosensory neuron; (d) opposing physiological responses of a visual-auditory neuron when the cross-modal stimuli are spatially coincident (left) and spatially disparate (right). In (a), the rostrolateral suprasylvian sulcus (rLS) and the anterior ectosylvian sulcus (AES, composed of subregions FAES, AEV, and SIV) are also labeled. In (b–c), the schematics of visual and auditory spaces are polar coordinate maps in which each concentric circle represents 10° of space. In (d), when the visual and auditory stimuli are within their respective receptive fields and, thus, at a similar location in sensory space, a significant response enhancement is evoked by their pairing (left). But, when the auditory stimulus is in an inhibitory area surrounding its receptive field (inhibitory surround not shown), it counters the effect of the excitatory visual stimulus. The percentage change from the best component unisensory response is calculated using the formula $[(\mathrm{VA} - S_{\max})/S_{\max})] \times 100$, where VA is the response to the combined modality presentation and $S_{\max}$ is the response to the most effective of the two modality-specific stimuli. The predicted sum of the combined modality-specific responses is depicted by the dashed line. *indicates $p < 0.05$. A, auditory stimuli; AEV, visual region of the anterior ectosylvian sulcus; FAES, auditory region of the anterior ectosylvian sulcus; SIV, somatosensory region of the anterior ectosylvian sulcus; V, visual stimuli; VA, combined visual-auditory stimuli.

with respect to the receptive fields of a given multisensory neuron. This spatial principle of multisensory integration, first noted in SC neurons, is intuitively obvious; when multiple stimuli from the different senses are provided by the same event, they generally originate from the same location, but when they are derived from different events, they are likely to be derived from different locations. In the former case, the stimuli falling into the respective receptive fields of the same neuron provide excitatory inputs that interact synergistically to amplify neural activity and the physiological salience of the event. The magnitude of this enhancement is greatest when the impact of the individual component stimuli is weakest; a principle known as inverse effectiveness. If an interaction is induced in the latter case, when the stimuli are spatially disparate, it is one of depression because the excitation induced by one stimulus falling within its receptive field is counterbalanced by the other stimulus falling into an inhibitory region bordering its excitatory receptive field (Figure 1(d)). We can see why it is important to maintain the register among

the different sensory maps and the receptive fields of individual multisensory SC neurons even if the peripheral sensory organs move relative to one another when scanning the visual field or moving the limbs and not the eyes or head.

Mechanisms Underlying Multisensory Integration

As previously stated, the operational definition of multisensory integration is that it is a statistically significant difference between the neural responses to two concurrently presented stimuli in different modalities (e.g., a cross-modal stimulus that is visual-auditory) and the response to the most effective of the individually presented modality-specific component stimuli (e.g., visual or auditory). This definition, which speaks to the relative efficacy of cross-modal versus modality-specific stimulation, addresses the potential benefit of pooling the influences of individual cues, but does not speak to the mechanisms that give rise to the multisensory response. Clearly, the simplest mechanism for producing multisensory enhancement from spatially congruent cross-modal stimuli is one that sums the influences of the individual modality-specific inputs. Indeed, it has been demonstrated that, for many cross-modal stimulus combinations, neurons within the SC combine their modality-specific influences linearly such that the response to the cross-modal stimulus is statistically indistinguishable from the sum of the unisensory responses to the modality-specific component stimuli. Thus, in many cases, a relatively simple mechanism of summation underlies the integration of excitatory influences to give rise to multisensory enhancement.

Although simple summation is an adequate description of multisensory integration in many cases, there are notable exceptions. In particular, superadditive interactions, wherein the multisensory response exceeds the sum of the unisensory responses have often been reported. Similarly, subadditive interactions have also been observed. Recent studies examining the conditions that give rise to different integrative modes in SC neurons have shown that their relative probability is dictated by the efficacy of the modality-specific component stimuli. Combinations of very weak stimuli, especially those near the threshold of the neuron, are those most likely to produce superadditivity, whereas combinations of highly effective stimuli are those most likely to produce subadditivity. Thus, the operations that multisensory neurons apply to their modality-specific inputs appear to be a manifestation of the inverse effectiveness principle, which describes the inverse relationship between stimulus efficacy and response enhancement.

Converging Unisensory Inputs Render Superior Colliculus Neurons Multisensory

SC multisensory neurons receive their converging sensory inputs from unisensory neurons in many structures. Some ascend from the periphery, and others descend from cortex. It is interesting to note that these descending corticocollicular inputs come from association cortices that contain both unisensory and multisensory neurons but are derived from the former. Of specific interest in the model species used here (i.e., the cat) is the anterior ectosylvian sulcus (AES), shown in Figure 2(a). The AES is functionally segregated into three largely unisensory subregions from which the corticocollicular projections are derived: a somatosensory region (SIV), an auditory region (FAES), and a visual region (AEV). Between these areas are transitional zones in which non-corticocollicular multisensory neurons are concentrated.

Multisensory Integration in Anterior Ectosylvian Sulcus Cortex Is Similar to Multisensory Integration in Superior Colliculus

Despite the fact that these transitional-zone AES multisensory neurons are independent of (i.e., do not project to) those in the SC and are involved in a separate circuit, they share many fundamental features. As is true in the SC, the different receptive fields of multisensory AES neurons are in the spatial register. They also exhibit the same spatial principle of multisensory integration and the same principle of inverse effectiveness. This suggests that parallel multisensory processes going on at different levels in the neuraxis are governed by many of the same integrative principles. In this way, the different networks of multisensory neurons involved in different aspects of a coordinated behavior are rendered coherent.

Superior Colliculus Multisensory Integration Depends on Descending Inputs from Two Cortical Areas

Although SC neurons receive parallel ascending and descending converging inputs from the different senses, they do not have equivalent effects on this process. It is the descending projection system that is essential for multisensory integration but not for rendering an SC neuron multisensory. Thus, temporarily deactivating these inputs by lowering the cortical temperature until constituent neurons became inactive revealed that the modality convergence pattern of SC neurons did not change but that they could no longer integrate their cross-modal inputs (Figure 2(b)). Two cortical areas proved to be involved in this process: the AES and an adjacent corticocollicular area in the rostral aspect of the lateral suprasylvian

Figure 2 Deactivation of the AES and multisensory integration in a population of the SC neurons: (a) control; (b) deactivated AES; (c) reactivated AES. The deactivation of the AES abolishes multisensory integration in a population of SC neurons. Traces at the top of the figure show the time courses of visual (V) and auditory (A) stimuli. Impulse rasters (each dot represents 1 impulse and each row of dots represents the response to one trial) and histograms show the neural responses. In (a), note the enhanced multisensory response in the control condition of this visual-auditory neuron, which, in this case, exceeds the sum of the unisensory responses. In (b), multisensory enhancement is lost during cryogenic deactivation of AES (other SC neurons depend on the AES and rLS or on the rLS alone for multisensory integration). Note that the unisensory visual and auditory responses are not significantly affected. In (c), multisensory integration is reinstated when the AES is reactivated by rewarming. *indicates $p < 0.05$. AES, anterior ectosylvian sulcus; rLS, rostrolateral suprasylvian sulcus; SC, superior colliculus; VA, combined visual-auditory stimuli. sulcus (rLS). Parallel effects on behavior were also demonstrated – when the AES or rLS was deactivated, there was little change in an animal's ability to orient to a visual cue, but the multisensory enhancement due to the presence of a spatially coincident auditory cue was lost and the multisensory depression induced by a disparate auditory cue was significantly reduced. This effect was due to the loss of multisensory integration capabilities in the SC and was also seen when the SC was damaged by ibotenic acid lesions, leaving cortex intact.

These results highlight the close interplay between areas of association cortex and the SC. Such circuits not only are a likely substrate for the modulation of subcortical processes by cognitive factors (e.g., attention and motivation), but may also serve as the conduit through which experience can shape sensory processing in the SC, both during development and in adulthood. Whether the evidence ultimately supports this contention and whether other species use similar circuits for this purpose remain to be determined. However, it is likely that these intriguing possibilities will be topics of discussion and exploration in the near future.

Evaluating Multisensory Integration in Humans Using Functional Brain Imaging

As our understanding of multisensory integration expanded based on the studies performed in the SC and cortex of animal models, a growing interest emerged in the neural mechanisms of multisensory integration in humans. Many of these studies have used recordings from scalp electrodes, from which event-related potentials (ERPs) can be recorded. These ERP records represent the sum of activity from many cortical neurons simultaneously and have revealed integrative phenomena in human subjects like those already discussed in animal experiments. The rapidly growing number of multisensory

studies in humans has recently been fueled by the advances in technology that allow the imaging of human brain activity. Of these technologies, functional magnetic resonance imaging (fMRI) has provided the greatest advances in understanding multisensory processing in humans. To date, most studies that have evaluated multisensory integration have been designed based on the physiological studies performed in the SC of animals. This translational science approach, in which data from animal models are applied to human studies, is quite logical, and studies have identified superadditive responses in several brain regions of humans during multisensory integration. In particular, the superior temporal sulcus (STS) has been implicated repeatedly as a multisensory region in human brain imaging studies. Other important regions have also been identified, including (but not limited to) regions in the parietal and frontal lobes. Of growing interest is the possibility that multisensory interactions occur at the level of the sensory-specific cortices. It has been demonstrated that stimulation of one sensory modality in relative isolation can suppress activity in other nonmatching sensory cortices. More recently, a vigorous debate has emerged concerning the actual integration of multisensory stimuli in the sensory-specific cortices. Although this debate calls into question the existence of purely sensory-specific cortices, much more work must be done to resolve this important issue. With continued advances in brain imaging technology, our current understanding of sensory interactions will serve as a foundation of what is certain to be an exciting future for studies of multisensory integration.

Introduction

Neurotransmitter release from presynaptic nerve terminals is mediated by the fusion of neurotransmitter-filled synaptic vesicles with the plasma membrane. Synaptic vesicle fusion is tightly coupled to voltage-induced Ca^{2+} influx and has latency on the microsecond timescale. This rapidity suggests that within a nerve terminal a population of synaptic vesicles is competent, or primed, to undergo membrane fusion immediately upon Ca^{2+} entry.

Synaptic vesicle priming and fusion requires members of the conserved soluble *N*-ethylmaleimide-sensitive factor (NSF) attachment protein receptor (SNARE) protein families, specifically, the plasma membrane-associated SNAREs (t-SNAREs, also called Q-SNAREs) syntaxin and synaptosomal-associated protein of 25 kDa (SNAP-25) and the vesicle membrane-associated SNARE (v-SNARE, also called R-SNARE) synaptobrevin. These SNARE proteins interact through their SNARE domain to form a parallel four α-helical bundle termed the SNARE complex. SNARE complex assembly *in trans* is predicted to bring the vesicle membrane into close proximity to the plasma membrane, a prerequisite for membrane fusion.

Because SNARE interactions can be detected prior to neurotransmitter release, interactions between SNARE proteins are thought to represent the molecular underpinnings of vesicle priming. By extension, proteins that interact with the SNAREs are candidates for regulators of vesicle priming. UNC-13/Munc13 is a presynaptic protein that interacts with syntaxin. Here we review the evidence implicating UNC-13/Munc13 in vesicle priming and discuss the current models for how UNC-13/Munc13 functions in vesicle priming and how its function is regulated.

Characterization of UNC-13/Munc13

UNC-13 was first implicated as a mediator of synaptic transmission from pioneering forward-genetic screens in the nematode *Caenorhabditis elegans* conducted by the now Nobel laureate Sydney Brenner. Brenner reasoned that mutations which disrupt genes required for synaptic transmission at neuromuscular junctions should result in animals that exhibit defects in locomotion, or are uncoordinated. Mutations in the *unc-13* locus result in severe locomotory defects; null alleles are essentially paralyzed. Paralysis in these mutants is not due to a gross defect in neurodevelopment or postsynaptic functions, suggesting that UNC-13 is required presynaptically for normal neurotransmission.

In *C. elegans*, *unc-13* encodes for at least three UNC-13 proteins derived from alternative splicing. All isoforms characterized to date contain a C1 domain, two C-terminal C2 domains, and two Munc homology domains (MHDs) (**Figure 1(a)**). Most contain an N-terminal extension containing a third C2 domain, a Rim-interacting domain (RID), and a calmodulin-binding domain (CBD). In general, these isoforms are grouped into two categories – long (L) and short (S) – based on the presence of this extended N-terminus.

UNC-13 is a conserved protein; homologs have been identified in nearly every organism examined that contains a nervous system. In *Drosophila*, the UNC-13 homolog (Dunc13) is encoded by a single locus which gives rise to three isoforms. In mice, UNC-13 homologs are encoded by four loci (Munc13-1, -2, -3, and -4), which may also exhibit alternative splicing. UNC-13, Dunc13, and Munc13-1, -2, and -3 are expressed primarily in neurons; UNC-13 and Dunc13 are expressed almost exclusively in neurons of the worm and fly, whereas Munc13-1, -2, and -3 exhibit tissue and temporal expression specificity.

In addition to similarities in sequence and tissue expression, mutational perturbation of UNC-13 and its homologs results in virtually identical synaptic transmission defects – a nearly complete block of neurotransmitter release from presynaptic nerve terminals. Although synaptic vesicles are abundant at presynaptic sites, virtually none are competent to undergo fusion with the plasma membrane. These phenotypes suggest that UNC-13/Munc13 is required for synaptic vesicle priming.

The SNARE complex crystal structure predicts that the assembly of *trans*-SNARE complexes during priming will bring the synaptic vesicle membrane into close apposition with the plasma membrane. However, previous analyses of synapses in which SNARE protein function was perturbed did not reveal changes in the number of plasma membrane-contacting vesicles. In contrast, a recent study using rapid high-pressure freeze fixation, rather than classic chemical fixation, to preserve the ultrastructure of *C. elegans* neuromuscular junctions found vesicle contact with the plasma membrane to be largely UNC-13 dependent. These data provide the first evidence for a morphological correlate of priming and further implicate UNC-13 in this process.

Figure 1 UNC-13/Munc13 and its molecular pathway: (a) UNC-13 and its homologs illustrated are their functional domains; (b) the probable priming by UNC-13/Munc13 of synaptic vesicles through interactions with UNC-18 and the SNARE protein syntaxin (SYX) which interacts with the SNARE proteins SNAP-25 (S25) and synaptobrevin (SNB); (c) several pathways that probably regulate UNC-13/Munc13 function at the synapse. Mechanism of Action of UNC-13/Munc13

To define the region of UNC-13/Munc13 required for vesicle priming, several groups conducted experiments to identify a minimal UNC-13/Munc13 rescuing fragment. Rescue of synaptic transmission in cultured hippocampal neurons derived from Munc13-1/2 double knockout mice requires a large fragment spanning virtually the entire region between C_2B and C_2C (amino acids 859–1531) containing both MHD1 and -2. This minimally rescuing construct produced a partial rescue of evoked synaptic transmission at excitatory synapses resulting from ~50% rescue of the fusion-competent vesicle pool.

In chromaffin cells, overexpression of full-length Munc13-1 can produce a doubling in the size of the primed pool of dense-core vesicles – dense-core and synaptic vesicles exocytosis utilize much of the same molecular machinery. To attain this elevated level of dense-core vesicle priming, a slightly larger fragment of Munc13-1, amino acids 1100–1735, which extends beyond the MHDs to include the third C2 domain, is required. This suggests that a fully functional Munc13-1 rescuing fragment contains both MHDs and C2C. Consistent with this premise, rescue of *C. elegans unc-13* mutants requires a similar construct that includes both MHDs and C_2C (amino acids 676–1420).

An earlier study using this conserved C-terminal region of Munc13-1 (amino acids 1181–1736) as bait in a yeast two-hybrid screen identified syntaxin-1B as a binding partner. The clones isolated in this screen encoded an N-terminal region of syntaxin covering the first two α-helices (HA and HB), suggesting that UNC-13/Munc13's role in vesicle priming is through its interactions with the syntaxin N-terminus. Consistent with this hypothesis, point mutations in the Munc13-1 minimally rescuing fragment that disrupted syntaxin binding abolished its dense-core vesicle priming ability. Similarly, alanine-scanning mutagenesis studies of the *C. elegans* UNC-13 MHD2 also identified residues that eliminated syntaxin binding and, as a consequence, reduced evoked neurotransmitter release. Together, these experiments strongly support the notion that UNC-13/Munc13 promotes synaptic vesicle exocytosis, and probably vesicle priming, through its interaction with syntaxin.

In solution, syntaxin adopts a default-closed confirmation in which its N-terminus, containing the H_{ABC} helices, folds over and occludes its C-terminal SNARE domain (also referred to as H3 domain). This observation led to speculation that Munc13 binding to the N-terminus of syntaxin may promote the opening of syntaxin to expose its SNARE domain, thereby facilitating SNARE complex assembly and vesicle priming. Through alanine scanning, two residues in the linker region between the H_{ABC} and SNARE domains of vertebrate Syntaxin 1A (LE165/166AA) were found to destabilize the closed conformation, rendering the protein constitutively open. Expression of the corresponding mutant form of syntaxin in *C. elegans* (syntaxin LE166/167AA) partially bypasses the requirement of UNC-13 in synaptic vesicles priming, suggesting that UNC-13/Munc13 promotes vesicle priming by promoting the opening of syntaxin (**Figure 1(b)**). However, evoked synaptic transmission and behavior are not fully rescued in these animals, implicating UNC-13 in additional steps in exocytosis.

Regulation of UNC-13/Munc13

Whereas the basic function of Munc13/UNC-13 in priming has been mapped to its C-terminus, the N-terminus contains several domains that are considered important in regulating this priming function.

Rab3/RIM Interaction

UNC-13/Munc13 interacts directly with the active-zone protein Rim through its N-terminal RID (**Figures 1(a)** and **1(c)**). Rim, like UNC-13/Munc13, is required for normal levels of priming, and its function requires interaction with UNC-13/Munc13. In addition, Rim interacts with the synaptic vesicle-associated guanosine triphosphatase (GTPase) Rab3 (hence its name, Rab3-interacting molecule). Rab3 has been implicated in regulating the release probability of primed synaptic vesicles.

Rab3, Rim, and Munc13 interact to form a tripartite complex. Rim, therefore, might regulate priming by recruiting Munc13 and synaptic vesicles to active zones through this tripartite complex. Indeed the active-zone recruitment of Munc13-1 and the ubiquitous (ub)Munc13-2 splice variant is regulated by Rim. Although UNC-13 is not grossly mislocalized, fewer synaptic vesicles are located near active-zone dense projections in *C. elegans* Rim/*unc-10* and *rab-3* mutants. If Ca^{2+} entry occurs preferentially at this site, regulating the distribution of primed synaptic vesicles could account for the postpriming functions of Munc13.

C1-Diacylglycerol Regulation

Phorbol esters are known to increase presynaptic efficacy by mimicking the actions of the endogenous second messenger, diacylglycerol. In addition to protein kinase C (PKC), Munc13/UNC-13 is a well-established phorbol ester receptor in which the N-terminal C1

domain is the binding target. Although the C1 domain is not essential for the basic priming activity of Munc-13/UNC-13, it is required for survival in mice, indicating that the C1 domain performs an important function. Genetic studies in *C. elegans* have also established an important regulatory pathway in which diacylglycerol regulates motor neuron output through an UNC-13-dependent mechanism.

Phorbol ester treatment has been shown to promote the plasma membrane association of Munc13 in human embryonic kidney (HEK) cells and chromaffin cells, suggesting the membrane recruitment of Munc13 may be a potential mechanism by which phorbol esters enhance release (**Figure 1(c)**). Consistent with this hypothesis, paralysis and impaired cholinergic signaling due to loss of diacylglycerol production in *C. elegans* phospholipase-C mutants (*egl-8*) can be partially bypassed by expressing a constitutively membrane-associated form of UNC-13 produced by N-terminal myristoylation. Furthermore, introducing a point mutation at a conserved histamine within the C1 domain of *C. elegans* UNC-13(H173K), which is predicted to disrupt phorbol ester binding, eliminates phorbol ester-induced enhancement of cholinergic signaling and reduces agonist-stimulated recruitment of UNC-13 to synapses. It is worth noting that the UNC-13 isoform in these studies lacks the N-terminal C2A domain implicated in active-zone recruitment and priming via interactions with Rim/Rab3a; therefore, the membrane translocation observed may be specific to this isoform. Indeed, analysis of the corresponding point mutation in the C1 domain of Munc13-1(H567K) was not associated with a detectable defect in membrane targeting.

What, then, is the nature of the phorbol ester-dependent increase in synaptic efficacy? Surprisingly, analysis of phorbol ester effects on wild-type synapses suggests that the level of vesicle priming is unaltered but that the release probability is increased. Furthermore, the release probability of Munc13(H567K) C1 domain mutants is the same as phorbol ester-treated wild-type synapses. This observation, coupled with the fact that phorbol ester application has no further stimulatory effect on the release properties of Munc13-1(H567K) mutant synapses, suggests this is a gain-of-function mutation, mimicking the wild-type phorbol ester-activated C1 state.

Based on these observations, it has been proposed that the C1 domain regulates the functional state of Munc13 downstream of priming, under basal conditions. Munc13 may be held in a folded inactive state through a C1 intramolecular interaction with the catalytic C-terminus, this folded conformation possibly favoring interactions between Munc13 C2A and Rim/Rab3a involved in basal priming. It has been proposed that the binding of diacylglycerol/phorbol ester to the C1 domain induces a conformational change in Munc13 by disrupting C1 intramolecular binding and driving C1–plasma membrane interactions, thereby unleashing an undefined catalytic post-priming action of Munc13 that increases vesicle release probability.

In a recent analysis of phorbol ester-dependent potentiation of hippocampal synapses, both phosphorylation of Munc18 by PKC and activation of Munc13 were shown to be required. Munc18 is a syntaxin-binding partner that plays an essential role in synaptic vesicle exocytosis. Interestingly, PKC-dependent phosphorylation of Munc18 reduces the binding affinity of Munc18 for syntaxin. Therefore, it appears that the convergent involvement of both Munc18 and Munc13 in synaptic potentiation may relate to their common interaction with syntaxin. Precisely how these diacylglycerol/phorbol ester-induced events lead to increased release probability has yet to be elucidated.

Double C2-Containing Protein Family

Small elevations of presynaptic Ca^{2+} (0.1–1 μM) are thought to augment release by enhancing priming in neurons and chromaffin cells, indicating that priming is a Ca^{2+}-regulated process. Although UNC-13/Munc13 proteins contain three C2 domains, their ability to bind Ca^{2+} has yet to be tested. However, members of the double C2-containing protein family (DOC2) are positive regulators of neurotransmitter release that exhibit Ca^{2+}-dependent translocation to the plasma membrane in the Ca^{2+} range implicated in promoting priming. Because DOC2 proteins are known to interact with Munc13, the Ca^{2+}-dependent translocation of DOC2 to the plasma membrane may be a mechanism to recruit and/or activate Munc13 in the micromolar Ca^{2+} range. This hypothesis may be supported by interference experiments in which introduction of the DOC2-interacting domain of Munc13 (Did) reduces both vesicle priming in superior cervical ganglion neurons and phorbol ester-induced potentiation at the calyx of Held. Furthermore, overexpression of DOC2 in PC12 cells enhances the primed vesicle pool, implicating DOC2 in this process. Although these experiments support a positive role for DOC2 in neurosecretion, the molecular mechanism by which the DOC2–Munc13 interaction may enhance priming remains to be determined.

Calmodulin-Binding Domain

Calmodulin, which is known to co-localize with Munc13 in the presynaptic compartment, is also activated in the 500 nM Ca^{2+} range implicated in

enhanced priming. In a screen for calmodulin-binding proteins in *Drosophila*, an N-terminal Cam-binding motif in Dunc13 was identified. Following this observation, Ca^{2+}-dependent interactions between the N-terminals of Munc13-1 and ubMunc13-2 and mammalian calmodulins (Calm1–3) were also found. Sequence homology between the amphipathic helix constituting the calmodulin-binding motifs of Munc13, Dunc13, and UNC-13 indicate that this domain, located adjacent to the C1 domain, is evolutionarily conserved (Figures 1(a) and 1(c)). Arginine substitution of a conserved tryptophan residue in the calmodulin-binding motif of both Munc13-1(W464R) and ubMunc13-2(W387R) completely abolish calmodulin binding. Munc13 isoforms carrying this tryptophan to arginine mutation could therefore be expressed in autaptic hippocampal neurons from Munc13-1/2 double knockout to test the function of the calmodulin–Munc13 complex.

Neurons expressing calmodulin binding-deficient Munc13 variants had normal evoked synaptic transmission and vesicle priming, indicating that basal priming and release does not require calmodulin binding to Munc13. However, striking differences were observed in Munc13-dependent synaptic plasticity in the absence of calmodulin binding. Specifically high-frequency stimulation-induced synaptic depression associated with wild-type Munc13-1 became more pronounced in the presence of Munc13-1(W464R) and the moderate augmentation normally observed following the stimulation train was reduced, results that suggest a deficiency refilling the primed pool of vesicles. Expression of calmodulin-insensitive ubMunc13-2 (W387R) also converted the synaptic facilitation normally observed with ubMunc13-2 to synaptic depression and greatly reduced posttrain augmentation. Consequently, in the absence of calmodulin binding, the normal differences in synaptic plasticity between Munc13-1 and ubMunc13-2 were eliminated. It therefore appears that calmodulin–Munc13 complexes are essential for Ca^{2+}-dependent short-term facilitation. Precisely how Cam-binding to Munc13 proteins promotes this activity-dependent facilitation has yet to be elucidated.

Abundance

UNC-13/Munc13 activity is also probably regulated by its abundance at the synapse; two mechanisms have been implicated in this mode of regulation: proteasome-mediated degradation and diffusion/translocation.

Acute inhibition of proteasome-mediated protein degradation at *Drosophila* neuromuscular junctions causes a rapid increase in synaptic transmission. Quantitative immunohistochemical analysis of these neuromuscular junctions indicates that Dunc13 levels increase with proteasome inhibition, suggesting that Dunc13 levels at neuromuscular junctions may be under the control of proteasome-mediated degradation and, at least in part, accounts for the increase in synaptic transmission. Consistent with this hypothesis, the N-terminal region of UNC-13 was shown to interact with the F-box protein ERI-1. F-box proteins provide substrate specificity to the ubiquitination pathway. However, neither Dunc-13, UNC-13, nor Munc13 has been shown to be ubiquitinated, and proteasome inhibitors failed to increase Munc13-1 levels in neuronal cell cultures, suggesting that this potential mechanism of regulation is cell-type specific.

Although synapses may appear isolated along a neurite, they do not act in complete isolation; synapses share their constituents. Fluorescence recovery after photobleaching (FRAP) and photoactivation experiments have shown that proteins can be exchanged between synapses, including Munc13-1. FRAP experiments using a yellow fluorescent protein-tagged version of Munc13-1 suggest that Munc13-1 within a synapse is exchanged with a half-life on the order of minutes to tens of minutes. This exchange may be a mechanism for the rapid redistribution of synaptic resources during plasticity. Consistent with this hypothesis, chronic suppression of spontaneous activity decreases the exchange of Munc13-1 within synapses.

Future Directions

In summary, functions have now been assigned to each of the UNC-13/Munc13 domains. Current evidence indicates that the basic priming activity of UNC-13/Munc13 is achieved primarily through an interaction of the conserved C-terminal domain either directly or indirectly with the N-terminus of syntaxin. Domains within the N-terminus of UNC-13/Munc13 appear to regulate the location and degree of priming and may potentiate release via additional mechanisms in response to various cues. Specifically, diacylglycerol/phorbol ester-dependent potentiation acts via the C1 domain, Ca^{2+}-dependent potentiation acts via the calmodulin-binding domain, and short- and long-term potentiation act via interactions of the C2A domain with Rim and Rab3.

What remains to be elucidated are the molecular mechanisms that underlie these important Munc-13/UNC-13-dependent functions. It is anticipated that high-resolution structural information gleaned by solving the crystal structures of Munc-13/UNC-13

domains interacting with proposed binding partners will provide important insights into the molecular rearrangements occurring during basal priming and synaptic plasticity. For example, the molecular mechanism coupling UNC-13/Munc13 to SNARE complex assembly has yet to be fully understood. Biochemical approaches will help to elucidate the timing and affinities of interactions between UNC-13/Munc13 and syntaxin as well as with the SNARE complex. Similarly, the proposed conformational change of Munc13 in response to C1 activation by diacylglycerol/phorbol ester, akin to that of PKC, can be explored using these approaches.

The synaptic membrane localization of Munc13 is potentially regulated by several molecular events, including Rim/Rab3a interactions, activation of C1 with diacylglycerol/phorbol ester, as well as interactions with DOC2. Recent advances in fluorescent imaging using tagged knockin mutagenesis will be helpful in addressing the role of specific domains in UNC-13/Munc13 dynamics and localization. Combining knockin technology with Förster resonance energy transfer (FRET) and FRAP should elucidate temporal and spatial interactions between Munc13 and its binding partners under various conditions. The use of high-pressure freeze fixation and total internal reflection velocimetry (TIRV) has also begun to provide insights into the changes in vesicle distribution accompanying the activity of UNC-13/Munc13 and its binding partners. It is likely that the continued application of these techniques in combination with domain specific mutagenesis will provide a more complete picture of the crucial role this fascinating protein plays in synaptic function.

Introduction

Munc18 is one of the most enigmatic proteins in the field of synaptic transmission. Loss-of-function mutations of Munc18-1 or of its orthologs in several eukaryotic species invariably lead to one of the most dramatic synaptic phenotypes – either a complete loss or a severe impairment of synaptic transmission. However, in spite of the availability of genetic knockouts, a wealth of biochemical and cell biological data, and the existence of three-dimensional structures at atomic resolution, the physiological function(s) of Munc18 remain unclear, although recent advances have brought us several important insights into the biology of Munc18.

Discovery, Molecular Structure, and Biochemical Properties

Munc18-1 (also referred to as Munc18a), was originally isolated in 1993 from a solubilized rat-brain homogenate by virtue of its tight binding to syntaxin 1, a member of a class of presynaptic soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) proteins. Munc18-1 turned out to be a mammalian homolog of the product of *Caenorhabditis elegans* gene *UNC18* (thus, Munc18 stands for the mammalian unc18 homolog). In *C. elegans*, *UNC18* belongs to a group of genes identified on the basis of severe locomotion defect (uncoordinated phenotype). These genes are defined by mutations causing paralysis, resistance to the acethylcholine esterase inhibitors, and accumulation of acetylcholine suggesting impairments in neurotransmitter release. Munc18-1 is also homologous to Sec1p, the product of a long-known yeast secretory mutant gene. Almost simultaneously with the discovery of Munc18-1 based on its syntaxin binding properties, cDNAs for the same protein were independently identified in two separate screens of rodent brain cDNA libraries based on its sequence homology with Sec1. The cloned protein was named n-Sec1 or rbSec1 (for neural Sec1 homolog or rat brain Sec1, respectively). To avoid confusion, we refer to the neuronal protein as Munc18-1 and to the entire gene family as SM proteins (for Sec1/Munc18-like proteins).

In mammals, Munc18s are represented by three highly homologous isoforms, referred to as Munc18-1, -2, and -3 (or as Munc18a, 18b, and 18c). Munc18-1 is a predominantly neuronal isoform essential for synaptic vesicle (SV) exocytosis. Munc18-1 is highly expressed throughout mammalian brain; its expression profile at the transcriptional level parallels the pattern of synapse formation in the developing rodent brain. In addition to brain, Munc18-1 mRNA is abundant in the spleen, lung, kidney, and testis and is detected at lower levels in several other nonneuronal tissues. At the protein level, Munc18-1 is also highly expressed in adrenal chromaffin cells and in pituitary glands, where it is involved in large dense-core vesicle (LDCV) release. Munc18-2 and 18-3 are widely expressed outside of the neuronal system and are implicated in multiple exocytotic and trafficking processes, such as mast cells granule exocytosis, Ca^{2+}-triggered exocytosis of dense-core vesicles in platelets, insulin-regulated glucose transporter (GLUT4) translocation to the plasma membrane in adipocytes and skeletal muscle, and glucose-stimulated insulin granule exocytosis from pancreatic islet β-cells. Genetic knockout of Munc18-3, a ubiquitous Munc18 isoform, suggested that it is important for normal development of embryos, including proper formation of the central nervous system (CNS).

Munc18s, proteins of apparent molecular mass 67–70 kDa, are composed of 592–594 amino-acid residues and share 52–63% amino acid identity evenly distributed throughout their sequence. Munc18s are highly conserved in evolution (rat Munc18-1 is 100% identical with the corresponding human protein, and there is 63%, 59%, and 25% identity between mammalian Munc18-1 and its orthologs *Drosophila* Rop, *C. elegans* Unc18, and *Saccharomyces cerevisiae* -Sec1p, respectively). In the human genome, Munc18 genes are localized to chromosomes 9 (Munc18-1), 19 (Munc18-2), and 1 (Munc18-3). Although Munc18s are hydrophilic proteins with no apparent transmembrane regions, in living cells they are found peripherally associated with plasma membranes, partly, although not exclusively, through their interactions with syntaxins.

Binding to Syntaxins and Functional Coupling to SNAREs

Mutations in genes encoding for Munc18 homologs in lower eukaryotes suggested a potential involvement of this protein family in regulated secretion. *Sec1* mutants in yeast accumulate post-Golgi secretory vesicles, reflecting a defect in a late step in exocytosis. Mutations in the *Unc18* gene in nematodes lead to the accumulation of acetylcholine, indicating an impairment of one of the final steps in the vesicular

traffic of acetylcholine in the neurons. Loss-of-function mutations in the *Drosophila* Rop gene (the fly version of Munc18 that is highly expressed in the fly nervous system and in other tissues actively engaged in secretion) results in a loss of neurotransmitter release in adult photoreceptor cells as well as in the mislocalization of a number of normally secreted products. Subsequent genetic knockout of Munc18-1 in mice produced one of the most severe synaptic phenotypes known so far. Null mutant embryos were alive prenatally, but died immediately after birth. Synapses from Munc18-1-deficient mice were totally silent, demonstrating a general, complete, and permanent loss of synaptic transmission. Interestingly, the brains of the mutant mice initially developed normally, but underwent massive apoptosis and degeneration after neuronal assembly was completed, indicating that initial synaptic connectivity does not depend on synaptic activity.

The tight binding of Munc18-1 to syntaxin 1 suggested a direct link between Munc18-1 and the synaptic fusion machinery. Genetic evidence also indicated a functional connection between Sec1p and the yeast syntaxin 1 homologs Sso1p and Sso2p. Overexpression of *Sso1* or *Sso2* in yeast partially complemented the *Sec1* phenotype. These observations have prompted a thorough biochemical characterization of direct interactions between Munc18 and syntaxins.

Munc18-1 binds to neuronal syntaxin 1 in a strikingly tight interaction, allowing the one-step purification of native Munc18-1 from a total mammalian brain homogenate using a syntaxin 1 affinity column. Attempts to directly measure the affinity of Munc18-1/syntaxin 1 binding *in vitro* resulted in K_d values ranging from 1.4 to 60 nM, but it is possible that even the lower number represents an overestimation due to the intrinsic limitations imposed by the methods. Further biochemical experiments demonstrated that all Munc18s directly interact with exocytotic plasma membrane syntaxins (syntaxins 1–4), although with different specificity. The specificity of Munc18/syntaxin interactions was extensively characterized using multiple *in vitro* binding assays. Thus, Munc18-1 and -2 directly interact with syntaxins 1, 2, and 3 but not with syntaxin 4, whereas Munc18-3 specifically binds to syntaxin 4 but not to syntaxins 1–3. However, the precise affinities for most of these interactions have not been measured, and it is likely that each Munc18 isoform has a different spectrum of binding affinities for the various syntaxins.

Tight binding of Munc18 to syntaxin is an evolutionarily conserved feature that is also observed in lower eukaryotes. Thus, Unc18 protein directly interacts with *C. elegans* syntaxin 1, and *Drosophila* Rop firmly binds to both mammalian and fly syntaxin 1 *in vitro*. However, several studies indicated that in yeast Sec1p instead binds to the assembled SNARE complexes.

The physiological relevance of Munc18/syntaxin 1 interaction was further strengthened by the observations that the levels of syntaxin 1 were dramatically decreased in Munc18-1-knockout mice (by 70%), and in *C. elegans* Unc18 mutants (by ~50%). Conversely, Munc18 levels are significantly reduced (by ~25%) in syntaxin 1a-knockout mice. However, detailed characterization of the Munc18–syntaxin interaction revealed a basic and still unresolved conundrum; in order to bind Munc18, syntaxin 1 has to be in a so-called closed conformation. This is the default conformation for syntaxin 1 in isolation, which involves an intramolecular interaction between three-helical N-terminal domain of syntaxin 1 (Habc domain) and its SNARE motif. *In vitro,* this conformation is incompatible with the participation of syntaxin in the SNARE-complex formation with two other neuronal SNAREs, synaptosomal-associated protein of 25 kDa (SNAP-25) and synaptobrevin/vesicle-associated membrane protein (VAMP). Thus, the essential positive role in neuronal exocytosis suggested for Munc18-1 by the gene knockout experiments came in a conceptual clash with the apparently inhibitory mode of Munc18-1 interaction with the closed conformation of syntaxin 1.

Structural Studies of Munc18

A detailed picture of the syntaxin 1a–Munc18-1 interaction at atomic level was obtained when the crystal structure of the complex was determined at 2.6 Å resolution (referred to as nSec1-syntaxin 1a complex in the crystallography study). The structure revealed an arch-like shape for Munc18-1 with a central cavity of ~15 Å formed by three domains (**Figure 1**). Domain 1 spans the 134 N-terminal residues of munc18-1 and consists of a five-stranded parallel β-sheet flanked by five α-helices. The second domain, which is composed of residues 135–245 and 480–592, also adopts an α-β-α fold. The sequence forming the third Munc18-1 domain (residues 246–479) is inserted in the middle of the sequences making up domain 2. The third domain is composed of two subdomains, 3a and 3b, that are bent at a 60° angle with respect to one another. Subdomain 3a also contains a mixture of α- and β-structural elements, whereas the subdomain 3b represents a cluster of α-helices. Syntaxin 1A binds in its closed conformation in the central cavity of Munc18-1. The interacting surfaces of the two proteins are largely polar and complementary in charge. Both the Habc domain and the SNARE motif of the closed

Figure 1 X-ray structures of SM proteins: (a) ribbon diagrams of the Munc18-1–syntaxin 1a complex (PDB accession code: 1DN1); (b) 180° rotation of the view depicted on the (a); (c) ribbon diagrams of the yeast SM protein Sly1p in a complex with the N-terminal peptide of the yeast syntaxin Sed5p (PDB accession code: 1MQS); (d) 180° rotation of the view depicted on the (c). In (a) and (b), the three structural domains of Munc18-1 are colored in different shades of blue; the SNARE motif of syntaxin 1A is colored in red, and the rest of the syntaxin molecule (the linker region, the three-helical Habc domain, and the N-terminal sequence) is shown in orange. The linker region and the N- and C-termini of syntaxin are indicated. In (c–d), the color code used for the structural domains of Sly1p is the same as (a) and (b); the N-terminal syntaxin peptide is shown in orange. SNARE, soluble *N*-ethylmaleimide-sensitive factor attached protein receptor. The figure was made using PyMOL (open source software, http://www.pymol.org). Note that recently revised structure of the Munc 18-1–syntaxin 1a complex (PDB accession code : 3C98) revealed an additional binding site for the N–terminal sequence of syntaxin 1a on the outer surface of Munc 18-1 (see text).

syntaxin make extensive contacts, predominantly with domains 1 and 3a of Munc18-1. Because subdomain 3a of Munc18-1 is involved in relatively few intramolecular interactions, it was suggested that this part of the molecule might be able to move with respect to the rest of the protein due to the presence of a single nonhelical glycine residue placed between the two subdomains. Such outward movement could affect the syntaxin conformation, creating more favorable conditions for the ordered association of the syntaxin SNARE motif with the SNARE motifs of SNAP-25 and synaptobrevin.

The crystal structure of isolated Munc18 from the squid (referred to as s-Sec1 in that study) is overall very similar to the structure observed for the mammalian protein in the complex with syntaxin 1. It did confirm the structural plasticity of subdomain 3a, but it also revealed a substantial flexibility in the orientation of domain 1 of Munc18. Because both subdomain 3a and domain 1 of Munc18 are primarily responsible for the binding to the closed syntaxin, these observations offer initial clues toward understanding the mechanisms regulating this interaction. Both structures have also revealed the presence of potential ligand-binding pockets on the surface of Munc18 opposite the syntaxin binding interface (e.g., a large negatively charged cavity with approximate dimensions $20 \times 15 \times 15$ Å localized between domains 1 and 2). It has been speculated that the binding of an effector molecule to this surface of Munc18-1 could cause a rotation in domain 1 with respect to domain 2 and therefore lead to a release of syntaxin.

A more recent crystal structure of mouse Munc 18-3 (Munc 18c) in a complex with syntaxin 4 peptide (see below) revealed the same modular structure and overall fold as for the neuronal Munc 18-1 and for the squid Munc18 (1.5 Å rmsd with 45% sequence identity between Munc 18-3 and Munc 18-1, and 1.3 Å rmsd

with 51% sequence identity between Munc 18-3 and the squid protein).

The crystal structure of the syntaxin 1a–Munc18-1 complex fully confirmed the binding mode suggested by the biochemical and nuclear magnetic resonance (NMR) spectroscopy studies and uncovered the atomic basis for the incompatibility between the syntaxin–Munc18-1 complex and the SNARE complex. Altogether, these studies indicated that syntaxin 1 must experience a large conformational change to switch between the two complexes. This premise has led to the proposal that an unidentified factor(s) helps to dissociate the syntaxin 1–Munc18-1 complex or causes conformational changes in Munc18-1, after which Munc18-1 is able to perform its essential positive function in neuronal exocytosis.

Phosphorylation of Munc18

In a search for potential factors or processes that could dissociate Munc18 from syntaxin, effects of posttranslational modifications of Munc18 were examined.

Phosphorylation, in particular by conventional protein kinase C (PKC), for many years has been implicated in regulating multiple stages of exocytosis in neurons and neuroendocrine cells. Munc18 is a likely candidate to mediate some of these effects because phosphorylation affects its biochemical properties and all three mammalian isoforms of Munc18 are phosphorylated in intact cells in response to different secretory stimuli or modulators of protein kinase activities.

In vitro, Munc18-1 can be phosphorylated by PKC and cyclin-dependent kinase 5 (Cdk5), but not by protein kinase A (PKA) or calmodulin-dependent protein kinase II (CaMKII). PKC phosphorylates Munc18-1 at two serine residues, Ser306 and Ser313, and this phosphorylation inhibits Munc18/syntaxin interaction *in vitro*. At present, only phosphorylation of Ser313 of Munc18-1 has been confirmed to occur *in vivo*. In bovine adrenal chromaffin cells and in rat brain synaptosomes, phorbol ester treatments or the application of secretagogs caused a marked increase in phosphorylation of Ser313, but not of Ser306, as revealed by phosphospecific antisera generated to these sites. The crystal structure of the Munc18-1–syntaxin 1a complex indicated that phosphoserine in position 313 could be sterically accommodated without disrupting the syntaxin-binding surface; however, the introduction of a negative charge in this area would have an effect on the electrostatically positive character of domain 3a and perturb its charge complementarity with the syntaxin 1a linker region. Ser306 is localized further away from syntaxin 1a in the complex, and it is not immediately apparent how the phosphorylation of this site could directly affect interaction between the two proteins.

A double-point mutant of both Ser306 and Ser313 to glutamate that demonstrated reduced binding to syntaxin 1a *in vitro* was employed as a phosphomimetic mutant to examine the role of Munc18-1 phosphorylation by PKC in the regulation of release. These studies, performed in transfected chromaffin cells, used carbon-fiber amperometry to analyze the extent and kinetics of single-vesicle release events from permeabilized cells. Although the mutant did not affect the number of exocytotic events, it did produce changes in single-vesicle release kinetics, implicating PKC-mediated phosphorylation of Munc18 in this process. However, a single-site phosphomimetic mutant, S313E, failed to reproduce this effect. In addition, in Munc18-1-knockout mice, which exhibit a severe reduction (but not a complete abolishment) of LDCV secretion in chromaffin cells, no changes in the kinetic properties of single LDCV fusion events were observed.

Munc18-1 phosphorylation by PKC was also implicated in a process of efficient replenishment of the releasable pools of vesicles in bovine chromaffin cells. Rescue experiments in *munc18-1* null mutant autaptic neurons with PKC phosphorylation deficient mutant of Munc18-1 (referred to as $M18_{PKCi}$) also demonstrated that Munc18-1 is an essential substrate in the PKC-dependent pathway and implicated Munc18-1 phosphorylation by PKC in short-term synaptic plasticity.

In summary, there is little doubt that Munc18 is physiologically phosphorylated by PKC, but the molecular mechanism by which PKC phosphorylation of Munc18-1 alters the parameters of release and synaptic plasticity is still unclear. One plausible model is that PKC-dependent phosphorylation of Munc18-1 dynamically regulates the strength of Munc18-1 interaction with syntaxin 1 by decreasing their binding affinity. Alternatively, PKC phosphorylation could promote the translocation of Munc18-1 to a different protein.

Cdk5 has been also shown to phosphorylate Munc18-1 *in vitro*. Phosphorylation occurs at Thr574 and results in a strong reduction of syntaxin binding, leading to a model whereby the phosphorylation of Munc18-1 by Cdk5 mediates the disassembly of the syntaxin–Munc18 complex. Cdk5, a serine/threonine protein kinase that is highly and ubiquitiously expressed in the adult brain, was also implicated in the regulation of neuronal activity and synaptic plasticity. It attracted special attention because Cdk5 was shown to modulate the dynamics of fusion pore during exocytosis. It was suggested

that this effect could be at least partly mediated by the phosphorylation of Munc18-1. However, the dynamics of M18-1 phosphorylation/dephosphorylation in rat brain nerve terminals indicated that the PKC, rather than Cdk5, is a primary kinase for the presynaptic Munc18. In addition, in the crystal structure of Munc18-1 Thr-574 is buried and structurally inaccessible to the kinase. Thus, the precise understanding of how phosphorylation of Munc18-1 by Cdk5 could modulate exocytosis needs further clarification.

Outside of the neuronal system, tyrosine phosphorylation of Munc18-3 (Munc18c) in response to glucose stimulation in adipocytes and insulin-secreting cell line was reported. The phosphorylation, which negatively affected Munc18-3–syntaxin 4 binding, was implicated in regulation of insulin granule exocytosis and in platelet-derived growth factor (PDGF)-stimulated glucose transporter 4 translocation in adipocytes. Crystal structure of Munc18-3 in a complex with syntaxin 4 peptide suggested a molecular basis for this regulation. Phosphorylation of Tyr219 on Munc18-3 could potentially affect Munc18 loop that forms a hydrogen bond with syntaxin 4 N-terminal peptide (see below).

Altogether these data emphasize the notion that protein phosphorylation could well be among conserved mechanisms regulating Munc18 function *in vivo*.

Munc18 Interacting Proteins and Proteins Implicated in Regulating Munc18–Syntaxin Interaction

Multiple proteins were reported to either directly bind to Munc18 or regulate Munc18–syntaxin interaction. Among them are: Mints, DOC2, granuphilin/Slp4-a, phospholipase D, Munc13, and Tomosyn.

Mint1 and Mint2 (Munc18-1-interacting proteins) are multidomain neuronal adaptor proteins that were initially suggested as mediating the function of Munc18-1 in neurotransmitter release. However, genetic knockout of Mint1 in mice demonstrated selective changes in presynaptic plasticity in inhibitory synapses, but did not reveal global impairments of synaptic functions. More recent studies on mice with genetic disruption of all Mint isoforms uncovered a decrease in Munc18-1 levels and a global change in neurotransmitter release, consistent with a modulatory role for the Mint–Munc18 interaction in release.

Double C2 domain (DOC2) proteins are vesicular adapter proteins that bind to Munc18 in multiple *in vitro* assays. Their capability to shift the equilibrium between syntaxin–Munc18 and DOC2–Munc18 complexes suggested that they may also regulate the release of syntaxin from the Munc18–syntaxin complex *in vivo*. Disruption of endogenous Munc18c–DOC2β complexes or manipulations with expression levels of DOC2β affected glucose-stimulated insulin secretion in transfected cells. However, deletion of DOC2α, the predominant neuronal isoform, in mice demonstrated that DOC2 is not essential for Ca^{2+}-dependent neurotransmitter release *per se*. Thus, at least in the neuronal system, it seems unlikely that DOC2s serve as direct regulators of Munc18–syntaxin interaction *in vivo*.

Several studies have been published on Munc18 interaction with granuphilin (also known as Slp4-a, a member of a family Rab3/Rab27 effectors specific for pancreatic beta-cells and pituitary glands). Granuphilin directly interacts with Munc18-1, syntaxin 1a, and with Munc18-1-syntaxin 1a complex in multiple binding assays leading to a proposal that granuphilin molecularly docks insulin granules to the fusion machinery. RNAi experiments in insulin secreting cells suggested that granuphilin functionally collaborates with Munc18 during insulin granules exocytosis; however, precise molecular mechanisms of this interaction require further elucidation.

It was also suggested that Munc18-1 directly associates with and negatively regulates the basal activity of mammalian phospholipase D (PLD); however, the physiological meaning of this interaction for regulated exocytosis is unclear.

Several proteins were also evaluated for their potential role in regulating Munc18-1–syntaxin 1 interaction; however, only Munc13 still firmly holds its position as a potential candidate for such a function.

Munc13-1, a mammalian homolog of the *C. elegans* Unc13, is a large neuronal multidomain protein implicated in priming of SVs during exocytosis. Disruption of *(M)UNC13* gene function in mice, *C. elegans,* and *Drosophila* results in the loss of evoked synaptic transmission. Although SVs are morphologically docked at the plasma membrane, they do not fuse in response to stimuli that normally release the entire readily releasable primed vesicle pool, suggesting a role for Munc13 in priming. The potential ability of Munc13 to regulate the Munc18-1–syntaxin interaction was suggested by the initial observation that Munc13 directly binds to the N-terminal sequence of syntaxin 1 *in vitro* and by the follow-up report showing that the *C. elegans* Unc13 protein can displace Unc18 from syntaxin. However, the strongest support for this idea comes from the fact that the overexpression of an open form of syntaxin 1 (called LE mutation, which switches the equilibrium toward the open syntaxin conformation in isolation and lowers the affinity of Munc18–syntaxin binding) rescued evoked SV release in *UNC13*-null mutants. These results

strongly suggested that Unc13 functions in priming by regulating the conformational state of syntaxin 1 to control SNARE complex formation. Interestingly, open syntaxin also restored evoked release in *UNC10* mutants. Unc10 represents the *C. elegans* homolog of RIM (Rab3-interacting molecule), which also directly interacts with Munc13. Together, these data suggest that RIM can facilitate Munc13 function. Thus, Munc13 in conjunction with RIM may represent an essential part of a mechanism releasing syntaxin from Munc18-1; however, the molecular details of this mechanism are still unclear.

Tomosyn is a large cytosolic syntaxin-binding protein implicated in the modulation of both constitutive and regulated exocytosis. In *C. elegans* its ortholog TOM-1 negatively regulates synaptic transmission presumably by affecting the priming step of SV exocytosis. *In vitro*, Tomosyn can displace syntaxin from the Munc18-1–syntaxin 1 complex; however, the physiological function of Tomosyn is most likely to be attributed to its ability to act as a competitive inhibitor of the SNARE complex. Tomosyn contains a C-terminal SNARE motif that can take place of the Synaptobrevin/VAMP SNARE motif in the genuine SNARE complex, as convincingly demonstrated by the X-ray crystallography studies.

Extended Family of SM Proteins

Whereas Munc18s and their yeast ortholog Sec1 are selectively involved in regulated secretion in mammals and yeast, respectively, their homologs function at different transport steps in eukaryotic cells. Altogether, these proteins form a large family known as the SM proteins. There are four SM proteins in yeast. and seven SM proteins in mammals (Table 1). In pairwise comparisons, SM proteins exhibit approximately a 17–27% overall sequence identity that is evenly distributed over their entire length. In yeast, the SM protein family is represented by Sec1p, Sly1p, Vps33p (also known as Slp1p or Vam5p), and Vps45p/Stt10p. Sec1p operates at the plasma membrane, Sly1p regulates traffic between the endoplasmic reticulum (ER) and Golgi, Vps45p functions in the *trans*-Golgi network (TGN)/endosome system, and Vps33p controls vacuole traffic. Their mammalian counterparts, Munc18-1, -2, and -3, mSly1, mVps45, and two mVps33 (Vps33a and -b) operate in analogous cellular compartments in a mammalian cell.

A wealth of genetic and biochemical data demonstrated a critical involvement of SM proteins in SNARE-mediated intracellular membrane fusion reactions. Most, although not all, of the SM proteins directly interact with their cognate syntaxins with high specificity and affinity. However, initial studies of the mechanisms of their binary interactions suggested that the binding of neuronal Munc18-1 to the closed conformation of syntaxin 1 is rather unique. The most prevalent mode of a direct interaction between SM proteins and syntaxin is irrespective of the open or closed syntaxin conformation and is largely mediated by a short N-terminal syntaxin sequence preceding the Habc domain (Figure 2). This interaction mode, which was originally found between SM proteins and syntaxins involved in vesicular transport between the ER and Golgi and through the TGN/early endosomes (Table 1), is evolutionarily conserved and, significantly, is compatible with SNARE complex formation. The N-terminal-binding mode has been demonstrated for several syntaxins and their cognate SM proteins: yeast Tlg2p with Vps45p, Sed5p and Ufe1p with Sly1p, and their mammalian counterparts (syntaxin 16 with mammalian Vps45, and syntaxin 5 and syntaxin 18 with mammalian Sly1). The crystal structure of yeast Sly1p in a complex with the N-terminal peptide of Sed5p and NMR studies of mammalian Sly1/syntaxin 5 interaction uncovered the structural basis for this binding mode. Whereas Sly1 shares a common arch-shaped fold with the neuronal SM proteins, the N-terminal syntaxin 5/Sed5p peptide binds in α-helical conformation to the groove on the outside surface of domain 1 of Sly1 (Figures 1(c) and 1(d)), a completely different interface compare to the binding of the closed syntaxin 1 to Munc18-1. Thus, the big central cavity of the SM protein occupied by the closed syntaxin in the Munc18-1–syntaxin 1 complex is free to mechanistically serve as the site of action for the positive function of the SM proteins in fusion (e.g., as a platform for the SNARE complex assembly).

Although syntaxin N-terminal-binding paradigm was initially uncovered for the SM proteins involved in trafficking between intracellular compartments, it

Table 1 SM proteins in yeast and mammals

Yeast SM protein	*Cellular compartment*	*Mammalian SM protein*	*Cellular compartment*
Sec1p	Plasma membrane, concentrated at the sites of exocytosis	Munc18-1, -2, -3	Plasma membrane
Vps45p	TGN, early and late endosomes	mVps45	Golgi/endosomes
Sly1p	ER/Golgi	mSly1	ER/Golgi
Vps33p	Vacuoles, enriched in the vertices of vacuole–vacuole contacts	mVps33A and B	n.d.

ER, endoplasmic reticulum; n.d., not determined; SM, Sec1/Munc18-like; TGN, *trans*-Golgi network.

Figure 2 Mechanisms of SM protein–SNARE coupling in membrane traffic: (a) Munc18-1 interacts with the closed conformation of neuronal syntaxin 1a (left) while SNARE complex formation requires an open conformation of syntaxin (right); (b) N-terminal peptide-based interaction among Vps45p/mVps45, Sly1p/mSly1, and their cognate syntaxins (Tlg2p/syntaxin 16 for Vps45p/mVps45; Sed5p/syntaxin 5 and Ufe1p/syntaxin 18 for Sly1p/mSly1); (c) Sec1p interaction with the assembled SNARE complex. Syntaxin is colored in different shades of red (the SNARE motif is in dark red; the linker region, the three-helical Habc domain, and the N-terminal sequence are shown in bright red). The other SNARE motifs involved in the SNARE complex are in green and dark blue. The SM proteins in all three panels are in light blue. N, N-terminus of syntaxins; SNARE, soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor. Note that rapidly emerging data (see text) suggest a significant convergence between these models. Binding to the assembled SNARE complexes containing cognate syntaxins has been recently described as a second interaction mode for Vps45p, Sly1p, Munc18-3 and neuronal Munc18-1, as well as high affinity binding of Vps45 to the likely 'closed' syntaxin 16.

was recently extended toward Munc18 proteins involved in regulated exocytosis. Crystal structure of Munc18-3 in a complex with syntaxin 4 N-terminal peptide revealed a striking evolutional conservation of syntaxin N-terminal-binding mode from yeast to mammals and further emphasized potential physiological significance of this interaction.

Another coupling mode is found for the SM proteins implicated in the vesicular trafficking through the 'digestive tract' of the eukaryotic cell, specifically through the vacuolar and prevacuolar/lysosomal compartments. Here, the yeast vacuolar SM protein Vps33p is engaged in a large multisubunit protein complex, including SNAREs, but not via direct interaction with the cognate syntaxin, Vam3p. Vps45p, which has been genetically proven to operate at the same trafficking step as yeast syntaxin Pep12p, also does not directly interact with this syntaxin but rather operates as an integral part of a large protein complex.

To add to the complexity of Munc18-SNARE coupling, the interaction between Munc18-1 and syntaxin-SNAP-25 heterodimer has also been reported.

The most striking distinctions in the mechanisms of Munc18–SNARE coupling are found between SM proteins involved in exocytosis in yeast and in the SV exocytosis at neuronal plasma membrane (Figure 2). Yeast Sec1p preferentially binds to the assembled SNARE complex, in sharp contrast to the high-affinity binding of neuronal Munc18-1 to syntaxin 1. Altogether, the apparent diversity of the Munc18–SNARE coupling mechanisms has considerably complicated the process of uncovering the biological function(s) of SM proteins. However, several most recent discoveries suggest that these apparently diverse mechanisms have more in common than previously thought.

Potential Role(s) of SM Proteins in Fusion and Munc18-1 Function(s) in Neuronal Exocytosis

The high degree of sequence conservation and the overwhelming evidence that SM proteins are critically involved in all SNARE-dependent intracellular

fusion reactions suggest that SM proteins must have a common biological function. A function for SM proteins in vesicular docking was suggested by observations that the deletion of Munc18-1 in mice results in a significant reduction of docked LDCVs in adrenal chromaffin cells and that disruption of *UNC-18* gene in *C. elegans* leads to a decrease of morphologically docked vesicles in the mutant synapses. However, docking of SVs in the prenatal neurons of Munc18-1-knockout mice is apparently normal, speaking against the universal character of the docking phenotype. Overall, the formulation of a unifying hypothesis to account for the molecular mechanisms of SM protein function was largely precluded by the lack of a common SM protein–SNARE coupling mechanism. Such a mechanism has recently started to surface.

A number of studies demonstrated that, in addition to Sec1p, several other SM proteins have a capacity to interact with assembled SNARE complexes. Both yeast Sly1p and Vps45p, in addition to their well-characterized binding to the N-terminal sequences of the corresponding syntaxins (**Figure 2**), exhibit a second mode of interaction with SNARE complexes containing their cognate syntaxins. This observation was later expanded to the mammalian proteins. An N-terminal syntaxin-binding mode was reported for the Munc18-3 (Munc18c)–syntaxin 4 interaction. Munc18-3 is also shown to directly bind to syntaxin 4-containing SNARE complexes *in vitro*. Moreover, the preformation of Munc18-3–syntaxin 4 complex is reported to increase the rate of SNARE complex assembly. This is in line with previous observations in yeast suggesting that Sly1p binding to Sed5p confers fidelity to the SNARE complexes *in vitro* and that the loss of Vps45p function negatively affects the ability of Tlg2p to form functional SNARE complexes *in vivo*. Altogether, these results suggest that it is the association of the SM proteins with the assembled SNARE complexes that might represent a missing unifying mechanism underlying a common physiological function(s) of the SM proteins in fusion. One of such common function(s) could be to provide a platform for a concerted process of SNARE-complex assembly.

How can this notion be reconciled with the inhibitory character of the neuronal Munc18-1–syntaxin 1a complex? Recent data showed that Munc18-1 also directly binds to and accelerates SNARE complex formation *in vitro*, and that removal of the N-terminal sequence of syntaxin 1 abolishes both the interaction and the activation effect on the complex formation. Moreover, the N-terminal syntaxin 1 sequence is critical for its biological function, as demonstrated by multiple cell-based assays and by the electrophysiological experiments in the calyx of Held synapses. NMR spectroscopy experiments revealed that this sequence is actually engaged in the interaction with Munc18-1 in the Munc18-1–syntaxin 1a complex. In the originally published crystal structure of the complex, the N-terminal residues of syntaxin 1a were apparently disordered and thus were absent from the final structure. However, subsequent reexamination of the electron density guided by the available structures of two other complexes (Munc18-3 with syntaxin 4 N-terminal peptide, and Sly1p with Sed5p N-terminal peptide) revealed that the N-terminal sequence of syntaxin 1a also binds to the predicted site on the outer surface of Munc18-1 in Munc18-1 syntaxin 1a complex. Despite overall similar binding mode, syntaxin 1a N-terminal sequence binds weaker and forms only 4 hydrogen bonds with Munc18-1, while syntaxin 4 N-terminal sequence forms 13 hydrogen bonds with Munc18-3. These variations in binding strength are primarily due to isoform-specific sequence differences. Interestingly, molecular modeling revealed potential presence of the syntaxin N-terminal binding mode in most but not all SM protein–syntaxin pairs suggesting that this property might have coevolved to satisfy a particular regulatory function. Altogether, these results once again point toward a unified syntaxin/SM-protein-binding mechanism and also support the notion that the universal biological function of the SM proteins in fusion could be performed via their interaction with SNARE complexes. The emerging view is that *in vivo* SM proteins are switching between distinct binding modes with their cognate SNARE proteins or protein complexes during different stages of the SNARE assembly/disassembly cycle. These interactions, although overall similar for most if not all SM proteins, could be of greatly different affinities dictated by the specific needs of a particular transport step. Some of these complexes could be rather transient by nature and difficult to detect. High-affinity binding of the neuronal Munc18-1 to the closed conformation of syntaxin 1 could be evolved to meet very special spatial and temporal requirements of the neuronal exocytosis. Physiological relevance of the closed syntaxin was confirmed by recent genetic studies in mice. The analysis of transgenic mice expressing open syntaxin 1 revealed massively accelerated rate of SV fusion confirming a critical role for the closed conformation of syntaxin 1 in regulating neurotransmitter release. The data also suggested that the closed conformation operates upstream of fusion reaction and controls the entry of SV into the fusion reaction that is then mediated by Munc18-1 binding to assembled SNARE complexes.

Muscarinic Receptors: Autonomic Neurons

R S Aronstam and P Patil, University of Missouri – Rolla, Rolla, MO, USA

Introduction

Muscarinic receptors recognize the neurotransmitter acetylcholine, translating this recognition into electrical transients and altered cell behavior by activating and suppressing an assortment of signaling pathways. Muscarinic receptors comprise one of the two classes of receptors for the neurotransmitter acetylcholine, with nicotinic receptors comprising the other class. Muscarinic receptors are selectively activated by the alkaloid muscarine from the mushroom *Amanita muscaria* and are blocked by belladonna alkaloids, such as atropine and scopolamine (Figure 1). Muscarinic receptors are involved in the transduction of cholinergic signals in the central nervous system, autonomic ganglia, smooth muscles, and other parasympathetic end organs.

The history of muscarinic systems is intimately associated with the development of receptor theory, pharmacology, and the discovery of neurotransmitter transmission. Muscarinic receptors are members of the superfamily of G-protein-coupled receptors, specifically class A (rhodopsin-like) receptors. Muscarinic receptors are related to the ionotropic nicotinic acetylcholine receptors only insofar as their physiological activator is acetylcholine; muscarinic and nicotinic receptors share little similarity in their structure, physiological functions, or pharmacology (except for a few close analogues of acetylcholine).

Muscarinic Receptor Subtypes

The genes for five subtypes of muscarinic receptors, M1–M5, were identified, cloned, and sequenced between 1986 and 1990. These receptor subtypes differ in their primary structure, distribution, pharmacology, and signal transduction activity (Table 1). This heterogeneity presents the possibility of selectively affecting specific muscarinic functions in the brain and other organs; accordingly, the pharmacology of muscarinic receptor subtypes has been the subject of intensive investigation. Unfortunately, the selectivity of antagonists for receptor subtypes rarely exceeds tenfold. In the absence of pharmacological uniqueness, knockout mice are proving exceptionally useful in delineating functions associated with specific receptor subtypes.

Our understanding of muscarinic receptor biology is largely dependent on (1) physiological and behavioral analysis of the actions of muscarinic agonists and antagonists (notably, smooth muscle contraction, cardiac function, vascular tone, glandular secretion, arousal, attention, and memory); (2) ligand binding studies employing radiolabeled probes (notably, the antagonists [^{3}H]*N*-methylscopolamine and [^{3}H]quinuclidinyl benzilate); (3) biochemical characterization of receptor proteins (including primary, secondary, and tertiary protein structure, and patterns of phosphorylation, glycosylation, phosphorylation, and lipid modification, dimerization, nitrosylation, and internalization); (4) measurement of receptor influence on intracellular second messengers (notably, inositol triphosphate (IP_3), diacylglycerol, Ca^{2+}, nitric oxide, cAMP, cGMP, and arachidonic acid); (5) analysis of receptor gene sequence and control; (6) genetic manipulation of receptor expression; (7) genetic manipulation of receptor protein structure; and (8) elimination of specific receptor subtypes using gene knockout technology.

The properties of the different subtypes are summarized in Table 1. A schematic diagram of the human M2 receptor is presented in Figure 2, a possible arrangement of the seven transmembrane domains is schematically represented in Figure 3, the amino acid sequence alignment of the five subtypes is presented in Figure 4, and an alignment tree of receptor amino acid sequences suggesting evolutionary relations is shown in Figure 5. The receptors were named on the basis of the order of their discovery, which reflects their relative abundance. Muscarinic receptors have been traditionally divided into two groups based on both their pharmacology and signaling properties: M2 and M4 comprise one group, and M1, M3, and M5 comprise the other (Figure 6).

Muscarinic Receptor Structure

Muscarinic receptor proteins are single polypeptides of 460–590 amino acids with an extracellular N-terminus and an intracellular C-terminus (Figures 2 and 3). The N-termini do not possess consensus sites for protein cleavage, and epitope tags applied to the N-terminus provide convenient markers to monitor receptor expression and transport.

The coding regions of muscarinic receptor genes are contained within a single exon. Hydropathic analyses of the amino acid sequences reveal seven regions of 20–24 amino acids that are likely to form membrane spanning α-helical structures. The amino acid composition of the membrane-spanning regions is

Figure 1 Structures of muscarinic ligands. Acetylcholine is the physiological agonist. Muscarine and atropine are the prototypical agonist and antagonist which define the receptor class. Gallamine is an allosteric receptor antagonist. Pirenzepine, AF-DX 116, and 4-DAMP are antagonists with a degree of selectivity for the M1, M2, and M3 receptor subtypes, respectively.

highly conserved (90% sequence similarity) among the five subtypes, as it is among the larger family of G-protein-coupled receptors.

Between the fifth and sixth membrane-spanning units is a large intracellular loop that is highly variable in composition and size. Several consensus sites for phosphorylation are located on the third intracellular loop, as well as on the C-terminal chain. A disulfide bridge is formed between a conserved cysteine adjacent to the third transmembrane segment and a cysteine in the middle of the second extracellular loop in all five subtypes. Chemical modification of these cysteine groups decreases agonist binding affinity as well as the ability of the receptor to couple to transducer

Table 1 Properties of muscarinic receptor subtypes

Property	*Subtype*				
	M1	*M2*	*M3*	*M4*	*M5*
Molecular weight[a]	51 240	51 715	66 127	53 058	60 186
Amino acids	460	466	590	479	532
Genomic location	11q13	7q31–q35	1q43	11p12–p11.2	15q26
G-protein coupling	G_q, G_{11}	G_i, G_o	G_q, G_{11}	G_i, G_o	G_q, G_{11}
Second messengers[b]	IP_3/DAG, NO	cAMP (↓)	IP_3/DAG, NO	cAMP (↓)	IP_3/DAG, NO
Tissues[c]	Brain, autonomic ganglia, secretory glands, vas deferens, sympathetic ganglia	Brain, heart, sympathetic ganglia, lung, ileum, uterus and other smooth muscles	Brain, secretory glands, smooth muscles	Brain, lung	
Brain regions	Cerebral cortex, hippocampus and dentate gyrus, striatum, olfactory bulb and tubercle, amygdala	Cerebellum, medulla, pons, basal forebrain, olfactory bulb, diencephalon	Cerebral cortex, thalamus, piriform cortex, olfactory bulb, brain stem nuclei	Occipital cortex, caudate and putamen, visual nuclei, olfactory tubercle, hippocampus	Midbrain
Subtype-selective antagonists[d]	Pirenzepine, telenzepine, mamba venom toxins	AF-DX-116, methoctramine, gallamine, himbacine	4-DAMP, hexahydro-sila-difenidol	Tropicamide, himbacine	
Functions revealed by analysis of knockout mice	Agonist-induced seizures, learning, control of locomotor activity; indirect inhibition of N- and L-type calcium channels; M current inhibition in sympathetic ganglion neurons; MAPK pathway activation	Agonist-induced akinesia and central tremor; corticosterone release; analgesia; hypothermia; smooth muscle contraction; bradycardia; inhibition of N- and P/Q-type calcium channels	Papillary and urinary bladder constriction; salivary secretion; smooth muscle contraction; control of dopamine release; maintenance of body mass and food intake	Dopamine release; acetylcholine release (hippocampus); depression of motor control; analgesia	Dilation of cerebral arteries and arterioles; dopamine release

[a]Molecular weights are calculated for the polypeptide contribution only.
[b]IP_3/DAG, stimulation of phospholipase C to release the second messenger inositol triphosphate (IP_3) and diacylglycerol (DAG) from phosphatidylinositol; NO, increase in nitric oxide production. cAMP(↓): inhibition of adenylate cyclase, thereby lowering cellular content of the second messenger cAMP.
[c]Only low levels of M5 receptor expression have been detected in tissues.
[d]Antagonist selectivity of the subtypes is relative; antagonists generally differ in their interactions with the different subtypes by a factor of less than 20.

Figure 2 Schematic diagram of a human M2 muscarinic receptor showing the primary amino acid sequence. Four consensus sites of glycosylation at asparagine residues are indicated on the extracellular N-terminal domain. The aspartate and tyrosine and threonine residues in the membrane-spanning regions that are thought to be involved in agonist binding are highlighted in yellow. Regions of the third intracellular loop involved in G-protein recognition and coupling are indicated by blue shading. Possible sites of threonine phosphorylation in the C-terminal domain are also indicated by highlighting.

Figure 3 Possible arrangement of muscarinic receptor transmembrane domains, as suggested by structural analysis of rhodopsin. Amino acid moieties involved in the binding of acetylcholine are located approximately one-fourth of the way into the plane of the membrane.

G-proteins. Moreover, nitrosylation of receptor cysteines after reduction of the disulfide bond severely diminishes ligand binding to the receptor. Elimination of either of these cysteines, however, precludes expression of the receptor. A conserved cysteine in the N-terminus may be a site for palmitoylation (thereby creating another intracellular loop) and an N-terminal polybasic region in four of the subtypes (all except the M2 receptor) may be involved in recruitment of adapter proteins in certain signaling pathways.

M3 receptors (at least) have been found to form disulfide-linked dimers on the cell surface. Two to four consensus sites for N-glycosylation are present in the extracellular N-terminal domain of each receptor, and 25% of the receptor mass may be contributed by these oligosaccharides. Although this carbohydrate component may affect the processing and orientation of the receptor, it plays no discernible role in ligand binding or signal transduction: enzymatic removal of the carbohydrate has little effect on the binding and signal transduction potential of mature receptors.

Chimeric receptors and mutational analysis have revealed sites on the receptor proteins that are specifically involved in ligand binding and coupling to transducer G-proteins. Acetylcholine binds to a site within a pocket formed by the roughly circularly arranged transmembrane domains (Figure 3). An aspartate moiety in the third transmembrane region participates in an ionic interaction with the quaternary nitrogen of acetylcholine, whereas a series of tyrosine and threonine residues located in the membrane-spanning segments approximately one-fourth of the distance through the membrane likely form hydrogen bonds with muscarinic ligands. In agreement with classical pharmacological analysis, the binding site for competitive antagonists is thought to overlap the acetylcholine recognition site but additionally involves contiguous hydrophobic areas of the receptor protein and membrane. Muscarinic receptors also possess a site(s) or region that participates in allosteric regulation by a variety of compounds, including gallamine (Figure 1). These ligands compete with classical muscarinic ligands but slow the dissociation of previously bound probes, indicating the existence of a ternary complex (receptor plus allosteric and orthosteric ligands). Gallamine binding is sensitive to modification of the sixth transmembrane domain as well as the third extracellular loop.

A number of regions have been identified that participate in the interactions of muscarinic receptors with transducer G-proteins. In particular, the second intracellular loop and the N- and C-terminal portions of the third intracellular loop are involved in coupling to G-proteins. Desensitization of muscarinic receptors may entail phosphorylation of conserved threonine residues on the C-terminal portion of the receptor, as well as other sites on the third intracellular loop. Prolonged stimulation of muscarinic receptors induces a rapid phosphorylation that is associated with a decrease in agonist affinity and an uncoupling from transducer G-proteins. Agonist-induced phosphorylation involves a G-protein receptor kinase (GIRK) and not kinases activated by Ca^{2+}, cAMP, cGMP, or phorbol esters. Phosphorylation-dependent internalization of muscarinic receptors appears to be mediated by arrestins.

The evolutionary relationship of muscarinic receptor subtypes is suggested by amino acid sequence (Figure 5). M1, M3, and M5 comprise one cluster, with M1 and M3 being somewhat more closely related. M2 and M4 comprise a second cluster. Analysis of nucleotide sequence of the coding regions reveals an essentially similar pattern. Sequence analyses reveal more genomic divergence within the two clusters than between the two groups. The five muscarinic receptor genes are scattered throughout the genome; the only two on the same chromosome (M1 and M4 on chromosome 11) are only distantly related.

Muscarinic Receptor Gene Structure

Whereas the coding sequences of the gene for each subtype are uninterrupted or intronless, the genes are

Figure 4 Amino acid sequence alignment of the five human muscarinic acetylcholine receptor subtypes. Conserved and semiconserved residues are indicated by the asterisks and dots below the sequences; possible N-terminal glycosylation sites are indicated by yellow shading; the conserved cysteines involved in disulfide bond formation are indicated by blue shading; the N-terminal site of palmitoylation is highlighted; sequences believed to be involved in receptor interactions with G-proteins are indicated by red bars; transmembrane regions are identified by the green shading. Alignment was performed using the ClustalW procedure provided in MacVector.

Figure 5 UPGMA distance tree illustrating the evolutionary relationship of the muscarinic receptor subtypes revealed by amino acid sequence. M1, M3, and M5 comprise a cluster; M2 and M4 comprise a second cluster. Analysis of nucleotide sequence of the coding regions reveals an essentially similar pattern. The 0.05 scale marker is approximately equivalent to a 5% difference in sequence.

Figure 6 Muscarinic receptor signaling pathways. The initial stages of signal transduction include receptor, transducer (G-protein), effector (typically an enzyme or ion channel), second messenger production (e.g., Ca^{2+}, cAMP, cGMP, DAG, and IP_3), and protein kinase activation. It has long been appreciated that M2 and M4 receptors inhibit adenylate cyclase through activation of G_i, whereas M1, M3, and M5 receptors stimulate phospholipase C-beta through activation of $G_{q/11}$. In fact, muscarinic signaling involves an impressive variety of other pathways. For instance, under the right conditions all receptors can stimulate adenylate cyclase through the activation of G_s. Other pathways are activated directly or secondarily. PKA, protein kinase A; PKC, protein kinase C; IP_3, inositol triphosphate; DAG, diacylglycerol.

complex, spanning large distances, and often contain multiple exons that result in multiple splice variants that are under the control of tissue-specific promoters. TATA and CAAT boxes are not involved in the transcriptional control of muscarinic receptor gene expression. The promoter structures of several muscarinic acetylcholine receptor subtypes have been analyzed. Consensus regulatory sequences, including binding sites for SP1, AP-1, and AP-2, as well as tissue-specific silencer elements, have been identified. All muscarinic receptor genes contain a large (10–26 kb) intron close to the 5′ end of the translational start site. The relatively simple M1 gene contains an upstream 657 bp exon with a flanking 900 bp promoter region that contains consensus sites for SP1, NZF-1, AP-1, AP-2, E-box, NF-κB, and Oct-1. The M2 gene spans over 126 kb on chromosome 7, and it contains four exons that result in at least eight different splice variants. The M2 gene has at least three distinct promoters that result in distinct tissue-specific expression, and these promoters are highly conserved between mammalian species. The M3 gene spans at least 285 kb encompassing eight exons (the coding sequence is in exon 8). Multiple AP-2 regulatory sequences are located in the 1.2-bp 5′-flanking promoter region, and the transcription factor AP-2α increases M3 expression.

Muscarinic gene sequences tend to be highly conserved; relatively few nonsynonymous polymorphisms have been reported.

Physiological Functions

Muscarinic receptors subserve a number of physiological functions. Muscarinic receptors are present in autonomic ganglia and on the target organs of postganglionic parasympathetic fibers. Thus, muscarinic receptors mediate such parasympathetic effects as smooth muscle contraction, blood vessel dilation, decreases in heart rate and cardiac contractility, and glandular secretion.

Muscarinic agonists have relatively little use in therapeutics, being limited to stimulating muscles of the gastrointestinal tract and bladder and to lowering intraocular pressure. A great deal of work has focused on developing M1 subtype-specific agonists that might be useful in alleviating the cholinergic losses that characterize Alzheimer's disease. It has been sporadically proposed that subtype-selective cholinomimetics would be useful in the treatment of psychiatric diseases. Arecoline, an alkaloid found in the betel nuts that are chewed by a significant portion of the world's population, is undoubtedly the most widely consumed muscarinic agonist. Arecoline causes parasympathetic stimulation (notably increased salivation) and produces euphoria and enhanced cognitive function.

Muscarinic antagonists are used clinically to inhibit parasympathetic activity in a variety of situations. For example, antimuscarinic drugs have been used in anesthesia (to reduce secretions), parkinsonism, overactive bladder, bradycardia, and irritable bowel syndrome.

In the central nervous system, cholinergic fibers arise in nuclei in the midbrain and pons to diffusely innervate muscarinic receptors on neurons in the thalamus and other diencephalic structures, as well as the reticular formation and other brain stem and cranial nerve nuclei. A second major projection system arises from the basal forebrain cholinergic system (which includes the medial sepal nucleus, diagonal band nuclei, and nucleus basalis) and innervates muscarinic receptors on neurons throughout the telencephalon. Cholinergic interneurons innervating muscarinic receptors are located in several brain structures, including the cerebral cortex, nucleus accumbens, and striatum. Muscarinic receptor density is particularly high in the striatum, cerebral cortex, hippocampus, and other specific nuclei. Muscarinic receptor subtypes display striking regional and laminar heterogeneity (Table 1). Central muscarinic systems are prominently involved in arousal, attention, learning, and memory. Other functions involving central muscarinic actions include movement, analgesia, and temperature regulation.

Subsets of M2 and M4 receptors have a presynaptic localization and play a role in the control of neurotransmitter release; the other receptors are predominantly postsynaptic.

Analysis of knockout mice lacking expression of specific receptor subtypes has shed considerable light on the physiological functions of receptor subtypes (Table 1). Muscarinic knockout mice are both healthy and fertile; recognition of deficits frequently requires specific focused analysis. These studies reveal that M1 receptors are involved in M current (potassium channel) regulation, agonist-induced seizures mitogen-activated protein kinase (MAPK) activation, certain learning paradigms, and inhibition of a slow, voltage-independent calcium current. M2 receptors are involved in the production of bradycardia; smooth muscle contraction (stomach, urinary bladder, and trachea); and central tremor, analgesia, and hypothermia. M3 receptors are seen to be involved in salivary secretion, pupillary constriction, and bladder detrusor contraction. M4 receptors are seen to be involved in limiting locomotor activity (including modulation of motor responses to dopamine). There is an interesting relationship between M5 receptors and dopamine neurotransmission: M5 receptors facilitate dopamine release, thereby affecting brain reward systems. M5 receptors also appear to play a specific role in the dilation of cerebral arteries and arterioles.

Muscarinic Signal Transduction

Muscarinic receptors alter the activity of receptive cells by a number of different signal transduction pathways (Figure 6). The biochemical pathways activated depend on the nature and quantity of the receptor subtype, transducer proteins, effector molecules, and protein kinase substrates expressed in the tissue, as well as the potential for cross-talk between the various transduction pathways. Conventional wisdom holds that the odd-numbered receptor subtypes – M1, M3, and M5 – efficiently couple through pertussis toxin-insensitive G-proteins of the $G_{q/11}$ family to a stimulation of phospholipase C (β subtype). Phospholipase C releases the second messengers diacylglycerol and IP_3 from the membrane phospholipid, phosphatidylinositol-4, 5-bisphosphate. Diacylglycerol activates protein kinase C, whereas IP_3 releases Ca^{2+} from intracellular stores by acting on specific receptors on the endoplasmic reticulum. M1, M3, and M5 also activate the MAP kinase pathway as well as phospholipase D (releasing arachidonic acid). Cross-talk between signaling pathways makes the distinction between proximal and indirect signaling events problematic.

M2 and M4, inhibit adenylate cyclase through actions involving G_i (any of the three G_i proteins may be involved). A few, but by no means all, isoforms of mammalian adenylate cyclase are inhibited by $G_{i\alpha}$ subunits (e.g., AC5 and AC6). An even larger number of adenylate cyclase subunits are inhibited by $G_{\beta\gamma}$ dimers. Thus, the molecular basis for inhibition of the enzyme is not always obvious. Inactivation of G_i by ADP-ribosylation catalyzed by pertussis toxin uncovers activation of adenylate cyclase by all receptor subtypes. In the case of M3 at least, this activation seems to be mediated by a muscarinic receptor–G_s interaction.

Thus, our initial binary classification of muscarinic signaling paradigms (i.e., receptor:transducer:effector = M1/M3/M5:G_s:phospholipase C_β or M2/M4:G_i:adenylate cyclase) has been extended in response to the identification of pathways that involve additional transducer proteins as well as an appreciation of secondary effects and cross-talk between the pathways. Other well-documented muscarinic actions include stimulation of adenylate cyclase, inhibition of phosphodiesterase, stimulation of phospholipase A2 (M1, M3, and M5), and stimulation of phospholipase D (M1 and M3).

Muscarinic receptor stimulation activates a number of depolarizing and hyperpolarizing currents through both direct and indirect mechanisms. Prominent effects include (1) stimulation of inwardly rectifying potassium conductances by M2 and M4 receptors; (2) activation of calcium-dependent potassium, chloride,

and cation conductances by M1, M3, and M5 receptors; (3) inhibition of the M current, a voltage- and time-dependent potassium conductance, by M1 and M3 receptors; and (4) inhibition of a calcium conductance by M2 and M4 receptors, directly via G_o and indirectly via reductions in cAMP.

Other novel biochemical effects of muscarinic receptor activation have been described. This signaling heterogeneity may reflect (1) multiple isoforms of signal transduction effectors (e.g., at least 11 isoforms of adenylate cyclase), (2) cross-talk between transduction pathways due to a lack of specificity or the presence of indirect and secondary effects, or (3) cell type-specific differences due to expression of different assortments of signal transduction molecules. Muscarinic receptor-mediated activation of both phosphodiesterase and nitric oxide synthetase has been reported.

Muscarinic receptors have substantial mitogenic potency. The molecular details of muscarinic receptors of the pathways that mediate these effects are incompletely understood. The activities of multiple kinases and phosphatases are affected by muscarinic receptors under specific conditions, including Raf, tyrosine kinases, MAPK, and phosphatidyl inositol-3-kinase. The activities of multiple small GTPases, including Ras and Rho, are also affected by muscarinic receptor activation.

Muscarinic signaling is subject to regulation by agonist-induced phosphorylation and downregulation (internalization). Mice deficient in G-protein-coupled receptor kinase-5 display muscarinic supersensitivity. Although domains located in the third intracellular loop are prominently involved in receptor phosphorylation and downregulation, a number of subtype-dependent variations in arrestin association and internalization pathways have been described.

Muscarinic receptors regulate the expression of a variety of genes, notably a variety of transcription factors and signaling factors. An appreciation of this regulation promises to increase our understanding of muscarinic physiology.

Introduction

Music is a phenomenon that appears to have been universally present throughout human history and across all human populations. The perception and performance of music are often delicately intertwined with a variety of perceptual (e.g., listening), sensorimotor (e.g., playing an instrument), visual (e.g., reading a musical score), mnemonic (e.g., playing a piece from memory), and affective (e.g., emotional interpretation) processes. For these reasons, music offers potentially powerful insights into complex brain organization and function. Additionally, musical aptitude and the unique effects of musical training are of specific interest to the study of the nature and effects of brain plasticity and reorganization.

Music is often compared to language, and indeed music does share many abstract similarities with language. In both language and music, perceptually distinct elements are combined into hierarchically organized sequences according to rules of syntax. While music and language are highly analogous in many respects, however, they are also quite different. Therefore the cognitive investigations of music perception provide the opportunity to reveal similarities and differences in the neural structures and functions involved in music and language perception. Furthermore, the search for the cognitive substrates of music perception complements the musicological investigations of the origins of music, its perceptual distinction from speech and other auditory input, and its evolutionary relationship to the development of language.

The past few decades have seen a major increase in the systematic study of the cognitive neuroscience of music. Recent advances in neuroscientific techniques, such as functional magnetic resonance imaging (fMRI), magnetoencephalography (MEG), and positron emission tomography (PET), provide new data to build upon findings from neurophysiologic and lesion-based studies. Because of the breadth of processes and brain regions involved in musical perception, the cognitive investigations of music perception traditionally dissect music into its distinct fundamental elements.

Pitch and Melody

Pitch is the fundamental building block of music. For this reason, the majority of research on the neurological correlates of music perception has focused on pitch and, to a lesser extent, on melodic phrase. The perception of pitch relies on the acoustic properties of the spectra (the ratios of the fundamental frequency to the harmonics) and the envelope (the rise and decay time) of each harmonic constituent. Melody is a musical phrase created when a series of pitches are organized into sequential temporal patterns of varying musical contour and interval.

Numerous studies spanning nearly 50 years strongly indicate a 'pitch center' in the posterior superior temporal lobe, composed of the auditory cortices and secondary auditory association areas. Early studies of patients with temporal lobe excisions note the prominence of the right hemisphere in pitch and melodic processing. Excisions that included the right lateral Heschl's gyrus significantly impaired the perception of changes in pitch, pitch direction, interval size, melodic contour, and complex tones. However, left-lateralized damage can also cause selective deficits in pitch and melodic processing. The results of a neuroimaging study using PET indicate a left lateral specialization of the core auditory cortex for temporal processing of sound, while the spectral processing of pitch correlated to activity in the right hemisphere belt cortical areas (Figure 1).

While considerable debate surrounds possible hemispheric specialization in pitch perception, recent studies have begun to investigate specialization of areas within the auditory cortices. Studies of primates have demonstrated the importance of the secondary auditory cortex in the tonotopic organization of pitch (Figure 2). Recent neuroimaging studies of humans have also implicated the importance of the secondary auditory association centers in complex pitch processing. When individuals were examined while listening to sequentially varied pitches – that is, a melody – increased activity was found beyond Heschl's gyrus in the superior temporal gyrus and planum polare. Research in music perception implicates possible dissociation between the perception of pitch height (the octave of a pitch) and pitch chroma (the note within the octave). A recent fMRI study offers a potential neural correlate, indicating that regions anterior to the primary auditory cortex are important for pitch

Figure 1 Merged positron emission tomography and magnetic resonance image volumes corresponding to the direct comparison of temporal and spectral conditions to one another. The image on the left shows a horizontal section taken through the region of Heschl's gyri, which showed significantly greater activity in the combined temporal conditions than in the combined spectral conditions. The section on the right is taken through the maxima corresponding to the anterior superior temporal region, which showed a greater response to the spectral conditions than to the temporal conditions. The bar graphs illustrate the percent difference between condition in regions of interest taken from corresponding locations. Reprinted from Zatorre RJ and Belin P (2001) Spectral and temporal processing in human auditory cortex. *Cerebral Cortex* 11: 949, with permission from Oxford University Press.

chroma while the posterior regions are important in the perception of pitch height.

Absolute Pitch

Absolute pitch perception is of specific relevance to the discussion comparing the effects of musical training, musical exposure, and innate musical predisposition. Absolute pitch is the ability to identify a musical note by pitch without reference to any other sound. Genetic factors are implicated, since absolute pitch is exceedingly rare – even among musicians, it has a sibling recurrence rate of 8–15%, and seems to be distributed differently across human populations. However, environmental factors are clearly important, since absolute pitch requires musical training before the age of 12 years in order to manifest itself.

Through neuroimaging studies, the functional and structural correlates of absolute pitch are beginning to be identified. Investigations of the structural correlates of absolute pitch show that musicians with absolute pitch show a greater leftward asymmetry of the planum temporale than do nonmusicians or musicians without absolute pitch. A follow-up study indicated that this asymmetry results not from an enhancement of the left superior temporal cortex, but rather from a structural reduction of the right planum temporale in those with absolute pitch. While these results suggest that a developmental 'pruning effect' may be needed for acquisition of absolute pitch, the possible relationship between innate brain structure and predisposition for absolute pitch needs further exploration.

A functional neuroimaging study using PET demonstrated that musicians without absolute pitch show greater activity in the right inferior frontal cortex, a region important for working memory for pitch, when making judgments of musical intervals compared to those with absolute pitch. Additionally, absolute pitch possessors show greater activation in the left posterior dorsolateral frontal cortex, a region associated with conditional associations in memory.

Figure 2 Characteristic frequency (CF) topographical map from the left hemisphere of one marmoset. Pitch-selective neurons (black squares) were found clustered near the anterolateral border of primary auditory cortex (AI). Frequency reversals indicate the borders between the AI/R and R/RT (rostral temporal) fields (R, rostral; C, caudal; L, lateral; M, medial). Reprinted from Bendor D and Wang X (2005) The neuronal representation of pitch in primate auditory cortex. *Nature* 436: 1163, with permission from Macmillan Publishers Ltd. Copyright (2005).

This region was active in all individuals in tasks requiring the identification of musical intervals, but was uniquely active in those with absolute pitch when listening to single tones, possibly correlating mnemonic association with the ability to identify pitch without relative reference.

Timbre

Another fundamental aspect of music is timbre, or tone color, the psychoacoustic property of sound that permits us to differentiate between two different musical instruments playing at the same pitch. The perception of timbre relies on the acoustic properties of the spectra (harmonics) and timing (envelope) and therefore the cognition of timbre relies upon the neural regions important in the processing of pitch.

Imaging studies focusing on the alteration of spectrally dissimilar sounds demonstrate activity in the superior temporal lobes, especially Heschl's gyrus and the superior temporal sulcus, with a degree of right lateralization. These findings are reinforced by data from patients who have undergone temporal lobectomy. Patients with right temporal lobe excisions show deficits in the discrimination of changes in timbre compared to left temporal lobe excision and normal control groups. Since the perception of timbre relies upon the fine spectral and temporal aspects of sound, deficits in timbral perception are usually described in conjunction with deficits in pitch perception. However, in one particularly unique case, a patient, following a right temporal stroke, lost the ability to discriminate between the timbre of previously familiar musical instruments while retaining normal perception of melody, rhythm, and other musical aspects.

Rhythm

The term 'rhythm' is often used to describe broad macroscopic temporal patterns in music that encompass the structural musical elements of pulse, meter, and rhythmic grouping. Pulse or beat is the periodic repetition of acoustic stimuli in time, such as the unaccented 'ticks' of the metronome. The speed of the underlying pulse of music defines the tempo of a piece of music, often measured in 'beats per minute.'

Meter is defined by regularly recurring patterns of stressed ('strong') and unstressed ('weak') beats, and in some notated music is regulated by the presence of a time signature. A more precise definition of rhythm frames it as the subjective perception of groupings of accented and unaccented beats, which vary in length and relationship over time.

Because rhythm develops over time, the perception of rhythmic patterns involves brain regions important in temporal processing. In music, meter and rhythm are often intimately linked with movement, such as in dance or the urge to tap your foot to a beat. The production of a timed motor response from an external stimulus involves a network that includes the sensorimotor cortices, superior temporal gyrus, cerebellum, and basal ganglia. Less well understood are the correlates of temporal perception without motoric reproduction, such as in tasks of passive rhythmic perception.

Early and contradicting lesion studies implicated both the left and right temporal cortices in the process of rhythmic sequences. More recent studies implicate a possible divergence in the perception of metric and rhythmic groupings. Damage to the temporal lobe in the right hemisphere impairs perception of meter, whereas left-lateralized damage impairs the discrimination of rhythmic patterns; however, such differences may only reflect the subtle differences in task and stimuli.

The specialization and complex interactions of the left and right hemispheres in the perception of temporal structures are not well understood. One fMRI study indicates separate processes in the cognition of metric (musical) rhythms and nonmetric (nonmusical) rhythms. Musical rhythms causes activation in the left premotor and left parietal areas and the right anterior cerebellar lobe, while nonmusical rhythms leads to activity in the right prefrontal, right premotor, and right parietal areas as well as in the bilateral cerebellar posterior lobe.

Further evidence of a leftward dominance for temporal processing implicates the recruitment of the 'language areas' in the perception of rhythmic patterns. Imaging studies of passive rhythmic perception show increased activation in the left inferior frontal gyrus, including Broca's area (BA 44/5) and BA 47. A case study of a subject with Wernicke's aphasia demonstrated a severe deficit in the perception of rhythm compared to pitch and melodic perception, indicating the importance of Wernicke's area (BA 22) in rhythmic perception. Additionally, musicians show increased activity in the left hemisphere in the passive perception of rhythm compared to nonmusician, suggesting that hemispheric specialization for rhythm perception can be enhanced by musical training.

Musical Structure

Music, much like language, is governed by rules and syntax (grammar). In Western tonal music, these rules are governed by a metric structure, a hierarchy of musical keys, the order of chord progressions (tonality), and rules of harmony (counterpoint). Only very recently have researchers begun to investigate the neurological correlates of the perception of musical structure and syntax. The majority of studies have focused on identifying the effects of presenting syntactically irregular chords within a structured harmonic sequence.

Converging data from neuroimaging and electroencephalographic studies indicate that violations of tonality activate the inferior frontal regions, including Broca's area (BA 44/5) and its homolog in the right hemisphere and BA 47, as well as the posterior temporal regions, including Wernicke's area. Since both Broca's and Wernicke's areas are crucial in the processing of language, this evidence indicates a significant overlap of these 'language areas' in the syntactic processing of both language and music. However, musical syntax involves a complex set of rules and harmonic relationships that extend beyond simple expectation of correct or incorrect chords. Isolating brain regions involved in this syntactic processing is rather difficult, especially since the correlates of the basic elements of music perception, such as pitch and rhythm, are not fully understood. For instance, a specific musical key (e.g., C major or G minor) determines both the pitch content (musical scale) and chords (harmony) permitted in a tonal musical phrase. In Western tonality, the various 24 different major and minor keys are cyclically interrelated based on a hierarchy prescribed in the musical 'circle of fifths,' and this hierarchy regulates the perceptual distance of musical keys and chords. An fMRI study designed to investigate the perception of melodic contour as a function of tonality (modulated through all 24 musical keys) implicates the rostromedial prefrontal cortex as a unique region that maintains a relative topographic map of tonality. These findings suggest a possible neural substrate for the perceptive ability to maintain the integrity of a melody despite musical transposition.

Musical Semantics

Although the issue of whether nonvocal music carries any inherent semantics is highly controversial, music certainly has the power to convey culturally relevant interpretations and associations. One study measured the N400 component of the event-related brain potential during the presentation of 'semantically' related words and musical excerpts, such as the word

'staircase' and an ascending musical scale. The findings argue that words with descriptive, qualitative, structural, or abstract similarities to a particular musical excerpt activate a response pattern similar to semantically related word and sentence pairs, indicating that superficial semantic interpretations of certain musical aspects might be shared. These findings, while provocative, underscore the need for further investigation of the effects of environment factors such as culture, language, and training on music perception and interpretation.

Musical Memory and Imagery

Memory is crucial to the perception of music, since the macroscopic structures of melody, rhythm, and harmony unfold over periods of time. As indicated by imaging and lesion studies, working memory for pitch requires the interaction of the right temporal and right frontal cortices. Measurements of cerebral blood flow using positron emission tomography during tasks of recognition and identification of music as 'familiar' show a broad network of activation, including the bilateral superior temporal cortices; bilateral orbital, medial, and inferior frontal regions; precuneus; angular gyrus; and parahippocampal gyrus.

Musical imagery is the subjective task of imaging music in the absence of auditory input. When individuals were asked to imagine the continuation of a truncated musical stimulus, activation was observed in the inferior frontal and superior temporal regions as well as the supplementary motor areas. In addition, measurements of the topography of event-related potentials (ERPs) found that activity in the imagination of the continuation of a melody is similar to the pattern activity when auditory stimuli are not withheld, further indicating that musical imagination employs auditory regions even in the absence of acoustic stimuli.

Emotion

Since music is ultimately abstract, the interpretation and understanding of music are highly subjective, depending on culture, degree of musical training, and personal preference. Nevertheless, the power of music to elicit particularly strong emotive responses is well recognized. At first glance this association seems quite unusual; however, neurophysiological investigations indicate that these emotive responses to music are associated with primitive neural systems associated with basic survival mechanisms, perhaps explaining why music has persisted through history despite the absence of any obvious evolutionary benefits. These associations between limbic structures and musical perception provide a potentially contradictory viewpoint to theories that postulate music to be the evolutionary side effect of an auditory system that has become specialized for language.

A seminal study used PET imaging to monitor neural responses to individual-selected music that elicited 'chills' down the spine. Increases in the subjective intensity of the emotive experience correlated to changes of cerebral blood flow in the ventral striatum, dorsal midbrain, amygdala, orbitofrontal cortex, and ventral medial prefrontal cortex – regions associated with processing of reward and pleasure, such as hunger and sexual drive. Similar imaging studies have also shown correlation between pleasant responses to music and activity in the subcallosal cingulate gyrus, prefrontal anterior cingulate, retrosplenial cortex, and hippocampus; the nucleus accumbens, ventral tegmental area, hypothalamus, and insula; and the inferior frontal gyrus, Heschl's gyrus, and the Rolandic operculum. Increasingly dissonant music correlated with increased activity in the right parahippocampal gyrus and right precuneus (Figure 3).

Lesion-based studies indicate both functional and structural dissociations between music perception and emotional responses to music. The recognition of emotional tone can be spared even when basic perception and recognition of music are impaired. Conversely, deficits in response to emotion in music are described even when basic music perception is unimpaired. A single case study found that following an infarction involving the left amygdala and insula, the patient lost the 'shiver down the spine' phenomenon he had previously experienced when listening to Rachmaninoff, but retained both pitch and speech perception.

Furthermore, the neurological correlates of the emotional responses to music seem to vary based on the subjective perception of emotional tone. Patients with either left or right medial temporal lobe resections, including the amygdala but sparing the superior temporal gyrus, were found to be impaired in the recognition of 'scary music', but unimpaired in the recognition of 'happy' or 'sad' music. Another patient with complete bilateral damage relatively restricted to the amygdala was selectively impaired in the recognition of 'scary music', but was able to identify 'happy' music as well as the control group could. In a similar study, patients with significant loss of the parahippocampal cortex were unable to identify 'unpleasant' music but were able to identify consonant music as pleasing. Another patient with significant impairment in tasks of music perception caused by bilateral lesions to the auditory cortex was found to be indifferent to musical dissonance but was able to identify music as either 'happy' or 'sad' as well as the

Figure 3 Cortical regions demonstrating significant regional cerebral blood flow correlations with dissonance level. Correlations are shown as *t*-statistic images superimposed on corresponding averaged magnetic resonance image scans. The *t*-statistic ranges for each set of images are coded by color scales below each column, corresponding to images a–c and d–f. (a–c) Positive correlations with increasing dissonance demonstrated relative cerebral blood flow activity in right parahippocampal gyrus and right precuneus. (d–f) Negative correlations with increasing dissonance (equivalent to positive correlations with increasing consonance) demonstrated relative cerebral blood flow activity in bilateral orbitofrontal cortex, medial subcallosal cingulate, and right frontal polar regions. Reprinted from Blood AJ, Zatorre RJ, Bermudez P, and Evans AG (1999) Emotional responses to pleasant and unpleasant music correlate with activity in paralimbic brain regions. *Nature Neuroscience* 2: 382–387 with permission from Macmillan Publishers Ltd. Copyright (1999).

normal controls could. When taken together, these results imply that the emotive interpretation of consonance and dissonance relies initially on the perceptional organization of sound (in the superior temporal gyri and other neocortical regions) that is subsequently relayed to limbic and paralimbic regions responsible for affective responses.

Musical Training

Professional musicians achieve expertise through years of rigorous training, usually starting at an early age. Studies comparing skilled musicians and nonmusicians demonstrate both morphological and functional differences in the musical brain. Such differences provide the opportunity to investigate the effects of musical training on brain plasticity and reorganization. Imaging studies comparing musicians and nonmusicians have shown structural differences in the motor cortex, the somatosensory and superior-parietal areas, the auditory cortex, the corpus callosum, and cerebellum.

In addition to the anatomical differences seen in brains of musicians and nonmusicians, functional differences in brain organization have also been observed. Neuroimaging studies comparing musicians and nonmusicians have demonstrated differences of activity in the auditory cortex, motor cortices, and cerebellum. These studies reveal both enhancements and reductions of activity, suggesting the complex effects of musical training on brain reorganization. One such MEG study demonstrated an enhanced cortical representation of the four fingers of the left hand used in string playing, compared to the nonmusicians and to the right hand of the string players themselves. Furthermore, increases in the cortical representation of the somatosensory and auditory areas in skilled musicians have been shown to correlate with age at which musical training was begun.

Some of the plastic effects of musical training can relate to the musician's specific area of training. Orchestra conductors show a superior spatial processing in the auditory periphery, reflecting the skill of localizing the sounds of various musical instruments in space. Instrumental performers show a preference to their own musical instrument in both functional and morphological enhancements of the auditory cortex, further indicating long-term training-induced plasticity. But even short periods of intense musical training can cause functional brain reorganization. While differences certainly exist in the musical brain, the precise nature and complex interaction of these structural and function brain changes caused by musical training are little understood. Furthermore, the relationship between brain structure and function and innate musical predisposition prior to training has not yet been fully explored.

Music and Culture

While music is universally present across cultures, the subjective interpretation of music depends on a host of factors, including culture, musical exposure, and musical training. Culturally specific definitions of music vary to such a degree that what is deemed highly musical in one culture may be perceived as completely unmusical in another. A majority of studies of the neural correlates of music perception have focused on individuals and stimuli from Western musical traditions. Yet, the functional and structural differences found between musicians and non-musicians invite investigation into possible effects of cultural exposure on music perception. Persons culturally exposed to Western music react to violations of musical syntax at a very young age, when musically untrained, when distracted, and even when explicitly primed for the violation. Furthermore, acquisition of implicit musical expectation seems to occur early in development, possibly within the first year of development.

Only a few studies have explicitly investigated the correlates between music perception and cultural exposure. Individuals show a behavioral preference in the ability to synchronize with culturally specific music, and electroencephalography (EEG) data indicate cultural-specific differences in listening strategies of musical phrase, musical instrument, and musical scale. However, while the processing of a familiar language may use distinct brain regions, one functional imaging study found no differences in the processing of culturally familiar and unfamiliar music – only differences correlating to the degree of musical training that were culturally independent.

Conclusion

The various ways music is perceived, performed, learned, identified, and interpreted indicate a broad system of complex neurological interactions involving a wide array of brain regions and structures. Historically, investigations of the cognitive neuroscience of music strive to isolate regions and processes associated with the individual aspects of music. Emerging neuroimaging literature continues to isolate substrates responsible for the perception of individual elements of music. While many argue this dissection of musical stimuli threatens the 'ecological validity' of music, this increased understanding of basic musical elements undoubtedly provides a foundation for future macroscopic comparisons and investigations. Ideally, an eventual convergence of musicologic, psychologic, and neuroimaging data will extend our knowledge to advanced concepts of musical learning, performance, and composition, as well as the complex questions surrounding the innate musical ability and musical creativity.

Musical Illusions

D Deutsch, University of California at San Diego, La Jolla, CA, USA

Introduction

Over the past decade, there have been significant advances in understanding the brain mechanisms underlying music perception. Functional imaging studies of normal individuals have provided considerable information concerning the anatomical structures involved. Studies of patients with musical deficits resulting from brain lesions have supplied much complementary information, as have studies of individuals with congenital amusia. Investigations of musical illusions – misperceptions of music by normal individuals – provide further insights into the brain circuitry underlying music perception. This entry reviews those musical illusions which have clear implications for the neuroscience of music. In exploring these illusions, we focus in particular on three issues:

1. *Innate differences in music perception.* Can we assume that music perception is the function of innate brain circuitry that is common to most individuals, or are there widespread and substantial differences in music perception that reflect innate differences in brain organization? Some of the illusions to be described point to widespread individual differences in the perception of music that correlate with handedness; these indicate that there are substantial variations in the innate brain circuitry underlying music perception.

2. *Neural plasticity in the development of music perception.* Recent imaging studies have indicated that musical practice produces alterations in brain organization, and that this happens particularly at an early age, when the effects of experience on brain function are particularly strong. In addition, a musical illusion to be described here has been shown to be heavily influenced by the speech patterns to which the individual has been exposed, particularly in childhood. The characteristics of this illusion indicate that the brain circuitry underlying music perception can be influenced by extramusical input, particularly at an early age. More specifically, it points to a strong influence of exposure to speech patterns in childhood on how music is later perceived.

3. *Modularity in musical processing.* Findings from neurophysiological and neuropsychological studies have indicated that there are distinct 'what' and 'where' pathways in the auditory system. In accordance with these findings, certain musical illusions indicate that there are separate decision mechanisms underlying what pitches we hear and underlying where the tones appear to be coming from, and that the combined outputs of these decision mechanisms can lead to illusory conjunctions. More specifically, we can think of a musical tone as a bundle of attribute values – having a pitch, a location, a loudness, a timbre, and so on, with the different attributes being subserved by distinct neural pathways. When more than one tone is presented at a time, the different outputs of these pathways must be correctly conjoined in order to produce veridical percepts. Some of the illusions described here can be explained as due to incorrect conjunctions of attribute values.

Stereo Illusions

Powerful musical illusions can be produced when two streams of tones arise in parallel from different regions of space. There are striking differences among listeners in the way these illusions are perceived. These differences have been found to correlate with the handedness of the listener, and so can be taken to reflect innate differences in brain organization.

The Octave Illusion

The octave illusion is produced by the pattern shown in the upper portion of Figure 1. Two tones which are spaced an octave apart (at 400 and 800 Hz) are repeatedly presented in alternation. The tones are 250 ms sine waves at equal amplitude, and they follow each other without pause. The identical sequence is presented via headphones to both ears simultaneously; however, when the right ear receives the high tone the left ear receives the low tone; and vice versa.

Surprisingly, this simple pattern is almost never perceived correctly, and instead gives rise to a variety of illusions. The type of illusion varies substantially across listeners, and the one most commonly obtained is shown in the lower portion of Figure 1. A single tone appears to be switching from ear to ear while at the same time its pitch appears to be switching between high and low. In other words, the sequence as heard at the right ear consists of 'high tone – silence – high tone – silence' while the sequence as heard at the left ear consists of 'silence – low tone – silence – low tone.'

The illusion becomes even more surprising when the listener's earphones are placed in reverse position. Now most people experience exactly the same thing – the tone that had appeared in the right ear still appears in the right ear, and the tone that had

Figure 1 The sound pattern that gives rise to the octave illusion, and the percept most commonly obtained by right-handers. Filled boxes indicate tones of 800 Hz and unfilled boxes indicate tones of 400 Hz. When this pattern is played continuously through headphones, most right-handed listeners perceive an intermittent high tone in one ear that alternates with an intermittent low tone in the other ear. Adapted from Deutsch D (1974) An auditory illusion. *Nature* 251: 307–309.

appeared in the left ear still appears in the left ear. This gives rise to the peculiar impression that the earphone that had been producing the high tone is now producing the low tone, and that the earphone that had been producing the low tone is now producing the high tone.

There is clearly no simple explanation for this illusory percept. However, if we assume that there are two separate decision mechanisms, one determining what pitch we hear, and the other determining where the sound is coming from, we are in a position to advance an explanation. The model is shown in Figure 2. To provide the perceived sequence of pitches, the frequencies arriving at the dominant ear (i.e., the right ear in most right-handers) are followed, while those arriving at the nondominant ear are suppressed from conscious perception. However, to provide the perceived locations, each tone is localized at the ear that receives the higher frequency signal, regardless of whether a pitch corresponding to the higher or the lower frequency is perceived.

More specifically, we can consider a listener who perceives the pitches corresponding to the frequencies delivered to the right ear. When the high tone is delivered to the right ear and the low tone is delivered to the left, this listener hears a high tone, since it is delivered to the right ear, and localizes the tone in the right ear, since this ear is receiving the higher frequency signal. However, when a low tone is delivered to the right ear and a high tone is delivered to the left, this listener now hears a low tone, since it is delivered to the right ear, but hears the tone in the left ear instead, since this ear is receiving the higher frequency signal. So the full sequence is heard as a high tone to the right, alternating with a low tone to the left. It can be seen from Figure 2 that reversing the position of the headphones would not alter this basic percept. However, given a listener who perceives the pitches corresponding to the frequencies arriving at the left ear instead, holding the localization rule constant, the same sequence is heard as a high tone to the left, alternating with a low tone to the right.

Evidence for this model has been obtained in a number of studies. The octave illusion therefore provides a strong indication, at the perceptual level, that the neural pathways underlying what pitch we hear, and those underlying where the sound is located, are at some stage distinct and separate, and operate in accordance with different rules. The combined outputs of these two mechanisms can then result in striking illusory conjunctions.

As another aspect of the octave illusion, it has been found, on a statistical basis, that right-handers and left-handers show different patterns of localization for the high and low tones at the two ears. Right-handers tend strongly to hear the high tone on the right and the low tone on the left; however, left-handers as a group do not show the same tendency. This handedness difference is in accordance with the literature showing that while most right-handers have clear left-hemisphere dominance, patterns of cerebral dominance among left-handers vary considerably. In one study individuals were categorized as strongly right-handed, mixed-handed, or left-handed, and these groups were subdivided into those who had only right-handed parents and siblings, and those who had a left-handed parent or sibling. As shown in Table 1, this categorization produced an orderly pattern of results: subjects who were strongly right-handed and with no left-handers in their family were most likely to hear the high tone on the right and the low tone on the left, while left-handers with left-handers in their family were least likely to do so. These findings are as expected from neuropsychological studies relating hemispheric dominance of function to patterns of handedness and familial handedness background, since those individuals with left-handers in their family are less likely to be strongly left-hemisphere dominant than are those with only right-handers in their family. As a further handedness correlate, left-handers as a group tend more than right-handers to obtain complex percepts on listening to the octave illusion. This is in accordance with studies showing that left-handers, on a statistical basis, tend to have weaker patterns of cerebral dominance than do right-handers.

Figure 2 Model showing how the outputs of two decision mechanisms, one determining perceived pitch and the other determining perceived location, combine to produce the octave illusion. Filled boxes indicate tones of 800 Hz and unfilled boxes indicate tones of 400 Hz (R, right; L, left). Adapted from Deutsch D (1983) Auditory illusions, handedness, and the spatial environment. *Journal of the Audio Engineering Society* 31: 607–618.

Table 1 Percentages of individuals reporting the high tone on the right and the low tone on the left on listening to the octave illusion, tabulated by handedness and familial handedness background

	Dextral	*Left- or mixed-handed parent*	*Left- or mixed-handed sibling*
Right-handed	87.2% ($N=86$)	64.0% ($N=25$)	79.3% ($N=29$)
Mixed-handed	67.7% ($N=31$)	44.4% ($N=9$)	58.3% ($N=12$)
Left-handed	55.6% ($N=9$)	50.0% ($N=16$)	33.3% ($N=6$)

From Deutsch D (1983) The octave illusion in relation to handedness and familial handedness background. *Neuropsychologia* 21: 289–293.

The Scale Illusion

We next inquire what happens when a pattern is presented that consists of more than two tones. The scale illusion provides an example. As shown in the upper portion of Figure 3, the sequence that produces this illusion consists of a major scale, with successive tones alternating from ear to ear. The scale is presented simultaneously in both ascending and descending form, such that when a tone from the ascending scale is in the right ear, a tone from the descending scale is in the left ear; and vice versa. In consequence, the right ear receives one disjunct pattern of pitches, while the left ear receives a different, and overlapping, disjunct pattern of pitches. The tones are 250 ms sine waves at equal amplitude, and the sequence is repeatedly presented without pause.

This scale pattern also produces a number of illusions, which vary strikingly across listeners. The illusion most commonly obtained by right-handers is shown in the lower portion of Figure 3. A melody that corresponds to the higher tones appears to be coming from the right earphone, and melody corresponding to the lower tones appears to be coming from the left earphone. When the earphone positions are reversed, the higher tones continue to be heard as in the right ear

Figure 3 The sound pattern that gives rise to the scale illusion, and the percept most commonly obtained by right-handers. A major scale is presented simultaneously in ascending and descending form. The components alternate between earphones such that when a component of the ascending scale is delivered to one ear a component of the descending scale is delivered to the other ear. The pattern is played continuously without pause. Most right-handers perceive a melody that is composed of the higher tones in the right ear and a melody composed of the lower tones in the left ear. Adapted from Deutsch D (1999) Grouping mechanisms in music. In: Deutsch D (ed.) *The Psychology of Music*, 2nd edn., pp. 299–348. San Diego: Academic Press.

and the lower tones as in the left ear. This produces the strange impression that the procedure of reversing earphone positions has caused the higher tones to migrate from one earphone to the other, and the lower tones to migrate in the opposite direction. As with the octave illusion, right-handers and left-handers differ statistically in the way they perceive the scale illusion: right-handers tend to hear the higher tones on the right and the lower tones on the left; however, left-handers as a group do not show the same tendency. This indicates that there is a perceptual tendency to perceive higher tones as coming from the dominant side of space and lower tones as from the nondominant side.

Variants of the scale illusion are easily produced. Figure 4 depicts a version involving a two-octave chromatic scale. In reality, the sounds coming from each earphone leap around in pitch; however, listeners instead hear two smooth melodies that correspond to the higher and lower tones in the combined pattern, and they perceive the higher tones as coming from one earphone (in right-handers, this is usually the right earphone) and the lower tones as from the other.

The scale illusion can also occur with the sounds presented to the listener via two loudspeakers in a normal room environment. In one experiment, piano tones were used as signals, and differences in timbre were introduced for the tones presented through the two loudspeakers. The differences in timbre gave rise to yet another perceptual dissociation: a new sound quality was heard, but it appeared to be coming simultaneously from both loudspeakers. This perceptual dissociation of timbre from pitch and location may be related to findings indicating that brain lesions can give rise to deficits in timbre perception with spared pitch perception.

Why, then, should the illusory conjunctions that give rise to perception of the scale illusion occur? One approach involves the notion of unconscious inference. When faced with a complex sound configuration the brain engages in a process of inference concerning the sources that produced the sounds. In everyday life, similar sounds are likely to be coming from the same source and different sounds from different sources. So the best interpretation of this implausible musical pattern, in terms of the real world, is that the higher tones are all coming from one source and the lower tones from a different source. We therefore mislocalize the tones in accordance with this interpretation.

A related approach derives from the writings of the Gestalt psychologists, who argued that we form perceptual configurations based on certain organizational principles such as proximity. In the case of vision, for example, we group together dots that are positioned in spatial proximity, and we perceive motion between neighboring lights that are turned on and off in succession. The principle of proximity is a useful heuristic, since in the real world elements that are proximal in an array are likely to be coming from the same source. In the scale illusion we group

Figure 4 The sound pattern that gives rise to the chromatic illusion, and a way it is often perceived by right-handers. A two-octave chromatic scale is played simultaneously in ascending and descending form. The components alternate between earphones such that when a component of the ascending scale is presented to one ear a component of the descending scale is presented to the other ear. Most right-handers perceive a melody that is composed of the higher tones in the right ear and a melody composed of the lower tones in the left ear.

together successive tones that are related by pitch proximity, and separate out those that are further apart, and we mislocalize the tones on this basis, so overriding low-level localization cues.

The Glissando Illusion

The glissando illusion is best heard with the listener seated in front of two stereophonically separated loudspeakers, with one to the left and the other to the right. The pattern that gives rise to the illusion consists of two components; the first is a synthesized oboe tone of constant pitch, and the second is a sine wave that glides up and down in pitch. As illustrated in Figure 5, these two components are presented simultaneously via the two loudspeakers, and constantly switch between the speakers such that when the oboe tone is emanating from the speaker on the right a portion of the glissando is emanating from the speaker on the left; and vice versa. A fragment of the pattern producing this illusion is shown in Figure 5. When each channel is presented separately, the listener correctly hears the oboe tone in alternation with a portion of the glissando. However, when both channels are presented together, the percept changes dramatically. The oboe tone is heard correctly as switching back and forth between the loudspeakers. However, the portions of the glissando appear to be joined together quite seamlessly, so that a single, continuous tone is heard that appears to move around in space in accordance with its pitch motion. When the switching rate speeds up and slows down, the speed at which the glissando appears to move around in space does not change, but instead remains tied to its pitch motion.

Handedness correlates again emerge in terms of the apparent spatial positions of the higher and lower portions of the glissando: right-handers tend strongly to hear the glissando move from left to right as its pitch moves from low to high, and then back from right to left as its pitch moves from high to low. However, non-right-handers as a group do not show the same tendency. In this sense, the glissando illusion is similar to the octave and scale illusions, since it reflects a tendency to hear higher tones as on the dominant side of space and lower tones as on the nondominant side. However, in the octave and scale illusions the apparent spatial positions of the higher and lower tones generally remain fixed for the duration of the pattern, whereas in the glissando illusion the gliding tone is perceived as moving slowly in space, in accordance with its pitch motion.

In considering why the glissando illusion occurs we can refer to the same principles as were discussed with respect to the scale illusion. In this case we link together portions of the glissando that are proximal in pitch, and that follow smooth trajectories. In the real world this perceptual strategy is likely to lead to the best conclusion in interpreting our auditory environment, since it is very unlikely that a sound which is changing smoothly in pitch is switching abruptly between two widely different locations.

Illusions Based on Octave Ambiguity

It has long been recognized that tones that are related by octaves have a certain perceptual equivalence. This is acknowledged in the system of notation for the traditional musical scale. The core of this scale consists of 12 tones, which correspond to the division of the

Figure 5 The sound pattern that produces the glissando illusion. This consists of an oboe tone of constant pitch and a sine wave that glides up and down in pitch, with the two repeatedly switching between loudspeakers. Listeners perceive the oboe tone correctly as alternating between loudspeakers; however, the glissando appears to be joined together quite seamlessly, and to be moving around in space in accordance with its pitch motion.

octave into semitones, and each tone is given a name (C, C#, D, D#, E, F, F#, G, G#, A, A#, and B). The entire scale, as it ascends in height, consists of repeating the same sequence of note names across successive octaves. Because all Cs sound in a sense equivalent, as do all C#s, all Ds, and so on, pitch can be characterized as varying both along a monotonic dimension of height and also along a circular dimension of pitch class (or note name). The circular dimension is illustrated in Figure 6. The two dimensions can be largely separated by the use of computer-produced tones with pitch classes that are clearly defined, but that are ambiguous in terms of height. For example, one can employ tones consisting only of components that are related by octaves. With the use of such ambiguous tones, striking illusions are produced.

Illusions of Pitch Circularity

When two octave-ambiguous tones are played in succession, the listener hears either an ascending pattern or a descending one, depending on which is the shorter distance between the tones along the pitch class circle. So, for example, the tone pair consisting of C# followed by D is always heard as ascending, since the shorter distance between these tones is clockwise. Similarly the tone pair consisting of F# followed by F is always heard as descending, since the shorter distance between these tones is counterclockwise. So when a series of octave-ambiguous tones is presented that repeatedly traverses the pitch class circle in clockwise direction (C, C#, D, and so on) listeners perceive a sequence that appears to ascend endlessly in pitch. When, instead, the tones repeatedly traverse the pitch class circle in counterclockwise direction (C, B, A#, and so on) listeners hear a sequence that appears to descend endlessly. So just as with the scale illusion, this circularity illusion provides an example of the perceptual tendency to link together elements of an array of tones on the basis of pitch proximity.

Figure 6 The pitch class circle. The notes of the Western musical scale are formed by dividing the octave into 12 semitone steps, and each note is given a name: C, C#, D, and so on. The entire scale is formed by repeating this sequence of note names across octaves.

The Tritone Paradox

We can then ask what happens when listeners are presented with pairs of octave-ambiguous tones that are related in such a way that proximity cannot be used as a cue in judging their relative heights. For example, what happens when listeners are presented with two tones in succession that stand in opposite positions along the pitch class circle, so that the same distance between them along the circle is traversed in either direction? Such tones form an interval of six semitones, known as a tritone. When such tone pairs are presented, striking perceptual differences among listeners emerge. For example, when D is presented followed by G#, some listeners clearly hear an ascending pattern, while other listeners clearly hear a descending one. Yet when, instead, A is presented followed by D#, the first group of listeners now hears a descending pattern, whereas the second group now hears an ascending one. Furthermore, for any given listener the pitch classes generally arrange themselves perceptually with respect to height in a systematic way: tones in one region of the pitch class circle are heard as higher, and tones in the opposite region as lower. This is illustrated in Figure 7, which reproduces judgments of the tritone paradox made by four different listeners. It can be seen that the judgments of each listener showed an orderly relationship to the positions of the tones along the pitch class circle; however, the direction of this relationship varied substantially across listeners. As a result, extended patterns formed of such tone pairs are heard by listeners in entirely different ways, as depicted in Figure 8.

It has been shown that the way the tritone paradox is perceived correlates with the pitch range of the listener's speaking voice. Perception of this illusion also varies with the language or dialect to which listeners have been exposed. For example, striking differences have been found between listeners who had grown up in California and those who had

Figure 7 Judgments of the tritone paradox made by four different listeners. Each graph shows the percentages of judgments that a tone pair formed a descending pattern, plotted as a function of the pitch class of the first tone of the pair. The judgments of all listeners showed orderly relationships to the positions of the tones along the pitch class circle; however, the direction of this relationship varied substantially across listeners. Data supplied by the author.

grown up in the south of England: in general, when the California group tended to hear a pattern as ascending, the English group tended to hear it as descending, and vice versa. It appears, therefore, that perception of the tritone paradox is based on an acquired pitch template that is used primarily for speech communication.

Further work has provided evidence that the pitch representation that influences perception of the tritone paradox is formed early in life. On study explored perception of the tritone paradox in mothers and their children. The children were all Californians; however, the mothers had grown up in many different geographical regions, including England, the European continent, and various parts of the United States. As expected, the group of mothers perceived this pattern in ways that differed considerably; however, although the children were all native Californians, their percepts were very similar to those of their mothers. In a further study, perception of this illusion was explored in individuals who were born in Vietnam, as well as in a group of English-speaking Californians. The Vietnamese group was divided into two subgroups: those who had arrived in the United States as adults and spoke fluent Vietnamese but little English, and those who had arrived as infants or young children and now spoke perfect English, though most were not fluent in Vietnamese. Perception of the tritone paradox by the two Vietnamese groups was very similar, and clearly differed from the paradox's perception by English-speaking Californians. The study therefore indicates that exposure to speech sounds during an early critical period can have a substantial influence on perception of music in adulthood.

Conclusion

The perceptual phenomena described in this article demonstrate that the auditory system is very prone

Figure 8 Perception of the tritone paradox by two listeners who experienced the illusion in a pronounced way. Each graph shows the percentages of judgments that a tone pair formed a descending pattern, plotted as a function of the pitch class of the first tone of the pair. The notations show how the identical series of tone pairs was perceived by these two listeners in entirely different ways. From Deutsch D (1999) Processing of pitch combinations. In: Deutsch D (ed.) *The Psychology of Music,* 2nd edn., pp. 349–412. San Diego: Academic Press.

to illusion. This is not surprising, considering the paucity of information that is supplied by the peripheral auditory system. There are roughly 16 000 peripheral receptors in each ear, compared with roughly 125 million receptors in each eye. In addition, the amount of brain tissue devoted to hearing is far less than is devoted to vision. As a further consideration, sound signals are mixed together and are subject to numerous distortions as they travel from their sources to our ears, so that the brain is faced with the very difficult task of reconstructing the original signals from the mixture of sounds that arrive at the ears. The musical illusions described here provide valuable information concerning the strategies adopted by the nervous system in interpreting our auditory environment, and they reflect the operation of both innate mechanisms and neural plasticity in the process.

Myelin: Molecular Architecture of CNS and PNS Myelin Sheath

S S Scherer and E J Arroyo, University of Pennsylvania Medical School, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

The Function of Myelin Sheaths

A myelin sheath is a multilamellar spiral of specialized cell membrane that surrounds a segment of an axon that is typically larger than 1 μm in diameter (Figure 1). Myelinated axons are completely covered by myelin sheaths (internodes) except at nodes of Ranvier, the small gaps (less than 1 μm in length) directly exposed to the extracellular milieu. By reducing the capacitance and clustering ion channels at nodes, myelin sheaths reduce current flow across the internodal axonal membrane, thereby facilitating saltatory conduction, one of the fundamental adaptations of vertebrates.

The Circumferential Organization of Peripheral Nervous System Myelin Sheaths

Ramon y Cajal (1928) understood that a myelinated peripheral nervous system (PNS) axon "consists of an external solid membrane – sheath of Schwann – of a tubular cell – Schwann cell – of a fatty sheath, and of an axon." He understood that the sheath of Schwann was not part of the Schwann cell, and that it continued across nodes of Ranvier. With the advent of electron microscopy (EM), the sheath of Schwann was shown to be composed of a basal lamina and associated collagen fibers. This basal lamina contains laminin 2 (composed of a trimer of α_2, β_1, and γ_1 laminin chains; Figure 2), type IV collagens, entactin/nidogen, fibronectin, agrin, and glypican. Of these, α_2 and γ_1 laminin are essential because eliminating either one disrupts the formation of the basal lamina and results in developmental defects in myelination.

By analogy to epithelial cells, the basal/abaxonal cell membrane apposes the basal lamina (Figures 1–3). The abaxonal membrane contains at least two receptors for laminin 2 – the integrin $\alpha_6\beta_4$ and dystroglycan (Figures 2 and 3). In epithelia such as the skin, $\alpha_6\beta_4$ heterodimers are found in hemidesmosomes, which join epithelial cells to their basal lamina via intermediate filaments. Schwann cells, however, do not have hemidesmosomes; $\alpha_6\beta_4$ integrin may be linked to the actin cytoskeleton and not to intermediate filaments. Mice lacking either the α_6 or the β_4 integrin subunit die soon after birth because of a profound skin defect, but myelination appears normal in co-cultures established from mice lacking β_4 integrin. Dystroglycan is composed of α and β subunits, which are products of the same gene. As depicted in Figure 2, dystroglycan binds to laminin 2 and to agrin. The intracellular domain of β dystroglycan forms a complex with periaxin, dystroglycan-related protein 2 (DRP2), a short dystrophin isoform (Dp116), utrophin, and β, δ, and ε sarcoglycan. In contrast to the continuous localization of $\alpha_6\beta_4$ integrin and even dystroglycan, DRP2 and periaxin are specifically localized to regions lacking cytoplasm (Figure 4), indicating that DRP2 and/or periaxin may bind to a component of compact myelin.

The importance of the dystroglycan complex in myelinating Schwann cells remains to be fully elucidated, but dystrophin as well as α, β, δ, and γ sarcoglycan are all essential in skeletal muscle cells since the absence of any one of these components results in myopathy. In mice, eliminating dystroglycan or especially the β_1 integrin gene in Schwann cells causes developmental defects in myelination. Recessive mutations in the mouse *Large* gene, one of the genes involved in glycosylation of β dystroglycan, also results in abnormal myelination. In humans, Dp116 may be required for proper myelination since a splice site mutation in the *Dystrophin* gene that abolishes dystrophin expression in peripheral nerve has been reported to cause a demyelinating neuropathy. The best evidence for an essential role of the dystroglycan complex is that recessive *Periaxin* mutations in humans cause an inherited demyelinating neuropathy known as Charcot–Marie–Tooth disease 4F (CMT4F). In addition to a demyelinating neuropathy, *periaxin* null mice also show a loss of the cytoplasmic channels/Cajal bands, the cytoplasmic channels on the outside of the myelin sheath (Figure 4). Cajal bands contain microtubules that provide the highways for trafficking cargo to and from the perinuclear region, where the rough endoplasmic reticulum and Golgi apparatus are located. The cell membranes of Cajal bands are enriched in caveole (and caveolin-1), as well as the K^+ channels Kir2.1, Kir2.3, and a Ca^{2+}-activated K^+ channel. In *periaxin* null mice, the cytoplasm uniformly surrounds the compact myelin, resulting in abnormally short myelin internodes.

Compact Myelin

Figure 5(a) shows a schematic PNS myelinated fiber. It depicts two internodes, one of which has been unrolled to reveal its trapezoidal shape. The myelin sheath has two domains – compact and noncompact myelin – each of which contains a nonoverlapping set

Figure 1 Ultrastructure of a myelinated fiber in the PNS. (a) This electron micrograph shows an axon, its myelin sheath (m), basal lamina (arrowheads), as well as the inner (i) and outer (o) mesaxons (from a 4-day-old mouse). (b) This electron micrograph shows that the compact myelin sheath is composed of alternating major dense (arrows) and intraperiod lines. Note the 'double nature' of the intraperiod line. From SS Scherer (1997) Molecular genetics of demyelination: New wrinkles on an old membrane. *Neuron* 18: 13–16, with permission of Elsevier.

Figure 2 Extracellular matrix receptors of myelinating Schwann cells. The dystroglycan receptor complex of myelinating Schwann cells is linked to three members of the dystrophin family – utrophin, DRP2, and Dp116. Of these, only utrophin has an actin binding domain, whereas DPR2 binds periaxin, which is shown binding to itself via its PDZ domains. Three sarcoglycans – β, δ, and γ – associate with dystroglycan. $\alpha_6\beta_4$ integrin also binds to laminin-2, which is a trimer of α, β, and γ subunits. The figure was modified from the one kindly provided by Drs. Diane Sherman and Peter Brophy.

of proteins (Figure 5(b). Compact myelin forms the bulk of the myelin sheath and is a spiral of closely packed membranes, with a periodicity of approximately 14 nm in conventional transmission EM (Figures 1 and 6) and slightly greater (18 nm) in fresh nerves by X-ray diffraction. The apposed membranes form the intraperiod line; the thin space that separates the membranes is contiguous with the extracellular space. The major dense line is contiguous with the cytoplasm.

Compact myelin is largely composed of lipids, mainly cholesterol and sphingolipids, including galactocerebroside and sulfatide. The targeted disruption of the genes required for the synthesis of sulfatide (*cst* null mice) or galactocerebroside and sulfatide (*cgt*

Figure 3 Circumferential organization of myelinating glial cells. This schematic drawing depicts the circumferential organization of a myelinated axon from the CNS and the PNS, including representative molecules. null mice) provided the unprecedented opportunity to perturb the lipid components of myelin. Surprisingly, except for the splitting of some central nervous system (CNS) myelin sheaths, compact myelin has a normal ultrastructure. Despite this normal appearance, axonal conduction velocity is dramatically slowed, which is likely related to abnormal paranodes.

The main myelin proteins of compact myelin are myelin protein zero (P_0), peripheral myelin protein 22 kDa (PMP22), and myelin basic protein (MBP). P_0 is by far the most abundant and is the main adhesive molecule in compact myelin. It is an immunoglobulin (Ig)-like cell adhesion molecule (CAM); its extracellular domain forms tetramers in the plane of the membrane. As shown in Figures 5 and 6, these tetramers interact with each other both in *cis* (in the plane of the membrane) and in *trans* (from apposed membranes). The Schwann cells in *Mpz* null mice still form a multilamellar spiral of membrane around axons, but the myelin is not compact. Mice that are heterozygous for a null *Mpz* allele also develop a late-onset demyelinating neuropathy, indicating that a reduction in P_0 causes instability of compact myelin. Thus, one of the ways that mutations in the human *MPZ* gene could cause demyelination (the disease is called CMT1B) is by haplotype insufficiency resulting in a dose-related decrease in the amount of P_0 protein.

PMP22 is a hydrophobic, intrinsic membrane protein of unknown function, and it is much less abundant than P_0. Nevertheless, the amount of PMP22 in compact myelin is critical. Humans with three (instead of two) copies of the *PMP22* gene have CMT1A, the most common inherited demyelinating neuropathy, probably because there is slightly more PMP22 in compact myelin. Conversely, humans with one copy

Figure 4 Cytoplasmic domains in myelinating Schwann cells. (a) This is a confocal image of three teased fibers from a rat sciatic nerve, double labeled with a rabbit antiserum against DRP2 (green) and a mouse monoclonal antibody against caveolin-1 (red). Figure 5 Schematic PNS myelinated axon; the proteins of CNS and PNS myelin sheaths. (a) One myelinating Schwann cell has been unrolled, revealing the regions that form noncompact myelin – the incisures and paranodes. Adherens junctions are depicted as two continuous (purple) lines; these form a circumferential belt and are also found in incisures. Gap junctions are depicted as (orange) ovals; these are found between the rows of adherens junctions. The nodal, paranodal, and juxtaparanodal regions of the axonal membrane are colored blue, red, and green, respectively. (b) CNS and PNS myelin sheaths contain distinct sets of proteins. In the PNS, compact myelin contains P_0, PMP22, and MBP; in the CNS, it contains PLP, MOBP, and MBP. In the PNS, the noncompact myelin contains E-cadherin, MAG, and Cx32; in the CNS, it contains Cx32 and claudin-11. Note that P_0 and MAG have extracellular Ig-like domains (semicircles), and that claudins, PLP, PMP22, and Cx32 all have four transmembrane domains. Adapted from Scherer SS and Arroyo EJ (2002) Recent progress on the molecular organization of myelinated axons. *Journal of the Peripheral Nervous System* 7: 1–12, with permission of The Peripheral Nerve Society.

of the *PMP22* gene have a different kind of inherited demyelinating neuropathy – hereditary neuropathy with liability to pressure palsies – probably owing to a modest decrease of PMP22 in compact myelin. The complete absence of PMP22, which has been created in *Pmp22* null mice (but has not been described in humans), leads to a severe demyelinating neuropathy, further demonstrating an essential role of PMP22 in compact myelin.

MBP is a cytoplasmic protein, and it comprises the bulk of the major dense line of compact myelin (Figures 1 and 6), as shown by its absence in *shiverer* mice, which completely lack MBP because of a recessive mutation in the *Mbp* gene. PNS myelin is not affected in *shiverer* mice at least in part due to the basic cytoplasmic domain of P_0, which may effectively substitute for MBP, as demonstrated by the phenotype of mice that lack both MBP and P_0.

These data demonstrate that both P_0 and PMP22 play essential roles in myelinating Schwann cells, and that a modest reduction in P_0 or PMP22 or a modest increase in PMP22 results in demyelination. Because

Figure 6 The localization of PNS and CNS myelin proteins in compact myelin. (Left) Electron micrograph of compact (PNS) myelin, which consists of alternating layers known as the intraperiod line (actually a double line) and the major dense line. (Right) Schematic depiction of how apposed cell membranes create the intraperiod and major dense lines. The disposition of P_0 (tetramers), PMP22 (dimers), PLP, and MBP monomers as well as the glycolipids galactocerebroside and sulfatide are shown. The approximate thickness of the lipid bilayers (based on X-ray diffraction), as well as the intracellular and extracellular spaces, is indicated for PNS myelin. Adapted from Scherer SS and Arroyo EJ (2002) Recent progress on the molecular organization of myelinated axons. *Journal of the Peripheral Nervous System* 7: 1–12, with permission of The Peripheral Nerve Society.

perturbations in the stoichiometry of any one component appear to alter the integrity of entire structure, compact myelin has been likened to a liquid crystal. How lipids, PMP22, and the other minor intrinsic membrane proteins 'fit' into the lattice of P_0 tetramers remains to be determined.

Noncompact Myelin

As depicted in Figures 5 and 7, noncompact myelin is found in the paranodes, the lateral borders of the trapezoid, and in Schmidt–Lanterman incisures (the funnel-shaped interruptions in the compact myelin). Noncompact myelin contains adherens junctions, tight junctions, and gap junctions; these join adjacent layers of the myelin sheath. Some of these junctions are also found in the inner and/or outer mesaxons, where the innermost or outermost layers of the myelin membrane contact the adjacent layer.

Adherens junctions (or 'desmosome-like' junctions in the older literature) typically span many layers and are most prominent in the outer layers of the myelin sheath (Figures 5 and 7). The adherens junctions of myelinating Schwann cells are composed of E-cadherin, perhaps the most prevalent member of the cadherin family. E-cadherin is a Ca^{2+}-dependent CAM that forms 'strand dimers' that bind homophilically with those on the apposing membrane (in *trans*). The cytoplasmic domain of E-cadherin binds p120 catenin and β-catenin; the latter links E-cadherin to the actin cytoskeleton. The role of adherens junctions

Figure 7 Tight junctions, adherens junctions, and gap junctions in PNS myelin sheaths. These are teased fibers that have been immunostained for claudin-19, E-cadherin, connexin32 (Cx32), and neurofilament heavy (NF-H), as indicated; DAPI is a nuclear counterstain. Claudin-19 and E-cadherin labeling are found in incisures (arrowheads) and mesaxons (arrows). Claudin-19, E-cadherin, and Cx32 labeling are found at paranodes (nodes are marked by apposing arrowheads). Scale bars = 10 μm.

is uncertain because deleting the E-cadherin gene in myelinating Schwann cells does not have an obvious effect on myelin sheaths. On the other hand, expressing a dominant negative p120 in myelinating Schwann cells has been reported to result in a loss of incisures.

Tight junctions limit the diffusion of ions and small molecules between apposed cell membranes, the paracellular pathway (Figures 5 and 7). A family

of molecules, the claudins, are the essential functional component of tight junctions. In myelinating Schwann cells, claudin-19 forms the tight junctions between the adjacent paranodal loops as well as at the inner and outer mesaxons; it is unsettled whether claudin-5 forms the tight junctions in some incisures. Claudins have a PDZ binding domain, and claudin-19 (and claudin-5) may bind to PATJ, MUPP1, ZO-1, ZO-2, and Par-3, all of which are PDZ proteins localized to paranodes and/or incisures. Except for the lack of tight junctions, the PNS myelin sheaths of claudin-19 null mice appear normal. The mice have subtle motor findings, but a subset of myelinated axons have slowed conduction, indicating that the tight junctions between the layers of the myelin sheath contribute to the normal propagation of action potentials. Curiously, no neurologic phenotype has been noted in humans with homozygous recessive mutations in claudin-19.

Small gap junction plaques had been noted between the rows of tight junctions in the PNS myelin sheath by freeze-fracture EM for decades. Their obscurity ended when mutations in *GJB1* were discovered to cause CMT1X, an inherited demyelinating neuropathy. *GJB1* encodes connexin32 (Cx32), which belongs to a family of approximately 20 connexin genes that encode gap junction proteins. Gap junctions formed by Cx32 are found in the paranodes and incisures of myelinating Schwann cells (Figures 5 and 7) and appear to provide a direct pathway for the diffusion of ions and small molecules across the layers of the myelin sheath. Mutations in *GJB1* may disrupt the diffusion of small molecules across the myelin sheath. Cx29 (the human ortholog is Cx31.3) is also localized to paranodes and incisures, but its functional role is unclear because it does not appear to form functional gap junctions on its own and does not appear to interact with Cx32.

The CNS Myelin Sheath

Unlike Schwann cells, which generate only one myelin sheath, each oligodendrocyte typically makes multiple myelin sheaths; the number varies from tract to tract and appears to relate to the caliber of the axons. Oligodendrocytes make fewer sheaths in tracts containing large myelinated fibers, which is the result of axon–oligodendrocyte interactions rather than an intrinsic trait of the oligodendrocytes themselves, as shown by transplantation studies. Oligodendrocytes also differ from Schwann cells in that their myelin sheaths lack a basal lamina, and their incisures lack distinguishing molecular markers.

Figure 8 Astrocyte/oligodendrocyte coupling. This figure shows that astrocytes (A) are coupled to astrocytes and oligodendrocytes (O) but not to neurons (N). Note that oligodendrocytes are not coupled to themselves and that A/A junctions are homotypic (Cx30/Cx30 or Cx43/Cx43), whereas A/O junctions are heterotypic (Cx30/Cx32 or Cx43/Cx47). Adapted from Rash JE, Yasumura T, Dudek FE, and Nagy JI (2001) Cell-specific expression of connexins and evidence of restricted gap junctional coupling between glial cells and between neurons. *Journal of Neuroscience* 21: 1983–2000, with permission of The Society for Neuroscience.

Another key difference is that oligodendrocytes are coupled to astrocytes (but not to themselves) by gap junctions. As depicted in Figure 8, astrocyte/oligodendrocyte (A/O) gap junctions are probably formed by two discrete pairs of connexins – Cx43/Cx47 and Cx30/Cx32. Astrocytes express Cx43 and Cx30; oligodendrocytes express Cx47 and Cx32. Cx47 is mainly found on oligodendrocyte somata, whereas Cx32 is also found on the outer aspects of myelin sheaths. There is compelling genetic evidence that A/O coupling is essential because recessive mutations in *GJA12/Cx47* cause a devastating CNS dysmyelinating disease in humans known as Pelizaeus–Merzbacher-like disease, and mice that lack both Cx32 and Cx47 develop severe CNS demyelination. The functional role of these A/O junctions is incompletely understood, but buffering the K^+ that is released during neural activity has been implicated. In addition, Cx32 is localized to the paranodal region of CNS myelin sheaths, although not as prominently as in PNS myelin sheaths.

CNS myelin sheaths are polarized. In addition to Cx32 and Cx47, their outer cell membrane contains myelin–oligodendrocyte glycoprotein (MOG), and their inner cell membrane contains myelin-associated glycoprotein (MAG) and Nogo (Figure 3).

The molecular components of compact myelin in the CNS myelin sheaths partially overlap with those of the PNS (Figures 5 and 6). Both contain high amounts of lipids, especially cholesterol and sphingolipids, including galactocerebroside and sulfatide.

P_0 and PMP22 are not present in CNS compact myelin; instead, proteolipid protein (PLP) and its alternatively spliced isoform, DM20, are the main proteins. Conversely, PLP is not present in PNS myelin, although DM20 is present in noncompact PNS myelin. Both PLP and DM20 are highly hydrophobic, intrinsic membrane proteins. Furthermore, either deletion or duplication of the human PLP gene results in CNS dysmyelination (Pelizaeus–Merzbacher disease), demonstrating again the importance of gene dosage for myelin proteins. Remarkably, CNS myelin appears nearly normal in *Plp* null mice – a finding that underscores our lack of knowledge about the function of PLP and DM20. As shown in Figure 5, the major dense line contains MBP and myelin–oligodendrocyte basic protein (MOBP). As demonstrated by the severe dysmyelinating in *shiverer* mice, MBP plays an essential role in CNS myelin, whereas CNS myelin appears normal in *Mobp* null mice.

CNS myelin has a distinctive structural feature that is not seen in PNS myelin – the so-called 'radial component.' This is a series of radially arranged, intralamellar tight junctions that span the thickness of the compact myelin, usually in a single sector (Figure 9). These tight junctions are composed of claudin-11, which also forms tight junctions between the paranodal loops. Like claudin-19 null mice, the neurological findings in claudin-11 null mice include mild conduction slowing. In contrast to mice lacking either PLP or claudin-11 alone, compact myelin in mice lacking both PLP and claudin-11 is decompacted, indicating that both of these proteins stabilize its structure.

Figure 9 Claudin-11 is localized to the radial component of compact myelin. (a) Freeze-fracture EM of a mouse brain. A series of interlamellar strands (arrows; enlarged in the inset) are found between each layer of the compact myelin sheath. (b and c) Immunoelectron microscopy localizes claudin-11 (arrows) to the interlamellar strands of freeze-fractured mouse brain (b) and optic nerve (c). The asterisks indicate axons. Reproduced from Morita K, Sasaki H, Fujimoto K, Furuse M, and Tsukita S (1999) Claudin-11/OSP-based tight junctions of myelin sheaths in brain and Sertoli cells in testis. *Journal of Cell Biology* 145: 579–588, with permission of The Rockefeller University Press.

Axonal Specializations at Nodes of Ranvier

Despite the differences between PNS and CNS myelin sheaths, the organization of the nodal region is quite similar. Transmission EM of the nodal axolemma reveals an electron-dense undercoating and scanning EM reveals a high density of large intramembranous particles (1200 μm^2). These large particles are mainly voltage-dependent Na^+ (Na_V) channels, which comprise a family of ten genes; however, $Na_V1.6$ appears to be the main one because it is expressed at all mature nodes. The gene encoding $Na_V1.6$ is mutated in mice with a recessively inherited motor endplate disease (*med*), which die of respiratory failure approximately 20 days after birth. $Na_V1.6$ is probably not the only nodal Na_V channel because nerve conduction velocity of sensory axons is only minimally slowed in *med* mice; $Na_V1.2$ and $Na_V1.8$ are the best substantiated.

Figure 10 The molecular organization of the nodal region. Schematic drawing of possible *cis* and *trans* interactions between the molecular components of nodes, paranodes, and juxtaparanodes. The pathways for diffusion of molecules through the paranodal tight junctions and the septate-like junctions are shown by the small and large red dotted lines, respectively. Adapted from Scherer SS and Arroyo EJ (2002) Recent progress on the molecular organization of myelinated axons. *Journal of the Peripheral Nervous System* 7, 1–12, with permission of The Peripheral Nerve Society.

The actual Na_V channel is composed of a single α subunit – a large, glycosylated, polytopic protein composed of four homologous domains. Mature channels are composed of one α and two β subunits (Figure 10); the latter are members of the Ig CAM superfamily. Four genes encode different β subunits; β_1 and β_3 are more closely related to each other than to β_2 or β_4. Both β_1 and β_2 have been localized to nodes; whether β_3 or β_4 are localized to nodes remains to be determined. In addition, it is unknown whether different combinations of β subunits have different interactions with, and thus different effects on, $Na_v1.2$, $Na_v1.6$, and $Na_v1.8$.

A variety of functions have been proposed for β subunits. In transfected cells, β subunits increase the delivery of α subunits to the cell membrane and can alter their electrophysiological characteristics. As CAMs, β subunits have multiple potential interactions with various nodal components: β_1 and β_2 can also interact homophilically and heterophilically with the extracellular matrix molecules tenascin-C and tenascin-R; β_1 and β_3 (but not β_2) can interact in *cis* with neurofascin and Nr-CAM; and β_1 (but not β_2) can interact with contactin and phosphacan, a secreted isoform of receptor protein tyrosine phosphatase β (RPTPβ). Furthermore, the cytoplasmic domains of β_1 and β_2 can recruit ankyrin-G. It remains to be determined which of these potential interactions play important roles at nodes of Ranvier, but the findings that β_2 is required for normal density of nodal Na_v channels *in vivo* and that β_4 interacts with $Na_V1.6$ to produce the 'resurgent' current that enables action potentials to be generated at high rates are provocative.

Two members of the L1 family of CAMs, neurofascin186 and Nr-CAM, are found in the nodal axolemma. Both bind to the ankyrin-G isoforms that are found at nodes (ankyrin-G 480 and 270 kDa). The binding of ankyrin-G 480/270 kDa to neurofascin can be modulated since phosphorylation of a highly conserved tyrosine in neurofascin abolishes binding. As depicted in Figure 10, these ankyrin-G isoforms also

interact with the α subunits of Na_V channels and with the K^+ channels KCNQ2 and KCNQ3. Like Na_V channels, these K^+ channels are localized to nodes and axon initial segments; KCNQ2 appears to be localized to all nodes and initial segments, whereas KCNQ3 is localized to a subset. KCNQ2 and/or KCNQ3 likely produce the slow K^+ current (K_s) that has been recorded from patches of nodal membrane. The importance of K_s is shown by a dominant mutation in the human *KCNQ2* gene; the mutant KCNQ2 reduces the activity of both KCNQ2 and KCNQ3, and it produces repetitive firing of motor axons (known as neuromyotonia or neuromyokymia). Both KCNQ2 and KCNQ3 have an amino acid sequence in their C-terminus that is strikingly similar to the sequence (found in the intracellular loop between the second and third domains) of Na_V channels that binds to ankyrin-G; this sequence is necessary and sufficient for binding to ankyrin-G 480/270.

Ankyrins are a family of three genes, each with extensive alternative splicing. The ankyrin-G 480/270 isoforms found at nodes and initial segments are distinguished by ANK repeats, a spectrin-binding domain, and a serine/threonine-rich domain. Ankyrins interact with the spectrin cytoskeleton, a lattice composed of α and β heterodimers that are localized just beneath the cell membrane. There are two α and four β spectrin genes, leading to many potential combinations. One particular splice variant of spectrin βIV (βIVΣ1) is specifically localized to initial segments and nodes, and it presumably binds ankyrin-G 480/270. Evidence for a role for spectrin βIV in this regard comes from the analysis of *quivering* mice, in which recessive mutations in the *spectrin 4* gene cause altered ion channel distributions in myelinated axons.

These data indicate that ankyrin-G 480/270 is a multivalent protein and links CAMs (neurofascin186, Nr-CAM, and β subunits of Na_V channels) and ion channels (Na_V, KCNQ2, and KCNQ3) to the spectrin cytoskeleton at nodes. In keeping with this idea, inactivation of the ankyrin-G gene in the cerebellum results in the mislocalization of neurofascin186, Nr-CAM, $Na_V1.6$, KCNQ2, KCNQ3, and spectrin βIVΣ1 in the initial segments of Purkinje cells. Since initial segments and nodes share many molecular characteristics, the nodal membranes of Purkinje cells should be similarly affected.

Glial Specializations at Nodes of Ranvier

The lateral borders of the Schwann cell cytoplasm are tipped with microvilli (Figures 5 and 10). These contain F-actin and the ERM proteins erzin, radixin, and moesin, which probably link intrinsic membrane proteins such as syndecan-3 and -4 to the actin cytoskeleton. Electron microscopists have long known that the tips of these microvilli contact the nodal axolemma, indicating that there are molecular interactions between the two cell types. These interactions likely begin in developing nerves, as clusters of Na_V channels are found at the lateral edges of developing myelin sheaths; the clusters (heminodes) of two adjacent internodes fuse to form a node. Furthermore, clusters of neurofascin and Nr-CAM appear before those of ankyrin and Na_V channels. An intrinsic membrane protein called gliomedin has been found based on its ability to bind to both neurofascin and Nr-CAM. Gliomedin is expressed by Schwann cells, localized to their microvilli, appears before ankyrin and Na_V channels, and is both necessary and sufficient to cluster neurofascin186, Nr-CAM, ankyrin-G, and Na_V channels. Thus, Schwann cells appear to induce the formation of nodes via their focal expression of gliomedin. Dystroglycan also appears to play a role at nodes because deleting dystroglycan in Schwann cells results in disorganized microvilli, reduced density of Na_V channels, and slowed conduction.

In the CNS, the processes of 'perinodal astrocytes' (astrocytes and glial progenitors) have been postulated to have a similar function as Schwann cell microvilli. These processes express tenascin-R, which can bind to Na_v channels and alter their electrophysiological properties; this may be the reason why myelinated optic axons in mice lacking tenascin-R have slowed conduction. Although CNS nodes contain RPTPβ, which can interact with tenascin-R and both the α and the β subunits of Na_v channels, the distribution of nodal Na_v channels as well as conduction velocity of CNS myelinated axons are normal in RPTPβ-deficient mice. Both tenascin-R and RPTPβ also interact with the high-molecular-weight form of contactin, which (in contrast to the PNS) is found at CNS nodes. Contactin regulates the surface expression of Na_v channels, and mice lacking contactin have reduced nodal Na_v channels clusters.

Specializations at Paranodes

At the paranode, the lateral edge of the myelin sheath contacts the axon; a loop of cell membrane slightly indenting the axon as it spirals around it, forming the axoglial junctions (Figure 11). For most myelin sheaths, the entire lateral edge remains in contact with the paranodal axolemma; some of the paranodal loops of the largest PNS myelin sheaths, however, do not touch the axonal membrane. A unique specialization known as septate-like junctions (or transverse bands) is found at axoglial junctions; freeze-fracture EM reveals that these are composed of rows of large

Figure 11 The ultrastructure of the paranode. (a) A transmission electron micrograph showing a CNS paranode in longitudinal section. The terminal loops of the myelin sheath indent the axonal membrane, to which they are connected to septate-like junctions. (b) A transmission electron micrograph showing lanthanum outlining the space between the septate-like junctions of CNS axons. The arrows indicate the locations of the spaces between adjacent glial loops; these spaces are larger than the spaces between adjacent rows of septate-like junctions. (c) A longitudinal freeze-fracture EM through a CNS paranode. The P face of the paranodal axolemma (AIP) shows scalloping (arrows) produced by the pockets of paranodal cytoplasm that are visible at the sides (P). The fracture plane then passes across the axon (Ax) so that the B face (AIE) of the axolemma on the other side comes into view. particles on the glial membrane that are in register with a double row of smaller particles on the axolemma. These junctions not only resemble invertebrate septate junctions but also contain similar molecules that are expressed by the axon or the myelinating Schwann cell: Contactin (a GPI-linked protein) and contactin-associated protein (Caspr, an intrinsic membrane glycoprotein) are localized to the paranodal axolemma, and neurofascin-155 (an intrinsic membrane protein) is localized to the paranodal loops. There is some uncertainty regarding whether neurofascin-155 binds to contactin or to contactin–Caspr heterodimers, but eliminating any of these three proteins in mice demonstrates that all of them are essential for the formation of septate-like junctions. Gene knockout studies in mice also show that galactocerebroside and sulfatide, as well as the tetraspanin protein CD9, are also required for septate-like junctions; all are expressed by myelinating Schwann cells and may be required to deliver and/or stabilize neurofascin-155 to septate-like junctions. In the absence of septate-like junctions, the paranodal loops of myelinating Schwann cells are slightly separated from the axolemma, whereas those of oligodendrocytes are often detached.

The cytoplasmic domain of Caspr contains a binding site for protein 4.1, which in turn can bind to the spectrin cytoskeleton. Of the family of 4.1 proteins, only 4.1B has been found in axons, and it is found throughout the internode but not at nodes (**Figure 10**). The cytoplasmic domain of Caspr also contains a SH3 binding site, which could allow Caspr to participate in signaling pathways within the axon.

Septate junctions function similarly to vertebrate tight junctions, forming intercellular junctions that prevent the diffusion of small molecules and ions. Because septate-like axoglial junctions do not prevent the diffusion of lanthanum (**Figure 11**) or microperoxidase into the periaxonal space, they are not 'tight' in the conventional sense. In addition to limiting the diffusion of large molecules, paranodal septate-like junctions have also been shown to sequester Kv1.1 and Kv1.2 K^+ channels. In the absence of septate-like junctions, erstwhile juxtaparanodal Kv1.1/Kv1.2 channels occupy the paranodal region, thereby apposing nodal Na_V channels, leading to current shunting and the slowing of action potential propagation.

Specializations at Juxtaparanodes

By freeze-fracture EM, the axolemma in the region extending 10–15 μm from the paranode contains clusters of five or six particles. The distribution of these juxtaparanodal particles corresponds to the distribution of delayed rectifying K^+ channels, likely composed of *Shaker*-type Kv1.1 and Kv1.2, which mix in varying proportions to form tetramers, the functional channels. The size of the particles (10 nm in diameter) compares well to the expected size of K^+ channels. Each Kv1.1 and 1.2 subunit is associated with a Kvβ2 subunit. Although they appear to be concealed under the myelin sheath, juxtaparanodal Kv1.1/Kv1.2 channels are thought to have an important physiological function, dampening the

excitability of myelinated fibers. The finding that *Kcnac1/Kv1.1* null mice have abnormal impulse generators near the neuromuscular junctions supports this idea. Similarly, mutations in the human *KCNAC1* gene cause a form of familial episodic ataxia that is associated with ectopic impulse generators in the distal aspects of motor axons, causing neuromyotonia/neuromyokymia.

Caspr2 and TAG-1 (transiently expressed glycoprotein-1, an Ig CAM) are also found in the juxtaparanodal axolemma in both the CNS and the PNS. Caspr2 has a similar domain structure to Caspr, especially in the extracellular region; its intracellular C-terminus contains a band 4.1 binding domain, a PDZ binding domain, but not an SH3 domain (Figure 10). Caspr2 co-localizes and even co-immunoprecipitates with Kv1.1 and Kv1.2, perhaps because they all bind to a common PDZ protein. Although PSD95 is localized to juxtaparanodes, Caspr2, Kv1.1, Kv1.2, and Kvβ2 are not mislocalized in mice that lack PSD95. Rather, *cis* interactions of Caspr2 with homodimers of TAG-1 may localize the complex of Caspr2/Kv1.1/Kv1.2/Kvβ2 to juxtaparanodes because TAG-1 can form homodimers with TAG-1 on the adaxonal membrane of the myelin sheath (Figure 10). In keeping with this model, Kv1.1 and Kv1.2 are mislocalized in mice that lack either TAG-1 or Caspr2 but not in mice that lack Kv1.1, Kv1.2, or Kvβ2.

The adaxonal Schwann cell membrane in the juxtaparanodal region contains hexamers (12 nm in diameter) by freeze-fracture EM. These particles have the appearance of hemichannels and are composed of Cx29. The importance of these putative hemichannels is unknown because the myelinated axons in *cx29* null mice appear normal, and how such hemichannels might function is a matter of speculation. Because TAG-1 and Cx29 are unlikely to interact directly, there must be other proteins that mediate this interaction (Figure 10).

The Internodal Region

The apical/adaxonal surface of the myelin sheath apposes the axon and is highly enriched in MAG in both the PNS and the CNS (Figure 3). MAG can bind to certain complex gangliosides, including GD1a and GT1b, but it remains to be shown that these are preferentially distributed on the internodal axonal membrane. In the CNS, the adaxonal membrane is also enriched in the Nogo, which may bind to the Nogo receptor on the internodal axonal membrane.

The internodal axonal membrane lacks the conspicuous structural specializations of the nodal region. Nevertheless, at least one important molecule, Na,K-ATPase, is distributed rather uniformly throughout the internode of myelinated axons, including the juxtaparanodes. Na,K-ATPase is composed of an α and a β subunit; the α subunit exchanges intracellular Na^+ for extracellular K^+. In the PNS, myelinated axons express α_1, α_3, or a combination of the two; in the CNS, myelinated axons express α_3. How α subunits are tethered to the internodal axonal cytoskeleton is unknown; in other cell types, Na,K-ATPase interacts with ankyrins.

In the PNS, a tripartite strand of glial proteins – consisting of a central strand of NF155 flanked on either side by strands of Cx29 – is localized on the adaxonal Schwann cell membrane at the inner mesaxon and at the innermost aspect of incisures (Figure 12). A tripartite strand of axonal proteins – consisting of a central strand of Caspr staining, flanked on either side by strands of Kv1.1/1.2/β2 and Caspr2 immunoreactivity – apposes the inner mesaxon ('juxta-mesaxonal') and the innermost aspect of incisures ('juxta-incisural'). This precise apposition suggests that the same *trans*-molecular interactions between myelinating Schwann cells and axons that are found at paranodes and juxtaparanodes extend into the internodal region. In contrast, there is no mesaxon-like staining of Cx29 or NF155 in CNS myelin sheaths,

Figure 12 Internodal specialization of myelinating Schwann cells. This is a schematic summary of the putative identities and distributions of intramembranous particles on the axonal and adaxonal Schwann cell membranes in the internodal region, as visualized by freeze-fracture electron microscopy. The location of the tight junction (TJ) at the inner mesaxon is indicated. Myopia

J Wallman, City University of New York, New York, NY, USA

© 2009 Published by Elsevier Ltd.

Introduction

Myopia is an important topic not only because it afflicts a disproportionately large fraction of educated people but also because myopia research has shown that the visual system has a function beyond light reception and perception, that of the homeostatic control of eye growth. Under normal circumstances, this neural control adjusts the growth of the eye so that the length of the eye matches the focal length of its optics, causing distant objects to be imaged on the photoreceptor layer of the retina, a condition called emmetropia. In myopia, the eye is too long relative to its focal length, causing distant objects to be imaged in front of the photoreceptors. Only nearby objects are in focus on the photoreceptors.

Much evidence points to the eye growing under homeostatic control. Thus if a neonate is born hyperopic (ocular length shorter than focal length), the eye elongates more rapidly than usual, thus overtaking the increasing focal length and correcting the hyperopia. Conversely, if an eye starts out myopic (ocular length greater than focal length), the rate of elongation is decreased, allowing the normal increase in focal length to correct the myopia. It is clear that vision provides much of the feedback guidance of growth. This has been shown by having young animals wear spectacle lenses that displace the plane of focus of the image, creating either hyperopia (image focused behind the photoreceptors) by negative lenses or myopia (image focused in front of the photoreceptors) by positive lenses. Within days or weeks, depending on the species, the eye increases or decreases its rate of growth, bringing the eye toward emmetropia while the animal is wearing the lenses. This control occurs in chicks, fish, guinea pigs, tree shrews, marmosets, and rhesus monkeys. On this basis, it is difficult to argue that it does not also occur in human children. Furthermore, another type of visually induced myopia occurs when animals are deprived of vision, but not of light, as by wearing diffusers over their eyes (form deprivation myopia). This also occurs in children with visual deprivations caused by cataracts, eyelid problems, and so forth.

Before this animal work, there were two principal views of human myopia. The predominant view, especially among ophthalmologists, was that myopia was a largely genetic condition, either in the sense of genetic determination of eye shape or in the sense of genetic defects of scleral structure, leading to excessive expansion as a consequence of the intraocular pressure and thus to excessive ocular elongation. The alterative view, frequently considered radical, was that excessive reading or other visual tasks involving viewing nearby objects perhaps drove the emmetropization mechanism to make the eye 'emmetropic' for the distance of the page. The radical aspect of these theories was that they led to the notion that myopia was partly iatrogenic, in that the fitting of progressively stronger corrective lenses by the physician or optometrist prevented the myopia from reaching an asymptote at which the page was naturally in focus without requiring accommodation. The consequence of the experimental work on animals in the past three decades has been that blur is now seen as an important cause of myopia.

This article summarizes first the experimental work on animals and then the studies on humans and then speculates on how the former can inform the latter.

Experimental Studies on Animals

All Blur Is Not Alike

As implied by the spectacle-lens compensation experiments mentioned earlier, the old story that myopia results simply from unsharp images is almost certainly untrue. Although eyes of many species (monkeys, guinea pigs, tree shrews, chicks, fish) become myopic by wearing negative lenses, eyes wearing positive lenses become hyperopic even when the environment is arranged to make all images blurred (at least in chick and tree shrew). These results imply that the eye can grow to compensate for opposite signs of blur (whether the image is focused in front or behind the retina), and it suggests that the sign of blur is more important than its magnitude. Furthermore, even though wearing diffusers or negative lenses causes myopia, there is evidence from experiments in chicks that form deprivation myopia is different from lens compensation myopia in that various manipulations of lighting and also optic nerve section have differential effects on the two types of myopia.

Spatial Factors: Myopia Is Local

When chick eyes that are blind because of optic nerve section wear diffusers or spectacle lenses, they

become myopic or hyperopic, much as intact eyes would, although some differences exist. This finding means that however the visual system determines that defocus is present and whether the sign of defocus is myopic or hyperopic, it must do it with the retina alone, without the processing power of the brain. Furthermore, if chick eyes wear diffusers or lenses that affect only part of their visual field, only the specific parts of the eye exposed to the defocus or deprivation become myopic or hyperopic. This finding means that local regions of retina must modulate the growth of the immediately underlying sclera, whether or not the brain is involved. Furthermore, the fact that the eyes can compensate for either positive or negative lenses worn over part of the visual field suggests that the visual system decodes the sign of the blur locally, rather than relying on differences in blur across the retina, although this suggestion has not been tested explicitly.

Surprisingly, the highly foveate retina of primates also shows evidence of control by the peripheral retina. Monkeys with foveal ablations emmetropize normally, and eyes with visual deprivation of the peripheral retina become myopic, as assessed at the fovea. Thus, whereas the peripheral retina is important in both chicks and monkeys, the effects of deprivation are less localized in monkeys, perhaps because their sclera is less rigid as it lacks the layer of cartilage present in nonmammalian vertebrates. The implications of peripheral defocus for the development of human myopia are discussed below.

Temporal Factors: Blur Does Not Add Linearly

Once it is accepted that the growth of the eye is not controlled simply by the fovea, the fact must be dealt with that even if ocular accommodation (focusing) kept the image at the fovea perfectly sharp (which it does not do), all other points on the retina would experience a rapid fluctuation in the degree and sign of blur as the eye looked from a near object (retinal regions seeing the more distant parts of the scene would experience myopic defocus) to a far one (retinal regions seeing the closer parts of the scene would experience hyperopic defocus).

How do these episodes of myopic and hyperopic defocus add together? It would be convenient if doubling the duration of hyperopic defocus doubled the compensatory myopia. However, experiments in chicks show this not to be the case. When defocus is presented in episodes of different length (darkness in between), one finds (1) that frequent brief episodes have more effect than do less frequent longer ones if the total daily amount of defocus is the same, but (2) that episodes lasting less than 2 min have no effect, no matter how often they are repeated. If myopic and hyperopic defocus (e.g., positive and negative lenses) are alternated, the eyes become hyperopic in compensation for the myopic defocus, even if the hyperopic defocus is five times as long as the myopic defocus. However, if the alternation is extremely rapid (more than once per second), the episodes of hyperopic and myopic defocus cancel. Although the experiments just described have been done only in chicks, a related manipulation was done in several mammalian species: If diffusers or negative lenses are removed for an hour each day, their effect is reduced in half (during the clear vision, the eyes would have experienced myopic defocus, as in the lens-switching experiments). One can view these results as arising from internal signals related to defocus that build up over minutes and then persist in the absence of defocus for much longer times (hours). One implication of these results is that perhaps in children, the development of myopia as a result of long periods of reading has as much to do with the pattern of interruptions from reading as it does with the total amount of reading.

Molecular Signals Correlated with Myopia

An implication of eye growth being under local control is that the retina must directly or indirectly influence the tissues subjacent to it. One would like to know what signals the retina sends to increase or decrease eye growth and what the recipient tissue is. (It seems more probable that there is a signal cascade than that the retina directly controls the sclera.) A number of molecular signals have been found that either change in level when animals develop form deprivation myopia or, when agonists or antagonists are injected, affect the degree of myopia. These include dopamine, acetylcholine, vasoactive intestinal peptide, fibroblast growth factor, transforming growth factor, melatonin, and sonic hedgehog. One must view these findings with caution because depriving an eye of vision affects many processes, most having little to do with control of eye growth. Of greater relevance, administration of some agonists or antagonists of these signals can also reduce the severity of form deprivation myopia without having much effect on normal eyes. However, it is unclear what the relation of form deprivation myopia is to normal control of eye growth.

The most intriguing and puzzling molecular signal is acetylcholine, acting at muscarinic receptors. For many years, it has been known that giving animals or children atropine or pirenzepine, which blocks these receptors, greatly reduces myopia. Originally, atropine was thought to act by blocking accommodation; once this possibility was eliminated, atropine was

then thought to act via the retina. This too has been largely ruled out, in part because even eyes in which the cholinergic neurons have been destroyed pharmacologically become myopic to form deprivation, and have the myopia blocked by atropine, and in part because the pattern of responses to various cholinergic drugs is difficult to reconcile with a single mode of action. Because most of the tissues of the eye, including sclera, have most or all the six muscarinic receptors, the relevant tissue has not been identified. This issue has some clinical importance because one could argue that one should not give healthy children drugs with unknown actions.

Dopamine has also been a persistent candidate for a signal controlling eye growth, both because its levels change with form deprivation or negative lenses and because dopamine agonists ameliorate myopia, but how and where it acts are obscure. The fact that dopamine varies strongly with patterns of illumination and is a signal that synchronizes circadian rhythms makes it risky to infer a role in eye growth from effects of deprivation. On the other hand, it hints at the possibility that circadian rhythms may be involved in eye growth.

Only two retinal signals have been identified which change in opposite directions when negative lenses (which stimulate ocular elongation and myopia) and positive lenses (which do the opposite) are worn: (1) Retinoic acid is synthesized by retina and choroid in both birds and mammals, and the amount of synthesis changes in opposite directions for negative and positive lenses; retinoic acid also directly influences scleral growth. (2) Glucagon is implicated by the fact that in chicks, the expression of the immediate early gene ZENK (also called zif 268, egr-1, NGF1A, and Krox24) in glucagonergic amacrine cells is turned up by positive lens wear and turned down by negative lens wear, and the general pattern of effects of glucagon agonists and antagonists is consistent with a role in eye growth. In mammals, however, glucagonergic amacrine cells seem not to exist, casting doubt on the generality of this eye growth control pathway.

Choroidal and Scleral Components

Because myopia generally results from an excessively elongated eye, and because the sclera defines the size of the eye, it is perhaps not surprising that some theories of myopia have held that the fault lay in a defective sclera. Indeed, when the mammalian eye elongates, the sclera thins, as though it were a balloon under pressure. A more modern view is that scleral remodeling underlies ocular elongation, a view upheld by the changes in synthesis of proteins, proteoglycans, and DNA, as well as of metalloproteinases, inhibitors of metalloproteinases, and of growth factors that accompany experimental myopia or hyperopia. Complicating our comparison of experimental results from birds and mammals is the fact, mentioned above, that unlike other vertebrates, most mammals have lost the layer of cartilage in the sclera. Thus in myopic eyes, proteoglycan synthesis increases in birds but decreases in mammals. However, if the two layers of the avian sclera are separated and analyzed separately, the fibrous layer decreases its synthesis as does that of mammals, whereas the cartilaginous layer increases its synthesis.

Coincident with the changes in synthesis of the sclera are changes in the mechanical properties of the sclera, which can be appraised by measuring the size of the eye when the intraocular pressure is increased or by stretching excised pieces of sclera. Birds and mammals differ in this assay as well, perhaps because the mammalian sclera contains contractile myofibroblasts. A theory integrating these mechanical and biochemical changes would go a long way toward linking the humoral changes resulting from visual conditions to changes in ocular length.

Interposed between the retina and the sclera lies the rather mysterious choroid, which contains a vascular layer nourishing the outer retina and which synthesizes various molecules that influence scleral growth. Beyond these roles, the choroid changes its thickness in response to defocus, becoming thicker if the image plane lies in front of the photoreceptors and becoming thinner if the image plane lies behind the photoreceptors, in both cases pushing or pulling the retina toward the image plane. Thus, this thickening and thinning is a second component of emmetropization, in addition to changes in ocular length. Furthermore, there is some evidence that the thickening by itself might inhibit ocular elongation, even if the thickening is transient and therefore easily missed by investigators. If this role is confirmed, it would mean that the small magnitude of choroidal changes in mammals (20–50 μm) compared with that in birds (100–1000 μm) might not mean that its biological role is any less important.

One can also ask which of the layers of the eye (retina, retinal pigment epithelium, choroid, sclera) is the one that determines the size of the eye and is thus the principal locus of control of eye size. Although it seems reasonable that the sclera, being both stiffest and most external, is the locus of control, there is no reason that the sclera might not adapt itself to the size of any of the other layers. Just as the expansion of the retina is thought to be controlled by the tensile strength of the retinal blood vessels, so the expansion of the eye might be controlled by the tensile strength of the choroidal blood vessels.

Human Epidemiology

Across many cultures, the prevalence of myopia is correlated to the level of education, reaching levels of 90% among medical students in Singapore (Figure 1). The stronger prevalence of myopia among the educated in Asia than elsewhere is unlikely to be principally a matter of genetics because young Chinese children in Australia have one-tenth the prevalence of myopia found in Singapore. Although there are substantial differences in lifestyle between the two countries (more preschool coaching in Singapore, more outdoor activities in Australia), statistical analysis suggests that known factors cannot account for the magnitude of the difference in the prevalence of myopia.

In several studies, children with two myopic parents are more likely to be myopic than those with no myopic parents. Because children resemble their parents in many ways beyond their genes, studies of monozygotic and dizygotic twins have been used to dissociate the genetic from the environmental. At least some of these studies found an interaction between environmental and genetic factors. In a study in Singapore, the effect on the prevalence of myopia of reading more than two books a week was greater in those with two myopic parents than in those with none (Figure 2). Recently, the prevalence of myopia has been shown to be less in children with large amounts of outdoor activity.

With respect to genetic explanations of myopia, there is good evidence that extreme myopia has a tight genetic linkage. However, two developments have made it difficult to hold that common myopia of moderate degree was entirely genetic in origin: First, the animal experiments mentioned earlier have shown that every animal can acquire myopia by visual manipulations. (Some authors argue that most of the animal experiments are done on young animals, when emmetropization is in process, and therefore doubt the relevance to the human myopia that occurs later in development.) Second, societies in which people spend most of their time outside have low prevalence of myopia, but when compulsory education (and other accompaniments of modernity) is introduced, the prevalence of myopia rises tenfold within a generation or so. Less dramatically, when rural regions become industrialized, the incidence of myopia goes up quickly. This, of course, could not be a genetic change. Therefore, one must view the 'geneticness' of myopia as being more like that of lung cancer or heart disease, in which environmental factors interact with genetic predispositions, than like that of blue eyes, which are simply genetic in the Mendelian sense.

It is unclear why intensive reading should predispose the eye to myopia or why outdoor activities should have a protective effect. The simplest explanation is that the eye is simply emmetropizing normally, but to a nearby world, which requires the eye to become myopic to have clear vision without constant accommodation. This explanation is likely to be too simple, in part because it fails to take into account the spatial and temporal aspects of the control of eye growth discussed earlier with respect to the animal experiments. Related to this, much work has been based on the notion that any blurred vision promotes myopia, and thus the blur caused by imperfect accommodation (the accommodation system is a negative feedback system which does not correct all the defocus presented to it) could cause myopia. Even the brief myopic blur that results from accommodation's not relaxing immediately after a long period of reading has been considered a cause of myopic progression.

Figure 1 The prevalence of myopia among a large cohort of military recruits was strongly correlated with the level of education they had attained. Adapted from Morgan I and Rose K (2005) How genetic is school myopia? *Progress in Retinal and Eye Research* 24(1): 1–38; data from Eong KG, Tay TH, and Lim MK (1993) Education and myopia in 110 236 young Singaporean males. *Singapore Medical Journal* 34: 489–492.

Figure 2 Evidence of the interaction of genetics and environment in determining the prevalence of myopia (< –3 D) in children reading more (red circles) or less (blue triangles) than 2 books per week. Data from Saw SM, Hong CY, Chia KS, Stone RA, and Tan D (2001) Nearwork and myopia in young children. *Lancet* 357(9253): 390.

Spatial Factors: Influence of Peripheral Refractive Errors

Much evidence has accumulated during the past 35 years that the pattern of refractive error across the eye – resulting from differences in eye shape – is correlated with whether the eye is myopic or hyperopic at the fovea (the only location typically measured by clinicians). Myopic eyes tend to be relatively hyperopic in the periphery, whereas hyperopic eyes tend to be relatively myopic in the periphery. Furthermore, a study of emmetropic students at a school for pilots in Holland showed that those with the peripheral pattern of refractions typical of myopia tended to become myopic much more often than those who had the pattern typical of hyperopia (Figure 3).

One can envision three explanations for this association between eye shape and myopia. First, one could imagine that children who read a lot develop elongated myopic eyes and that this elongation causes the sides of the eye to be drawn in closer to the optic axis, making the periphery hyperopic. The tension exerted by the zonule fibers that support the lens could exacerbate this tendency to pull the sides of the eye in. Once the periphery is hyperopic, the homeostatic growth control will be faced with opposite demands from the periphery (grow more) and from the center (grow less). The balance between these conflicting signals would probably be tipped in favor of further elongation of the eye because there is much more periphery than there is fovea (60 times the area from 30° to 31° eccentricity than between 0° and 1° eccentricity). Correcting the central myopia with negative spectacle lenses would increase the hyperopia of the periphery. Second, one can imagine that in a child who reads a lot, the periphery is subjected to myopic defocus by the world more distant than the book. This could cause the periphery to slow its growth and become hyperopic in compensation for the myopic defocus. Children who spend a lot of time outdoors would experience a flatter world in the sense that the defocus would be uniform across the visual field. Third, it could be that some children at birth have an eye the shape of which predisposes them to myopia or hyperopia. Longitudinal studies of peripheral refractive error in young children may clarify the influence of each of these factors.

Figure 3 Association between the refractive state across the retina and subsequent development of myopia in students in a school for pilots. The diagrams under the x-axis represent the pattern of hyperopia (upward lines) and myopia (downward lines) across the retina for two orthogonal meridians. Data from Hoogerheide J, Rempt F, and Hoogenboom WP (1971) Acquired myopia in young pilots. *Ophthalmologica* 163(4): 209–215; plotted by Earl Smith, University of Houston.

Human Interventions

The logic of many visual explanations of myopia has been that all blur (at least all blur during reading) is bad, leading to myopia. Thus, many studies have attempted to reduce blur by having children wear bifocals or progressive addition lenses (like those worn by adults of a certain age who have the age-related diminution of accommodation called presbyopia). Although some positive results have been reported, the magnitude of the amelioration of myopic progression has been quite modest. This might be because children have so great an accommodative range that they have little incentive to use the lower segment of the bifocals or progressive lenses. Alternatively, it may be that under normal circumstances, the level of accommodation is determined more by the needs of the binocular fusion (vergence–accommodation) than by blur, and so reducing the accommodative demand alone may not reduce blur as much as expected. In a large multicenter trial of progressive addition lenses, the children who benefited the most were those who read more and had esophoria, less myopia, and two myopic parents. Overall, there is little support for the prophylactic value of blur reduction. More directly, a recent small study had children wear a fully correcting lens over their dominant eye and a weaker lens over the other eye, so that this eye would experience not only reduced hyperopic defocus, but myopic defocus, when accommodation focused the dominant eye; this myopic defocus slowed the myopic progression, suggesting that the sign of defocus is more important than its magnitude.

The most consistent slowing of the progression of myopia has come from treating children with atropine. Many studies over the past decades have shown that

daily treatment greatly reduces myopic progression, but the basis of this effect is not understood. Because atropine also blocks accommodation and papillary constriction, recent studies have looked to pirenzepine as a more benign prophylactic agent.

If spatial and temporal factors have the importance that is emerging from human and animal studies, it would seem that searching for a magic bullet to stop myopia might be a futile endeavor. Rather, one would need to understand how different spatial and temporal distributions of blur are integrated to determine the refractive distribution across the retina, measurements not easily made with existing technology. With respect to the spatial factors, if correcting foveal myopia exacerbates peripheral hyperopia, which in turn increases foveal myopia, then a treatment different from existing spectacles, contact lenses, or refractive surgery would be required – perhaps lenses which have opposite corrections for central and peripheral retina. With respect to the temporal factors, if children are like chicks in having long periods of hyperopic defocus canceled by briefer periods of myopic defocus, it may be that finding the correct timing of distant vision to offset the effects of long periods of reading might do more to stop eyes from becoming myopic than could any pharmacological intervention.

Implications of Animal Studies for Human Myopia

The finding that fish, birds, guinea pigs, tree shrews, marmosets, and rhesus monkeys all show compensation for imposed defocus from spectacle lenses makes it difficult to argue that human eyes do not also respond in a compensatory way to imposed defocus. Once one accepts that eye growth is under visually guided homeostatic control and that entire the retina controls eye growth, it becomes difficult to ignore that large areas of retina experiencing hyperopic defocus might participate in driving the eye toward myopia, even if the small region around the fovea is emmetropic. Similarly, once one accepts that brief episodes of myopic defocus imposed by positive lenses can compensate for long periods of hyperopic defocus, it suggests novel prophylactic measures to prevent human myopia, either by having children interrupt reading at intervals or by having myopic defocus imposed by more direct means. Thus the biology of eye growth control may well lead to an understanding of the etiology of human myopia.'

Myosin Transport and Neuronal Function

P C Bridgman and M Ahmed, Washington University School of Medicine, St. Louis, MO, USA

Transport Requirements of Neurons

Neurons are highly polarized cells with a cell body containing the nucleus and the majority of the synthetic machinery interposed between two distinct functional compartments, axons and dendrites (Figure 1). The vast majority of the cell cytoplasm is located in these long processes, indicating that the requirement for transport from the main site of synthesis and assembly to functional compartments in neuronal processes is greater than in any other cell type in the body. Even localized synthesis of materials that occurs far from the cell body requires the initial transport to the appropriate compartment or site.

Microtubules act as the main transport tracts in both axons and dendrites. However, the orientation of microtubules differs. Axons have microtubules oriented with their plus or fast-growing ends distal, whereas dendrites have microtubules with a roughly equal mixed polarity distribution. This means that the requirements for long-range transport are different for the two types of processes. Delivery of essential components to distal sites in axons appears to be straightforward because of the uniform microtubule orientation and the known directionality of microtubule-based motors kinesins and dyneins. However, because of the approximately equal mixed polarity in dendrites, it is not clear how net transport to distal sites occurs in these processes or how microtubule motors differentiate dendrites from axons. Multiple mechanisms resembling those used to maintain polarity in epithelial cells probably contribute to the maintenance of these two distinct main compartments.

In addition to axons and dendrites, most neurons have two much smaller functional compartments required for chemical neurotransmission: presynaptic terminals and dendritic spines (Figure 1). Microtubules usually do not fully penetrate into these regions, indicating that they cannot normally serve as efficient transport tracts. Dendritic spines are rich in actin filaments. Presynaptic terminals also have actin filaments, although the amount is less than in spines. Actin filaments have been shown to serve as transport tracks in other cell types as well as neurons and therefore may provide the main transport tracks for these actin-rich, microtubule-poor regions. Furthermore, it is possible that actin filaments and associated motor proteins may act as 'traps' in dendrites to facilitate delivery of components to distal sites similar to that seen in melanocytes, a cell type responsible for producing and delivering pigment containing organelles (melanosomes) to neighboring cells in skin via dendritic processes. The motor proteins responsible for actin-dependent transport are members of the large family of myosins that has at least 17 members, the majority of which were discovered within the past two decades.

Neuronal Myosins and Transport Function

The recent period of new myosin discovery primarily expanded the category of 'unconventional' myosins and was eye opening because it provided new possibilities for transport motors. Neurons have multiple isoforms of conventional nonmuscle myosin II as well as a number of unconventional myosins. Not surprising is the finding that these unconventional myosins appear to be involved in transport processes in neurons. It is also possible that myosin II may contribute to transport. Somewhat unexpected is the specific type of transport function that appears to involve unconventional myosins. Two types predominate: transport of plasma membrane components including transport required for receptor recycling and local delivery of proteins or translational machinery including mRNA. Both potentially play important roles during development and in synaptic plasticity. Therefore, the focus is on myosin-dependent transport in neurons that is potentially linked to pathfinding during development and synaptic plasticity in the mature nervous system. The general proposal is that myosins act primarily to mediate local transport, whereas microtubules mediate long-range transport. This general hypothesis is supported by studies and provides an appropriate basis for understanding myosin-based transport functions in neurons. It also implies that there is targeted switching between the two motor systems at specific locations in both axons and dendrites. In part, this switching will depend on the relative amounts and close proximity of the two polymers that act as the transport tracks in the different locations. However, the regulation of this switching may also involve signaling mechanisms that are cell type specific.

Properties of Neuronal Myosins Involved in Transport Functions

Although there is evidence for conventional myosin II being involved in axonal transport, most transport

Figure 1 Neuronal compartments include the axon (1), dendrites (2), and smaller, more discreet regions such as the presynaptic terminal (a) and spines (b). Microtubule-based transport is responsible for the net movement of newly synthesized materials from the main site of synthesis in the cell body (arrows) into axons and dendrites. Actin-based transport predominates within actin-rich compartments such as presynaptic terminals and spines. The compartments are not shown to scale.

functions in neurons are associated with the myosins that are classified as unconventional. Three types of unconventional myosins predominate: myosin I, myosin V, and myosin VI. However, another unconventional myosin, myosin X, has been added to the list. The unconventional myosin I and V categories contain multiple members.

There are 30 isoforms of the single-headed myosin 1, at least eight of which are present in vertebrates. The primary neuronal forms appear to be Myo1b,-1c, and-1d. The N-terminal motor domain of myosin 1 is the most conserved region and is similar to other myosins (Figure 2). The neck region binds calmodulin as a light chain and is also suspected to be a lipid binding site in high calcium. The C-terminal tail domain has low sequence similarity between myosin 1 isoforms, allowing for a diversity of binding partners. In Myo1c, this region also has a high-affinity binding site for lipid headgroups. Similar to single-headed kinesins, myosin 1 transport function requires the binding of multiple molecules to cargo to allow movement along actin filament tracks.

Myosin V exists in three isoforms – Va, Vb, and Vc – but only the first two are highly expressed in nervous tissue. All isoforms are dimers with a long neck region that binds multiple light chains (mainly calmodulin) and a globular tail portion that contributes to cargo binding (Figure 2). The properties of myosin Va have been extensively studied. It is a processive motor, meaning that it can make a large number of steps (up to several hundred) along an actin filament before being released. This ability is a consequence of its biochemical cycle that allows at least one of its two heads to be bound to actin at all times. It moves hand over hand along the actin filament. This property makes it a good candidate for a general cargo carrying transport motor, a function that has been most directly demonstrated in melanocytes. Myosin Va binds to melanosomes through Rab27a and an adaptor protein, melanophilin/Slac2. Binding of melanophilin activates myosin Va ATPase activity, indicating that cargo binding may trigger association and movement along actin filaments. The major portion of the melanophilin-binding domain is coded by the melanocyte-specific exon F of the myosin Va gene. Exon F is not expressed in neurons, resulting in very weak binding of the neuronal form of myosin Va to melanophilin. Adaptor proteins that facilitate vesicular binding and activation of the neuronal form of myosin Va have not been identified, although interactions with several synaptic proteins have been described. Myosin Vb and Vc have a similar association with Rab proteins (11a and 8, respectively) and have functional interactions with endosomes.

Myosin VI was discovered in *Drosophila* and was immediately implicated in transport functions. It is widely expressed in nervous and sensory tissue, with particularly high expression in hair cells. Mutations in myosin VI are linked to deafness. The Snell's waltzer (sv) mouse is a myosin VI null and exhibits deafness, as well as circling, head-tossing, and hyperactivity.

Similar to myosin Va, myosin VI is processive and walks along actin in large step sizes of 30–60 nm. This is usual given that the neck region is short (Figure 2). Although it shares many structural elements with other myosins, it has been observed to walk to the minus end of actin filaments. It is one of only two myosins that show this unusual characteristic and is the only two-headed minus end-directed motor protein (although the predominant native form may be single headed and only dimerize in some circumstances). This directionality is consistent with a role in endocytosis because in general actin filaments are polarized so that their fast-growing or barbed end is directed toward or associated with the plasma membrane. Similar to myosin V, its interaction with

Figure 2 Diagrams comparing the different classes of myosin found in neurons. The general protein domains found in most forms of myosin are shown in the diagram for myosin V and are color coded for comparison in the other classes. The neck regions (blue) show the bound light chains. Myosin 1 exists only as a monomer. Myosin V and X are known to form dimers. Myosin VI may exist as both a monomer and, in some circumstances, a dimer. Coil–coil regions are responsible for dimer formation.

vesicular components or other cargo is likely to involve one or more adaptor proteins.

Myosin X is differentially expressed in adult nervous tissue, having detectable levels only in the cerebellum. However, during development it is more widely expressed, with a peak in the cerebrum between postnatal days 5 and 15. A headless form of myosin X is also expressed in brain with a similar expression profile in cerebrum to the full-length protein. It may act as negative regulator of myosin X motor function. The headless form is not detectable in adult cerebellum. Myosin X is also upregulated following peripheral nerve injury, indicating that it may play a role in nerve regeneration. Myosin X has head and neck domains similar to other unconventional myosins and probably forms dimers (Figure 2). The tail domain is unusual because it contains myosin homology 4 (MyTH4) and band 4.1, ezrin, radixin, moesin (FERM) domains. The MyTH4 domain has been shown to bind to microtubules, whereas the FERM domain facilitates interactions with proteins such as integrins.

Myosin Transport during Nerve Outgrowth

Growth cones are actin-rich structures that contain a variety of myosins (Figure 3), including multiple isoforms of myosin II and myosins 1, Va, and VI. Particles have been observed to move along actin filaments in growth cones, but the significance of this motility has not been fully determined. Evidence has accumulated for actin-dependent trafficking of local translational machinery for β-actin in motile cells. Local translation of β-actin contributes to growth cone turning, suggesting that this actin-based transport may be a key step in growth cone-dependent steering in response to certain guidance cues. The specific myosin(s) involved has yet to be identified, but the direction of movement (toward the periphery) is most consistent with a (+) end-directed myosin such as myosin 1, V, or II.

A functional organelle transport role for myosin 1, V, or VI in growth cones has not been firmly established. Data on the roles of myosin V and VI in the

Figure 3 Actin-based transport in nerve growth cones. Growth cones contain multiple forms of myosin. Integrins are transported to the periphery along actin filaments by myosin X. Vesicles can be transported bidirectionally by myosin Va and myosin VI. Retrograde flow of actin filaments is driven by myosin II (with possible contributions by Myo1c). The side view at the top indicates the interaction between myosin II and actin that results in retrograde flow (arrow) or traction force when the flow mechanism is coupled to the substrate via adhesion complexes (multicolored structures).

regulation of neurotransmitter release may shed light on myosin VI's function in growth cones. Myosin V has been shown to be present in chromaffin cells and PC-12 cells, where it regulates release of secretory granules. In presynapatic terminals, myosin VI regulates brain-derived neurotropic factor (BDNF)-dependent neurotransmitter release characteristics. It seems plausible that the roles of these myosins in growth cones may be similar. Growth cones respond to neurotrophins such as BNDF and nerve growth factor, release neurotransmitters, and recycle synaptic vesicle membrane locally similar to presynaptic terminals.

Both Myo1c and myosin II have been shown to contribute to the retrograde flow of actin filaments (bulk rearward movement of actin networks or bundles from the leading edge without a shape change) in growth cones. Although this movement is not typically associated with transport functions, it is clearly a locally important phenomenon for motility that is at least partially driven by myosins. The mechanism of retrograde flow has been linked to the generation of traction forces necessary for the advance of growth cones.

Myosin X is a relatively recently discovered unconventional myosin that is uniquely located and appears to have a specific transport function. Myosin X localizes primarily to filopodia (long actin-rich peripheral protrusions) of migrating cells, including filopodia of growth cones. It interacts with integrins and functions in transporting integrins to the tips of filopodia. Knockdown of myosin X results in loss of filopodia, whereas overexpression promotes filopodia formation. It may also act as a molecular clutch linking integrins that have bound their ligand to the underlying actin cytoskeleton. Because of the location in filopodia and interaction with integrins, myosin X may have an important role in growth cone steering in response to guidance cues.

Myosin Transport in Mature Neurons

Myosin transport in mature neurons appears to be related primarily to synaptic plasticity. Myosins are present in both presynaptic terminals and dendritic spines. Receptor recycling in dendritic spines is the most completely described function. Myosin V and VI are both involved. In addition to recycling, transport of smooth endoplasmic reticulum (ER) into spines is myosin Va dependent. Myosin Va and VI have been found to be located presynaptically, although their functions in this location are less well documented.

Transport in Dendritic Spines

Spine actin is organized with the barbed or fast-growing end oriented primarily toward the spine head membrane. This means that myosins that walk toward the barbed end will move toward the spine head and those that walk toward the minus end will move away from the spine head and toward the stalk. This is significant for understanding transport in spines because spines contain both myosin V and VI, as well as myosin II (Figure 4).

Myosin VI has been shown to bind to a complex of proteins from brains that contain the AMPA receptor subunits: GluR1 and GluR2, as well as AP-2 and SAP97. SAP97 acts as a postsynaptic scaffold protein and AP-2 is involved in receptor-mediated internalization. Cells derived from mutant mice that lack myosin VI expression show defective internalization of AMPA receptors but do not show general defects in clathrin-mediated endocytosis. This indicates that myosin VI is critical for the specific uptake of AMPA receptors and thus may play an important role in regulating some forms of synaptic plasticity. The orientation of actin filaments in spines is consistent with

Figure 4 Actin-based transport in dendritic spines. Myosin VI is responsible for the movement of clathrin-coated endocytotic vesicles containing AMPA-type glutamate receptors away from the spine head membrane to endosomes. Myosin Vb contributes to the movement of recycled AMPA receptors back to the membrane of the spine head. Myosin Va contributes to the transport of smooth endoplasmic reticulum (SER) into spines. Myosin II regulates spine shape.

internalization and myosin VI-dependent transport away from the postsynaptic membrane to endosomes that may be within the spine or dendrite. Early, sorting and recycling endosomes are present in dendrites or spines and thus are likely to process the protein complex for degradation or recycling. For recycling, the return pathway to the postsynaptic membrane remains uncertain, but it has been shown that myosin Vb interacts with a complex of proteins that includes the GluR1 subunit of the AMPA receptor and therefore may provide the transport motor for the return of this subunit. This interaction involves Rab11, which has also been shown to mediate interactions between myosin Vb and muscarinic acetylcholine receptors. Since myosin Vb is a barbed end-directed motor and is found in dendrites and spines of hippocampal neurons (after DIV 28), it may provide this receptor subunit delivery transport function. Rab8 has been shown to be critical for AMPA receptor recycling. Myosin Vc has been shown to interact with Rab8, indicating the possibility that this isoform of myosin V may also contribute to AMPA receptor recycling. However, no data are available on myosin Vc expression in hippocampal neurons.

Myosin Va has an important role in transporting smooth ER into dendritic spines of Purkinje cells. Transporting smooth ER appears to be a general property of myosin V because it has been shown to have this function in a variety of species, including in yeast, squid axons, and *Xenopus* oocytes. Surprisingly, hippocampal neurons from dilute-lethal mice (myosin Va null) often still have spine-associated smooth ER, indicating that some spines do not rely on myosin Va for transport. Hippocampal neurons also express myosin Vb, which may possibly take over this function in the absence of Va.

Transport in Presynaptic Terminals

Both myosin Va and myosin VI have been localized to axons and presynaptic terminals. Some initial information about possible functional roles in presynaptic terminals is now available.

Myosin Va has been shown to bind to SV2-positive vesicles in neurons and the absence of myosin Va results in abnormal accumulation of these vesicles in presynaptic terminals, as well as a general increase in terminal volume. Myosin Va binds to a synaptobrevin–synaptophysin complex in a calcium-dependent manner, indicating that it may modulate some aspect of presynaptic function. The neck region of myosin Va, which contains multiple calmodulin binding sites, has been shown to interact with syntaxin-1A in chromaffin cells. This interaction appears to regulate the late sustained phase of chromaffin granule exocytosis in response to increases in intracellular calcium above 0.3 μM. Presumably, myosin Va acts to transport vesicles from the reserve to the readily releasable pool in chromaffin cells. Whether a similar function occurs in presynaptic terminals is not clear because electrophysiological experiments have not found significant changes in release properties in the absence of myosin Va.

Myosin VI has a role in regulating BDNF-mediated neurotransmission in hippocampal neurons. Myosin VI interacts with a complex of proteins that includes GIPC1 and TrkA or TrkB. GIPC1 appears to have an adaptor function and binds directly to myosin VI. The absence of myosin VI or GIPC1 impairs basal synaptic transmission from hippocampal slices and BDNF-induced long-term potentiation. The exact mechanism through which myosin VI influences synaptic transmission remains to be determined, but considering its general role in endocytosis, it seems likely that it acts mainly in the retrieval of synaptic vesicles following exocytosis.

Myosin Transport of mRNA, Translational Machinery, and Organelles in Axons and Dendrites

In mature neurons, myosin Va has been shown to associate with ribonucleoprotein complexes (that can include mStaufen, Pur α, or fragile X mental retardation protein) and mRNA that participate in local translation of proteins. This association has been observed in both axons and dendrites. The axonal form of this complex is known as periaxoplasmic ribosomal plaques. Although it is not clear if myosin Va has a direct transport role for these complexes, the association and known function of myosin V in other organisms such as yeast is consistent with a role in the transport of synthetic machinery for local synthesis. It is probable that this role will be expanded as more is learned about myosin V transport functions in actin-rich regions such as spines.

Myosin Va has also been shown to affect the amount, transport, and distribution of neurofilaments in axons. However, neurofilament transport does not require actin filaments, making it unlikely that neurofilaments are directly transported by myosin Va. Thus, what role does myosin Va play in axonal neurofilament formation and maintenance? Upregulation and local translation of neurofilament subunits has been described following nerve injury, suggesting that local production may contribute to axonal neurofilament formation. If myosin Va localizes or transports components necessary for local synthesis of proteins, including neurofilaments, then it is possible that disruption of the machinery required for this function could alter neurofilament transport and formation. Alternatively, local translation of microtubule motors is myosin Va dependent, and disruption in the production of microtubule motors interferes with neurofilament transport.

Organelle transport in axons and dendrites does not require myosin motors, but rate and directional changes may involve myosin 1 or Va activity. Transient binding to actin could cause pauses in transport and allow organelles to interact with microtubule-based motors with the opposite directional polarity. Alternatively, myosins may ride as passive passengers on organelles transported by microtubule motors and then become activated when microtubules terminate within actin-rich regions. The activation of myosins could immobilize or locally transport organelles into actin meshworks at specific sites, preventing them from being transported along microtubules in the opposite direction. This could lead to accumulation of components at distal functional sites in dendrites.

Myosin Transport and Neuronal Function

Data on myosin transport functions in neurons are consistent with a general role in the polarized delivery or retrieval of components (including synthetic machinery) from the actin-rich cytoplasmic domains that include dendritic spines and presynaptic terminals. Myosins also appear to directly participate in receptor and synaptic vesicle turnover or recycling in these compartments through transport functions closely associated with exocytosis and endocytosis. Whereas transport between dendrites or axons and spines or presynaptic terminals requires switching between microtubule and actin filament tracks, as well as motor proteins, recycling within these compartments is independent of microtubules and therefore may be solely dependent on myosin transport.

Napping

S C Medrick and S P A Drummond, University of California at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

To answer the question of what the function of napping may be, we must first define 'function.' Though this article concentrates mostly on the function of napping for behavior, it would be possible also to write about the function of napping across cultures and history. For example, there is a long history of napping in southern regions of the globe, in which it is practiced in the form of a siesta. By the first century BC, the Romans had coined a word for the afternoon break, *meridiari*, derived from the Latin word for 'midday.' Later, the church divided the day into periods designated for specific activities, such as meals, prayer, and rest. Midday became known as *sexta*, as in the sixth hour (noon, by their way of counting), a time when everyone would take rest and pray. The word has survived as the familiar term, 'siesta.' This postprandial sleep custom disappeared in northern Europe with the industrial revolution, but remained a strong tradition in southern Europe and many Latin American cultures, where people would shutter their businesses for a few hours to return home, eat a meal, sleep, and then return to work from 4 p.m. until 9 p.m. While the 'siesta' culture continues today in these regions, enthusiasm for the siesta has cooled substantially.

Presently, napping is most popular in highly industrious cultures such as Japan and Germany, whereas countries such as Spain or Italy have begun phasing out the practice. Current beliefs about midday rest are being reassessed from an empirical perspective, as evidenced by the fact that this topic is enjoying the spotlight of an entire entry in an encyclopedia of neuroscience for the first time. One reason for this resurgence of interest in the function of naps is due to the changing needs of modern culture. An increase in 24 h work cycles, the regularity of international travel and communication with global markets, and long work days and longer commutes have brought on a host of secondary problems that require attention – reports show continual decreases in nocturnal sleep, increases in sleep disorders, and increases in sleepiness-related accidents. The nap is thus being increasingly investigated as an inexpensive, noninvasive, short period of sleep strategically implemented for sleepiness and fatigue management, sustained productivity and alertness, and optimal cognitive processing.

This emerging body of research is summarized in the following sections, with emphasis on the possible biological basis of effects of napping, implementation during night shift and sleep deprivation studies, and promising new directions investigating the dose- and sleep stage-dependent benefits possible through targeted napping schedules designed to improve performance on a wide variety of behavioral measures.

Definitions and Demographics of Napping

What Is a Nap?

Naps, at least as discussed herein, are defined as intended periods of sleep that can last anywhere from 3 min to 3 h and can be taken anytime during the day or night. Meta-analysis of surveys and diary studies of American populations show that naps usually range between 0.5 and 1.6 h. Naps should be distinguished from microsleep, which is a brief, involuntary period of sleep lasting from seconds to minutes. In addition, naps should be distinguished from 'major' sleep periods that typically occur overnight and typically last at least 5 h or more (of course, in night shift workers, these major sleep periods occur during the day).

Changes in Napping Behaviors across the Life Span

Napping patterns shift throughout life. In infancy, two basic types of sleep emerge: quiet sleep and active sleep. These are the infant equivalent, respectively, of nonrapid eye movement (NREM) and rapid eye movement (REM) sleep seen in adults. Over 50% of neonate sleep is active (though premature babies can achieve levels as high as 80%), but that number will drop to 30% by the end of the first year. Infants have shorter sleep cycles than adults do, with the typical cycle lasting 50–60 min as opposed to 80–100 min in adults. Interestingly, infants also commonly show sleep-onset active sleep especially after feeding, a sleep pattern considered pathological in adults. By the age of 2 years of age, REM occupies 20% of total sleep, a figure that remains relatively common throughout the rest of life. Napping emerges a little before the first birthday, when sleep coalesces into a nocturnal sleep period, a shorter nap (30 min to 1 h) in the morning around 10 a.m., and a longer nap (1–3 h) in the afternoon. Eventually napping consolidates into one long afternoon nap and then the nap disappears in most children around age

four, reappearing in teenage years and into college years, when up to 60% of students report regular napping habits.

Recent evidence suggests that men take more naps than women do, even though nocturnal sleep hours average about the same for both sexes. On average, men's nocturnal sleep appears to be less efficient, so men may simply need a nap more than women do. Specifically, studies of young adults show that males not only spend more time in bed awake compared to females, but also enjoy less slow-wave sleep (SWS) and REM compared to females. Troubled sleep occurs in women as well, of course, but typically begins later in life, resulting in part from hormone fluctuations that occur across a woman's lifetime.

Napping behavior also changes as a function of aging. Older adults nap more frequently and later in the day compared with younger adults. There may be multiple underlying causes for these differences, including nocturnal sleep deterioration, weaker circadian rhythm and circadian phase advance, or simply that the elderly have more time to practice elective napping. Some studies have shown that napping in older adults is related to decreases in slow-wave activity and reduced sleep efficiency, whereas napping is not related to nocturnal sleep parameters in normal adults or insomniacs.

A number of studies have investigated how napping interferes with nocturnal sleep parameters; effects are likely due to the relieving of sleep pressure, the biological drive to go to sleep that increases as a function of time awake. In general, naps are reported to not interfere with nocturnal sleep. Exceptions to this are that (1) naps can decrease slow-wave activity in subsequent sleep episodes when naps are taken within a 2–3 h window from nocturnal sleep (bedtime) and that (2) when naps are taken during a night shift, the subsequent daytime sleep can show decreased slow-wave activity.

Is Napping a Natural Part of Our Circadian Rhythm?

Timing of Naps

When napping is examined in the laboratory, the consistent finding is that daytime sleepiness is a regularly occurring phenomenon. The afternoon 'nap zone,' first proposed by Broughton, is a period between 14:00 and 16:00, when daytime sleep propensity is highest. Such a propensity for diurnal sleep has been demonstrated in a variety of different experimental milieus, including with removal of all temporal constraints or 'free-running' conditions during ultrashort routines, in which sleep–wake schedules occur over a 90 min period, and as evidenced in the classic 'M-shaped' time-of-day function in studies of sleep propensity using the Multiple Sleep Latency Test (MSLT), a test in which the time it takes to fall asleep, sleep onset latency, is measured at regular intervals across the day. Even in studies when individuals are specifically asked not to nap, resistance to daytime sleep has been most weak during these afternoon hours. Due to the increased sleep propensity because of the time of day, as well as the historical develop of napping behaviors, it has been (perhaps misleadingly) termed 'the postprandial dip.' Studies have shown, however, that the energy slump occurs even in the absence of lunch and/or without knowledge of the time of day.

Physiological Evidence for 'Nap Zone'

A fluctuation in core body temperature (CBT), a fundamental measure of circadian rhythms, represents the best physiological marker to correlate with increased afternoon sleep propensity. Generally speaking, there is a rise in temperature across the daytime and a decrease during the night. The falling temperature traditionally has been considered one important trigger for onset and method of sustainment for nocturnal sleep. CBT starts to fall prior to habitual bedtime and reaches its lowest point approximately two hours prior to habitual wake time (typically between 03:00 and 05:00 in most adults). Though circadian fluctuation of CBT can be fit with a simple sinusoid function spread across the 24 h period, further investigations have found that CBT is better described by adding a 12 h bicircadian component to the model, which corresponds to a robust finding of a dip in temperature in the afternoon (Figure 1).

The afternoon dip in temperature corresponds to the time when individuals show a greater sleep propensity. Although decreases in CBT are temporally correlated with increases in sleepiness, a direct mechanistic link has yet to be discovered. Sedative-hypnotics such as melatonin and benzodiazpines decrease CBT and increase peripheral heat loss, which has been directly related to sleep onset latency. In contrast, agents such as caffeine, amphetamines, nicotine, and cocaine decrease sleep propensity and increase CBT. Further, studies have shown that the best predictor of sleep onset (better than melatonin) was the distal–proximal skin gradient, an index of peripheral heat loss. Thus, it is likely that a decrease in temperature (CBT and peripheral heat) is a trigger for sleep in general, and possibly also for afternoon naps. The duration of a sleep episode may also be related to the direction of change in CBT – that is, long nocturnal sleep occurs during an extended period of decreased temperature while short sleep occurs

Figure 1 (a) Double-plotted 24 h rectal temperature rhythms from 18 young adults on a nycthemeral routine, together with best fitting composite 24 and 12 h sinusoids (see text). (b) The same fitted model, but with the 12 h amplitude raised from 0.152 to 0.304 °C. when CBT increases. Studies have found that increases in CBT are related to more frequent awakenings. Further research is needed to disentangle the causal relationship between changes in CBT and daytime sleep onset.

Behavioral Markers for the 'Nap' Zone

Anecdotal evidence for behavioral measures of the 'nap' zone can be easily found in any typical workplace, with decreased productivity and increased caffeine consumption during the afternoon, as well as an increase in traffic accidents during this time of day (even after taking into account the increased number of cars on the road). On the other hand, it has been more difficult to find consistent laboratory evidence for behavioral markers. Two factors are most likely the cause. First, there may be specific cognitive processes that are vulnerable to circadian peaks and troughs, while others are not. For example, tasks that rely on continuous performance show dips in the afternoon, such as card sorting, serial search, a variety of signal detection tasks, and physical exertion such as sprinting. Memory tasks and perceptual tasks, on the other hand, have not shown a strong circadian component. Second, individual differences are likely to produce a large source of variation. Intriguing findings of individual differences in vulnerability to a midafternoon performance deficit on a monotonous visual vigilance task demonstrate that only half of the individuals show the 14:00 performance dip. Monk and colleagues compared the CBT of the 'dippers' to the 'nondippers' and showed that performance decreases coincided with a flattening of the CBT in the dippers, whereas CBT in the nondippers continued to increase in a linear manner during this period. Monk proposed that an individual's propensity for midday decreases in performance may be predicted by a combination of the individual's endogenous circadian pacemaker and the length of time the individual has been awake (i.e., magnitude of sleep pressure). Specifically, Monk stated that "the size (or timing) of the 12 h temperature rhythm component might be predictive of the size (or presence) of a post-lunch dip in performance." Further research investigating other biological and genetic determinants of midday dip vulnerability, such as morningness and eveningness measures proposed by Horne, will be extremely interesting pieces of information for answering these questions.

What Is the Function of Naps?

Now that we have provided evidence in favor of naps being a natural part of sleep–wake cycles, at least in some individuals, we turn our attention to the possible function of naps. As already stated, the concept of 'function' can take many forms. For example, one can ask whether the function of a nap is the same as the function of sleep in general, or if it serves a purpose separate from that of the major sleep period. While we do not yet fully understand why we sleep, we do know that a variety of molecular, genetic, and physiological processes occur exclusively, or primarily, during sleep. For the most part, research has not examined whether these same changes occur during naps. What has been examined, though, are the behavioral and cognitive benefits of a nap under a variety of conditions. In other words, research has examined how naps help individuals function better. Thus, it is this more operational definition of function that we discuss here.

Sleepiness versus Fatigue Countermeasures

In the broadest sense, naps are used operationally as either sleepiness countermeasures or fatigue countermeasures. The distinction between sleepiness and fatigue is one that is, unfortunately, often blurred or confused, but is an important distinction to keep in mind. Sleepiness is the physiological propensity to fall asleep, either intentionally or unintentionally. As discussed earlier, the circadian rhythm of the CBT is one traditional biomarker of sleepiness. When naps are used as a sleepiness countermeasure, the intended function is to increase arousal and alertness. This increased alertness level may, in turn, produce better performance. In contrast, fatigue refers to a decrease in physical or cognitive efficiency related to time-on-task and workload, independent of whether someone has a propensity to fall asleep. When naps are used as a fatigue countermeasure, the intended function is to directly boost performance. Most often, the term 'fatigue countermeasure' is incorrectly used to cover both functions (of not only naps, but also interventions such as caffeine) when used in operational settings.

Napping in Sleep-Deprived Conditions

Until recently, napping research has focused primarily on treating sleepiness during extended work periods, such as long-haul truck driving, transatlantic airplane routes, and NASA space flight, as well as during nontraditional work schedules such as night shifts. In both of these circumstances sleepiness due to sleep deprivation is a common danger and has been implicated as contributing to accidents during work and transit from work to home, as well as to increased health problems in these workers.

Night shift work is particularly vulnerable to extreme performance decrements due to unintentional sleep, increased sleepiness, and decreased performance for most skills, including vigilance, reaction time, serial addition/subtraction, spatial orientation, and flight simulator operation. Critical hours for increased errors and slowness are between 03:00 and 05:00 (coinciding with CBT nadir). The two main sources of reduced alertness and performance during night work are (1) the circadian rhythm of sleepiness and alertness (as discussed earlier) and (2) increased homeostatic sleep pressure. Contributing to this difficulty with night shift work is the poor adaptability of circadian regulated processes such as endocrine, sleep, CBT, adrenaline, alertness, and other physiological rhythms to even long-term (2–3 months) reversal of sleep–wake cycles. Even workers on permanent night shift schedules do not show a change in the timing of the circadian system and continue to show reduced performance and increased mistakes after years on the night shift. Thus, the need to find sleepiness and fatigue management solutions for this population is an imperative.

Work-related napping strategies have categorized three types of naps: prophylactic napping (taken in anticipation of sleep deprivation), compensatory napping (taken after sleep deprivation has begun), and operational napping (napping during working hours). Overall, prophylactic napping taken just before the work night seems to best enhance performance overnight, although a combination of prophylactic napping and caffeine may work even better. With respect to operational napping, it has been found that both pilots and truck drivers unofficially nap during night shifts and long-haul transportation trips. Research has shown that a 20 min operational nap between 01:00 and 03:00 significantly improves speed of response on a vigilance task measured at the end of the shift, compared with a control condition. The potential problem with napping during the night is that there is increased risk for waking with sleep inertia. Sleep inertia is the feeling of slowness, irritability, and poor decision-making ability that can occur during the first 20–30 min after waking from deep sleep, although this period may be shorter with naps than with longer sleep periods. Methods for combating sleep inertia, however, have been proved successful, including exposure to bright light, washing the face, exercise, and, of course, a dose of caffeine. Apart from performance on specific measures, napping has been shown generally to improve alertness, productivity, and mood, and this may be especially so under sleep-deprived conditions,

during night shift work, and during prolonged periods of driving.

Cognitive Benefits of Napping Linked to Specific Stages of Sleep

It is perhaps unsurprising that napping has been shown to be an effective sleepiness countermeasure, and that improved alertness can, in turn, have a positive impact on performance. What may be even more interesting to explore is whether napping can be a fatigue countermeasure independent of alerting effects, and whether naps can even enhance normal performance when fatigue and/or sleepiness are not an issue. Recent studies investigating the impact of napping on a variety of memory consolidation measurements have in fact provided evidence for both of these functions. Studies on the benefit of napping on performance have demonstrated that short daytime sleep episodes not only can decrease sleepiness but also show selective enhancement of various forms of memory, as well as increase alertness and physical and mental stamina. Furthermore, these studies have related these napping-related improvements to specific sleep stages.

An important methodological aspect of napping that has been exploited by these studies is that sleep during naps can be titrated to have specific stages of sleep without disturbing the napper's sleep. This is accomplished primarily by manipulating the duration and timing of the nap. Such manipulations have been attempted during nocturnal sleep studies by depriving individuals of sleep during the first or the second half of the night, in order to isolate SWS or REM sleep. Although selective cognitive benefits have been shown, this method does not actually isolate stage two, SWS, or REM. Naps, on the other hand, have shown a high degree of specificity in performance between stage one alone versus stage one and two combined, and naps with SWS alone versus SWS and REM combined.

Hayashi et al. demonstrated the recuperative power of napping for sleepiness and alertness measurements even with a 5-min nap limited to stage one sleep. They report that performance improvement on a visual detection task and digit symbol task, as well as decreases in slow eye movements during testing, required a nap with stage two. Walker demonstrated that a nap can improve performance on a motor learning task to the same degree as can a full night of sleep, with stage two sleep playing an important role.

Naps rich in SWS have been shown to improve declarative memory for pictures or word pairs after a nap, as well as prevent deterioration in performance that develops across the day. Mednick and colleagues have reported a series of studies establishing the efficacy of naps in combating performance deterioration. These studies utilized a visual perceptual task in which individuals reliably show significant decreases in performance with repeated testing across the day, even when the test is only given twice. Importantly, they found that a 60 min midday nap rich in SWS can reverse perceptual deterioration and restore performance to baseline, with long-lasting benefits to performance (Figure 2).

Figure 2 Same-day improvement in no nap, 60 min nap, and 90 min nap groups, with and without rapid eye movement (REM) and slow-wave sleep (SWS). (Left) No-nap group shows deterioration at 19:00 from baseline test at 09:00. (Center) Performance after naps with SWS but without REM shows neither deterioration nor improvement. (Right) Naps with SWS and REM led to significant improvement. Only two individuals in the 90 min nap group showed no REM. Reprinted by permission from Macmillan Publishers Ltd: *Nature Neuroscience* (Mednick S, Nakayama K, and Stickgold R (2003) Sleep-dependent learning: A nap is as good as a night. *Nature Neuroscience* 6(7): 697 –698.), copyright (2003).

Naps including both SWS and REM actually led to an improvement in perceptual performance equivalent to that following a full night of sleep. Furthermore, when individuals are tested after a nap and a full night of sleep, they demonstrate as much benefit as with two nights of sleep, indicating that sleep-dependent learning is similarly effective whether it is from daytime naps or nocturnal sleep. Also, the benefits from napping and nocturnal sleep are additive (Figure 3). It should be emphasized that these sets of studies examined performance after a normal night of sleep, rather than following a period of sleep deprivation. Thus they showed that naps can enhance performance beyond even 'normal' levels.

Summary

In examining the function of naps it appears that modern culture has redefined the functionality to suit the needs of an increasingly 24 h society. The

Figure 3 Improvement for nap and no-nap groups. (Left) Improvements 24 h after training for the no-nap group's second retest, the 24 h control group's first retest, and the 90 min nap group's second retest, all at 09:00 on day 2. Dashed line shows nap group's improvement on day 1. (Right) Improvement 48 h posttraining with no nap. amount of nocturnal sleep continues to decrease as labor demands increase in duration, as well as with the increase in around-the-clock work schedules. Thus the nap serves as both a fatigue and sleepiness countermeasure. Some studies demonstrate that napping in the afternoon may in fact be an inherent part of our natural sleep–wake cycle, as evidenced by physiological and performance decreases during the afternoon that temporally coincide with increased propensity to sleep. Most research on napping has examined either alertness or specific cognitive benefits. An important consideration that has emerged from this body of research is that specific stages of sleep can confer specific benefits to performance. Overall, naps seem to confer a number of possible benefits, but this area of investigation is still young. Present directions of research are investigating the cognitive benefits of napping and the possibility of fitting a nap to an individual's needs by adjusting the duration and time of day of the nap. Important areas for future research concerning the function of naps will include the medical, physiological, and psychological benefits of napping that have been reported to occur with nocturnal sleep.

Narcolepsy

E Mignot and L Lin, Stanford University, Palo Alto, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

What Is Narcolepsy?

The sleep disorder narcolepsy was first recognized, named, and described in the late nineteenth century when an unusual association of excessive daytime sleepiness and episodic muscle weakness that was believed to be more than simply 'epileptoid' phenomenon was noted. The unusual muscle weakness episodes triggered by emotions that occur in this condition were called 'cataplexy' soon thereafter. Until relatively recently, whether or not narcolepsy was a symptom or a disease entity was much debated. The discovery of a human leukocyte antigen (HLA) association in 1980 added credence to the hypothesis of a unique disease entity with a discrete etiology. This was subsequently confirmed by the discovery of hypocretin (orexin) deficiency as the major cause of narcolepsy–cataplexy.

In its typical form, symptoms include sleepiness, cataplexy, sleep paralysis, hypnagogic hallucinations, and disturbed nocturnal sleep. Sleepiness, abnormal sleep onset into rapid eye movement (REM) sleep, and cataplexy are the most important symptoms. Whereas much is known about the pathophysiology of narcolepsy with cataplexy, little is known regarding the cause of narcolepsy without cataplexy. For this reason, international classifications and research studies typically separate narcolepsy into cases with and without cataplexy. As discussed later, narcolepsy without cataplexy is more likely to be etiologically heterogeneous.

Approximately 1 person in 2000 in the United States and Western European countries has narcolepsy with cataplexy. The exact prevalence of narcolepsy without cataplexy (defined as isolated unexplained daytime sleepiness with abnormal REM sleep onset periods) is unknown but likely to be higher. Narcolepsy is typically diagnosed many years after disease onset. Early detection and treatment is critical to ensure normal schooling and to prevent associated loss of social status. The disorder is socially isolating, and many patients have problems holding a job and maintaining an active social and affective life.

Narcolepsy Symptoms

Excessive daytime sleepiness is the most troublesome symptom and most often causes patients to consult. Typical complaints are frequent and overwhelming sleep attacks and the need to nap frequently during the day. A wide range of severity may be seen, from simply needing a nap everyday or nodding when at rest to an almost constant feeling of irresistible drowsiness. Sleepiness in narcolepsy may be confused with fatigue and depression.

Cataplexy, a brief and sudden loss of muscle strength triggered by emotions, is very important clinically for the diagnosis of narcolepsy. It is the only symptom specific of narcolepsy, but unfortunately it is not present in all patients. Typically, patients feel weak in the knees and have to sit down when they are emotionally excited – for example, in the context of a funny joke, a good laugh, or when becoming angry. Other attacks of muscle weakness may affect the head (head dropping), the jaw (jaw dropping), the face, or the arms. Cataplexy is frequently mild. It may occur only a few times per month or several times a day. Strong attacks may escalate to a complete body paralysis episode lasting up to a few minutes. Cataplexy may be confused with epilepsy or other neurological/psychiatric problems. Importantly, patients are awake and conscious during cataplexy. Cataplexy should also not be confused with catalepsy, a symptom characterized by increased muscle tone and body rigidity, most often in the context of schizophrenia.

The other symptoms (sleep paralysis, hypnagogic hallucinations, and insomnia) are only weakly indicative of narcolepsy. They are also observed in normal individuals or in association with other sleep disorders. Sleep paralysis is characterized by an inability to move when waking up or when falling asleep. The first episode of sleep paralysis is often frightening, but the paralysis always ends after a few seconds to a few minutes. Hypnagogic hallucinations ('hypnagogic' means 'when falling asleep') are dreamlike visions or auditory perceptions that occur when patients are tired or actually falling asleep. Patients with vivid dreamlike hallucinations have occasionally been misdiagnosed as schizophrenic.

Contrary to popular belief, patients with narcolepsy do not typically sleep more than normal people. Rather, they are unable to stay awake or asleep for long periods of time. Insomnia is thus common in patients with narcolepsy. Patients with narcolepsy typically fall asleep easily at any time during the day and night but have great difficulties staying asleep at night. The total amount of sleep during the 24-h day is thus often normal.

Dissociated REM Sleep in Narcolepsy

Many of the symptoms in narcolepsy are due to abnormal transitions from wakefulness to REM

sleep (called sleep-onset REM periods), a state associated with vivid dreaming, rapid eye movements, and a complete muscle paralysis. In normal subjects, REM sleep first occurs 90–120 min after falling asleep and then reoccurs periodically throughout the night. In narcolepsy, abrupt transitions from wakefulness to REM sleep often occur before the patient is completely asleep. This problem produces 'dissociated' states in which the patient is half awake and half in REM sleep, for example, being paralyzed (sleep paralysis) or dreaming (hypnagogic hallucinations) but awake. Cataplexy is also considered similar to REM sleep paralysis but occurs when the brain is excited by an emotion such as laughing or anger.

Genetic Predisposition to Narcolepsy–Cataplexy

The occurrence of narcolepsy–cataplexy involves both genetic predisposition and environmental triggers. Approximately 75% of reported monozygotic twins are discordant for narcolepsy, suggesting the importance of environmental factors. Multiplex families are rare, but a 10- to 40-fold increase in relative risk is reported in first-degree relatives.

One of the major genetic susceptibility factors for narcolepsy–cataplexy is HLA-DQB1 (Figure 1(a)). Almost all patients with typical cataplexy carry DQB1*0602, an HLA subtype found in 12% of Japanese, 25% of Caucasian, and 38% of African American controls. HLA-DQB1*0602 is always associated with DQA1*0102, another HLA allele encoded by the nearby DQA1 gene, located less than 20 kb telomeric to DQB1 (Figures 1(a) and 1(b)). The DQB1 association is especially tight in subjects with hypocretin deficiency; only four HLA DQA1*0102–DQB1*0602 negative narcolepsy subjects with low or undetectable cerebrospinal fluid (CSF) hypocretin-1 have been identified to date (out of several hundred subjects with CSF testing).

The DQB1*0602 association in narcolepsy is primary and not due to linkage disequilibrium with other loci. It is mostly due to DQA1*0102–DQB1*0602, but it is not simply a dominant effect. Indeed, DQB1*0602 homozygotes have a two- to fourfold higher risk than DQB1*0602/X heterozygotes, and specific DQB1*0602 heterozygotes are either at increased (e.g., DQB1*0602/DQB1*0301) or decreased (e.g., DQB1*0602/DQB1*0601 or DQB1*0602/DQB1*0501) risk (Figure 1(c)). Additional smaller effects have also been suggested for specific DRB1 alleles, another HLA locus located in the same region. The complexity of the HLA allele association in narcolepsy mirrors that reported in various autoimmune diseases, such as type I diabetes.

Genetic factors other than HLA are likely to be involved in the genetic susceptibility to narcolepsy–cataplexy but are not as well established or replicated. They are also likely to contribute far less to overall genetic risk than HLA-DQ. Studies in multiplex families suggest linkage to 4p13–q31 and 21q11.2 and possible associations with tumor necrosis factor (TNF)-α, catechol-O-methyl-transferase, and TNF receptor-2 polymorphisms. Notably absent in this list is the preprohypocretin gene and its two receptors, hypocretin receptor-1 and -2. Indeed, only a single mutation in any of these three loci has been identified. This case, an HLA-DQB1*0602-negative boy with hypocretin deficiency, had an unusually early onset of narcolepsy–cataplexy at 6 months of age. This boy had a potential dominant mutation in the signal peptide of the preprohypocretin gene that produces impaired hypocretin trafficking and, presumably, cell death.

Narcolepsy–Cataplexy Is Tightly Associated with Hypocretin Deficiency

The role of hypocretin in narcolepsy was first demonstrated in familial canine narcolepsy, a disease caused by mutations in the hypocretin receptor-2 gene, and through the study of a mouse preprohypocretin gene knockout model. This was followed by the demonstration of low CSF hypocretin-1 in 90% or more of cases with narcolepsy and cataplexy. Postmortem studies have shown a selective loss of 50 000–100 000 posterior hypothalamic neurons that produce the neuropeptide hypocretin (orexin) (Figures 2(a) and 2(b)). Loss, rather than decreased expression, is suggested by the concomitant loss of associated co-localized markers dynorphin and neuronal pentraxin-2. The HLA association and associated hypocretin deficiency is particularly strong (>90%) in patients with definite cataplexy (Figure 3). This association lends support to the hypothesis that narcolepsy is an autoimmune disorder.

Neurobiology of the Hypocretin Systems and Relevance to Narcolepsy

The hypocretin peptides (also called orexins) are encoded by the preprohypocretin gene. This gene encodes two related amidated polypeptides, hypocretin-1 and hypocretin-2, with high sequence homology. Hypocretin-1 (orexin-A), a 33-amino-acid peptide, has two disulfide bonds and is remarkably stable in biological fluids. It has an approximately equal affinity for the two known hypocretin receptors, hypocretin receptor-1 (HCRTR1) and hypocretin receptor-2 (HCRTR2). Hypocretin-2 (orexin-B), a

Figure 1 Genetic susceptibility to narcolepsy: human leukocyte antigen effects. (a) Human leukocyte antigen (HLA) genes are numerous and located within the major histocompatibility complex on human chromosome 6. The HLA genes with the tightest genetic association with narcolepsy–cataplexy are the HLA class II region genes DRB1, DQA1 (encoding the DQα chain of the DQ molecule), and DQB1 (encoding the β chain of the DQ molecule). (b) Crystal structure of a DQ molecule associated with a peptide. The HLA-DQ molecule is a heterodimer formed by the polymorphic DQα and DQβ chains (encoded by DQA1 and DQB1 genes, respectively). The two chains form a peptide binding groove in which antigenic peptide (here, the hypocretin-1 peptide) can bind, to be presented to other cells of the immune system for the development of the immune response. (c) Specific DQA1–BQB1 allele combinations and genetic risk for narcolepsy–cataplexy in various ethnic groups. Allele groupings are ranked from the most predisposing to the most protective combinations. Almost all combinations with DQA1*0102–DQB1*0602 are at increased risk; one copy of DQA1*0102–DQB1*0602 is required in almost all cases for developing narcolepsy with cataplexy and hypocretin deficiency. Note that the highest odds ratio (OR) is observed for DQA1*0102–DQB1*0602 homozygotes. Other allele combinations confer various degrees of susceptibility, as often observed in other HLA-associated diseases. (b) Reproduced from Siebold C, Hansen BE, Wyer JR, et al. (2004) Crystal structure of HLA-DQ0602 that protects against type 1 diabetes and confers strong susceptibility to narcolepsy. *Proceedings of the National Academy of Sciences of the United States of America* 101: 1999–2004. (c) Reproduced from Mignot et al. (2001).

smaller peptide of 29 amino acids, has a tenfold higher affinity for HCRTR2.

Hypocretin neurons have tight functional interactions with cholinergic and monoaminergic systems regulating sleep (Figure 2(c)). These cell groups are enriched in hypocretin receptors, with a complementary distribution of the two receptors at the anatomical level. HCRTR1 is particularly abundant in the adrenergic locus coeruleus, whereas HCRTR2 is highly expressed on histaminergic cells of the tuberomammillary nucleus. Other regions of interest include hippocampus, paraventricular thalamus, and ventromedial hypothalamic nucleus for HCRTR1, and cortex, septal nuclei, paraventricular thalamus, paraventricular and arcuate hypothalamic nuclei, and pontine gray area for HCRTR2. In almost all cases, these two receptors have excitatory effects, although there is suggestion of promiscuous coupling of these receptors to multiple G-proteins with occasional inhibitory effects.

It has been hypothesized that the loss of excitatory input to monoaminergic cell groups mediates the sleepiness and short REM sleep in narcolepsy. Indeed, the activity of most monoaminergic cell groups such as locus coeruleus, raphe, and tuberomammillary nuclei, but not the dopaminergic systems in the

Figure 2 Preprohypocretin *in situ* hybridization in the posterior hypothalamic region in a narcoleptic (a) and control (b) human subject. Note the hypothalamic location of cell body and widespread projection through the entire neuroaxis. Scale bar = 1 cm (a, b). Reproduced from Peyron C, Faraco J, Rogers W, et al. (2000) A mutation in a case of early onset narcolepsy and a generalized absence of hypocretin peptides in human narcoleptic brains. *Nature Medicine* 6: 991–997. (c) Reproduced from Peyron C, Tighe DK, van den Pol AN, et al. (1998) Neurons containing hypocretin (orexin) project to multiple neuronal systems. *Journal of Neuroscience* 18: 9996–10015.

ventral tegmental area and substantia nigra, is depressed during sleep and almost silent during REM sleep. The fact that narcolepsy is typically treated with drugs that indirectly stimulate monoaminergic transmission (e.g., amphetamine-like compounds and antidepressants) is also in line with this hypothesis.

Interestingly, hypocretin effects on wakefulness after intracerebroventricular injections are largely blocked or attenuated by monoaminergic blockers, most notably antihistaminergic compounds, suggesting a primary role for downstream histaminergic systems. An important role for histamine is also suggested by findings indicating significantly decreased CSF histamine levels in narcolepsy–cataplexy, a result contrasting with more variable changes in other monoamine and metabolites.

Without hypocretin, narcoleptic patients have sleepiness, inappropriate REM paralysis during wakefulness (cataplexy and sleep paralysis), REM dreaming before falling asleep (hypnagogic hallucinations), and disorganized nighttime sleep. Rapid transitions into REM sleep can be observed during nocturnal sleep and while napping. Finally, narcolepsy is often associated with an increased body mass index and obesity, a possible consequence of sleepiness and decreased energy expenditure.

Little is known regarding the normal function of hypocretins. Hypocretin neurons integrate metabolic and sleep/wake-related inputs. The relative contribution of these various factors may vary across species. In rodents, these cells have receptors for leptin and ghrelin, and they are sensitive to glucose changes, likely facilitating wakefulness in reaction to changes in food availability. In rodents, electrophysiological recording of these neurons indicate maximal activity during wakefulness, especially during purposeful activity. Activity is low during non-REM and REM

Figure 3 HLA-DQB1*0602 positivity (top) and hypocretin deficiency (bottom), as measured in the cerebrospinal fluid (CSF). (Top) Almost all patients with typical cataplexy are DQB1*0602, suggesting etiological homogeneity. DQB1*0602 positivity decreases in patients with atypical and no cataplexy, but it is still higher than control values. Subjects with idiopathic hypersomnia (isolated sleepiness and no REM transitions) have a normal DQB1*0602 frequency, suggesting no pathophysiological overlap. (Bottom) CSF hypocretin-1 in controls, narcolepsy, and idiopathic hypersomnia. The large majority of subjects with typical cataplexy have low CSF hypocretin-1. Quantitative receiver curve analysis has indicated that values below 110 pg ml^{-1} are most predictive of a narcolepsy diagnosis, although control values are typically above 200 pg ml^{-1}. Only 20–40% of cases without cataplexy have low CSF hypocretin-1. None of the controls or cases with idiopathic hypersomnia have low CSF hypocretin-1. (Top) Reproduced from Lin L and Mignot E (2007) HLA and narcolepsy: Present status and relationship with familial history and hypocretin deficiency. In: Bassetti C, Billiard M, and Mignot E (eds.) *Narcolepsy and Hypersomnia*. New York: Dekker/Taylor & Francis. (Bottom) Reproduced from Mignot E, Lammers GJ, Ripley B, et al. (2002) The role of cerebrospinal fluid hypocretin measurement in the diagnosis of narcolepsy and other hypersomnias. *Archives of Neurology* 59: 1553–1562.

sleep. Hypocretin release is also tightly coupled with locomotor activity in rodents, an effect less evident in wake-consolidated species such as the squirrel monkey. Hypocretin release is also driven by the circadian clock and peaks at the end of the active (wake) period. Finally, hypocretin release is increased by even a brief sleep deprivation, suggesting a role for the hypocretin system in consolidating wakefulness in the face of a mounting sleep debt. This last role of hypocretin may explain the inability of narcolepsy patients to stay awake for periods typically longer than a few hours, as sleep debt is increasing. As expected for a wake-promoting signal, these cells are more active during active wake, decrease their activity during non-REM sleep, and are least active during REM sleep. The sleep stage-specific activity is consistent with a role in promoting wakefulness and inhibiting REM sleep.

Is Narcolepsy an Autoimmune Disorder?

The tight HLA association and the involvement of both genetic and nongenetic factors in the pathophysiology of narcolepsy suggest an autoimmune basis for the disorder. This hypothesis is also consistent with the peripubertal onset of the disease but not the even sex ratio found in the disorder. The discovery of hypocretin-producing cells as a potential target has given further credence to the autoimmune hypothesis. HLA-DQ is expressed on the surface of B cells,

macrophages (including microglia), and activated T cells. It is a heterodimer composed of an α and a β chain encoded by the polymorphic DQA1 and DQB1 genes, two genes in tight linkage disequilibrium. HLA-DQ binds peptide fragments and can present the resulting complex to other cells of the immune system, as recognized by the T cell receptor complex (Figure 1).

How HLA molecules in general and HLA-DQ in particular predispose to autoimmune disorders is not well understood. It probably involves the ability of some HLA alleles to bind and consequently present specific autoantigens to the rest of the immune system. In other HLA-associated diseases, however, antibodies directed toward the potential target (e.g., islet cell antibodies in type I diabetes) or T cell clones with primary responsiveness to target antigens (e.g., against myelin basic protein in multiple sclerosis) can be detected. In narcolepsy, however, all attempts to demonstrate T cell reactivity against hypocretin peptides or to detect autoantibodies directed at hypocretin-producing cells have failed.

These generally negative results do not necessarily exclude the possibility of an autoimmune mechanism, but they do raise the possibility of other, more complex neuroimmune mechanisms. Another possibility is an infectious agent with particular tropism toward hypocretin-producing cells, although HLA association in infectious diseases is usually not very tight or it is primarily to a single allele. Alternatively, it has been suggested that these neurons could be unusually sensitive to excitotoxicity. Interest in the autoimmune arena has been rekindled by case reports that intravenous immunoglobulin may reduce the development of narcolepsy severity if administered within a year of onset.

Narcolepsy without Cataplexy

The importance of cataplexy in the diagnosis of narcolepsy has long been suggested by clinical studies. The finding that almost all cases with definite cataplexy (defined as recurrent episodes of muscle paralysis triggered at least sometimes by typical emotions such as laughing or joking) are HLA-DQB1*0602 positive strongly suggests etiological homogeneity in these cases. This was further confirmed by the finding that almost all HLA-positive patients with cataplexy have low CSF hypocretin-1 (Figure 3). In contrast, HLA-DQB1*0602 is typically found in 40% of patients without cataplexy or with doubtful or atypical cataplexy (rare events or only events triggered by unusual emotions). This is matched by a much lower percentage of patients without cataplexy who have low CSF hypocretin-1 (5–30% of patients, depending on the specific case series) (Figure 3). Some of these cases (approximately one-third) are children with recent onset ($\leq$4 years) who are likely to develop cataplexy within a few years.

These results are consistent with two possible, nonexclusive pathophysiological models for narcolepsy without cataplexy. In the first model, narcolepsy both with and without cataplexy is part of the same disease continuum, with similar pathophysiological effects on hypocretin transmission. Narcolepsy with cataplexy is a generally more severe form of the disease, most commonly associated with an almost complete destruction of the hypocretin system. HLA-DQB1*0602 may be a severity factor more likely to predispose to complete hypocretin destruction. Only in rare cases with cataplexy would hypocretin cell loss be partial but sufficient to produce normal levels of hypocretin and a narcolepsy phenotype. In these cases, compensation by the remaining hypocretin cells likely maintains CSF hypocretin-1 at normal levels. Projections with more effects on CSF hypocretin-1 but of less functional importance for the phenotype (e.g., hypocretin afferents to the spinal cord) also may be more spared in cases with cataplexy and normal CSF levels.

In narcolepsy without cataplexy, cell loss would be less pronounced. The severity of the disease would be generally lower and the cell loss insufficient to result in low CSF hypocretin-1. The HLA-DQB1*0602 association with narcolepsy without cataplexy is weaker. Only in rare cases might neuroanatomical destruction be pronounced, resulting in low CSF hypocretin-1 but still sparing a select hypocretin cell subpopulation projecting to cataplexy-triggering pathways. In support of this model is a study by Thannickal et al. in which 14% of hypocretin cells remained in a case without cataplexy versus 4.4–9.4% remaining cells in five other subjects with cataplexy. Lesion studies in rats also indicate a 50% decrease in CSF hypocretin-1 with a 77% destruction of hypocretin cells, suggesting some degree of compensation.

The fact that HLA-DQB1*0602 is slightly increased in frequency in cases without cataplexy but with normal CSF hypocretin-1 is also consistent with this hypothesis. This finding, however, remains to be confirmed in a population-based sample because HLA positivity may have been increased in clinical samples due to a bias in inclusion (some clinicians use HLA typing to confirm the diagnosis of narcolepsy without cataplexy). The model also predicts that a large number of narcolepsy without cataplexy cases may exist in the general population but have a milder phenotype, consistent with our observation of slightly decreased REM latency in normal population subjects with HLA-DQB1*0602. Similar milder forms of the disease or long latent periods have been suggested for

other autoimmune diseases, such as DQ2-associated celiac disease, B27-associated spondylarthropathies, and DR3/DR4-associated type I diabetes. In type I diabetes, for example, a larger number of individuals, especially relatives of affected probands, may be positive for islet cell antibodies without ever developing the disease.

In the second model, the cause of cases without low CSF hypocretin does not involve partial hypocretin cell loss. Other systems downstream of hypocretin, such as hypocretin receptors, histamine, or neuroanatomical systems not associated with hypocretin neurobiology, may be involved. Of note, the two models may not be entirely exclusive. A partial hypocretin cell loss may, for example, not be sufficient in itself to produce symptoms but could lead to narcolepsy when associated with additional defects downstream. A similar model, albeit speculative, has been proposed in some obese-type diabetes children in which both types I and II may coexist. In these cases, subjects with partially reduced islet cell numbers may be asymptomatic when lean but develop insulin resistance if obesity develops and the remaining islet population is unable to produce enough insulin to keep up with increased tissue demand.

To distinguish between these models, neuropathological studies of narcolepsy without cataplexy cases are urgently needed. It is also imperative to study narcolepsy without cataplexy not only in clinical samples but also in the general population because clinical cases may represent a more severe and selected subpopulation. We believe that the most likely explanation will be a combination of these models, including both disease heterogeneity with respect to hypocretin neuropathology and severity gradients for hypocretin cell loss as discussed previously. The extent of this overlap remains to be defined.

The previous discussion is important because the real population-based prevalence of narcolepsy without cataplexy is unknown. Data by our group and others suggest that several percent of the population have unexplained sleepiness and REM transition. Whether a small or large portion of these subjects have a mild degree of hypocretin dysfunction (possibly related pathophysiologically to narcolepsy–cataplexy) is unknown.

Therapies for Narcolepsy

Good sleep hygiene, education, and treatment compliance are important to the management of narcolepsy. Referral to support groups such as the Narcolepsy Network is helpful. Fixed wake-up times, sleep diaries, and regular sleep schedule are recommended. Obesity may develop especially in young children when disease onset is abrupt. It is useful to restrict diet, encourage exercise, and treat sleepiness aggressively at this stage. The risk of driving while sleepy, especially prior to adequate therapy, must be discussed and, if appropriate, regulatory agencies notified. Patients with narcolepsy must avoid jobs that put others in danger and should consider activities that are less sedentary. Jobs that involve repetitive tasks or sitting and looking at a computer all day can be difficult. Employers or teachers can be asked to accommodate 15- to 30-min scheduled naps.

Modafinil is now first-line, standard-of-care treatment for sleepiness associated with narcolepsy. Amphetamine-like stimulants, such as methylphenidate, dextroamphetamine, amphetamine racemic mixture, and methylamphetamine, can also be used but have a number of disadvantages. They are potentially addictive and should preferably be reserved for patients with a well-established diagnosis (e.g., those with cataplexy). Additionally, side effects such as palpitations, hypertension, and nervousness may occur because of their action on the autonomic nervous system. The mode of action of amphetamine-like stimulants and modafinil on wakefulness is thought to involve increased dopaminergic transmission through the inhibition of dopamine reuptake (modafinil and methyphenidate), by increasing dopamine release (methyphenidate), or through more complex effects on release and storage (amphetamine).

Antidepressants are commonly used to treat cataplexy. The rationale for their efficacy is the profound REM suppressant effects most antidepressant share. They are also effective for sleep paralysis and hypnagogic hallucinations, a sometime disabling symptom. Tricyclics are very effective but have anticholinergic side effects. Serotonin reuptake specific inhibitors are efficacious, but relatively high doses are generally needed. Newer medications targeting norepinepherine reuptake, such as venlafaxine and atomoxetine, are most effective. The dual serotoninergic/noradrenergic reuptake inhibitor venlafaxine is a typical first-line treatment. Atomoxetine, a specific adrenergic reuptake inhibitor typically prescribed for attention deficit hyperactivity disorder, can also be used and as it is mildly stimulant. Patients should be warned that rebound cataplexy usually occurs when medications are discontinued, changed, or skipped.

Sodium oxybate (γ-hydroxybutyrate (GHB)) is unique because it is efficacious on all symptoms. This naturally occurring compound is a potent but short-acting hypnotic that consolidates slow-wave and REM sleep, most likely via $GABA_B$ agonistic effect. It has been available since the 1970s but was only recently approved for the treatment of cataplexy. It is thought that the consolidation of nocturnal sleep and REM sleep leads to decreased daytime symptoms. The drug

is carefully controlled and can be addictive. It is typically reserved for narcoleptic with both disturbed nocturnal sleep and cataplexy.

Narcolepsy is frequently associated with other sleep disorders. Sleep apnea, a condition in which patients snore and gasp during sleep, is common and must be treated especially if GHB is to be used. Periodic leg movements (repetitive leg twitching occurring during sleep) are also common but very rarely need treatment.

Perspectives for New Treatments

The realization that narcolepsy and related pathologies are not rare is fueling pharmaceutical interest in this area. Novel symptomatic agents are being developed. Agents that act on the histaminergic system, such as H3 antagonists (compounds that increase histamine release through the blockade of the H3 autoreceptor), are being studied. These compounds are wake promoting and effective in animal models of narcolepsy.

New treatments aimed at replacing the missing hypocretin hormone are being developed and will probably be much more effective. These may involve developing hypocretin receptor agonists, preferentially of the HCRTR2 type, using gene therapy or using cell-based replacement therapy. Research aimed at discovering the process that destroys the hypocretin-containing cells in the brain is ongoing. Understanding this process is necessary before truly preventive and curative strategies can be developed.

Natriuretic Peptides

M L Kuroski de Bold and A J de Bold, University of Ottawa Heart Institute, Ottawa, ON, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The natriuretic peptide (NP) system comprises three polypeptides hormones: atrial natriuretic factor (ANF or ANP), brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP). These peptides are encoded by three different genes which encode a similar 17-amino-acid disulphide loop present in all three peptides (Figure 1). ANF and CNP amino acid sequences are highly conserved. In contrast, the amino acid sequence of BNP varies considerably among the species.

Peripherally, ANF and BNP are synthesized and stored in atrial cardiocytes. Increased secretion of these peptides over baseline is observed in response to stretch of the atrial wall and various neurohumoral stimuli. ANF and BNP are also present in the ventricles of the heart in concentrations that are many times lower than that of the atria. These NPs are expressed in tissues other than cardiac, such as in kidney and gonads. ANF and BNP gene expression in neural tissue is widespread.

ANF and BNP share potent vasodilatory, diuretic, natriuretic, and antigrowth properties. They also inhibit renin and aldosterone production and sympathetic tone (Figure 2). The diuretic and natriuretic actions exerted by these hormones occur without the expected rebound response by the renin–angiotensin–aldosterone and sympathetic systems.

CNP does not have natriuretic activity but is a potent vasodilator and inhibits smooth muscle proliferation. CNP is present in significant amounts in the central nervous system (CNS) and in the vascular endothelium. In cerebrospinal fluid CNP is the most abundant NP.

There are three subtypes of receptors for NPs: NP receptor A (NPR-A), NP receptor B (NPR-B), and NP receptor C (NPR-C) (Figure 3). ANF and BNP bind to NPR-A, which has guanylyl cyclase activity. The ligands thus induce an increase in intracellular cyclic guanosine monophosphate (cGMP) levels as a first step in a signaling cascade that may involve enzymes or ion channels. ANF has 50 times more affinity for NPR-A than BNP. NPR-A is expressed in a variety of tissues including kidney, adrenals, lung, thymus, and the gastrointestinal tract. In the brain, NPR-A is found in the cortex, hippocampus, thalamus, amygdala, and cerebellum.

CNP binds exclusively to NPR-B, which is also a guanylyl cyclase. It is the most abundant NP receptor in the rat hypothalamus.

NPR-C is a clearance receptor. The affinity of this receptor for NP is ANF > CNP ≥ BNP. There is some evidence showing that NPR-C might be coupled to G-protein signaling. Peripherally, NPR-C is expressed by many tissues. In the CNS, NPR-C is localized in the striatum, neocortex, hippocampus, amygdala, and pituitary gland, among others.

Natriuretic Peptides in the CNS

ANF

ANF is present in areas that are involved in neuroendocrine regulation such as the hypothalamus, thalamus, septum, olfactory bulb, and cortex. In the CNS, most ANF-containing cell bodies are found in the anterolateral region of the third ventricle. High levels of ANF are found in the anteroventral third ventricular area (AV3V) and septal regions. The distribution of ANF and its receptor in the brain, much of it shared with the angiotensin 2 receptor, suggest that they might be involved in the modulation of blood pressure, fluid regulation, and sympathetic tone. In the spontaneously hypertensive rat, a reduction in ANF-binding sites in all areas of the brain has been reported as compared with normotensive Wistar rats. An upregulation of ANF receptors in the subfornical organ has been shown after acute dehydration.

ANF and inflammation In the brain, microglial cells, the macrophage-like cells that are activated by neuroinflammation induced by lipopolysaccharide, brain injury, or infection, have been shown to express the message for the ANF receptors NPR-A, NPR-B, and NPR-C. Exposure of microglial cells *in vitro* to bacterial endotoxin induces a significant intracellular increase in nitric oxide and interleukin-1β. These effects are inhibited by ANF.

The hypothalamic–pituitary–adrenocortical (HPA) system and ANF Several studies indicate that ANF plays an important role in the modulation of the neurohumoral response to stress hormones (e.g., vasopressin, cortisol, and catecholamine). An increase in the release of corticotrophin-releasing hormone stimulates the secretion of ANF, which in turn decreases cortisol and catecholamine secretion and decreases sympathetic activity. Thus, the decrease in the stress hormone response due to ANF supports the notion that this peptide might exert a direct interaction with

Figure 1 Human natriuretic peptides amino acid sequence. Atrial natriuretic factor (ANF), brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP) share a 17-amino-acid ring created by a disulphide bond between two cysteine residues. The conserved amino acid residues are shown.

Figure 2 Main sites of synthesis for natriuretic peptides (ANF, atrial natriuretic factor; BNP, brain natriuretic peptide; CNP, C-type natriuretic peptide) and their biological actions are shown. ADH, antidiuretic hormone; ACTH, adrenocorticotropin; CRH, corticotrophin-releasing hormone; $U_{Na}V$, urinary sodium excretion; UV, urine volume; GFR, glomerular filtration rate.

the hypothalamic–pituitary–adrenocortical (HPA) system and the autonomic nervous system in conditions such as panic and anxiety disorders. Most of the studies to date have been short term; the long-term effects of ANF upon the CNS need to be investigated.

CNP appears to have the opposite effects of ANF, but there are few studies reported on this peptide's effects on the brain.

ANF and alcohol withdrawal High ANF circulating levels and brain-secreted ANF appeared to be involved in modifying the clinical symptoms of alcohol withdrawal (AW) reactions. In AW there are significant changes in volume and electrolyte homeostasis due to the changes in the secretion of hormones such as ANF, aldosterone, and renin. In humans, it has been shown that in patients with severe AW, the plasma ANF,

Figure 3 Natriuretic peptide receptors. Atrial natriuretic factor (ANF) and brain natriuretic peptide (BNP) binding activates natriuretic peptide receptor A (NPR-A), a process that requires adenosine triphosphate (ATP), which results in the increased production of cyclic guanosine monophosphate (cGMP). NPR-B, natriuretic peptide receptor B; NPR-C, natriuretic peptide receptor C; CNP, C-type natriuretic peptide; KHD, kinase homology domain; GTP, guanosine triphosphate.

renin activity, and aldosterone levels were increased as compared to age-matched controls. During partial recovery, plasma renin activity and aldosterone returned to normal levels but ANF remained high for the duration of the observation period. It was also noted that patients who developed delirium tremens showed plasma ANF levels significantly higher than in those who were undergoing withdrawal but who did not exhibit delirium tremens. This study confirmed the fact that in alcoholic patients there are significant alterations of the hormones that regulate fluid and electrolyte homeostasis and that measurement of ANF might be a useful diagnostic tool to predict the onset of delirium tremens.

The relationship between ANF and alcohol has been investigated in alcohol-tolerant/dependent mice. Upon alcohol withdrawal these animals exhibit hyperreactivity to noise, handling, and convulsion similar to humans. The hyperreactivity to handling was measured following removal of alcohol before and after intracerebral administration of ANF. It was found that medium to high doses of ANF significantly reduced handling-induced convulsions. These studies suggest that ANF plays a significant role in the control of the CNS symptoms of alcohol withdrawal.

BNP

BNP was originally isolated from the porcine brain, but its main site of synthesis, storage, and release is, like ANF, in the atria of the heart. BNP-binding sites are found in the subfornical organ, supraoptic nucleus, and paraventricular nucleus. BNP was shown to compete with the majority of the high-affinity binding sites for ANF in the rat's brain. Immunohistochemically, BNP is localized in the hypothalamus of the rat and the cynomolgus monkey. These findings suggest that BNP in concert with ANF is involved in CNS mechanisms for modulating cardiovascular homeostasis.

CNP

CNP is abundantly expressed in the brain and vascular endothelial cells. CNP and its cognate receptor NPR-B have been detected in various regions of the brain (e.g., the subfornical organ, median preoptic nucleus, and interpeduncular nucleus). CNP and NPR-B are also found in the olfactory epithelium, suggesting that they might play a role in the differentiation of olfactory receptor neurons. CNP and NPR-B gene expression is present in the embryonic mouse nervous system as early as embryonic day 10.5. The structures included developing ganglia, cranial trigeminal ganglion, and segmental dorsal ganglia. These studies show that CNP through its receptor NPR-B exerts multiple effects such as stimulation and inhibition of DNA synthesis in Schwann cells and embryonic hindbrain precursors. CNP has also been shown to inhibit proliferation of olfactory precursors; thus, it is apparent that through NPR-B, CNP could play area- and phase-specific tasks throughout the development of the peripheral and central nervous

systems. Nevertheless, the exact function of CNP in the CNS has not been elucidated as yet.

Natural Images: Coding Efficiency

D J Graham and D J Field, Cornell University, Ithaca, NY, USA

Introduction

Images and movies of the natural world are known to share a variety of statistical regularities. Such stimuli show consistent spatial statistics, spatiotemporal statistics, contrast and intensity distributions, and chromatic structure. Consider the images shown in Figure 1. The top row shows white noise and the bottom row shows natural scenes. A process that generates random white noise images will generate all possible images with equal probability. However, because of the statistical regularities of natural scenes, the possibility of seeing a natural scene generated from a white noise process is extremely low. For even a small 8×8 pixel patch, the entropy of the white noise patches with 8 bits of gray level is $8 \times 8 \times 8$, or 512, bits. This results in a total of 2^{512}, or about 10^{154} equally probable images. Natural scenes are considerably redundant (i.e., they have much lower entropy), with estimates that they contain approximately 40% of the entropy of white noise for small (8×8) patches, and still lower relative entropy for larger patches. This difference would in turn imply that a single white noise pattern out of 10^{90} would have the basic statistics of natural scenes (assuming a flat distribution). Although the precise ratio requires an estimate of the true distribution, the estimate does demonstrate just how redundant natural scenes are. Because of this redundancy, it is possible to build a visual system that is efficient if it is specifically dedicated to representing such an environment. A visual system can reduce the size of its problem space and focus its efforts on what it is likely to encounter in the world. Because of this redundancy, visual systems can be shaped by evolution and development to take advantage of the environment.

Using the supposition that the visual system employs codes that approach optimal efficiency with respect to predictable (i.e., redundant) structure, one can go some way in explaining why visual neurons show the coding properties they do. A number of studies have shown success at predicting many of the basic linear properties of visual neurons. In the following sections we will review some of this work. But we note that this work and any extension of it depend on the appropriate definition of efficiency. In the classical definition of efficiency used in engineering, a system is most efficient if all of its work (within limits imposed by thermodynamics) is done in service of its task. In this view, efficiency presumes that the system has some well-defined tasks, and that the system's design is a direct reflection of the need to do as little work as possible to achieve those tasks. But how do we define these tasks for biological systems?

Efficient for What Task?

Many sensory systems, the task or 'goal' of which is often readily definable and measurable, have sensitivity that is near their physical limits. With respect to the brain as a whole, however, the only clearly defined task is the most general one in biology: differential reproductive success. But this goal tells us little about why a visual system would have the structure it does. Clearly, the visual system is involved in vision, but to treat it as an independent subsystem with some basic input/output relationship is too much of a simplification. Certainly, the output of the visual system cannot be reduced to a behavior. And although it may seem computationally reasonable, there is little reason to presume that the output of the visual system is simply some 'object-detector.' There are three reasons for this: (1) object recognition is not a well-localized processing task in cortex, (2) no known congenital disorder obliterates this ability exclusively, and (3) patients with visual agnosia caused by lesions typically show severe deficits in other visual faculties. Even though object recognition is distributed, one might still propose that object recognition could be the collective goal of the visual system's many parts. But object recognition surely competes for neural real estate with areas whose goals include accurate spatial mapping, motion predictions, and a host of other tasks.

This difficulty in defining the visual system's general goal is likely to prove a significant hurdle for studies attempting to apply efficient coding theories to later stages of processing. In addition, our current ability to predict a neuron's behavior is significantly limited at these later stages. Much of the success of efficient coding techniques has been in the application to neurons relatively early in the visual pathway (retina, lateral geniculate nucleus (LGN), and V1). For neurons in these areas, the family of response properties is relatively well defined and it is possible to talk about how the information in the visual image is represented with the array of neurons in each of these areas. This in turn allows us to address the question of whether the array of neurons is processing the information efficiently. However, the approach still requires a precise definition of efficiency.

Figure 1 A process that chooses pixel intensity randomly will produce white noise images (top). Images resembling natural scenes (bottom), would almost never occur in such a process.

Defining Efficiency

For those who have proposed theories of optimality in early visual coding, much of the discussion has centered on the metric of efficiency. The majority of the work in the field focuses on what we will call representational efficiency. Such studies employ the tools of information theory, and they have explored the properties of neurons that are involved in representing the image. These studies have focused on issues relating to correlations and statistical independence in the firing rates of neurons. Much of this work has involved neural networks and computational models of visual areas. A second line of research has focused on what we call metabolic efficiency. Several influential reports have described investigations of the metabolic costs of generating spikes, and others have argued that constraints that minimize wiring are important for explaining known neuronal properties. In this article, we propose a third form of efficiency that we call learning efficiency. We argue that an important consideration for any sensory system is the challenge of learning about the relative probability of events in the world based on a handful of samples. To the extent that the visual system is optimally efficient at carrying out its multitude of tasks, these efficiency rules are likely to each contribute significantly to a description of why the visual system is designed as it is. Visual systems may approach optimality (in the engineering sense of the word) across each of these three dimensions, but as we will argue, one of these dimensions – learning efficiency – is one that engineers rarely consider. These dimensions are not necessarily orthogonal to one another, nor do they currently all have well-defined units of measurement. These dimensions are mere sketches of the terrain over which the human visual system appears to have been optimized through evolution. Furthermore, we believe these dimensions can find application in other modalities as well, though here we focus on the visual system. Together, these efficiency dimensions may also suggest ways to design efficient artificial visual systems.

Representational Efficiency

Marcelja, in 1980, was the first to propose that neurons found in the primary visual cortex (V1) show a number of similarities to the mathematical functions

described by Gabor's 1946 theory of communication. Later studies (by Field and Tolhurst, in 1986; and Jones and Palmer, in 1987) confirmed that Marcelja's Gaussian-modulated sinusoid model (i.e., the Gabor function model) provided a good first-order approximation to the receptive field properties of these neurons. Some of the first computational models of the early visual system (e.g., by Watson, in 1983; and Daugman, in 1985) demonstrated how an array of neurons with these properties can represent a visual image. However, this work left unresolved the important question of 'why' such a solution might evolve.

One approach suggests that an understanding of the 'why' question requires consideration of the environment in which the system functions. This approach suggests that theories should be guided by an understanding of the statistics of natural scenes. Early television researchers, and later, in 1987, Field and Burton and Moorhead, found that the Fourier spatial frequency spectra of natural scenes typically fall off as $1/f^k$, where f is spatial frequency and k is approximately 1.2. This regularity expresses the same redundancy as the autocorrelation function of scenes, which measures how similar neighboring points are in terms of luminance. The $1/f$ structure follows from two properties: (1) neighboring points are correlated and (2) the images are roughly scale invariant. A number of studies have shown that there are a wide variety of forms of redundancy found in natural scenes that go beyond the pairwise correlations and spatial frequency spectra (see later). However, pairwise correlations have been the source of a number of theories regarding efficient coding and many researchers imply that these are the most relevant statistics, so we begin with a discussion of such correlations.

Correlation and Decorrelation

When the notion of stimulus redundancy is considered, most analyses typically refer to the pairwise correlations in the data. Many of the earliest theories of efficient sensory coding developed from the notion that if the neural responses to two stimuli are correlated, then an efficient system should strive to represent the data with reduced correlation. This is certainly one important form of redundancy. In recent work, Chandler and Field argue that the pairwise correlations (as represented by the power spectra) account for approximately 40% of to the total redundancy in natural scenes (for 8×8 natural scene patches).

In theory, any representation with significant correlations implies that most of the signal lies in a subspace within the larger space of possible representations. By choosing a representation that codes for only that subspace, it is possible to represent the data with significantly reduced dimensionality (e.g., a reduced number of neurons, or a smaller dynamic range of responses). Srinivasan, Laughlin, and Dubs showed that the center-surround structure of fly large monopolar cells is well matched to the correlations in a collection of scenes they considered relevant to the fly. Given a certain level of noise, they found that a weighted, linear sum over space transmits the greatest amount of information about their collection of natural inputs. Atick and Redlich continued this line of inquiry, arguing that the amplitude spectra of natural scenes are effectively flattened once they reach retinal outputs. The argument is that the roughly linear rise in sensitivity with increasing spatial frequency is inversely related to the $1/f$-distributed fall-off in natural scene spectra, thus allowing neighboring neurons to be uncorrelated (i.e., have a flat spectrum). Atick and Redlich argued that this decorrelation is reflected in a flattening of the spatial frequency response of retinal ganglion cells. However, this argument is dependent on appropriate spacing of retinal neurons. Moreover, the current evidence suggests that neighboring neurons are significantly correlated in the presence of natural scenes.

We have recently argued that an independent goal of retinal coding is to achieve compression while maintaining equal response magnitude across the array of neurons of different sizes. This approach achieves a form of response spectrum flattening but it is quite independent of whether the neurons are tuned and spaced ideally to achieve decorrelation. This work suggests that, in order to explain the details of neural response properties, we must acknowledge that decorrelation in the retina and LGN is far from complete and that efficient coding schemes must consider additional constraints.

Optimal Information Transfer

Another strategy attempts to utilize each level of response magnitude with equal frequency. To this end, Laughlin compared the distribution of local contrasts in the blowfly environment with contrast responses in large monopolar cells in the creature's eye. The intensity-response function measured for these cells is well matched to a distribution of natural contrasts, such that the range of possible responses approximates the information-theoretic ideal. In other words, contrast responses in the fly are distributed across the range of environmental contrasts in such a way as to minimize the number of 'code words' necessary for transmitting information about the entire range of contrasts at a given fidelity. Later studies have shown that adaptation of visual neurons with respect to local luminance,

orientation, and contrast can also be addressed using this maximum information transfer (infomax) approach. A more elaborate extension of infomax models combines feedback of stored predictors from higher cortical areas with typical natural inputs. These schemes optimize over families of representations that minimize error between the input and a top-down representation. Feedback representation optimization models of this sort effectively produce a system whereby primary visual areas reduce their response as higher areas provide better descriptions of input 'content,' in line with recent imaging findings. It should be noted that in many infomax models, optimal redundancy reduction (decorrelation) and maximum information transfer strategies are equivalent.

Beyond Correlations: Sparseness and Independence

The pairwise correlations found in natural scenes represent only one form of redundancy. Figure 2 shows two images – a natural scene and noise – with similar $1/f$ structure and therefore similar pairwise correlations. There are a number of ways to describe the differences between these two images. For example, they differ in their phase spectra. But the two images can also be described in terms of differences in their sparse structure. For the $1/f$ noise image, all linear representations produce response distributions that are Gaussian. However, for the natural scene, some projections of the data are non-Gaussian. That is, when the appropriate array of linear filters is used to represent a natural scene, the histogram of activity will be a non-Gaussian histogram.

As noted by Field, a non-Gaussian histogram implies low entropy in the first-order responses and relatively high entropy in the higher order relationships between the filters for a linear transform (i.e., more independent). In other words, a system that produces maximally non-Gaussian histograms produces a representation wherein the neurons are maximally independent. This is the basic idea behind sparse coding algorithms and independent components analysis (ICA).

In a code with maximal independence, the firing of each neuron provides maximal unique information (i.e., the sharing of information with other neurons has been minimized). If the data consist of an array of relatively rare, sparse events, then matching the neurons to those events will produce activity that is sparse. The definitions of sparseness have varied in the literature. In general, 'sparse' implies a relatively high probability of no activity across the population, and some proportion of relatively active neurons. In the computational literature, in which neurons are often modeled as linear operators, the kurtosis (the fourth statistical moment) of the response histogram can be used to describe relative sparseness. Other metrics, such as the sparseness index, have proved more useful for spike trains.

Field demonstrated that arrays of linear neurons with properties like those found in primary visual cortex appear to maximize the sparse response to natural scenes. Olshausen and Field further demonstrated that a neural network that attempts to represent natural scenes and maximize sparseness will produce an array of neurons with spatial properties like those found in cortical simple cells. That is, a system that is forced to produce a faithful representation of the input using only a handful of neurons (each firing near its maximum response when it is active) gives simple-cell-like receptive fields. This suggests that at least at the level of primary visual cortex, visual system representations show evidence of being efficiently matched to the sparseness of natural scenes. Similar results have been found for spatiochromatic stimuli and spatiotemporal patterns.

It must be emphasized that sparse outputs of these networks result from the sparse structure of the data. It would be relatively simple to produce a

Figure 2 Noise with a spatial frequency amplitude spectrum like that of natural scenes (left) has the same pairwise correlations as does the natural scene (right), but lacks other statistical regularities of scenes.

nonlinearity that forces a sparse output independent of the input, one that would not be an efficient coding strategy. The networks described earlier expressly search for the sparse structure that exists in the data. Moreover, recordings of primate visual neurons in response to natural scenes have also been shown to produce a sparse output. Visual neurons show sparse responses both in early stages of cortical processing, such as V1, and in higher levels, such as inferotemporal cortex. Highly sparse firing is a widespread phenomenon in a variety of brain areas and species, including monkey association areas, rabbit motor areas, rat somatosensory areas, rat auditory areas, rat hippocampus, and centers believed to be involved in bird song generation.

However, the sparse response of these neurons is not direct evidence that these neurons are efficiently representing the environment. All of these neurons are nonlinear, and higher level neurons are very nonlinear. A proof that these codes are efficient would require a clear understanding of how the array of neurons represents the input image. We are not at this level of understanding – and we may never be. Most visual neurons beyond the retina can be modulated by higher levels of processing. Although a number of studies have implied that a decent theory of primary visual cortex is close at hand, Olshausen and Field have argued that we are still a long way from such a theory. Part of the argument comes from the work of the Gallant lab. This work has been an effort to measure the responses of primate visual neurons to a set of natural stimuli and to predict from these responses how each neuron would respond to an arbitrary natural scene. Gallant and colleagues have found that even in V1, typically less than 50% of the response variance to new stimuli can be predicted. In higher levels of the visual system, that prediction accuracy is further reduced. In addition, as noted by Olshausen and Field in 2005, recording studies select only a small portion of the neurons in any given area, and researchers typically record only from large pyramidal neurons that produce large spikes. Other neuron types (e.g., granular neurons that produce smaller spikes) are often not surveyed in these studies, which has led to the interesting suggestion by Shoham and colleagues that there exists a neural 'dark matter' problem.

Optimality with Nonlinear Systems

Despite the difficulties in providing a clear metric for defining efficiency in nonlinear systems, a number of efforts have been made to generalize efficiency arguments to account for the known nonlinear properties of visual neurons. One particularly fruitful approach involves a technique called slow feature analysis. According to this model, a stimulus moving across an image results in quick changes to the neurons responding to the input (for a linear array of neurons). If we consider the histogram of neural activity integrated over some time period, we would find that the activity is less sparse than in a single time frame. However, the changes in images are not random and are often caused by objects or backgrounds showing consistent movement. Slow feature analysis attempts to take into account this redundancy in the movements of features. The technique attempts to find nonlinear solutions that are capable of describing the moving images with a relatively consistent set of neurons, despite the changes that are occurring. Slow feature analysis has been demonstrated to produce nonlinear behavior like that shown with complex cells. It has been argued that current implementations of slow feature analysis are mathematically equivalent to a form of spatiotemporal ICA. Given that object identities are relatively invariant over time, there is hope that these lines of work will eventually be capable of producing object-level representations like those found in inferotemporal cortex. However, we have not yet reached that point.

There exist a variety of techniques that come under the general heading of nonlinear ICA. Although this area of research is too vast to be reviewed here, it should be noted that many of these studies have generated some of the nonlinear properties of visual neurons. However, since we do not yet have a complete model of the nonlinearities in these neurons, we cannot yet argue that such techniques are capable of accounting for the full array of neural properties in any region of visual cortex.

Without a clear account of how information is represented in any given area, we are left without any kind of proof that the information is represented efficiently. Linear models that optimize sparseness and independence do produce simulated neurons with many properties like those found in V1. This certainly supports the notion that V1 is directed toward an efficient code for natural scenes. But as we will argue in the next sections, there are both metabolic and learning costs for high sparseness and therefore a more complete understanding of efficient coding requires examining factors beyond those considered in proposals of representational efficiency. Both the design of artificial visual systems and the development of algorithms for representing natural scenes will likely benefit from our understanding of a larger range of evolutionary constraints, like those described in the following sections. These additional biological constraints require a broadening of current notions of efficient design beyond representational

efficiency. We may someday find that the best artificial systems look remarkably like systems we find in biological systems, and it is likely that a full account of biological systems will require an understanding of these biological requirements.

Metabolic Efficiency

Consideration of representational efficiency as discussed in the preceding sections leads to important insights into the design of visual systems. It provides a number of metrics of efficiency that are generally independent of the limitations of energy or of neural hardware. In this section, we consider attempts to explain the properties of neurons from a consideration of metabolic constraints. We discuss two broad hypotheses of efficient neural design: spike efficiency and neural wiring optimization.

Spike Efficiency

Any information-processing strategy in the nervous system will incur metabolic costs. If we accept that information is primarily transmitted through the use of spikes, then a relevant question is whether one of the constraints on information processing is the number of spikes. Two studies have made detailed efforts to estimate the metabolic cost of spikes, and both have come to the conclusion that the high cost of spikes indeed results in an important constraint on neural processing. Both Attwell and Laughlin, in 2001, and Lennie, in 2003, found that the total available metabolic resources and the cost of a spike limit the firing rate to less than 1 Hz – and probably less than 0.2 Hz. As subsequently noted by Olshausen and Field, most studies have found firing rates significantly higher, suggesting that the cells that are typically recorded have unusually high firing rates. Levy and Baxter earlier argued that when the cost of spiking is considered, maximum information transfer is attained when only 2–16% of the neurons are firing. Lennie estimated that the limited resources imply that at any given moment, only 1/50th of the population of cortical neurons will show high firing rates. Thus, in order to save energy individually and across populations, visual neurons must adopt highly sparse patterns of firing. Therefore, we can argue that from both a representational point of view and a metabolic point of view, sparse firing is efficient.

A related debate centers on the optimal histogram of activity for a real neuron that can only produce a positive firing rate. If the goal of a neuron is to maximize the total information rate while minimizing the mean activity, the most efficient distribution is the exponential distribution. There is certainly a similarity between the histograms of activity of visual neurons (in response to natural signals) and the exponential distribution. However, on close inspection, the exponential model does not appear to fit. For example, Treves et al. found that for neurons in inferotemporal cortex, the exponential model could be rejected in 84% of cases. The lack of any particular successful model led these authors to conclude that there was "no special optimization principle or purpose to the firing distributions found."

Moreover, we question whether the goal should be to optimize the information rate. Consider a case in which there are n possible causes or features in an image and there exist n neurons available to represent those features. One could argue from a representational viewpoint that one should match the neurons to the features. If each feature had a particular response probability, then matching that feature would produce a histogram of activity that matched the histogram of the feature, not one that necessarily matched the histogram corresponding to the optimal compression algorithm. Certainly we do not expect that there is a match between the number of features and the number of neurons. But this example is meant to show that if we expect neurons to provide an explicit representation of their environment, part of the impetus for that explicit representation may be to match the probability distributions of the environment – not simply to maximize information rates.

Minimum Wiring

In addition to metabolic constraints, any neural architecture will be dependent on the anatomical 'wiring' available. This so-called wiring optimization principle dates back to Ramón y Cajal. This type of metabolic efficiency is typically measured by comparing the wiring volume and distribution of real neurons with calculations of the minimum volume needed to connect model cells and cortical areas to one another. Mitchison has argued that stripe patterns in cortex (e.g., ocular dominance columns) are efficient at minimizing the volume of dendritic wiring needed by areas receiving input from two separate sources, compared to alternative arrangements. Durbin and Mitchison found that a highly reduced model of cortical wiring arrangement matched real wiring in certain ways and minimized a model of wiring cost. Along the same lines, Koulakov and Chklovskii found that pinwheel patterns of orientation preference in cortex allow efficient wiring. In a related study by Chklovskii et al., neural wiring density and local signal delay have similarly reached an optimal compromise. Together, these studies suggest that intracortical wiring optimization can help explain why

cortical maps have the topography they do. Cherniak et al. and others have shown that minimal wiring may also help explain why brain areas are placed and interconnected as they are. In an early study using a reduced anatomical model of the *Caenorhabditis elegans* ganglia, Cherniak employed a connection-optimizing algorithm to search for connectivities that minimized total wiring. The actual wiring of the ganglia matched the optimal arrangement from a family of possible orderings.

Some have argued that brain evolution and development impose invariant connectivity ratios, which may tend to enforce optimal wiring. For example, Changizi and Shimojo suggest that across phyla the average number of synapses per neuron scales with the number of neurons per physiologically defined area, and that the number of connections among areas (per area) scales with the number of areas. However, this approach has several limitations. It should be noted that the number of ways that an efficient wiring system could strive to optimize the cost of adding cell volume, increasing cell metabolism, delaying and attenuating the signal, and making projections during development is essentially unlimited. But when considered in concert with representational constraints, minimum wiring arguments can provide insights about efficient receptive field design.

Learning Efficiency

In addition to the fact that neural systems, unlike human-engineered ones, are difficult to assess in terms of their goals and costs, they also differ from traditionally engineered systems because they are produced through development and learning rather than through carefully planned assembly. Indeed, part of the reason why the level of efficiency of a brain is hard to measure is that it becomes specialized to a variety of tasks – often concurrently – during development, the combination of which helps the adult creature reproduce. Therefore, in order to explain why the visual system of the adult has the structure it does, given a proposal of efficient processing of natural scenes, we must consider how visual system representations may depend on efficient learning and development. This efficiency dimension in particular is an example of somewhere our intuition about the brain seeking desperately to conserve energy can lead us astray. Indeed, learning efficiency could be at odds with metabolic cost optimizations, since the proportion of metabolic energy consumption in infant human brains (which are most subject to this constraint) is roughly 3 times that for adults.

In discussions of efficiency in sensory systems, many studies have used various types of neural networks and other learning algorithms to generate early sensory processes. There are certain basic problems that any learning algorithm must overcome. We examine one of these issues – invariance. Then we describe evidence of contributions to learning efficiency from innate, purely learned, and hybrid strategies, which span the well-known nature/nurture debate.

Sparseness and Invariance

Certain constraints are imposed on a system that must learn about its environment from a relatively small number of examples. In essence, efficient learning is dependent on finding a balance between selectivity of neurons for specific features and invariance across examples having features that vary in irrelevant ways (e.g., lighting). This task is further complicated because each example is likely to be seen just once in a lifetime. A second instance is unlikely to be presented with the same lighting, the same position, the same size, and the same orientation as the first. To allow any calculation of the probability of what is likely, it is critical that the system be capable of generalizing to multiple instances of that object.

Sparse coding, in the strict version, does not help with this problem. The typical argument against hierarchical sparse codes is that a system that develops a neuron for every object would require too many object detectors in order to function. This 'grandmother cell' hypothesis has been critiqued elsewhere, but it is worth noting that plausible models of object recognition suggest the need for grandmother cell-like coding for certain tasks (e.g., distinguishing between different faces) and sparse population codes for other tasks (e.g., categorization). That is, object recognition may require a variety of strategies that vary in their degree of sparseness.

It has also been argued that optimizing for sparseness and independence can assist a system in identifying novel inputs and in detecting new relationships. Consider the case in which objects are uniquely represented by just one neuron versus the case in which the object is identified by the relative activity of 100 neurons. In the single-neuron case, to learn that two objects often co-occur requires a relatively simple algorithm (e.g., Hebbian learning). But when identification requires a particular activity profile among many neurons, the learning algorithm would require a far more complex association among the 100 units involved in the representation.

Overcompleteness

An important property of visual representations beyond the optic nerve is that they are highly overcomplete. Visual cortex in humans contains on the order of 1000 times more neurons than do the two optic

nerves. In macaque V1 alone, there are approximately 50 times more output fibers than input fibers. These overcomplete codes must involve significant redundancy. Overcompleteness has been suggested by Barlow as an optimally efficient way "to model the redundancy in images, not necessarily to reduce it." And as Riesenhuber and Poggio pointed out, overcompleteness allows any particular signal to be represented with a higher degree of sparseness than is possible with complete codes, a property which is useful for generalization during learning, as described earlier. In order to achieve efficient learning, one must consider solutions that may not be optimally efficient from a strict representational efficiency point of view. That is, solutions that are representationally efficient (e.g., maximum information transfer arguments) may not help explain how the system achieves efficient learning.

'Hard-Coded' Efficiency

Though every part of the visual system undergoes developmental change, some efficient properties of the adult cells are thought to be innate. Maloney found that the distribution of natural chromaticities could be efficiently and accurately coded using just three wavelength vectors, and that the three cone spectral sensitivities in particular may optimally achieve color constancy based on typical surface spectral reflectances in the natural world. Others have proposed that the distribution of spectral sensitivities in primates is optimally weighted so as to separate nutritious fruit from surrounding foliage, a genetic adaptation that could have aided propagation of trichromatic primates.

Moreover, at the level of the retina, there is a deep conservation of 'virtually all functional and structural features of importance' and of the developmental program in the vertebrate retina according to Finlay et al. This may indicate that visual system development is optimized to allow successful elaboration, robustness, and specialization (what is referred to as 'evolvability') for a range of species that live in a variety of habitats using a single developmental and organizational scheme. It can therefore be seen as an efficiency which is innate, but which is connected to the types of variations present in a changing visual environment.

The development of classical receptive field organization in cortex does not appear to require learning, and relatively little spatial refinement is needed to achieve adult level acuity. One area of debate centers on the question of the necessity of visual experience in order to achieve adult receptive field structures, which presumably contribute to efficient representations in the brain. Recent studies have suggested the prevailing view – which proposes that animals dark-reared during the critical period of development are left with unrefined receptive fields because visual experience had no chance to 'prune' dendritic arbors – could be in need of reevaluation.

Efficient Learning from the Environment

In higher levels of cortex, learning leads to a marked decrease in mean response in prefrontal and inferotemporal cortex, which has been linked to the detection of novel stimuli. In particular, learning based on natural stimulus matching in monkeys led to systematically lower mean responses to learned natural stimuli in prefrontal cortex, and these responses did not vary with the addition of noise. At lower levels of cortex, learning has a minor effect on classical response properties such as orientation tuning and receptive field size in V1 cells). Learning also has a relatively small effect on responses in V4 to noise-degraded natural stimuli. Therefore, efficient learning strategies may be an important principle, especially in higher levels of visual cortex.

Hybrid Strategies: Efficient Innate Learning

Finally, there is evidence that spontaneous activity in the visual system, in a time period before a creature's eyes open, may help refine the organization of the visual system. There is good evidence that suppressing spontaneous activity in the retina (so-called retinal waves) can affect the refinement of retinal projections to the LGN. As some have noted, spontaneous, patterned activity is observed in cortex, hippocampus, thalamus, retina, and spinal cord in a variety of creatures. Simple programs of the sort that could theoretically produce spontaneous, patterned activity could well be coded into genes, and the 'running' of these programs could produce the necessary statistical properties that a developing visual system needs to operate at a basic level once the eyes open. We refer to this as notion as 'innate learning,' since it employs elements of both learning and innateness. These innate learning strategies are efficient in the sense that in the absence of external stimuli, they require far fewer genetic instructions in order to develop proper response properties, compared to full genetic specificity.

However, innate learning in the form of spontaneous retinal activity is not required for the initial formation of ocular dominance columns or of orientation selectivity. There is strong evidence that retinotopic maps and ocular dominance patterns fail to refine properly in animals reared in altered visual environments (e.g., strobe environments, binocular deprivation, environments with altered spatial statistics). But it should be noted, especially considering the brief time during which spontaneous activity has been so far studied,

as stated by Carrasco and colleagues, that "the extent to which spontaneous and visually driven activity contribute to the development and maintenance of stimulus specificity is unclear."

In short, learning efficiency may require solutions that would not be predicted by representational efficiency arguments or metabolic efficiency arguments alone. The difficulty of learning invariant properties of objects based on a handful of presentations is one reason why this is so. The degree to which the visual system is efficiently engineered to learn is dependent on innate properties, on learned associations, and on patterns of spontaneous activity, the combination of which may approach 'optimal' efficiency in concert with metabolic and representational constraints.

Conclusion

Visual systems have been argued to be operating near theoretical limits of optimality – not simply parsimoniously – for certain tasks. But given the profusion of ways that brain structure, cell development and function, and neural representation are believed to be optimal in some way, we argue that visual system design represents a compromise among these many demands for efficiency. We have attempted to elucidate a variety of ways in which visual systems can strive for efficiency. No single quantity (e.g., energy consumption) applies strict limits to brain design (except in the absolute sense), nor is the system optimized to perform a single, 'optimizable' task. There is much to be learned from investigating the contribution from a variety of constraints on efficiency.

Nausea and Vomiting

This article is reproduced from the previous edition © 2004, Elsevier B.V.

Biological Significance

Although nausea (unpleasant sensation associated with the urge to vomit) and vomiting (forceful oral expulsion of gastric contents) may be most frequently encountered in a clinical context as a symptom of disease (e.g., raised intracranial pressure, migraine, hypertrophic pyloric stenosis, labyrinthitis, renal failure, Addison's disease), as a symptom of viral (e.g., Norwalk virus) or bacterial infection (e.g., *Staphylococcal enterotoxin* B, *Salmonella typhimurium,* meningococcal meningitis), as a side effect of drug therapy (e.g., antitumor chemotherapy, digoxin, morphine, oral L-DOPA, theophylline, oral contraceptives, some antibiotics (e.g., erythromycin), as accidental ingestion of plant (e.g., Ackee toxin Jamaican vomiting sickness), nicotine, veratridine, tremetone (milk sickness) or animal (e.g., batrachotoxin, ciguatoxins) toxins, or as sequelae to treatment (e.g., radiotherapy, postoperative nausea and vomiting (PONV)), it is important to remember that both are components of a biologically important, hierarchically organized system presumed to have evolved to protect the body against the accidental ingestion of toxins. Usually, every effort is made to avoid ingestion of hazardous agents by taking evasive action based on taste, smell, and visual cues, but not all toxins taste bitter or have a warning coloration and so may be inadvertently swallowed. In addition, toxins may be elaborated postingestion. Therefore, a mechanism is clearly required by which the toxin can be detected and ejected once it is in the body; hence, detection systems are located at both pre- (e.g., gut mucosa) and post- (e.g., circulation) absorptive sites.

A curious feature of vomiting is why it is evoked by such a wide range of stimuli. In contrast to vomiting evoked by ingested toxins, which is clearly appropriate in that it leads to expulsion, that induced by most clinical and some natural stimuli, such as snake bite, motion, and pregnancy (especially in the first trimester, when it is often called 'morning sickness'), appears 'inappropriate' as the stimulus remains. However, for the reflex to be evoked, all that is required is for the stimulus to activate one of the triggering systems either directly or indirectly. It has been argued that motion sickness is also part of the defensive system against ingested toxins. Morning sickness is argued to protect both the mother and embryo against potentially hazardous foods (e.g., teratogens) at a time when both are vulnerable, the mother because of immunosuppression and the fetus because it is at a key period of organ development.

Vomiting occurs in representative fish (e.g., shark, skate, trout, tuna), amphibia (e.g., frog, salamander), birds (e.g., pigeon, petrel), reptiles (e.g., snake, crocodile), and mammals (e.g., musk shrew, cat, dog, ferret, pig, cynomologous monkey, marmoset, sperm whale). Reflexes for the oral ejection of upper gut contents have been described in some invertebrates (e.g., arthropods such as grasshoppers, sea anemone, *Pleurobranch* mollusk). While the reflex may be triggered by ingested toxins, many species appear to use vomiting or regurgitation for other functions such as voiding indigestible food residues such as squid beaks (e.g., sharks, sperm whales), bones (owls), or trichobezoars (e.g., crocodile, cat); for feeding the young or mates (e.g., albatross, African wild dog); and for defense (e.g., petrel). (In mammals this can be distinguished from vomiting by the patterns of neuromuscular activity, particularly the diaphragm and abdominal muscles, but as they are not present in all species, such a distinction may be semantic.)

Despite its potential biological significance, rodents (e.g., rat, mouse) and lagomorphs (e.g., rabbits) do not have this reflex. While the reason is not known, it is thought that sensitivity of the taste system and the ability to generate conditioned taste (food) aversions (CTAs) in these species enable them to avoid toxin ingestion, but they may lack some of the brain stem pathways required for the vomiting reflex (perhaps in the nucleus tractus solitarius (NTS); see subsequent discussion), although both vomiting and nonvomiting species have an area postrema (AP). In addition, these animals may have anatomical features (e.g., a long narrow abdominal esophagus) or physiological differences (e.g., inability to shorten the esophagus sufficiently) that would make ejection of gastric contents difficult, or they have behavioral responses (e.g., pica, the ingestion of nonnutritive substances such as clay) or biochemical mechanisms to allow them to deal with ingested toxins. Rodents without a vomiting reflex do have a gag reflex elicited from the pharynx. The presence of the reflex does not depend upon the size of the mammal, as it is present in both a shrew (*Sorex unguiculatus*) weighing approximately 10 g and a sperm whale. Research studies of the emetic reflex have used nonhuman primates (e.g., cynomologous monkey,

marmoset) and cats and dogs, but recently the ferret (a carnivore), piglet (an artiodactyl), and *Suncus murinus* (the house musk shrew, an insectivore) are being used increasingly.

Motor Components

Irrespective of how the vomiting reflex is triggered in mammals, the motor components are the same, and in this respect the reflex may be viewed as an example of a stereotypical motor program.

Preejection or Prodromal Phase

Prior to the actual expulsion of upper gut contents, a considerable number of motor changes mediated by the autonomic nervous system have taken place, particularly in the gastrointestinal tract (Figure 1). These include relaxation of the proximal stomach to confine the food together with any toxin to the stomach from where it can be ejected. This is mediated predominantly by vagal efferent activation of myenteric nonadrenergic, noncholinergic inhibitory nerves, probably using nitric oxide (NO) and vasoactive intestinal peptide (VIP) as transmitters. Another motor change is a retropulsive giant contraction sweeping from the mid-small intestine to the stomach, which is proposed to return any previously emptied and contaminated gastric contents to the stomach for ejection. It has also been proposed that this contraction may propel alkaline pancreatic and intestinal fluid into the stomach to buffer gastric contents before ejection. The contraction is vagally mediated, mainly involving activation of atropine-sensitive cholinergic nerves. When expulsion occurs, these gastrointestinal changes always precede it, but they may also occur in the absence of vomiting. Tachycardia, cutaneous vasoconstriction, and sweating also occur in the prodromal phase and are probably mediated by the sympathetic nerves. Increases in the plasma levels of adrenaline, adrenocorticotropic hormone (ACTH), growth hormone, prolactin, and vasopressin (ADH) have been reported during the prodromal phase. Some changes are likely to be a reflection of general stress (e.g., adrenaline), whereas others (e.g., vasopressin) may be specific to nausea.

Ejection Phase: Retching and Vomiting

The expulsion of gastric contents (vomiting) is brought about by the coordinated rhythmic contraction of the diaphragm, external intercostals (inspiratory), and abdominal muscles (rectus abdominus, external oblique) compressing the stomach and ejecting the contents through the mouth via the esophagus (see Figure 1). The propulsive pressure exceeds 100 mmHg. Some evidence also suggests that during expulsion longitudinal shortening of the esophagus occurs, and there may be an esophagopharyngeal retrograde contraction that could contribute to the oral expulsion of gastric contents. Retching, which usually precedes vomiting and in contrast to vomiting occurs as multiple events, differs in that gastric contents are not ejected orally. This is thought to be because during retching the entire diaphragm contracts rhythmically under the influence of the

Figure 1 A diagram summarizing the major visceral and somatic motor changes comprising the vomiting reflex. EMG, electromyogram; UOS, upper esophageal sphincter.

phrenic nerve, whereas during vomiting the bulk of the diaphragm contracts but the periesophageal region (crural fibers) is inactive to permit ejection of gastric contents. The function of retching is not known, although it is suggested that it helps to overcome the antireflux barrier present in the region of the gastro-esophageal junction. The factors that regulate the number of retches in a burst of retching or determine whether a vomit follows retching are not known, although studies in the ferret showed an inverse relationship between gastric volume and the number of retches prior to a vomit. Blood gas levels have also been implicated in this transition.

In nonmammals other neuromuscular mechanisms may be used for ejection of gastric contents. These include retrograde contraction of the stomach (e.g., dogfish) and oral eversion of the stomach (toad, skate); the mechanism by which the latter occurs is unclear but may involve relaxation of the stomach and an increased intra-abdominal pressure.

Coordination of the Motor Components

The motor systems that comprise the vomiting reflex are almost all employed in nonemetic reflexes and hence the magnitude, combination, and sequence of activation of these outputs make the reflex unique. The individual brain stem nuclei involved in the control of the autonomic and somatic motor components of emesis have largely been identified. For example, the dorsal motor vagal nucleus and nucleus ambiguus provide the vagal output to the gut and heart; the presympathetic neurons in the ventrolateral medulla regulate the drive to the preganglionic sympathetic neurons in the spinal cord that supply the cutaneous vasculature; and the ventral respiratory group of neurons (e.g., nucleus retrombigualis, Bötzinger complex) provides the drive to the diaphragm and intercostal muscles involved in the somatic motor components of emesis. However, it is still not known exactly how the various components are coordinated. In particular, the visceral and somatic motor nuclei must interact to ensure that the gastrointestinal and other preejection changes precede contraction of the diaphragm and abdominal muscles. Whether there is a single nucleus that corresponds to the old concept of a 'vomiting center' is still hotly disputed, but the parvicellular reticular formation, the Bötzinger complex (part of the ventral respiratory group of neurons), and the NTS (the major integrative nucleus for visceral information and location of the dorsal respiratory group of neurons) have all been proposed to fulfill this function to varying degrees.

Triggering the Emetic Reflex

How the multitude of stimuli that can evoke vomiting activate the central pathways outlined previously is not known, but three major pathways have been identified, and they provide a framework within which some emetic stimuli may be discussed (Figure 2).

Gastrointestinal Afferents

Vomiting can be evoked by overdistention of the upper gut (e.g., overeating or motility disorder) and by the presence of chemical irritants (e.g., hypertonic solutions or copper sulphate) or toxins (e.g., plant alkaloids, such as emetine, a constituent of the clinical emetic ipecacuanha, or bacterial toxins) in food. These stimuli activate mechanoreceptors or mucosal chemoreceptors with afferents principally in the vagus nerve, which projects to the medulla (NTS and AP), to trigger the emetic motor pathways. Biologically, this is probably the most important route for activation of emesis.

Studies in several species (dog, monkey, ferret, and *Suncus*) have implicated mucosal vagal afferents as the predominant pathway in the acute phase of vomiting induced by systemically administered antitumor agents (e.g., cisplatin) and whole-body radiation. It is proposed that these stimuli induce the formation of free radicals in the enterochromaffin cells of the upper gastrointestinal tract. This triggers a calcium-dependent release of 5-hydroxytryptamine (and probably other neuroactive substances, e.g., substance P), which activates 5-HT_3 receptors (see subsequent discussion) located on the vagal afferents terminating in close proximity.

Vagal afferents from the heart can also evoke nausea and vomiting and are responsible for these symptoms during infarction.

Area Postrema

The AP is a circumventricular organ located at the caudal extremity of the fourth ventricle outside the blood–brain and cerebrospinal fluid (CSF)–brain barriers and is therefore ideally suited to its proposed function as a chemoreceptor. Ablation studies have implicated the AP in the mediation of emesis by a wide variety of systemic agents (e.g., cytotoxic drugs and the dopamine D_2 agonist apomorphine) and led to it being called the chemoreceptor trigger zone (CTZ) for emesis. Although there is no dispute that suitable activation can trigger emesis and perhaps influence the sensitivity of other emetic inputs, it is probably more accurate to regard the AP as having a wider chemoreceptive role with an involvement in conditioned taste aversion, salt balance, and food intake. Because of the close proximity of the AP to

the central emetic circuitry and sites of termination of abdominal vagal afferents (particularly the NTS), collateral damage may be difficult to avoid and thus could confuse the interpretation of lesion studies. Teleologically, it may be argued that a toxin detector in the central nervous system (CNS) would be of little use because after the toxin has been absorbed it cannot be expelled by vomiting. Hence, the emetic role of the AP is probably a reflection of its general chemoreceptive role and connectivity, a role supported by its presence in nonvomiting species.

Vestibular system

In 1881, Irwin observed that the vestibular system (semicircular canals and otolith organs) was critical for motion-induced emesis. This and other studies led to the idea that overstimulation was the major trigger, but this did not account for all the experimental observations. Current hypotheses are based on the idea of sensory conflict or rearrangement. Some view this as a disparity between different sets of incoming information (e.g., from vision and the vestibular system), a sensory conflict, whereas others tend more toward the view that the conflict lies not between modalities but between what the body expects to happen in a given situation and what actually occurs: a sensory motor or efference–copy conflict. Psychophysical studies support both hypotheses. Conclusive neurophysiological studies are awaited, although there are several regions where visual and vestibular information converge, for example, second-order vestibular-nucleus neurons and the flocculus, nodulus, and uvular regions of the cerebellum. Ablation of the latter renders the dog refractory to motion-induced emesis. The exact pathways by which the medullary emetic circuitry is activated are not known, but both the lateral medullary reticular formation and the NTS receive vestibular inputs, and individual neurons in the NTS have been shown to receive vestibular and gastrointestinal inputs.

Sensitivity to motion sickness is a predictor of the emetic response to other emetic stimuli such as pregnancy sickness, postoperative nausea and vomiting, and anticancer chemotherapy-induced emesis. This suggests that the vestibular system may have a 'modulatory' influence on the brain stem emetic pathways, setting their sensitivity. Based on studies of different racial sensitivity to motion stimuli (Asians are more sensitive than Westerners), some evidence suggests genetic determinants of sensitivity.

Nausea

The term nausea is derived from the Greek word for ship and well illustrates man's early experience of sea travel. Although we know that activation of the

pathways described previously, usually at a lower intensity than that required to induce vomiting, can induce nausea, the precise CNS pathways by which this sensation is generated are not known. Magnetic source imaging has implicated the inferior frontal gyrus. The main reason for the relative paucity of knowledge of the mechanisms underlying nausea is that while in animals retching and vomiting are obviously the same as in humans, in animals we can only study what we conclude are the 'behavioral equivalents' of nausea (e.g., conditioned taste aversion, pica) and not the actual sensation experience (cf. pain studies). In the preejection phase in humans, increases in vasopressin (ADH) may be many times maximal antidiuretic levels, and this has led to the suggestion that it may be a useful index of nausea, or even involved in its genesis. As nausea can be induced in patients with diabetes insipidus, it is clear that ADH is not obligatory for its genesis. The involvement of disturbed gastrointestinal motility (e.g., tachyantria) in the genesis of nausea from all causes is not resolved, but in cases in which there is gastric stasis resulting in distension, it is possible that nausea (and vomiting) is caused by visceral afferent activation. Understanding nausea is still a major challenge but, fortunately, most drugs alleviating vomiting also mitigate nausea, although usually at a reduced efficacy.

Biologically, the function of nausea appears to be the induction of a learned aversion to the stimulus responsible (e.g., contaminated food, sea travel), although this does not appear to apply to nausea induced by alcohol or pregnancy.

Anti-emetic Agents

The selection of anti-emetic agents relies on knowledge of the pharmacology of the pathways involved in triggering emesis in the various clinical settings. Some of the better-understood pharmacological therapies are outlined in this section.

Motion sickness is well controlled using centrally acting muscarinic (e.g., hyoscine) or histamine (H_1, e.g., diphenhydramine) receptor antagonists. Neurophysiological studies have shown that these agents modulate activity in the vestibular nuclei. Recent studies using more selective muscarinic receptor antagonists (e.g., zamifenacin) have implicated M_3 receptors in motion-induced emesis in humans, but the site of action is not known.

The severe acute (first 24 h) vomiting that may be induced by cytotoxic drugs (e.g., cisplatin) or radiation therapy for carcinoma is completely controlled in approximately 60% of patients (particularly in combination with steroids, see below) and reduced in most of the remainder using antagonists selective for 5-hydroxytryptamine3 (5-HT_3) receptors (e.g., granisetron, ondansetron, tropisetron, dolasteron) located on the peripheral terminals of abdominal vagal afferents (see previous discussion) and neurons in the nucleus tractus solitarius and AP. These agents are not effective against the delayed phase (2–7 days) of emesis associated with cytotoxic therapy. The anti-emetic efficacy of 5-HT3 receptor antagonists in chemotherapy-induced nausea and vomiting can be enhanced by the coadministration of the steroids dexamethasone and methyprednisolone, but the mechanism of action is not known, although allosteric modulation of the receptors has been suggested in addition to the well-known anti-inflammatory actions of glucocorticoids. Cannabinoids (e.g., nabilone) have been shown to be slightly superior to conventional anti-emetics in chemotherapy-induced emesis. 5-HT_3 receptor antagonists also have demonstrable efficacy in patients with postoperative nausea and vomiting.

When nausea and vomiting are induced by gut motility disorders (e.g., delayed gastric emptying), they can be alleviated by using agents that stimulate motility (e.g., the D_2 receptor antagonist/5-HT_4 receptor agonist metoclopramide) and hence have an indirect anti-emetic effect. However, if the vomiting is due to a physical obstruction (e.g., hypertrophic pyloric stenosis in neonates) then surgery is the appropriate treatment.

Pregnancy sickness, affecting more than 80% of women in the first trimester, is arguably the most common form of emesis. Its etiology is unknown, but it is proposed that the steroids secreted in early pregnancy sensitize the central emetic pathways. Empirical therapy ranges from pyridoxine to diphenhydramine; because of concern about potential adverse effects of drugs on the fetus, treatment of this type of emesis is difficult and arguably is unnecessary because the condition is self-limiting. Rarely (in approximately 1 in 1000 pregnancies) severe emesis continues during pregnancy and is termed hyperemesis gravidarum, but as with the sickness in early pregnancy, the etiology is uncertain. Treatment is essentially supportive, correcting any nutritional, fluid, or ionic imbalances.

While research has focused on pharmacological therapies, complementary therapies, such as ginger, acupressure (P6 point), and acupuncture have been claimed to successfully treat nausea and vomiting induced by motion, pregnancy, chemotherapy, and postoperatively. In anticancer therapy-induced emesis, behavioral interventions such as cognitive behavioral therapy are being investigated together with the role played by the patient's expectations of outcome in influencing the magnitude of the emetic response.

Research into novel pharmacological therapies continues with attempts to identify anti-emetics with

a broad spectrum of action against a variety of stimuli. Preclinical studies demonstrate that 5-HT_{1A} receptor agonists (e.g., 8-OH-DPAT), μ opioid receptor agonists (e.g., fentanyl), and the vanilloid receptor agonist resiniferatoxin have some broad-spectrum anti-emetic activity. Cannabinoid (CB1) receptor agonists also have anti-emetic activity in preclinical models, as do NMDA (LY 233053), non-NMDA receptor antagonists (e.g., NBQX), mixed dopamine D_2/D_3 receptor antagonists, and cyclo-oxygenase inhibitors (meloxicam, indomethacin). Preclinical studies with a number of highly selective and potent $neurokinin_1$ (substance P receptor) receptor antagonists (e.g., vofopitant GR-205171, ezlopitant CJ-11974, aprepitant MK-869, L-758, 298 (water-soluble prodrug of MK-869, CP-99, 994) have shown that they are capable of blocking vomiting induced by cytostatic drugs, radiation, oral copper sulphate, intravenous apomorphine, and motion. This broad spectrum of action suggests a brain stem site of action most likely in the NTS, but other sites cannot be excluded. Clinical studies have been undertaken with representative agents. Efficacy has been demonstrated in limited studies of PONV (GR-205171) and more extensive studies in chemotherapy-induced nausea and vomiting (CJ-11, 974, CP-122, 721, MK-869/L-758, 298), with the agents usually given in combination with dexamethasone plus or minus a 5-HT_3 receptor antagonist, demonstrated improved control of both acute and delayed emesis. The effect on delayed emesis is of particular interest, and the first drug in this class (aprepitant, Emend) was approved by the FDA in April 2003 for the treatment of acute and delayed chemotherapy-induced nausea and vomiting. Further studies are awaited to fully assess the clinical potential of this class of agent.

Damage to the right side of the brain can trigger a debilitating impairment known as the left hemineglect (selective inattention) syndrome. Patients with this syndrome minimize the salience of events in the contralesional side of the environment, display a reluctance to shift attention in a leftward direction, and cannot effectively search for targets embedded within the left hemispace. The left hemineglect syndrome is assumed to reflect damage to a large-scale frontoparietal network that normally sustains the adaptive distribution of spatial attention.

In this context, the term 'spatial attention' designates a set of interrelated sensory, motor, and cognitive processes that collectively enable the selective allocation of neural resources to motivationally relevant parts of the environment. The spatial representation of events according to their emotional salience, their targeting for oculomotor fixation or manual grasp, the anticipatory biasing of regions where interesting events are expected to occur, and the search for objects embedded among distractors are components of spatial attention.

Experiments in monkeys traced the two major nodes of an analogous spatial attention network to posterior parietal cortex (e.g., 7a in the inferior parietal lobule (IPL) and lateral intraparietal (LIP) in the intraparietal sulcus) and a premotor/prefrontal area that includes the frontal eye fields (FEF). These two areas are reciprocally interconnected and contain neurons that encode spatial coordinates in multiple reference frames, represent extrapersonal space in terms of salience rather than object characteristics, and direct orientating and search behaviors toward salient events. They collectively provide a coarse mapping of salient extrapersonal events and encode the intent to generate saccadic eye movements or arm reaching movements toward behaviorally relevant events. Both of these areas receive peristriate information and project to the superior colliculus in a way that would allow them to exert a top-down modulation of oculomotor and visual areas involved in the motor and sensory aspects of spatial attention.

In general, area 7a has more sensory properties and may play the major role in encoding a salience-based representation of the extrapersonal events, whereas areas LIP and FEF tend to have a closer relationship to the programming of saccades in the direction of behaviorally relevant targets. Although Chafee and Goldman-Rakic have shown that neuronal firing is greater in the FEF just before a memory-guided saccade and in the LIP just after the onset of a salient spatial cue, these two areas are functionally interdependent and display relatively few differences in response patterns. They collectively represent an advanced state of sensorimotor synthesis in which perception can be represented as salience rather than sensory features, and action as intent rather than movement.

Axonally transported tracer experiments in the monkey brain showed that area 7a/LIP and the FEF are reciprocally interconnected not only to each other but also to the cingulate gyrus. Cingulate neurons in the awake animal respond to behaviorally relevant extrapersonal events and may participate in the remapping of salience following saccadic eye movements. Through its connections with the amygdala and parahippocampal complex, the cingulate gyrus provides a limbic component of the spatial attention network.

The complexity of this network and the heterogeneity of lesion sites associated with the neglect syndrome account for the large variety of clinical manifestations and explanatory theories. Research in this field has proceeded in two major directions: investigation of patients with the hemispatial neglect syndrome and functional imaging of neurologically intact subjects performing tasks of spatial attention that are impaired in these patients. This research has led to exciting new insights but has also generated two major questions. The first is related to hemispheric asymmetry. Although severe contralesional neglect is far more common after right than after left hemisphere lesions, functional imaging has not yet revealed a consistent asymmetry of neural activity during tasks of spatial attention in normal subjects. The second question concerns the location of neglect-causing lesions. Although functional imaging highlights the engagement of dorsal frontoparietal cortex in spatial attention tasks, clinical evidence links the neglect syndrome to more ventral lesions of the inferior parietal lobule and temporoparietal junction. This review summarizes clinicoanatomical correlates of the neglect syndrome and functional imaging experiments on spatial attention. The two questions discussed previously will not be resolved, but the facts that generate them will be reviewed.

The Neuropsychology of Neglect

Contralesional neglect is more lasting and severe after lesions in the right side of the brain. This asymmetry

is consistent with a neural model postulating that the left hemisphere directs attention primarily to the contralateral hemispace, whereas the right hemisphere directs attention to both hemispaces or, alternatively, serves a more global orienting function. According to this model, left hemisphere lesions do not cause prominent neglect because the right hemisphere continues to direct attention to either side of space. When neglect is severe, the patient with a right hemisphere lesion may behave almost as if one-half of the universe had abruptly ceased to exist in any meaningful form. One patient may shave, groom, and dress only the right side of the body; another may fail to eat food placed on the left side of the tray; another may omit to read the left half of each sentence or even the left side of every word printed anywhere on the page; still another may fail to copy detail on the left side of a drawing and may show a curious tendency to leave an uncommonly wide margin on the left side of the paper when asked to write.

Neglect behavior has perceptual, motor, and motivational components. Perceptual aspects of neglect can be probed with tests of extinction, line bisection, and covert attentional shifts. Extinction is said to exist when patients who respond accurately to unilateral stimulation from either the left or the right side consistently ignore the stimulation on the left under conditions of bilateral simultaneous stimulation. If extinction occurs in only one modality, it can conceivably reflect a subtle disruption of relevant sensory pathways or even a callosal disconnection syndrome. Multimodal extinction, however, almost always reflects the representational aspect of neglect. In the traditional version of the line bisection task, patients are asked to mark the midpoint of a horizontal line drawn on a sheet of paper. Patients with left hemineglect tend to place their mark substantially rightward of center, suggesting that the representational impact of the left side becomes diminished and that it takes a longer segment on the left to balance the salience of a shorter segment on the right.

A rightward skewing of mental representations was demonstrated by Bisiach and colleagues in experiments in which patients were asked to mentally retrieve prominent features along the Piazza del Duomo in Milan as they imagined themselves looking toward the cathedral. Patients with left neglect were more accurate in listing details situated on the right side of the square as viewed from that vantage point. Upon being asked to imagine looking at the square while facing away from the cathedral, the same patients showed better recall of the items that had been omitted when assuming the former vantage point. Thus, the impaired evocation of left-sided details in the first part of the experiment was not due to an obliteration of the information but to an inability to activate the part of the representation which fell to the left of the imaginary perspective. In addition to this difficulty in activating the left side of previously encoded mental representations, patients with left neglect also display a relative deficit in encoding the left side of sensory experience during the compilation of new representations.

A task developed by Posner and colleagues has played an influential role in this field of investigation. No eye movements are allowed, central fixation is required at all times, and the attentional orientation is shifted covertly within a mental representation of the ambient visual scene. These shifts can be triggered exogenously through sensory priming or endogenously through centrally presented arrows which induce directional expectancy. Patients with left hemineglect but no hemianopia show much longer reaction times when responding to targets in the left. They also display an excessive difficulty disengaging attention from a cue in the right hemispace when the task requires a subsequent leftward shift of covert orientation to targets on the left. This resistance to disengagement is partially analogous to the phenomenon of extinction.

Patients with neglect can also display a reluctance to scan and explore the left hemispace even in the absence of obvious gaze or limb paresis. The resultant impairments of search behaviors are readily elicited by tasks which require the patient to circle or check targets on a sheet of paper. Patients omit many more targets on the left, need more time to find left-sided targets, use a disorganized scanning strategy, make fewer and lower amplitude eye movements to the left, and have longer visual fixation times on right-sided targets. The use of a 90° mirror, which reverses the direction of a manual movement needed to mark a target from the direction of the shift in visual attention that leads to its detection, shows that target cancellation impairments reflect a failure to look left in some patients and a failure to reach to the left in others. The frequent observation that targets oriented randomly on the page are far less efficiently detected than targets organized into rows and columns implies that an inability to endogenously impose an orderly scanning strategy contributes to the severity of the neglect.

Patients with left unilateral neglect also display difficulties in manual search. Blindfolded search for small objects by manual palpation is intact on the right side of the table not only with the right hand but also with the left hand, whereas it becomes ineffective on the left side of the table even when the intact right hand is being used. These observations show that left neglect is associated with impaired tactile exploration within the left hemispace regardless of the limb

that is being used. Thus, motor programs involved in exploration appear to be organized not according to the muscle groups that are being activated but, rather, according to the hemispace within which the movement is to be discharged.

A major role of any attentional system is to shift the attentional spotlight toward extrapersonal events of emotional and motivational significance. Patients with unilateral neglect devalue the left side of the world and behave not only as if nothing is actually happening in the left but also as if nothing of any importance could be expected to emanate from that side. The influence of this factor can be probed by varying motivational valence. For example, a patient showed marked improvement in detecting targets on the left when he was promised one penny for each accurate detection. Another patient with severe left hemineglect failed to reach for food on the left side of a tray and would bitterly complain that his tea had been left out. On a day when the nurse was instructed to withhold breakfast, the patient became unusually hungry by noontime but did not show any change in the severe neglect of left-sided targets in a letter-cancellation task. When his lunch tray was brought, however, he had no reluctance to reach for his tea on the left side of the tray. These anecdotal observations suggest that a devaluation of sensory events on the left may contribute to the emergence of neglect and that the relationship between neglect and motivation may be material specific so that hunger decreases the spatial distribution of neglect for edible items but not for letters on a test sheet.

Many aspects of neglect are based on top-down processes that impose a spatial bias on the encoding of a percept or the reactivation of its representation. In patients with extinction, for example, reaction times to unilateral right-sided stimuli are longer than those to bilateral stimuli. Since both conditions are reported as unilateral right-sided stimulation by the patient, the extinguished stimulus appears to gain access to the central nervous system and exert a covert influence on behavior. According to a case report by Marshall and Halligan, a patient with left hemineglect who was shown line drawings of two houses, one of which had flames coming out of the left side, judged the two drawings to be visually identical but chose the one without flames when asked to select the house she would prefer to live in.

In the preceding account, the word 'left' has deliberately been used without further qualification, as if it constituted a fixed attribute such as color or texture. This is clearly not the case since there is no left or right without a specific frame of reference. At least four frames of reference define the leftness of an extrapersonal event: egocentric (defined with respect to the observer), allocentric (defined with respect to another extrapersonal event), world-centered (defined with respect to a fixed landmark in the environment), and object-centered (defined with respect to a principal axis in the canonical representation on an object). Since the eyes, head, and trunk can rotate and tilt with respect to each other, the egocentric frame of reference contains retinocentric, cephalocentric, somatocentric, and gravitational coordinates so that an event which is in the left according to one egocentric coordinate could be on the right according to another. Furthermore, perceptual and conceptual factors influence the segmentation of the stimulus field into individual clusters with their own left and right sides. Left hemineglect is defined as a behavioral state in which a location in one of the egocentric lefts, in the environmental left, in the canonical or object-centered left, in the allocentric left, and in the segmentational left is endowed with less perceptual salience and becomes less likely to attract attentional capture through search and orienting behaviors.

Spatial Attention Network in the Human Brain

Contralesional neglect can arise in patients with parietal, frontal, cingulate, or subcortical lesions. In the group of patients with parietal lesions, some investigators point to the IPL (or temporoparietal junction) as the critical site, whereas others emphasize the importance of the superior temporal gyrus, an opinion that is difficult to reconcile with the auditory functions of the superior temporal gyrus. A study by Hillis and colleagues based on the remote cortical dysfunction caused by subcortical lesions suggested that interference with IPL function may cause the egocentric (observer-centered) aspects of neglect, whereas interference with superior temporal gyrus function may cause its allocentric and object-centered aspects. Reaching deficits, extinction, and extinction-like phenomena (e.g., a slowing of attentional disengagement in tasks of covert attentional shifts) may be associated with superior parietal lobule (SPL) lesions, whereas the distortions of spatial representation may be associated with IPL lesions. In the frontal lobes, some studies show that the critical lesion site is in the FEF, whereas others implicate the inferior frontal gyrus. It is also not clear if subcortical lesions cause neglect because of the tissue they destroy or because of the remote cortical dysfunction they induce. A relatively attractive hypothesis involves the possibility that 'parietal neglect' might be predominantly perceptual, whereas 'frontal neglect' might be predominantly motor. In support of this possibility, several studies have shown that 'perceptual' tasks such as extinction and line bisection are more likely

to be associated with parietal lesions, whereas 'motor' tasks such as target cancellation are more likely to be associated with frontal lesions. Ingenious experiments with pulleys and mirrors have shown that errors in line bisection and target-detection tasks can be attributed to representational biases in patients with parietal lesions and to directional hypokinesia in patients with frontal lesions. Other studies, however, have not been able to confirm the presence of a relationship between directional hypokinesia and frontal lesions.

The strong interconnectivity between the frontal and parietal components of this network raises the possibility that damage to one may induce distal hypometabolism in the other through the process of diaschisis. It therefore seems unrealistic to expect a strict behavioral dissociation between the manifestations of neglect that result from parietal versus frontal lesions since these two components of the attentional network collectively subserve a level of sensorimotor integration in which the boundaries between action and perception become blurred.

Functional Imaging of Spatial Attention

In neurologically intact volunteers, numerous tasks of attentional shifts in the visual or auditory modalities, with or without eye movements, guided by exogenous or endogenous cues, and entailing variable components of manual or oculomotor search, have elicited conjoint activations in the FEF and in the banks of the intraparietal sulcus (IPS), together with additional but more variable clusters of activity in other posterior parietal, temporoparietal, cingulate, and prefrontal regions. These experiments have supported the contention that the FEF and posterior parietal cortex exert a top-down modulation of the superior colliculus and visual areas of the cerebral cortex so that the representation of significant events and the actions necessary for their attentional capture can be promoted. It is interesting to note that spatial attention tasks most commonly activate the IPS and FEF, whereas the clinical observations suggest that the lesions responsible for neglect tend to be more ventral in location.

According to functional imaging experiments, frontal components of the spatial attention network (FEF, supplementary eye fields, and middle frontal gyrus) are more closely related to the compilation of a prospective motor code for overt search, whereas the parietal components (IPS, SPL, and IPL) are more closely related to the maintenance of the underlying spatial representations that guide the search. The IPL/SPL region may also mediate the cue-induced voluntary reorientation of spatial attention and the remapping of the attentional landscape based on the spatial distribution of salience.

The FEF has an internal functional segregation characterized by a partially overlapping mosaic of areas mediating saccadic eye movements, visual search, working memory, and covert shifts of attentional orientation. Functional heterogeneity is also emerging within the cingulate component of the network where an anterior sector seems to mediate processes related to cognitive control, target detection, vigilance, conflict resolution, and response selection, whereas a posterior sector seems to mediate the anticipatory allocation of attention toward locations where relevant events are expected to occur. As shown by Small and colleagues, posterior cingulate activations linked to anticipatory spatial biasing are further enhanced by monetary incentive, supporting the contention that posterior cingulate neurons mediate the motivational modulation of spatial attention.

Some functional imaging experiments have yielded results consistent with right hemisphere specialization, whereas others have not. The critical role of the right hemisphere for spatial attention, so convincingly illustrated by clinical observations on neglect patients, is therefore not obvious in functional imaging experiments.

Conclusions

It is becoming increasingly clear that neglect cannot be attributed to a unitary deficit of orientation, representation, or intention. Instead, it represents an outcome of interacting perturbations in each of these processes. As in the case of aphasia and amnesia, neglect is a 'network syndrome.' It represents damage to one or more interactive components of the distributed network shown in Figure 1, in which each component has a different pattern of physiological and anatomical specialization.

The spatial attention network revolves around cortical epicenters in the posterior parietal cortex, FEF, and the cingulate gyrus. Each of these macroscopic components serves a dual purpose: it provides a local network for regional neural computations and also a nodal point for the linkage of distributed information. Although each component displays a relative specialization for specific behaviors, spatial attention as a whole is the emergent property of the entire network. Compiling a salience map of the extrapersonal space and transforming spatial coordinates into targets for reorienting attention can be included among the relative specializations of the parietal component; translating representations into systematic search behaviors reflects one of the relative specializations of the FEF, and calibrating spatial expectancy according to motivational valence represents one of the specializations of the cingulate component. The coherent

Figure 1 A large-scale network for spatial attention.

engagement of this network as a whole enables motivationally relevant extrapersonal events to become the selective targets of attentional behaviors.

Although much has been learned about the spatial attention network shown in Figure 1, many crucial questions remain. In particular, the computational features of the network, its interactions with other partially overlapping networks, the internal functional heterogeneity of its major components, and the physiological basis of right hemisphere specialization are among the major questions that will be attracting new and exciting insights.

Neocortex: Origins

F Aboitiz, Pontificia Universidad Católica de Chile, Santiago, Chile

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The origin of the mammalian neocortex is probably one of the most controversial themes in modern comparative neurobiology. There have been long-standing arguments on this issue (dating from early last century), and still there is no general consensus about it. This is partly due to the enormous anatomical diversification that is observed in the cerebral hemispheres of distinct vertebrate groups. Starting from a relatively conserved embryonic plan that divides the hemispheres into a dorsal pallium and a ventral subpallium, different brain components have expanded in each vertebrate class, producing profound distortions of the ancestral adult condition. For example, cartilaginous fishes are characterized by the development of a central pallial nucleus located at the dorsal midline, while bony fish develop a brain in which the ventricular region everts to the outside, separating the medial hemispheres in the dorsal aspect. Amphibians possess quite a simple brain with little neuronal migration outside the internal ventricular zone, and almost no expansion of cell masses. Their pallium has been subdivided into medial, dorsal, and lateral components. On the other hand, the pallium of reptiles and birds (sauropsida) displays a cortical, laminated architecture containing a medial/dorsomedial (hippocampal) cortex, a lateral (olfactory) cortex, and a small dorsal cortex interposed between these two (in birds, the region corresponding to the dorsal cortex has been termed the Wulst, or more recently, the hyperpallium). These components correspond to the different pallial subdivisions in amphibians. In addition, the brains of sauropsids display a conspicuous nuclear structure that bulges into the ventricle, the dorsal ventricular ridge (DVR), which receives many thalamic sensory projections (Figure 1).

Mammals are characterized by the presence of a neocortex (Figure 1). This structure is bound medially by the medial cortex or hippocampus, and laterally by the lateral or olfactory cortex. Deep to some cortical areas like the insular region there are structures such as the claustral complex. These and other dorsal structures make up the pallium, while the ventral subpallium includes the basal ganglia and related nuclei. The neocortex of mammals is indeed a unique structure, consisting of six laminae that remain somewhat conserved across species and cortical regions. Furthermore, it is subdivided into several distinct areas in the tangential domain, some of them being sensory, others motor, and still others receiving multimodal input. In several mammalian groups there is a clear trend of tangential neocortical expansion that results in the increase of both surface area (leading to the formation of fissures and convolutions) and the number of cortical areas. The neocortex receives most of its extrinsic input from dorsal thalamic nuclei, many of them conveying sensory information from somatosensory, auditory, or visual modalities, and projects back to the thalamus, to the amygdala, to the entorhinal cortex (which in turn projects to the hippocampus), and to several subcortical structures, including the spinal cord.

Historical Background

Early in the last century, concepts on the evolution of the amniote brain (i.e., reptiles, birds, and mammals) were dominated by Elliot Smith's interpretation that sauropsids were characterized by the expansion of subpallial structures like the basal ganglia, leading to the development of the DVR. On the other hand, mammals would have expanded the pallial region, producing the neocortex. Interestingly, other authors, such as Nils Holmgren and Bengt Källén, proposed a pallial origin for the reptilian DVR, which they described as arising from a deep proliferative region that overlaps with the lateral cortex. Holmgren termed this region as the hypopallium, and considered it to be related to deep-brain mammalian structures like the claustrum or parts of the amygdalar complex. However, these views were eclipsed by Elliot Smith's claim for a subpallial origin of the DVR.

Subsequent analyses performed in the 1970s, taking advantage of newly developed histochemical procedures, revealed that the reptilian DVR does not contain acetylcholinesterase activity as the basal ganglia do, and is therefore a pallial structure. Furthermore, tract-tracing experiments performed by Harvey Karten and collaborators, showed that the avian DVR (more specifically, its anterior part, ADVR, or nidopallium) received thalamic sensory projections similar to those reaching some parts of the mammalian neocortex. More precisely, collothalamic nuclei (i.e., thalamic nuclei receiving input from mesencephalic sensory centers, conveying visual and auditory information) project to the ADVR/nidopallium of birds, and to the lateral neocortex of mammals (visual extrastriate and

Figure 1 The cerebral hemispheres of reptiles and mammals. In the dorsal aspect of the hemisphere, reptiles display a cortex, with medial/dorsomedial (MC), dorsal (DC), and lateral (LC) components, and a dorsal ventricular ridge (DVR) consisting of an anterior part and a posterior part (not shown). The anterior DVR receives most sensory projections from mesencephalic-receiving thalamic nuclei. The medial and dorsomedial cortices of reptiles (MC) have been compared to the hippocampal formation (HIP) of mammals, and the lateral cortex (LC) is considered homologous to the mammalian olfactory cortex (OC). The dorsal cortex (DC) of reptiles has characteristics of both the entorhinal cortex (adjacent to the hippocampal formation; not shown) and the neocortex (NC) of mammals. The latter appears subdivided into a dorsal aspect, NCd, and a lateral aspect, NCl. There is no consensus regarding the homology of the anterior DVR. According to some authors, this structure corresponds to the mammalian lateral neocortex (NCl), while others consider that it relates to the claustroamygdaloid complex (AM, CL). Reproduced from Northcutt RG and Kaas JH (1995) The emergence and evolution of mammalian neocortex. *Trends in Neuroscience* 18: 373–379, with permission from Elsevier.

Figure 2 Harvey Karten's original cell-equivalent hypothesis, in which visual processing circuits of the avian nidopallium (N) and arcopallium (Arc) are homologous to those of the different layers in the mammalian extrastriate visual cortex. En, entopallium (a component of the nidopallium); H, hyperpallium; M, mesopallium; P, pulvinar nucleus; R, rotundus nucleus.

auditory cortices). On the other hand, lemnothalamic nuclei (receiving direct sensory input from ascending lemniscal systems, carrying visual or somatosensory input) project to the avian hyperpallium, and to the dorsal neocortex of mammals (primary visual and somatosensory cortices). Thus, Karten proposed that the avian hyperpallium (dorsal cortex of reptiles) was homologous to the dorsal neocortex of mammals (both receiving lemnothalamic input), while the ADVR/nidopallium of birds and reptiles was homologous to the mammalian lateral neocortex (both receiving collothalamic input). Furthermore, relying on similarities in intrinsic connectivity, it was proposed that different components of the avian ADVR corresponded to specific neocortical layers in mammals (Figure 2).

This hypothesis dominated the views of early mammalian brain evolution and neocortical origins for several years. Nevertheless, there were always some dissenters, backed by the early embryological studies and by the different topographical position of the mammalian neocortex and the reptilian DVR. In these alternative views, the most likely homolog of the whole mammalian neocortex was the reptilian dorsal cortex, which is located in a similar relative position as the neocortex: interposed between the lateral (olfactory) and the medial (hippocampal) cortices. Thus, in the origin of mammals, collothalamic projections originally destined to the ADVR or its equivalent region might have deviated or sent collaterals toward an expanding dorsal pallium or dorsal cortex. This change was considered to be more likely to occur than a transformation of the topographic positions of the embryonic proliferative zones and the adult structures. Supporting this view, the mammalian neocortex bears other patterns of connectivity that are not found in sauropsids, like the interhemispheric connections and the corticospinal tract. This is to be expected from a structure that increases in size and consequently increases its connectivity domains. Additional considerations on the topography, development, and connectivity of the sauropsidian ADVR led to the revival of Holmgren's hypothesis of homology between this structure and either the dorsal claustral complex or the basolateral amygdala of mammals.

Developmental and Genetic Evidence

An important breakthrough in this controversy was provided by the analysis of regulatory gene expression patterns in the developing telencephalon, which identified three main compartments during the specification of the cerebral vesicles: the subpallium, being positive for regulatory genes such as *Dlx1* and *Dlx2*; the medial, dorsal, and lateral pallia (or medial, dorsal, and lateral cortices), expressing genes such as *Emx1*, *Tbr1*, and *Pax6*; and the intermediate territory or ventral pallium located between these two, expressing *Tbr1* and *Pax6* but not *Emx1* (Figure 3).

Figure 3 Patterns of regulatory gene expression in the developing telencephalon of sauropsids and mammals. All pallial components (medial, dorsal, and lateral; blue) express the markers Emx1, Tbr1, and Pax6, with the exception of the ventral pallium (yellow), which is positive for Tbr1 and Pax6 but not for Emx1. The subpallium (SP, red) expresses *Dlx* genes. According to this evidence, the ventral pallium gives rise to the reptilian anterior dorsal ventricular ridge (ADVR), to the avian nidopallium (N), and to the claustroamygdalar complex (AM) of mammals. a, vc, termination of auditory and visual collothalamic pathways, respectively; vl, termination of visual lemniscal pathways; DP, dorsal pallium; LP, lateral pallium; Cx, cortex; M, mesopallium; W, Wulst or hyperpallium. Adapted from Aboitiz F, Morales D, and Montiel J (2003) The evolutionary origin of the mammalian isocortex: Towards an integrated developmental and functional approach. *Behavioral and Brain Sciences* 26: 535–586, with permission from Cambridge University press.

Interestingly, the ventral pallium maps into parts of the claustrum and the amygdala of mammals and into the DVR of sauropsids, indicating a common developmental origin for these structures, and supporting embryonic homology between the territories producing the reptilian ADVR and parts of the claustroamygdalar complex of mammals. Nevertheless, it is not clear that in the adult state there is any precise homology between the different ventral pallial derivatives in sauropsids and mammals, as both structures are likely to have undergone distinct evolutionary histories. In fact, fossil evidence indicates that the lineage of mammal-like reptiles diverged quite early from the reptilian line, and that their brains were extremely simple in their gross morphology, resembling more the brains of modern amphibians than those of modern reptiles.

In an attempt to accommodate these data to Karten's original hypothesis, it has been proposed that the lateral neocortex of mammals arose by virtue of a transformation of a ventral pallial structure into a dorsal pallial phenotype. This may have resulted either from the acquisition of dorsal characteristics of a yet unspecified territory, or from duplication of the ventral pallium and subsequent transformation of its dorsal moiety. Nevertheless, these hypotheses might be difficult to refute, as any dorsal pallial feature in the lateral neocortex could be considered to result from the transformation from a ventral to a dorsal pallial structure. Instead, these proposals require positive evidence, such as a direct sign of ventral pallial origin in the lateral neocortex.

Reptilian Dorsal Cortex: Neocortical and Entorhinal/Subicular Features

Furthermore, the presumed homology – between visual and somatosensory areas in the reptilian dorsal cortex, and primary visual and somatosensory areas of the mammalian neocortex – has been questioned by some authors. For example, somatosensory projections to the dorsal cortex have not been observed in either lizards or turtles, and thus may not represent an ancestral character of sauropsids. In addition, visual projections to the dorsal pallium reach a region that in turtles includes the dorsal cortex and the pallial thickening, and in lizards, are restricted to the pallial thickening. The pallial thickening is located in the lateral aspect of the pallium of some reptiles and its homologies and embryonic origins are unclear. Moreover, the multimodal dorsomedial pallium of amphibians and reptiles has several features reminiscent of the mammalian entorhinal cortex. Like the latter, the reptilian dorsal cortex has important connections with the medial/dorsomedial or hippocampal cortices. In addition, the reptilian dorsal cortex does not participate in vision but rather in spatial learning and memory. Thus, the dorsal cortex of reptiles shares features with the entorhinal/subicular cortex of mammals, but also contains a direct visual (and sometimes somatosensory) sensory input that, if perhaps not being strictly equivalent to the mammalian visual (or somatosensory) cortex, may serve to feed sensory information to the hippocampus for establishing sensory associations during learning.

The Dorsalization Hypothesis

Considering the evidence discussed herein, Aboitiz and collaborators proposed that the mammalian neocortex arose as an expansion of an ancestral pallial region with dorsal characteristics, which acquired a massive lemnothalamic and collothalamic input. This may be conceived as a dorsalization effect, in which the activity of genes (*FGFs*, *Wnts*, *Emxs*, *Lhx2*, *Pax6*, and others) or signaling pathways involved in dorsal pallial specification was enhanced, thus producing an increase in proliferative activity leading to the expansion of a primitive dorsal cortex into a neocortex. More precisely, the embryonic dorsal pallium represents a transitional zone that receives influence from several signaling sources, including the anterior forebrain expressing FGF8; the medially located cortical hem expressing Wnts and BMPs, and regulating other genes like *Emxs* (these signals specify both the medial pallium and the neocortex); and the *Pax6*-dependent antihem that specifies the lateral and ventral pallium. The expansion of this transitional tissue may have somehow resulted from the interaction between these three morphogenetic fields.

This process was not only the result of a developmental transformation; probably it was also favored for functional reasons. As nocturnal animals, early mammals probably had refined senses of smell and hearing, which was reflected in the development of a large olfactory bulb, a middle ear, and external outer ears. Strong associative networks involving olfaction and other senses developed in the dorsal pallium and the hippocampus, which participated in the establishment of learned maps of space. These networks benefited from the expansion of the dorsal pallium, which in turn facilitated the projection of collothalamic pathways that were originally directed to the ventral pallium or to the subpallium into this structure.

Lamination of the Neocortex: The Preplate

The neocortex is not only the result of the tangential expansion of the dorsal pallium. There is also a dramatic increase in radial thickness, as the reptilian cortex is only a few cells deep while the mammalian neocortex is organized in vertical columns about 100 cells in depth. As mentioned, the adult neocortex consists of six laminae, the most superficial (layer I) being a cell-poor layer in which tangential axons from Martinotti cells and other axons run along various distances. The development of the neocortex is quite a conspicuous one, in which the first cells to arrive make up a transient embryonic structure termed the preplate, consisting of Cajal–Retzius cells and pioneer neurons. The former derive in large part from the medially located cortical hem and migrate laterally into the neocortex, while pioneer neurons derive mainly from the subpallium. Reelin-secreting Cajal–Retzius cells are involved in radial glia maintenance and in controlling the latest steps of neuronal migration to the cortex, and pioneer neurons display an axon directed subcortically that acts as a guide for growing thalamocortical axons. Subsequently, radially migrating neurons that make up the true neocortical plate arrive from the cortical ventricular zone and split the preplate into two layers: a superficial marginal zone, containing the Cajal–Retzius cells and other cells, and a deep subplate below the emerging cortical plate, containing most pioneer neurons and other cells such as excitatory neurons (**Figure 4**). The latter receive transient contacts from arriving thalamic axons before they enter into the mature cortex. Most of the cells in the marginal zone and the subplate die during development or dilute with cortical expansion, while cells of the cortical plate remain in adulthood. Interestingly, the development of the cortical plate occurs in an inside-out sequence in which the earliest-produced cells end up in the deepest cortical layers, and the latest-produced cells

Figure 4 Lamination of the mammalian neocortex. The earliest cells to arrive at the embryonic cortex make up a preplate (not shown). The preplate becomes divided into two layers: a superficial marginal zone (MZ, future layer I), containing Cajal–Retzius cells (diamond-shaped cells above, brown) that secrete reelin (yellow stars), and a deep subplate (SP), containing pioneer neurons (diamond-shaped cells below, red) whose axon serves as a guide for growing thalamocortical axons. Cells that locate between these layers make up the cortical plate (green ovals) and arrange in five laminae (VI–II in the mature neocortex). These laminae are generated in an inside-out sequence in which early-produced neurons locate above late-produced ones (arrow represents progressively later neurogenetic times).

end up in the more superficial layers. This implies that late-produced neurons have to cross the layers of early-produced neurons and locate above them. Additionally, inhibitory neurons originating in the subpallium populate the developing cortical plate, also following an inside-out gradient in which early-produced cells arrive at deeper layers and late-produced cells arrive at superficial layers. This whole process contrasts with the situation of the much thinner reptilian cortex, where cells migrate in an outside-in sequence, early layers locating more superficially than late-produced layers.

Is there any correspondence between the reptilian cortical cells and the different layers making up the mammalian neocortex? Miguel Marín-Padilla originally proposed that neurons of the mammalian preplate (more specifically, those making up the subplate) were homologous to the reptilian cortex, the cortical plate being a developmental addition to the mammalian brain. However, other authors proposed that the mammalian preplate and the subplate emerged as devices to support the development of corticocortical connectivity in mammals. Instead of corresponding to the mammalian preplate, the reptilian cortex was claimed to be homologous to the deep neocortical layers V and (especially) VI of the mammalian cortical plate.

There are reports of a subplate-like structure in reptiles consisting of tangentially migrating interneurons, but no excitatory neurons have yet been described in it. On the other hand, in a marsupial, no subplate was detected and corticothalamic axons were seen directly penetrating the cortical plate, instead of establishing transient contacts below it as they do in placental mammals. If this observation is correct and true for all marsupials, it would imply that at least part of the subplate (its excitatory component, which receives arriving thalamic axons) is an acquisition of placental mammals. Moreover, in some mammals, including some marsupials, there is an adult cortical layer inferior to layer VI, termed layer VIb or VII, which contains persisting subplate cells. These cells have been considered to be closely related to the deepest neurons in the cortical plate. Furthermore, there is molecular evidence for an intimate relation between the inferior layers of the cortical plate and the subplate. The gene *Tbr1* marks both subplate neurons and the earliest cortical plate neurons, and mutations in this gene cause defects in both structures. Thus, in the origin of mammals (or of placental mammals), a subplate-like structure containing tangentially migrating neurons might have incorporated excitatory cells that originally belonged to the cortical plate, that aided in the guidance of thalamocortical axons.

Origin of the Superficial Neocortical Layers and the Inside-Out Neurogenetic Gradient

Additional molecular evidence supports the concept of the superficial neocortical layers IV–II as developmentally distinct from the inferior layers VI and V. Among other features, mutants for the gene *Pax6* exhibit cortical migration defects, consisting of the inability to migrate and differentiate supragranular neocortical neurons belonging to layers IV to II. Furthermore, early-produced cortical plate neurons destined to neocortical layers VI and V are produced in the embryonic ventricular zone and express the marker gene *Otx1*. On the other hand, late-produced neurons, which depend on *Pax6* for their development and are destined to superficial layers IV–II, are produced in the subventricular zone surrounding the ventricular zone, and express the marker gene *Svet1*. Thus, *Pax6* may be involved in the origin of the superficial neocortical layers by recruiting the subventricular zone in the neurogenetic process. Further findings indicate that the proneural genes *Ngn1* and *Ngn2* specify the laminar characteristics of early-born cortical neurons, but upper-layer cortical neurons are specified in an *Ngn*-independent manner, requiring instead the synergistic activities of *Pax6* and *Tlx*. There is also comparative evidence indicating a progressive development of the subventricular zone in large-brained mammals, its near absence in the reptilian embryonic dorsal cortex, and its independent development in the avian nidopallium. It will be of interest to determine what, if any, is the contribution of the subventricular zone and of the genes *Pax6*, *Svet1*, and *Tlx* to dorsal cortical development in reptiles.

In this context, the effect of mutations in some genes involved in the regulation of cortical cell migration has provided further clues to the development of the laminar organization of the neocortex. For example, the reeler mutant mouse, deficient in the extracellular protein reelin, shows a striking inversion of the developmental gradient in the cortical plate, in which early-produced neurons become located superficially and late-produced neurons arrange in the inferior layers. Furthermore, in this mutant the preplate is not split and is compressed above the cortical plate. In the adult, no cell-poor layer I is detectable, as the cortical plate cells are observed immediately below the subpial layer. Electron microscopy analyses indicate abnormal attachments between the neurons and the radial glia, suggesting that these neurons did not detach correctly from the latter. There have been several hypotheses for the participation of reelin in the control of neuronal migration, including a role as

a stop signal, as a glial detachment signal, or as an attractor for migrating neurons. Overall, the evidence indicates that reelin has a role in the final stages of neuronal migration and, more important to our purposes, in detaching migrating neurons from the radial glia, and in the generation of a cell-free superficial marginal zone. Reelin is present in several other brain regions besides the cerebral cortex, and its patterns of expression reflect an evolutionarily stable framework. However, reelin expression is strongly amplified in the mammalian cortical marginal zone in relation to the reptilian marginal zone, indicating that this molecule has been one key element in the origin of the neocortex. Furthermore, the level of reelin expression correlates with the degree of columnarity present in the dorsal cortex of different reptiles, suggesting that it may have contributed to the radial organization of the mammalian neocortex.

Another molecule of interest is the cyclin-dependant kinase cdk5; cdk5 and its activator, p35, are fundamental for the adequate lamination of the neocortex. Recently, two modes of radial migration have been characterized: nuclear translocation, in which the leading process of the neuron is attached to the subpial layer and the cell body is dragged toward the periphery as a consequence of the shortening of this process; and cellular locomotion, in which cells migrate along the radial glia in their pathway to the cortex. Interestingly, early-produced, deep-layer cortical neurons migrate mainly by translocation, while late-produced, superficial neurons use glial-guided locomotion to reach the cortical plate. Mutants for the enzyme cdk5 show strong deficits in locomotion, and therefore the superficial layers of the cortex fail to form. In these animals, neurons are not able to reach the cortical plate by birth and remain in the subcortical intermediate zone. However, early-produced layer VI cells which migrate by translocation do so correctly and are able to split the preplate normally. Moreover, mutants for the cdk5 activator p35 display milder defects in locomotion, and neurons from all layers are able to reach the cortical plate by birth. However, within the cortical plate, cells arrange in an inverted outside-in gradient reminiscent of the reeler mouse, but with the difference that the preplate has been partially split and there is a normal marginal zone. *N*-Cadherin-mediated cell aggregation in migrating neurons is inhibited by cdk5/p35, which provides a possible mechanism by which normally migrating cells may use this cascade to bypass a migration-suppressing signal (*N*-cadherin or a related molecule) present in postmigratory neurons, to move above them. Considering that early-produced cortical plate cells are more likely to correspond to reptilian cortical cells, it is conceivable that the cdk5-independent mechanism of translocation represents an ancestral condition, while the activation of the cdk5 pathway represents an evolutionary innovation of the mammalian brain, associated with new modes of neuronal migration and, by virtue of the activator p35, contributing to the generation of the inside-out neurogenetic gradient that is characteristic of the neocortex.

A Scenario for the Origin of Neocortical Lamination

Based on this evidence, a possible scenario for the evolution of cortical lamination is that initially there was a radial expansion of the primitive mammalian cortex, producing late-born, phylogenetically new neurons which participated in local processing circuits, as opposed to the older neurons that function as an output layer. These new elements originated in an expanded subventricular zone, by virtue of the action of the gene *Pax6*, among others. The acquisition of an inside-out neurogenetic gradient was possibly related to the ancestral organization of afferents to the primitive cortex. The neocortex differs from other structures, including the hippocampus, the olfactory cortex, and the reptilian cortex, in the strong radial organization of its inputs, in which afferents penetrate the cortical plate from the underlying white matter (aided by subplate cells and pioneer neurons); in these other structures the afferents arrange tangentially in the superficial marginal zone (**Figure 5**). Radial expansion of the primitive cortex in the context of a primitive outside-in developmental pattern would have left the new, local processing neurons located below the early-produced output neuronal layer, separating them from the superficially located afferents. In such context, there would be a benefit to those individuals in which late-produced neurons were able to cross the layer of early-produced cells, generating an intermediate layer between the input axons and the output cells. In other words, the inside-out neurogenetic gradient was produced in order to maximize synaptic contacts between the new, late-born neurons, and the superficially located cortical afferents. In this process, the cdk5 signaling pathway facilitated new mechanisms of radial migration, and especially its activator p35 was important in permitting late-born neurons to cross the barrier formed by previously migrated cells. Finally, an important increase in the expression of reelin by Cajal–Retzius cells permitted the preservation of a neuron-free marginal zone. Reelin also contributed to stop radial migration by detaching migrating neurons from the radial glia, thus facilitating the migration of young neurons past old ones.

Figure 5 Postulated sequence in the evolution of neocortical lamination. In a primitive state (I) like that of reptilian cortex, with an outside-in neurogenetic gradient (arrow downwards), pioneer neurons (pointed ovals, red) locate in the superficial marginal zone and guide thalamocortical axons (Y-shaped lines) tangentially above the cortex (ovals, blue, green, and yellow). A second stage (II) may be exemplified by the hippocampus, which already displays an inside-out gradient (arrow upwards) while its afferents are located superficially. The neocortex of the hedgehog (Insectivora) represents a third stage (III), where axons enter the cortical plate from below but many run obliquely and end tangentially in the marginal zone. Finally (IV), the primary sensory cortex of advanced mammals displays axons radially entering the cortex and synapsing with neurons in layer IV, and a large proportion of pioneer neurons locate in the subplate below the cortex.

As the neocortex expanded tangentially, however, the distance traveled by tangential afferent axons became increasingly longer, with a consequent impairment in transmission time. A solution to this problem was provided by the rerouting of these axons via the subcortical white matter, making a shortcut to their final targets. This was possible by virtue of the displacement of the pioneer neurons attracting the thalamic afferents, from a superficial position in the marginal zone of reptiles, to a deeper position in the subplate of mammals. Thus, there were several steps in the acquisition of a neocortex, including the increase in cortical thickness, the origin of the inside-out gradient, and the displacement of axonal trajectories from a superficial to a subcortical position. Interestingly, intermediate stages may be found between the reptilian cortex, displaying superficial, tangential inputs, and the advanced mammalian neocortex, with radially organized inputs. For example, like the neocortex, the hippocampus has an inside-out developmental gradient, but also a superficial localization of afferents, indicating a step above the reptilian cortex. A subsequent stage may be represented by the neocortex of the primitive insectivore *Erinaceus*, in which axons penetrate the cortex radially from the underlying white matter, cross obliquely to the marginal zone, and run tangentially there for some distance. Finally, in the sensory neocortex of advanced mammals, afferents enter the cortex radially and synapse in spiny stellate neurons of layer IV (Figure 5).

Final Comments

Summarizing the views presented here, the mammalian neocortex displays several unique characteristics and therefore the term 'neocortex' is indeed appropriate. One main dicussion in relation to its origins concerns the ancestral structure that gave rise to it. There are two main proposals in this regard, one that claims that the neocortex partly arose from the DVR of reptiles, and the other that prescribes that it originated as an expansion of the dorsal pallium. Current developmental evidence tends to favor the latter, as the reptilian DVR has embryonic origins similar to those of the mammalian claustroamygdalar complex in the ventral pallium. The neocortex is also unique in its laminar structure. Recent genetic and developmental analyses have provided important insights as to the mechanisms and possible sequence of events that gave rise to the neocortex, producing its characteristic inside-out neurogenetic gradient and the rerouting of thalamic afferents from a superficial to a deep, subcortical position. All this evidence strengthens the view that development may not only give clues to evolutionary processes, but also that variations in the developmental processes are the main events in the generation of new structures in evolution.

Neocortical Organization in Monotremes

L Krubitzer and K Campi, University of California at Davis, Davis, CA, USA

© 2009 Published by Elsevier Ltd.

Introduction

Monotremes are a unique order of mammals that includes only three extant species: the duck-billed platypus (*Ornithorynchus anitinus*), the short-billed echidna (*Tachyglossus aculeatus*), and the western long-billed echidna (*Zaglossus bruijni*). Like other mammals, monotremes possess a segmented jaw, have three bones that comprise the middle ear, are warm blooded, and lactate. However, they have retained at least some characteristics of therapsid reptiles, such as laying eggs and the presence of a cloaca (in fact, the term 'monotreme' literally means 'single hole'). Although these animals are often referred to as primitive or ancestral, they are not the ancestors of all mammals. Instead, monotremes formed a very early radiation of mammals that originally evolved from early synapsids, which are considered to have been reptile-like mammals (Figure 1). Monotremes are of interest from a neurobiological perspective because it is thought that they may have retained features of brain organization that were present in the first mammals.

Of course any extant mammal is a compilation of both retained characteristics and newly derived features, and monotremes possess both general and specialized features of the body and the brain. For example, as determined by the fossil records, the first mammals appeared about 200 Ma (Figure 1), during the late Triassic or early Jurassic period, and are thought to have laid eggs; however, they were shrew-like animals that did not possess a bill, unlike the three extant monotreme species today. Thus, the distinct bill of the platypus and the unique bill and tongue of the echidna are newly derived features that are associated with navigation, mate selection, and prey capture, and these features are related to highly specialized lifestyles of these three species. This idea also holds true for features of brain organization. Studies of monotreme neocortex suggest that they have retained a number of general mammalian characteristics, as well as incorporated a number of newly derived features associated with their unique morphological specializations and behavior. This article describes the organization of somatosensory, visual, auditory, and motor cortex, as determined from architectonic analysis, electrophysiological recordings, and anatomical connection studies in two of the three extant monotreme species, the duck-billed platypus and the short-billed echidna (to our knowledge, the neocortex of western long-billed echidna has not been examined). We will compare the neocortical organization in monotremes with that of other species to determine which features are common to all mammals. Such a comparison allows us to infer the organizaton of neocortex of early mammals.

Gross Brain Morphology

The brains of the platypus and the echidna are distinctly different from each other; the platypus has a smooth, relatively small brain (Figures 2(a) and 2(b)), and the echidna has a convoluted, large brain with commensurate expansion of the cortical sheet (Figures 2(c) and 2(d)). In the echidna, the major sulci of the brain are termed the α sulcus and the β sulcus (Figure 2(c)), and much of the cortical surface is buried within the fissures (Figure 2(d)). In the platypus, sensory cortical areas occupy the caudal two-thirds of the entire cortical sheet, and motor cortex occupies much of the remaining rostral cortex. Similarly, in the echidna, sensory cortex is located in the caudal portion of the neocortex, caudal to the α sulcus, and motor cortex is located just rostral to sensory cortex, between the α and β sulci. While there is very little cortex rostral to motor cortex in the platypus, in the echidna there is an enormous expansion of the cortical sheet rostral to motor cortex, the function of which is unknown.

The size of pyriform cortex also differs between the platypus and the echidna. The pyriform cortex is separated from the neocortex by the rhinal sulcus and is located lateral (ventral) to the neocortex. In the echidna, the relative size of pyriform cortex with respect to the neocortex is very large compared to the pyriform cortex of the platypus. As in many other mammals, the olfactory bulb of the platypus is smooth and relatively small; however, the olfactory bulb in the echidna is extremely large and contains a number of fissures. The increased size of pyriform cortex and the olfactory bulbs in echidnas may be related to the expansion of the frontal lobe (discussed in the section titled 'Multimodal and frontal regions of cortex').

Somatosensory and Electrosensory Cortex

Much of what is known about the organization of the neocortex in monotremes comes from studies of the somatosensory system. This is likely due

Figure 1 A cladogram depicting the phylogenetic relationships of reptiles, birds, and the three major groups of mammals, including monotremes. A large vertebrate group, the synapsids, arose more than 300 million years ago (Ma) and includes all mammals. Early synapsids are considered to be mammal-like reptiles that ultimately gave rise to the first mammals more than 200 Ma. Monotremes arose about 200 Ma, before the radiation of marsupials and placental mammals, approximately 180 Ma. Fossil records indicate that extant monotremes, which include the platypus and two species of echidnas, are highly derived, particularly in the structure of their bill, and in this respect do not resemble the first mammals.

to the unique morphological specialization of the bill, which is critical for the survival of these species and dominates the organization of the nervous system along the entire neuroaxis. Previous functional mapping studies have demonstrated that the somatosensory neocortex of both the platypus and the echidna is composed of three separate fields, a primary somatosensory area (S1 or area 3b), a rostral field (R), and a field just caudal to S1 that is in the position of the parietal ventral area (PV) in other animals (Figure 2).

The primary somatosensory area is a large field in both the platypus and the echidna and is topographically organized, with the tail and feet represented most medially, followed by the representation of the trunk, forelimbs, and face more laterally. In both the platypus and the echidna, the most striking feature of S1 is the bill representation, and in the platypus, neocortical specializations associated with their electrosensory abilities are remarkable. Specifically, the platypus has evolved electrosensory receptors that are located in a striped pattern down the bill and are interdigitated with the mechanosensory receptors, which are also arranged in stripes (Figure 3). Unlike electroreception in some electric fish, electroreception in the platypus is passive. Electrosensory receptors enable the platypus to locate electrical signals emitted from the muscle of small prey such as insects and crayfish, which generate electrical fields that can be as small as $20\,\mu V\,cm^{-1}$. Unlike other mammals, the platypus uses electrosensation combined with somatosensation (instead of vision, audition, and olfaction) for most daily activities, including navigation, mating, and feeding. Correspondingly, the bill representation comprises about 90% of S1. In cortex that has been sectioned tangentially and stained for cytochrome oxidase (CO), the bill representation of S1 stains heterogeneously, with CO light regions interdigitated with CO dark regions (Figure 3). These dark and light regions contain neurons responsive to mechanosensory and electrosensory stimulation, respectively.

Like the platypus, the echidna also has an extremely large representation of the bill in S1. However, there are substantially fewer electroreceptors in the bill of the echidna (only a few hundred to 2000) compared with the 40 000 receptors found on the platypus bill. Thus, it is likely that electroreception is not used to the same extent in the echidna as it is in the platypus. Nevertheless, the echidna does use its bill and elongated tongue when foraging for termites and other insects, and this specialization is reflected in the organization of the somatosensory cortex. Most notably, the rostral 1 cm of the bill assumes the greatest amount

Figure 2 Gross brain morphology in the echidna and the platypus, depicting the location of sensory and motor areas (a,c), and flattened cortex depicting all the known sensory and motor areas of the cortex in each species (b,d). The echidna has a large, highly fissured, gyrencephalic brain, while the platypus has a smooth, lissencephalic brain. In the platypus, much of the entire neocortex is composed of the primary somatosensory area (S1), the rostral somatosensory field (R), the parietal ventral area (PV), and motor cortex (M). In the echidna, sensory cortex, including S1, is located caudally in the brain, and M is located between two major sulci, termed α and β. The rostral field (R) in echidnas is buried in the β sulcus. Primary sensory areas (S1, A, and V1) have been identified in both species. A small amount of cortex surrounding A has been identified as multimodal (MM). The relative amount of S1 cortex in the platypus is quite large, and most of this is occupied by the representation of the bill (see **Figure 3**). The echidna cortex is of particular interest because frontal cortex has undergone an extreme expansion, and such an expansion is not observed in the platypus. H, hippocampus; VIS, visual cortex; Vr, rostral visual field; V+S, visual and somatosensory cortex. Arrow directions M and R refer to medial and rostral, respectively.

of cortical space within the entire representation of the bill, and the receptive fields for neurons in this rostral representation are extremely small. As in the platypus, S1 in the echidna stains darkly for myelin, and architectonic analysis by Hassiotis and colleagues has demonstrated that S1 can be readily distinguished with acetylcholinesterase stains (AChE) and a monoclonal antibody reaction to neurofilament protein (SMI-32).

A second field, just rostral to S1, termed the rostral field (R), has been identified electrophysiologically and architectonically in both the platypus and the echidna. As in S1, R contains a complete representation of the contralateral body with a similar medial to lateral organization; however, neurons in R respond to stimulation of deep receptors whereas neurons in S1 respond to cutaneous stimulation. Like S1, R also contains an enlarged representation of the bill in both the platypus and the echidna. R can be distinguished from S1 architectonically because it stains lightly for myelin and CO compared with S1. Furthermore, architectonic studies show that the laminar distribution of AChE in R is distinct from that of S1.

Finally, a cortical field just caudal to S1, termed PV, has been described in both the platypus and the echidna. This field contains a complete representation of the cutaneous receptors of the contralateral body that is distinct from the representation in S1. This field is in the relative position of PV described in other mammals and has a similar topographic organization. Within PV, the tail is represented medially, the hind limb is represented caudolateral to the tail, the forelimb is represented rostrolateral to the tail, and the bill is represented lateral to these representations. Like S1 and R, there is an enormous magnification of the representation of the bill. Together, the bill representation in all three fields comprises approximately 64% of the entire cortical surface. Such magnification of a single body part is rarely seen in other mammals. PV, in both platypus and echidna

Figure 3 An illustration of the platypus (above), depicting the location of electrosensory receptors (white stripes) on its bill. The enormous size of the bill representation within the three separate somatosensory fields in the platypus neocortex (below) reflects the importance of the bill for survival behaviors. Within the primary somatosensory area (S1), mechanosensory receptors (shaded regions), interdigitate with the representation of electrosensory receptors. See **Figure 2** for abbreviations.

brain sections, stains moderately for myelin, and architectonic analysis in the echidna indicates that PV can be readily distinguished from S1 with a number of different stains, including AChE, parvalbumin, and SMI-32.

Anatomical studies have been done only in the echidna. Specifically, degeneration studies by Welker and Lende and neuroanatomical tracer studies by Ulinski have demonstrated that the major projection from the thalamus to S1 is from the ventral posterior nucleus. Cortical area R also receives input from the ventral posterior nucleus. Cortical connection experiments have shown that S1 has dense connections with R and PV, moderate connections with motor cortex, and sparse connections with visual cortex.

Taken together, the architectonic, electrophysiological, and anatomical data indicate that three somatosensory fields are present in the platypus and the echidna: S1, R, and PV. All these fields have a greatly magnified representation of the bill, and in the platypus, S1 modules associated with electrosensory reception have been identified.

Visual Cortex

Relatively little is known about the organization of visual cortex in monotremes. In the platypus, studies of visual cortex organization are rare, but the limited data that exist from electrophysiological recording studies demonstrate that two fields are present, a caudal (Vc) and rostral (Vr) visual field (**Figure 4(a)**). The caudal visual field, Vc, contains neurons that are responsive only to visual stimulation. Although the visuotopic organization of this field is not as precise as in other mammals, Vc contains a representation of both the upper and lower central visual hemifield. Because neurons in Vc respond vigorously to visual stimulation and have relatively smaller receptive fields than neurons in Vr, this field may be homologous to V1, as described in other mammals. The rostral visual field, Vr, contains a representation of the visual hemifield; however, neurons in this field have larger receptive fields and respond less vigorously to visual stimulation. Architectonic analyses of these fields indicate that both are coextensive with a darkly myelinated zone, although Vc is slightly less myelinated than Vr.

In the echidna, early evoked potential studies by Lende demonstrated that visual cortex is located just medial to somatosensory cortex, and this has been confirmed in more-recent microelectrode recording studies by Krubitzer. Cortex in which neurons are responsive to visual stimulation has been subdivided into two and sometimes three distinct fields on the basis of architectonic analysis and anatomical connections. For example, architectonic analysis by Hassiotis and colleagues is consistent with electrophysiological recording studies by Lende and by Krubitzer and demonstrates that there is a visual field representation in the position of V1 which can be readily distinguished from the surrounding fields using myelin stains and AChE reactivity. Based on architecture, these investigators also distinguish a second field rostromedial to V1 that may correspond to V2 in other mammals. Furthermore, injections placed in the caudolateral portion of this field (which may be V1 plus the rostral area as defined by Hassiotis and colleagues; and Vc plus Vr as defined in

Figure 4 The functional organization of visual cortex in the platypus (a) and auditory cortex in the echidna (b). For both, the illustration at the top is an enlarged drawing of the area in the inset in the whole brain below. (a) Although the data are limited to a few platypus, there appear to be two representations of the contralateral hemifield. There is a caudal field, which appears to be homologous to V1 described in other mammals, and a rostral field, which may correspond to V2 in other mammals. On the basis of their location, these are termed Vc and Vr, respectively. (b) There appear to be two auditory fields in the echidna. In the caudolateral field, frequencies are represented from high caudally to low rostrally in isofrequency bands, much like A1 in other mammals. Because of the similarities between this field and the primary auditory area described in other mammals, we have termed this field A1. A rostromedial field (RM) is also present, in which frequencies are represented from low to high in a caudal to rostral progression. See **Figure 2** for abbreviations.

platypus) resulted in labeled cells and axon terminals immediately around the injection site, in cortex far rostral to the injection site, and in cortex lateral to the injection site. Finally, limited architectonic analysis and anatomical connection studies show that the cortex located caudal to the darkly myelinated V1, which has been previously demonstrated to contain neurons responsive to visual stimulation, has reciprocal connections with V1.

On the basis of cortical connections, architectonic analysis, and electrophysiological recordings in the platypus and the echidnas, it appears that at least two and possibly three fields exist in visual cortex. One of these fields, based on architecture, appears to be homologous to V1 described in other mammals. However, thalamocortical connections of visual cortex suggest that major differences exist between visual cortex in monotremes and other mammals.

Thalamocortical connections of visual cortex have been examined only in the echidna by Welker and Lende. Using degeneration methods, these investigators found that lesions in visual cortex resulted in degeneration of a nucleus that they termed the occipital pole region (OP) of the thalamus. This is different from other mammals in which the major source of input to V1 is the lateral geniculate nucleus (LGN). In a previous review we proposed several alternative interpretations of their result. The first is that the lesioned region may not have been V1, as other data described above indicate; at least two and possibly three fields exist in this region. A second possibility is that the LGN was misidentified, although this seems unlikely since most other investigators who examined the architecture of the thalamus in monotremes place the LGN in the same location as did Welker and Lende. Third, it is possible that OP corresponds to the pulvinar in other mammals and that connections have been altered in marsupial and placental mammals. Finally, it is possible that none of the visual areas defined in the platypus and the echidna correspond to V1 and that V1 and its unique pattern of connectivity evolved later in marsupial and placental mammals. Support for the latter two hypotheses (that OP corresponds to the pulvinar and that V1 is a more recently evolved cortical field in marsupials and placental mammals) comes from studies of retinal projections in the echidna. These studies demonstrate that the superior colliculus, rather than the poorly differentiated OP, receives the majority of input from the retina.

Taken together, the data indicate that at least two and possibly three visual fields are present in monotremes, but the connections of these fields in monotremes appear to be somewhat different from those in other groups of mammals. It is uncertain whether this difference is a reflection of a primitive form of brain organization present in the common ancestor or whether these differences represent derivations of animals that have reduced visual pathways and rely very little on vision.

Auditory Cortex

The location of auditory cortex in both the platypus and the echidna was described in early evoked potential studies by Lende and by Bohringer and Rowe, respectively, and in more-recent microelectrode recording studies by Krubitzer. In the platypus, early studies indicated that auditory cortex completely overlaps visual cortex; however, recent studies have provided evidence for a small region of cortex, just caudal to the medial portion of S1 and lateral to V1, in which neurons respond solely to auditory stimulation (**Figure 4(b)**). Architectonic analysis of this cortex demonstrates that this field, which appears to be homologous to A1, stains darkly for myelin. A small belt of cortex immediately surrounding auditory cortex in the platypus contains neurons responsive to more than one modality.

In the echidna, auditory cortex has been examined using electrophysiological recording procedures as well as architectonic analysis. Early functional mapping studies demonstrated that, as in the platypus, auditory cortex in the echidna is unimodal and is located just lateral to V1 and caudal to the medial portion of S1. In studies in which the neural response to pure tone frequencies was determined, the data show that two tonotopically organized fields are present: a rostromedial field, in which frequencies are represented from low frequencies caudally to high frequencies rostrally (**Figure 4(b)**), and a caudolateral field, in which low frequencies are represented rostrally and high frequencies are represented caudally. The internal organization of this caudal field suggests that it is homologous to A1, as described in other animals. Architectonic analyses of the auditory cortex in echidnas demonstrate that these auditory fields are darkly myelinated and that they are particularly distinct in AChE- and parvalbumin-stained tissue.

There are only a few studies of the anatomical connections of auditory cortex in monotremes, and these are limited to studies in the echidna. For example, Dann and Buhl demonstrated that auditory cortex has patchy connections with adjacent fields, which may be other auditory fields. Degeneration studies of auditory cortex by Welker and Lende reported that lesions to auditory cortex result in degeneration of posterior regions of the thalamus, in the location of the medial geniculate nucleus (MG), although they did not specifically identify the MG nucleus architectonically.

Together, the data indicate that monotremes have a separate region of cortex that is devoted to processing unimodal auditory inputs. This cortex is architectonically distinct from surrounding cortex and receives inputs from posterior portions of the thalamus, likely MG. Limited electrophysiological and connection data in monotremes suggest that within this unimodal auditory region, two fields are present, one of which may be homologous to A1 described in other mammals.

Motor Cortex

Studies of motor cortex in monotremes began more than a century ago. In these early experiments, electrical stimulation of both the platypus and the echidna neocortex produced movement maps that were roughly topographically organized from foot to forelimb to face in a mediolateral progression. Subsequent studies by Lende and by Bohringer and Rowe confirmed these early findings and provided more details about the topography of motor cortex and its relationship to sensory cortical areas. In the platypus, it appears that almost all motor cortex completely overlaps somatosensory cortex, including what would be S1, R, and PV. In contrast, in the echidna, motor cortex appears to form a separate representation that may only partially overlap R. Architectonic studies in the echidna by Ulinski have illustrated that just rostral to cortical area R is a reduced layer IV and a very thick pyramidal cell layer (layer V), similar to area 4 or motor cortex described in other mammals. A recent architectonic analysis by Hassiotis and colleagues has confirmed this and has also identified a region of transitional cortex between M and R.

There are only a few studies on the anatomical connections of motor cortex in monotremes, and these are limited to studies of thalamocortical connections in echidnas. Degeneration studies by Goldby and by Welker and Lende demonstrate that the region of cortex defined as M1 (located between the α and β sulci) receives projections from the ventral lateral nucleus (VL) of the thalamus. However, it should be noted that the region of degeneration in these lesion studies was large and included posterior portions of the dorsal thalamus other than VL. These data are consistent with the idea that at least echidnas have a separate motor

cortex that receives input from the motor nucleus of the thalamus, as in other mammals.

Taken together, the data indicate that there may be two distinct types of motor cortex organization in monotreme neocortex. The first is a sensory–motor amalgam in which somatosensory and motor cortex are completely overlapping. This type of sensory–motor amalgam appears to be present in platypus and has been previously described by Lende in some marsupials. The second type of organization consists of a separate motor representation that is distinct from somatosensory cortex. This type of organization occurs in echidnas and is commonly observed in placental mammals. As in placental mammals, the primary source of input to motor cortex in echidnas is from VL of the thalamus.

Multimodal and Frontal Regions of Cortex

An interesting feature of cortical organization in both the platypus and the echidna is that the amount of nonspecific sensory cortex that resides between known unimodal sensory areas is extremely small. In both species, the small belt of cortex lateral to V1 and caudal to S1 and surrounding A1 contains neurons that respond to auditory and somatosensory stimulation, visual and auditory stimulation, or visual and somatosensory stimulation. In most other mammals, this region is somewhat larger, even in small-brained mammals, and is occupied by multimodal cortex (MM; cortex in which neurons respond to more than one modality). In primates, the geographic location of this region (termed posterior parietal cortex) has shifted away from auditory cortex with the expansion of the cortical sheet and is dramatically expanded and contains multiple cortical fields. The observation that sensory cortex in monotremes is dominated by primary sensory areas (S1, V1, and A1) and only one or two other fields devoted to processing sensory information for each sensory system, combined with the limited extent of multimodal or association cortex, suggests that unimodal sensory cortical areas emerged early in evolution. These data in monotremes, when compared with the neocortex of marsupial and placental mammals, suggest that association cortex, including regions of posterior parietal cortex, became increasingly differentiated, and in some groups of placental mammals such as primates, it came to occupy either as much cortical territory as unimodal sensory fields or more.

One of the most remarkable observations in the neocortex of the echidna is the enormous expansion of cortex rostral to motor cortex. This cortex contains neurons that are unresponsive to any mode of sensory stimulation, at least in anesthetized animals. Based on the position of this area on the cortical sheet as well as patterns of projections from the mediodorsal nucleus of the thalamus, entorhinal cortex, amygdala, basal forebrain, pyriform cortex, substantia nigra, and the ventral tegmental areas, previous studies have proposed that this cortex is similar to prefrontal cortex in some mammals. However, the lack of the expanded frontal cortex in the platypus, as well as other mammals, including a variety of marsupial and placental mammals, which have only a very small region of cortex rostral to motor or sensory motor cortex, indicates that this expanded neocortex in the echidna arose independently and is a derivation of the echidna brain. Previously we proposed that the expansion of cortex rostral to motor cortex in echidnas might be associated with the elaboration of the olfactory system. As noted above, both pyriform cortex and the olfactory bulb in the echidna (**Figure 2**) are relatively large compared with its other brain structures and compared with these same structures in the platypus. Although olfaction has not been well studied in the echidna, it is possible that the expanded frontal cortex in the echidna is comparable to orbitofrontal cortex in other mammals and that it is related to the enhanced olfactory abilities of echidnas.

Comparisons with Other Mammals

While the organization of monotreme neocortex is interesting in and of itself, the importance of understanding cortical organization in monotremes is underscored when comparisons are made across all three mammalian lineages (monotremes, marsupials, and placentals). For example, as in other mammals, monotremes have undergone several modifications, which include a reconfiguration of sensory receptor morphology; expansions of cortex related to behaviorally relevant body parts, such as the bill representation in S1 and the expansion of frontal cortex in echidnas; and alterations in cortical connectivity. Similar modifications to the neocortex have been observed in marsupial and placental mammals, suggesting that the types of alterations made to evolving brains is highly constrained such that brain organization, even in distantly related species, often takes a similar form.

In addition to these modifications, a comparative analysis allows us to appreciate that there are a number of features of cortical organization that are similar in all three groups of mammals. First, there is a constellation of cortical fields that includes the primary sensory and motor areas (S1, V1, A1, and M1), as well as additional unimodal fields such as PV, R, Vr, and a second auditory field. Another interesting

Figure 5 General phylogenetic relationship of the three major groups of mammals, and the cortical organization in representative mammals from each group. A comparative analysis indicates that all mammals have a constellation of cortical fields, including S1, R, PV, V1, A1, and two or three additional unimodal sensory areas. All mammals appear to possess either a separate motor area or a sensory–motor amalgam. Finally, all mammals have multimodal cortex. This type of analysis allows us to deduce the cortical organization of the common ancestor, which likely had these features of neocortical organization as well. Changes to the plan of cortical organization observed in different lineages include an expansion of the cortical representation of behaviorally relevant body surfaces, the expansion of the cortical sheet, the addition of new cortical fields, and alterations in connectivity. 1 and 3b are somatonsensory areas; A and A1, auditory cortex; A2, second auditory area; AAF, anterior auditory field; C, caudal; CT caudal temporal field; DI, dorsal intermediate visual area; DL, dorsal lateral visual area; DM, dorsal medial visual area; FEF, frontal eye field; FM, frontal myelinated field; FST, fundal superior temporal area; FV, Frontal ventral visual eye field; ITc, caudal inferotemporal area; M, motor cortex; M1, primary motor area; MM, multimodal cortex; PV, parietal ventral areas; R, rostal somatosensory field; S1, primary somatosensory area; SMA, supplementary motor area; S2, second somatosensory area; U2, ultrasonic area; VA and VP, divisions of the ventral visual area; V1, visual cortex; V2, second visual area; Vr, rostral visual field; VS, ventral somatosensory area.

observation that can be made by comparing the cortical organization in monotreme, marsupial, and placental mammals is that there is more than one sensory field present for any given modality in all lineages. Until recently, it was believed that only primary sensory areas existed in monotremes. This notion led to the assumption that primary cortical fields are the evolutionarily oldest fields and that second and third sensory areas were added hierarchically in marsupial and placental mammals. The presence of at least three somatosensory fields, two visual fields, and two auditory fields in all mammals investigated suggests that the first mammals had two to three sensory areas for each modality and possibly a separate motor field as well. Thus, there is no clear evidence that primary cortical areas are phylogenetically older than other unimodal sensory areas.

Finally, a comparative analysis reveals that MM is present in all mammals, although its relative size and location is altered in different species. For instance, in monotremes, MM assumes a very small proportion of the neocortex and surrounds auditory cortex (**Figure 5**). In marsupials, MM has been identified just caudal to somatosensory cortex, lateral to visual cortex, and medial to auditory cortex. In placental mammals such as primates, this cortex has undergone a dramatic expansion and is composed of a number of cortical fields, although its location between visual, somatosensory, and auditory cortex is similar to that of MM in smaller-brained mammals such as mice. The presence of MM in all mammals investigated suggests that the first mammals had a small MM which was the forerunner of the more expanded posterior parietal cortex in marsupial and, particularly, placental mammals. This suggests that the potential for cross-modal integration of sensory inputs, which ultimately leads to the planning and execution of complex overt and covert behaviors, was present in a very primitive form in the common ancestor of all mammals.

Neonatal Circuits

Introduction

Rhythmic patterns of coordinated movement are produced by networks of spinal neurons known as 'central pattern generators' (CPGs). These circuits have been studied using isolated spinal cord preparations that can generate a pattern of motor discharge that resembles locomotion (locomotor-like activity). The isolated spinal cord is more experimentally accessible than the equivalent *in vivo* preparation and allows network function to be studied under controlled ionic and pharmacological conditions. For technical reasons, studies of central pattern generation in isolated preparations are restricted to the neonatal period and cannot be performed on adult mammals. In this article, we first consider the general properties of the locomotor-like rhythm in the neonatal rat and mouse cords and then discuss our knowledge of the specific circuitry responsible for this behavior.

Segmental and Spatial Distribution of the Pattern-Generating Circuitry in Neonatal Spinal Cord

The hind limb locomotor CPGs of the neonatal rat are distributed along the lumbar cord with a rostrocaudal decline in the rhythmogenic capacity of each segment. In the rat and mouse, rhythmogenic activity can also be observed in isolated sacrocaudal segments (Figure 1), indicating that rhythmogenic circuitry is not unique to the limb moving segments. The sacrocaudal network controls the axial and tail musculature during locomotor and other movements. Experimental activation of this network produces alternating left/right rhythmic bursts in sacral motor neurons. The thoracolumbar and sacrocaudal networks are coupled in the rostrocaudal direction via propriospinal/descending neurons, the axons of which travel in the lateral, ventral, and ventrolateral funiculi. These connections coordinate activation of the limb, axial, and tail musculature during movement.

It has been proposed that the locomotor rhythm is generated by antagonistic 'half-centers' activated by common tonic excitation and linked by reciprocal inhibitory pathways. Consistent with this idea, intracellular recordings from lumbar motor neurons in the neonatal rat show that the locomotor drive potentials produced in lumbar motor neurons during rhythmic activity induced by bath application of *N*-methyl-D-aspartate (NMDA) and 5-hydroxytryptamine (5-HT; serotonin) are generated by an alternating sequence of phasic excitation and inhibition. However, several findings argue against the half-center model as a mechanism for spinal rhythmogenesis. For example, the locomotor-like rhythm can be generated in isolated hemicords that necessarily lack contralateral inhibitory connections. Furthermore, studies of sacrocaudal networks in the neonatal rat spinal cord have shown that reciprocal inhibitory pathways between flexor and extensor motor neurons are not activated during the sacrocaudal rhythm. As a result, flexor, extensor, and abductor tail muscles are coactive on one side of the tail during rhythmic activation of the sacrocaudal networks (Figure 1(c)). Because the sacrocaudal rhythm persists after separating the cord midsagittally, it is clear that this rhythm does not require activation of either crossed or reciprocal synaptic inhibition (Figure 1(d)).

It is now believed that the function of the contralateral inhibitory and excitatory connections is to regulate the timing of motor neuron activation. Because contralateral motor neurons alternate during locomotion it is assumed that the contralateral inhibitory connections are substantially more powerful than are the excitatory connections during normal locomotion. However, an increase in the excitatory crossed connections – such as occurs in certain mutant mice or as in the presence of inhibitory amino acid receptor blockers – can change the contralateral motor neuron activation from alternation to synchrony (see later).

Sensory Pathway Interneurons and Pattern Generation in Neonatal Spinal Cord

Studies of Lundberg and colleagues have revealed that segmental pathways activated by high-threshold flexor reflex afferents (FRAs) produced a locomotor-like alternating flexor–extensor discharge in cats subjected to spinal cord transection ('spinal cats') treated with L-3,4-dihydroxyphenylalanine (L-DOPA) and monoamine oxidase blockers. It has been suggested that these FRA pathways are actually part of the locomotor pattern generators, because stimulation of FRA components can reset the L-DOPA-induced rhythm. In addition, application of opioids to spinal

cats can block the spontaneous locomotor-like rhythm induced by L-DOPA and the alternating flexor–extensor pattern produced by stimulation of various FRA components.

Alternatively, FRA interneurons may be interposed between the locomotor CPGs and their target motor neurons. Studies of the sacrocaudal network in the neonatal rat and mouse have revealed that low- and high-intensity stimulation of sacrocaudal afferents (SCAs) can produce a coordinated activation of the locomotor and sacrocaudal CPGs (Figure 2(a)). The high accessibility of the sacrocaudal network and the extraordinary capacity of SCA pathways to produce rhythmic patterns in the lumbar and sacral cord have been recently exploited to study the role of the pathway interneurons in pattern generation.

This work has revealed that the SCA-induced locomotor rhythm involves synaptic activation of relay neurons in the sacrocaudal cord. It was found that the SCA-induced locomotor rhythm could be

Figure 1 Continued

abolished after blocking synaptic transmission in the sacrocaudal segments by low-calcium, high-magnesium solution (**Figure 2(b)**). Moreover, specific application of μ-opioid receptor agonists to the sacrocaudal segments blocks SCA-induced rhythmic activity in the cord, although the rhythmogenic capacity of these networks is not impaired. This is because they can still be activated by bath application of NMDA/5-HT or by stimulation of the ventromedial medulla in the presence of μ-opioid receptor agonists. Physiological studies have shown that the axons of the majority of the sacrocaudal relay neurons activated by SCAs cross the spinal cord at the sacrocaudal level and ascend rostrally to the lumbar CPG mainly through the ventral funiculi (**Figures 3(a) and 3(b)**). More recent anatomical and physiological studies have indeed identified groups of sacrocaudal interneurons in the ventral horn, the intermediate zone of the gray matter, and the ventral parts of the dorsal horn (**Figure 3(c)**). These interneurons are innervated by SCAs and project their axons rostrally through the contralateral ventral funiculus. SCA stimulation activates these interneurons, an effect that is blocked by μ-opioid receptor agonists and which recovers in the presence of naloxone. It is suggested that these sensory pathway interneurons do not participate directly in the genesis of locomotion, and further studies are required to determine whether they contribute to sacrocaudal rhythmogenesis.

Specific Interneuronal Circuits

To understand the operation of locomotor networks requires identification of the constituent interneurons, their synaptic connections, and their intrinsic properties. In adult animals, spinal interneurons are generally defined by their synaptic connections. Such characterization is more difficult in the neonate because the connections may change during development and because the inputs and outputs of developing interneurons are frequently inaccessible. For these reasons, researchers have sought to identify subsets of developing neurons by their expression of various genetic markers. Among the most useful of these are combinations of transcription factors – proteins that regulate the expression of several genes. The interneuronal classes that have been identified using this approach contain the precursors of several different adult interneuron types.

We first consider the development of two types of interneurons that have been characterized in detail in the adult cat: the Renshaw cell and the 1a inhibitory interneuron. Both of these neurons have been shown to be rhythmically active during adult locomotion and are presumed to play an important role in locomotor activity. Renshaw cells, first described in cat in the 1940s, are the only known synaptic targets of motor neurons within the spinal cord. The 1a inhibitory interneurons receive direct inputs from primary muscle spindle afferents and project monosynaptically to antagonist motor neurons. Despite these differences, Renshaw cells and 1a inhibitory interneurons share many aspects of their connectivity. For example, they are each reciprocally interconnected among their own class and between each other (Renshaw–1a interneuron) and they both project monosynaptically to motor neurons.

In the neonatal mouse, shortly after birth, it has been possible to record activity from interneurons that receive direct monosynaptic connections from motor

Figure 1 Pattern generation in the isolated spinal cord of the neonatal rat. (a) Bath application of *N*-methyl-D-aspartate (NMDA) and 5-hydroxytryptamine (5HT) produces coordinated rhythmic activity in the lumbar (L2) and sacrocaudal (S2) segments of the spinal cord. The sacrocaudal rhythmicity is virtually blocked while the lumbar rhythm persists following transection of the cord at the lumbosacral junction. Recordings were obtained from the left (L) and right (R) ventral roots of L2 and S2 in preparations isolated from postnatal day 3 pups. (b) The α1 adrenoceptor agonist methoxamine (100 μM) produces rhythmic activity in the isolated sacrocaudal (S2) segments of the neonatal rat spinal cord. Intracellular recordings from a left S2 motor neuron (L-S2 MN; upper record, blue) show the development of tonic depolarization and superimposed sub- and then suprathreshold membrane potential oscillations in the presence of methoxamine. Ventral root population recordings from the left (L; blue) and right (R; black) S2 ventral roots are shown below the intracellular trace. (c) The sacrocaudal rhythmicity does not depend on activation of reciprocal inhibitory pathways between flexor and extensor centers. Electromyelogram recordings from left (L) and right (R) flexor and extensor muscles of the tail are shown following transection of the cord at the lumbosacral junction. The rhythmic pattern is characterized by alternating left/right activation of the tail muscles and by coactivation of flexor and extensor muscles within a given side of the tail. This flexor–extensor synchronicity indicates that reciprocal inhibitory pathways are not activated during the rhythm. The rhythm was induced by 10 μM noradrenaline and 3 μM NMDA. The circular diagrams (right) show the phase relation between the activities of the left and right muscles and between those of the ipsilateral extensor and flexor muscles during the rhythm, in five different experiments. (d)The sacrocaudal rhythm does not depend on activation of crossed inhibitory pathways between the left and right hemicords. Recordings from left and right ventral roots of Co1 in the isolated coccygeal cord (S4/Co1 cut) and in a midsagittally split S2/Co3 preparation (S1/S2 cut, midsagittal split; different preparation; data are rectified and integrated). Rhythmic activity was induced by 5 μM noradrenaline and 4 μM NMDA. (a) From Strauss I and Lev-Tov A, unpublished data. (b) Adapted from Gabbay H and Lev-Tov A (2004) Alpha-1 adrenoceptor agonists generate a 'fast' NMDA-receptor independent motor rhythm in the neonatal rat spinal cord. *Journal of Neurophysiology* 92: 997–1010. (c, d) Adapted from Gabbay H, Delvolvé I, and Lev-Tov A (2002) Pattern generation in caudal-lumbar and sacrococcygeal segments of the neonatal rat spinal cord. *Journal of Neurophysiology* 88: 732–739.

Figure 2 Sensory activation of the locomotor rhythm. (a) Recordings from the left and right ventral roots of the flexor dominating L2 (black) spinal segments and the extensor dominating L5 (blue) segments are shown during a stimulus train (50 pulse, 3 Hz) applied to the left coccygeal Co1 dorsal root at 1.8 T threshold. Upper set of recordings, 50 Hz–5 KHz; lower set of recordings, the same data following rectification and low-pass filtering at 10 Hz. Note the typical left/right alternating pattern as well as the ipsilateral alternation of flexor and extensor bursts. (b) The sacrocaudal afferent-induced locomotor rhythm is mediated by synaptic activation of sacrocaudal interneurons. Recordings of the activity produced by stimulus trains (40 pulse, 4 Hz, 2 T) applied to S4 dorsal roots, before (control; top), after bathing the sacrocaudal segments in low-calcium/high-magnesium Kreb's saline (in a sacrocaudal (SC) chamber; middle), and after repeating the stimulus train following ejection of calcium from a micropipette onto the S3 segment (bottom). The region exposed to Ca^{2+} ejection (red) was controlled using a suction pipette positioned across the ejection site. The experimental bath was divided into sacrocaudal and thoracolumbar chambers using an L6/S1 Vaseline wall. (a) From Etlin A and Lev-Tov A, unpublished data. Figure 3 Sensory activation of locomotor CPGs by SCAs: the mediating pathways. (a, b) Sacrocaudal afferent stimulation activates sacrocaudal interneurons, the axons of which cross the sacrocaudal spinal cord and project rostrally through the ventral funiculi. The activity produced by stimulation of the left coccygeal Co2 dorsal root (40 pulse, 4 Hz, 1.5 T) and recorded from the left and right lumbar L2 and sacrocaudal S2 ventral roots (a; control) is severely impaired following a midsagittal split extending from the caudalmost end of the cord to caudal S2 (a; split to S2). The rhythmic activity induced in the lumbar cord by sacrocaudal afferent stimulation (40-pulse trains at 4 Hz and 1.5 T) (b; control) is virtually unaffected by bilateral lesion of the lateral (LF) and ventrolateral (VLF) funiculi at the L6–S1 junction (b; bilateral LF, VLF). Extension of the lesion to the lateral part of the left ventral funiculus (VF) blocks the activity at the ipsilateral side (b; bilateral LF, VLF; left lat. VF). Extension of the lesion to the right lateral VF (b; bilateral LF, VLF, lat. VF) virtually eliminates the rhythmic activity in the lumbar cord. (c) Sacrocaudal relay neurons and their afferent innervation. Projected confocal microscope image of a cross section at the rostral S4 segment in the neonatal mouse spinal cord. The right S4 dorsal roots (DR) were filled with Texas Red Dextran (red), the right S4 ventral roots (VR) were filled with Cascade Blue Dextran (blue), and a strip of the left ventral funiculus was filled with Fluorescein Dextran (green) at the rostral half of S2. The micrograph shows a dense ipsilateral neuropil of labeled ventral funiculus fibers with retrogradely labeled interneurons in the contralateral side of the segment. Putative contacts between the labeled interneurons and S4 afferents were found following 3-D reconstruction of the confocal images (not shown). Figure 4 Synaptic potentials in a neonatal mouse Renshaw cell evoked by stimulation of motor axons are mediated by cholinergic NMDA and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid/kainate receptors. (a) Recording and stimulating arrangement. (b) Superimposed synaptic potentials recorded in a Renshaw cell in response to a single stimulus applied to motor axons of the sciatic nerve (control). The membrane potential of the cell was held at −70 mV throughout the recordings. Application of the glutamate receptor antagonists 2-amino-5-phosphonovaleric acid (APV) and 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) for 25 min depressed the amplitude of the response (APV/CNQX). The response fully recovered after 22 min of washout (wash APV/CNQX). Subsequent exposure to cholinergic antagonists depressed the amplitude of the potential. Each response is an average of five stimuli delivered at 0.1 Hz. (c) Glutamate is enriched in some motor neuron synaptic boutons contacting Renshaw cells. Confocal images of a calbindin-immunoreactive dendrite (gray) from a presumed Renshaw cell and several retrogradely labeled motor neuron varicosities labeled with Texas Red Dextran (TxRed-Dxt) and co-immunolabeled for the vesicular acetylcholine transporter (VAChT; blue) and glutamate (green). The white circles identify boutons immunoreactive for all three markers, and the yellow circles show a cholinergic motor neuron terminal without glutamate immunoreactivity. Adapted from Mentis GZ, Alvarez FJ, Bonnot A, et al. (2005) Noncholinergic excitatory actions of motoneurons in the neonatal mammalian spinal cord. *Proceedings of the National Academy of Sciences of the United States of America* 102: 7344–7349.

neurons and also from primary muscle afferents. Such cells exhibit many of the characteristics of adult Renshaw cells. These include their ventromedial location, their rapid firing following a single antidromic stimulus, and their expression of calbindin, a calcium-binding protein (see Figure 4). The number of terminals expressing a vesicular glutamate transporter specific for primary muscle afferents (VGLUT1) increases during the first three neonatal weeks and then decreases as the animal matures into adulthood. However, even in the adult mouse, some primary afferent terminals remain on putative Renshaw cells, although it has not yet been established if such terminals are physiologically active. In the neonatal mouse, the 1a inhibitory interneurons are believed to be located dorsally to the Renshaw cells but they have not yet been studied electrophysiologically. The great similarity between the synaptic connections of Renshaw cells and 1a inhibitory interneurons is perhaps not surprising given that they both derive from a common precursor population – the V1 class – of interneurons that express the *engrailed-1* transcription factor.

Collectively, findings in the adult cat and the neonatal mouse raise two possibilities: first, that the

properties of the Renshaw cell and the 1a inhibitory interneuron differ between the mouse and cat, and second, that the two interneuronal types differentiate from a common population that shares the connections of both cell classes. According to the second idea, Renshaw cells would differentiate from this precursor population by shedding their primary afferent connections whereas the future 1a inhibitory interneurons would selectively lose their motor neuronal inputs. It is also possible that these two identified interneuronal populations are not truly distinct but rather are drawn from a population continuum. At the extremes would be the classical Renshaw cell and 1a inhibitory interneuron as defined from studies of the adult cat. Between these extremes, might be a population that shares the connectivity patterns of both.

In the adult cat, the motor neuronal synaptic inputs to Renshaw cells were believed to be mediated entirely by the neurotransmitter acetylcholine. In the neonatal mouse, however, it has been found that the synaptic potentials produced in putative Renshaw cells by stimulation of motor neuron axons are mediated by cholinergic and glutamatergic/aspartergic neurotransmission (Figure 4). Such dual transmission has been observed in several different cell types in the developing nervous system, and its discovery has challenged the long-held view that motor neuron actions are exclusively cholinergic. At present, the function of this dual transmission is unknown. Clues to its possible role come from the observation that stimulation of the ventral roots in the neonatal mouse can trigger locomotor-like activity that persists in the presence of cholinergic antagonists but which is blocked by glutamatergic antagonists (Figure 5). This observation raises the possibility that neonatal motor neurons may make glutamatergic/aspartergic synaptic contacts with interneurons that have access to the locomotor central pattern generator.

Interneurons Involved in the Patterning of Motor Neuron Activity during Locomotion

In the past 10 years, several classes of developing spinal neurons have been identified based on their expression of transcription factors. As discussed in the previous section, it is not known how these developing neurons mature into the interneurons of the adult cord. Nonetheless, the participation of these primitive interneuronal types in the locomotor-like activity expressed by the neonatal cord has been studied by several groups. In considering this work, it is important to distinguish between two distinct aspects of locomotor behavior. The first is the rhythmicity exhibited by both motor neurons and interneurons, about which very little is known. The second is the timing of activity in the various motor neuron pools that innervate the limbs, the axial muscles, and the tail. For example, during locomotor-like activity both antagonistic and contralateral motor neurons alternate their discharge during each cycle whereas synergistic motor neurons fire bursts at the same time. Most studies of developing interneurons have focused on their contribution to the timing of motor neuron discharge.

One of the first interneuronal classes to be identified genetically was a group of ventrally located neurons expressing the ephrin-A4 (EphA4) receptor. This receptor and its ligand ephrin-B3 are thought to prevent axons from crossing the midline. Animals with a mutation in the EphA4 receptor exhibit an abnormal gait in which both hind limbs are activated in synchrony (hopping) rather than in alternation. The spinal neurons expressing the EphA4 are thought to be excitatory glutamatergic neurons, the contralateral projections of which are abnormally profuse in the mutant animals. More recently, it has been shown that cells expressing the EphA4 receptor form a heterogeneous population, although some of them fire rhythmically during locomotion and have direct glutamatergic projections to ipsilateral motor neurons. A second class of excitatory interneuron has been identified; it located in the lower thoracic and upper lumbar segments and expresses the homeobox gene HB9 transcription factor. This factor was known to be involved in consolidating motor neuron fate, so it was surprising to find it expressed in interneurons. Nonetheless, the $HB9^{+}$ interneurons have been shown to fire in phase with ipsilateral flexor motor neurons during locomotor-like activity. Dual recordings from these cells have shown that they are connected by electrical synapses that contribute to their synchronization during a flexor burst.

It is important to emphasize that experiments of this type do not reveal the functional role of the interneurons during locomotion. One way to approach this problem is to study locomotor deficits when particular interneurons have been prevented from developing using genetic means. This has been accomplished in mice by knocking out the homeobox DBX1 transcription factor, which results in the loss of the V0 class of interneuronal precursors. These are inhibitory interneurons that send their axons across the midline of the spinal cord. Animals lacking V0 interneurons have defects of left/right alternation suggesting that some of the V0 interneurons are involved in regulating the timing of contralateral motor neuron activity during locomotion. The same approach has been used to study a second class of inhibitory interneurons with projections that are

Figure 5 Locomotor-like activity in the neonatal mouse (P3) can be triggered by motor axon stimulation. (a) Ventral root recordings (L1 right and L1 left) during an episode locomotor-like activity induced by a train of stimuli applied to the motor axons of the sciatic nerve (dorsal roots cut). The recordings were made before (control), after 1 h of cholinergic block (mecamylamine 50μm, DHβE 50μm, atropine 5μm) followed by the NMDA receptor antagonist APV (100 μm) and washout of all drugs. The stimuli are shown at the top of the traces. Note that the alternating locomotor-like rhythm persists in the presence of cholinergic antagonists (see expanded traces in (b)) but is abolished by APV. (b) Expanded timescale display of the traces shown in (a), and of the simultaneously recorded L5 activity (not shown in (a)). Adapted from Mentis GZ, Alvarez FJ, Bonnot A, et al. (2005) Noncholinergic excitatory actions of motoneurons in the neonatal mammalian spinal cord. *Proceedings of the National Academy of Sciences of the United States of America* 102: 7344–7349.

believed to be exclusively ipsilateral. Knockout of this class (V1) of interneuron results in a slowing of the locomotor rhythm induced by drugs.

Intracellular recordings from contralaterally projecting commissural interneurons located in the ventromedial part of the lumbar cord have revealed a heterogeneous set of firing patterns and connectivity. Included in this population are cells projecting monosynaptic excitation or inhibition to contralateral motor neurons and other cells with connectivity that changes from rest to locomotor activity. It is likely that these recordings included some of the cells derived from the V0 category that have been implicated in the control of left/right alternation.

Nerve Growth Factor

J C Petruska and L M Mendell, State University of New York at Stony Brook, Stony Brook, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Early History

The discovery of nerve growth factor has its origin in studies of the relationship between the number of sensory and motor neurons and the size of the peripheral tissue to be innervated. In the course of these investigations, studies carried out in culture indicated that a diffusible factor from mouse sarcomas could elicit substantial outgrowth of fibers from sensory and sympathetic ganglia. Further experiments demonstrated that nerve fiber growth-promoting factors were located in snake venom and also in mouse salivary glands, the mammalian homolog of the reptilian glands secreting the active venom. The factor responsible for this effect was called nerve growth factor (NGF). It was eventually purified and found to exist in two forms called NGF 7S (S is sedimentation constant) and NGF 2.5S. These two different forms are the consequence of being composed of different peptide chains: NGF 7S (MW 130 kDa) consists of two copies of each of three chains (α, β, and γ). NGF 2.5S (MW 26 kDa) contains only the β chains and is the active form of NGF isolated from mouse salivary glands.

Neurotrophin Family

It is now known that NGF is a member of a family of growth factors that collectively are referred to as neurotrophins. Other members of the neurotrophin family are brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4/5 (NT-4/5 was so named because in the early days it was known as NT-4 or NT-5). These molecules exhibit a homology of approximately 55% with NGF.

A precursor form of neurotrophins (proNGF, pro-BDNF, and proNT-3) has been identified in neural tissues *in vivo*. ProNGF has been shown to activate the p75 receptor and thus elicit neural apoptosis.

Neurotrophin Receptors

NGF exerts its effects by activating two transmembrane receptors. One of these is the trkA receptor, a member of the tropomyosin receptor kinase (trk) family. The other is the p75 receptor. These are often called the high-affinity and low-affinity receptor, respectively; however, the differences relate more to kinetics of binding than to affinity, which is in the nanomolar range for both receptors. There is evidence that trkA and p75 function cooperatively to mediate the cellular effects of NGF, with p75 acting as a chaperone to improve the binding to trkA. Structural studies suggest that the interaction is more likely to take place within the cell via convergence of signaling pathways from trkA and p75. This issue remains to be definitively resolved. However, the different intracellular signaling elicited by activated p75 and trkA suggests that NGF could elicit some effects via independent pathways.

Members of the neurotrophin family signal largely through different trk receptors: NGF, trkA; BDNF, trkB; NT-3, trkC; and NT-4/5, trkB. However, they all signal via the p75 receptor. Therefore, it is the presence of specific trk receptor types that determines which neurotrophin can be active in any particular tissue. Trk receptors can also be present in a truncated form with the cytoplasmic end absent. Neurotrophins bind to such receptors but elicit no cellular action, effectively diminishing their functional effect.

Neurotrophin Signaling

NGF exerts its trkA-mediated effects by becoming internalized and activating diverse signaling pathways. In many situations, NGF is internalized in the axon terminals and is transported to the cell body where the cell signaling takes place. This requires specialized cellular machinery. It has been suggested that clathrin plays a crucial role in internalizing the NGF/trkA complex into endosomes that are transported to the cell body. Another suggestion is that a novel membrane protein named Pincher is responsible for internalizing NGF/trkA complex via a process known as macroendocytosis which has properties of both macropinocytosis and endocytosis.

Reports have also indicated that the neurotrophin NT-3 can signal via trkA with a molecular mechanism different from that mediating NGF/trkA signaling. The NT-3/trkA complex is not internalized, unlike NGF/trkA. It activates local membrane signaling, which is believed to play a role in determining local axonal growth, rather than the cell body signaling elicited by the transported NGF/trkA complex which promotes survival and differentiation.

TrkA Signaling

The trkA receptor is a 140 kDa glycoprotein which binds NGF. The NGF-activated trkA receptor undergoes dimerization and autophosphorylation at several tyrosine residues that selectively trigger activity

in several intracellular signaling pathways via binding of specific effector proteins to phosphorylated docking sites. Phosphorylation at Tyr751 activates PI3-kinase and the Akt protein kinase, which has been associated with NGF-induced cell survival. Similarly, phosphorylation at Tyr490 is required for association of the Shc adapter proteins that triggers the Ras–MAP kinase signaling cascade and nuclear transcription factors such as CREB and c-fos. The resulting changes in gene expression elicit differentiation and neurite growth. Phosphorylation at Tyr785 activates phospholipase C-γ, causing release of intracellular Ca^{2+} and activation of diacyl glycerol via IP_3. This leads to increased levels of protein kinase C (PKC).

p75 Signaling

Activation of p75 leads to the activation of numerous intracellular pathways, notably ones promoting apoptosis and cell survival. This suggests that the balance of activity between these two pathways is of crucial importance. In addition, activation of the p75 receptor also activates the enzyme sphingomyelinase promoting synthesis of ceramide. This pathway may be responsible for an independent p75-mediated action on cell physiology.

NGF and Development

Axon Growth

NGF promotes fiber outgrowth of sensory neurons cultured from embryonic mouse. *In vitro* studies suggest that NGF elicits its effects on axonal growth by activating PI3K in growth cones. This signaling pathway enhances actin polymerization. It also inactivates glycogen synthase kinase 3β, leading to upregulation of adenomatous polyposis coli (APC), a microtubule-binding protein. Blockade of NGF signaling removes APC from growth cones and results in their collapse.

Cell Survival

The neurotrophic hypothesis was advanced to describe the effect of neurotrophins on neuronal survival. It states that neurotrophins are required for survival of neurons innervating peripheral tissues but that they are present there in limiting amounts. Sensory, motor, and autonomic cells grow into peripheral tissue and compete for the appropriate trophic molecule. Sensory and sympathetic neurons which express trkA compete for the available NGF. The 'winners' survive; the 'losers' die via apoptosis. This is believed to be an important mechanism for matching the number of central neurons to the size of the periphery to be innervated.

Early studies in the dorsal root ganglion (DRG) demonstrated that prenatal depletion of NGF using an antibody to NGF results in reduction of cell number in the ganglion. The loss of cells was shown to be limited to small-diameter cells identified as nociceptors because it was largely restricted to cells expressing peptides known to be involved in nociception (substance P (SP) and calcitonin gene-related peptide (CGRP)). Other work has shown that cells dying as a consequence of NGF depletion project to lamina II, the known termination site of nociceptive afferent fibers. *In vivo* studies suggest that the effect of NGF on DRG cell number in rats lasts until approximately postnatal day 2.

Postnatal Development

NGF also has developmental effects on nociceptors beyond postnatal day 2 since treatment of neonatal rats with an antibody against NGF depletes Aδ high-threshold mechanonocieptors (HTMs) in the sensory nervous system. This depletion is most profound when NGF is antagonized between postnatal days 4 and 11, and it is accompanied by an increase in the proportion of Aδ low-threshold mechanoreceptors known as D-hairs. The proportion of another population of Aδ receptors innervating deep tissue is unaffected, suggesting that the effect of NGF is not to simply kill nociceptors since all remaining populations of cells would be expected to increase in number. Thus, Aδ HTMs require NGF available in the skin in order to undergo final differentiation to HTMs. If epidermal NGF is not available, these terminals migrate to the dermis to innervate D-hair follicles. This change has been referred to as a phenotypic switch.

The cell loss of sensory neurons related to disrupting the NGF/trkA system during development was recognized to be much greater than would have been expected based on the numbers of neurons expressing trkA and responsive to NGF in adult animals. Subsequent work demonstrated that although trkA is expressed by virtually all small- (and many medium-) diameter sensory neurons up to early postnatal development, by 4 weeks of age this expression pattern changed dramatically such that one-third to one-half of small-diameter neurons replaced trkA expression with components of the glial-derived neurotrophic factor (GDNF) receptor complex (GFR-α and c-Ret). Neurons that convert from trkA to ret expression lack p75 from early postnatal times (**Figure 1**) and become the nonpeptidergic small-diameter sensory neurons (in that they lack CGRP and SP, although some express somatostatin). These GDNF-sensitive nociceptive neurons have spinal terminations in the inner portion of lamina II, distinct from the superficial portion of lamina II where trkA-positive nociceptors

Figure 1 Section of P10 rat lumbar DRG demonstrating the distribution of different receptors using immunohistochemistry; trkA (green; a, d), p75 (red; b), and TRPV1 (purple; e). Bottom panels show the combined labels; trkA/p75 (c) and trkA/TRPV1 (f). Cells that were trkA+ but p75 (green; c) will lose their trkA expression and develop c-ret/GFR-α expression as described in the text. TRPV1-expressing cells also express trkA (whitish cells; f) throughout development. Based on unpublished data from A Davenport, JC Petruska, and LM Mendell.

terminate. They also differ in that most trkA+ sensory neurons do not bind the lectin IB4.

Developmental Effects of Other Neurotrophins

The neurotrophin NT-3 has been demonstrated to have effects on the development of large-diameter muscle afferent fibers known to express its high-affinity receptor, trkC. Depriving the developing rodent of a functional NT-3/trkC signaling system results in animals with an absence of sensory fiber projections into the ventral horn. This occurs primarily because the spindle afferent fibers responsible for these projections fail to survive. NT-3 also has been shown to be an important factor in promoting the final stages of muscle spindle axon elongation into the ventral horn to synapse with motor neurons. Furthermore, NT-3 is required for postnatal development of certain cutaneous receptors, specifically D-hairs and the Merkel cells associated with type I slowly adapting mechanoreceptors. Interestingly, BDNF appears to regulate the sensitivity of slowly adapting mechanoreceptors in the absence of any effect on Merkel cells; that is, the effect may be on the properties of the mechanosensitive channels in the axon terminals. However, NT4/5, like BDNF, a ligand for the trkB receptor, is required for the survival of D-hair receptors (i.e., the two trkB ligands can elicit quite different actions).

Biological Effects of NGF *In Vivo*: Nociception

It has become clear in the past few years that administration of NGF in the adult results in painful sequelae. It is now appreciated that this results from the binding of NGF to trkA receptors, although a possible independent role for the p75 receptor has also been demonstrated. The administration of NGF does not elicit spontaneous pain; rather, it sensitizes subsequent responses to nociceptive inputs (Figure 2). The duration of the sensitization in experimental models depends on the mode of administration of the NGF. Systemic administration of NGF results in sensitization lasting several days, whereas the effects

Figure 2 Differing roles of NGF on nociceptors during development. Data obtained from rat.

of local administration last on the order of hours to 1 day. The onset of hyperalgesia occurs within minutes of administration, with thermal hyperalgesia occurring within 5 min. Mechanical hyperalgesia has been reported to begin several hours after administration, but in some behavioral studies it has been found to begin within 10 min (i.e., only slightly longer than the latency for thermal hyperalgesia). This is an important issue since the thermal hyperalgesia is generally ascribed to a direct peripheral action of NGF on sensory neurons. The locus of sensitization of mechanical stimulation is not well documented; a delayed response might be attributed to an indirect central action of NGF, whereas a rapid response might indicate a direct effect in the peripheral terminals.

The nociceptive effects of NGF administration have been observed in animal models in which they are inferred from changes in the response to aversive stimuli; for example, the Hargreaves test, which measures putative nociceptive effects as a decrease in the latency of limb withdrawal from a standard noxious heat stimulus. However, more definitive evidence of the nociceptive effects of NGF administration has been obtained in humans as an unanticipated outcome of a phase I clinical trial for the use of NGF to counter the degenerative changes considered to contribute to the symptoms of Alzheimer's disease. This trial had to be terminated early because of the pain experienced by the otherwise healthy subjects when NGF was administered systemically. In a subsequent study, NGF was administered locally to human volunteers and was also found to be associated with pain. These human studies provide important direct proof of the nociceptive effects of NGF.

Mechanisms of Acute NGF-Induced Sensitization of Nociceptors

Via trkA Although the rapid sensitizing effects elicited by local injections of NGF indicate a peripheral site of action, these studies cannot definitively prove that such a mechanism exists, nor do they indicate which cell types in the periphery are involved. Numerous cell types in the periphery are endowed with trkA receptors (e.g., mast cells and autonomic efferents). The effects of NGF can be reduced or even abolished by inactivation or elimination of sympathetic efferents and mast cells. Additionally, neutrophils have been shown to contribute to NGF-induced hyperalgesia. The relative contribution of these different cell types to NGF-elicited hyperalgesia is not known and their action may be coordinated. For example, mast cells contain NGF as well as expressing trkA receptors on their surface membrane, raising the possibility that NGF activation of mast cells causes an explosive release of NGF due to recurrent action of NGF (i.e., positive feedback). TrkA receptors are also well-known to be expressed on nociceptors themselves. These are also likely to contribute to the sensitization by NGF since numerous investigators have demonstrated that exposure of dissociated small-diameter sensory neurons to NGF acutely enhances their response to capsaicin or noxious heat (measured using Ca^{2+} imaging or patch clamp recording) (Figure 3(a)). The enhanced response of TRPV1 is likely due to its phosphorylation by various intracellular messengers activated by NGF.

There is evidence that each of the intermediates mentioned previously in the general discussion of signaling pathways activated by NGF participates in sensitizing the response of TRPV1 to noxious heat or capsaicin. However, these studies, carried out under different conditions with different methods (patch clamping, Ca^{2+} imaging, and behavior), suggest that the signaling depends very much on the conditions of the experiment. Thus, the effectors activated by these signaling pathways appear to switch from axon growth and survival to sensitization after the animal is born, a proposition confirmed directly by the finding that NGF does not sensitize the response of TRPV1 to noxious heat in trkA-expressing cells on postnatal day 2, despite the fact that the two receptors are co-expressed.

Via p75 Evidence suggests that NGF can acutely influence the response of nociceptors by its action on the p75 receptor. As noted previously, NGF acting through the p75 receptor elicits enhanced levels of ceramide, which has been demonstrated to increase

Figure 3 Examples of acute sensitization by neurotrophins: cell type, trk receptors, and receptors sensitized by neurotrophin action are displayed schematically (top). (a) The response (inward current, top traces) of a trkA-expressing cell (recorded in voltage clamp using dissociated DRG cell patch clamp) to noxious heat (lower traces) is acutely sensitized by NGF. (b) The response (inward current) of a lamina II cell (recorded in voltage clamp using spinal slice patch clamp) to exogenously applied NMDA is acutely sensitized by BDNF. (c) The response (voltage change in current clamp) of a spinal motor neuron (sharp electrode in neonatal hemisected spinal cord) to application of NMDA is sensitized by NT-3. (a) Adapted from Galoyan SM, Petruska JC, and Mendell LM (2003) Mechanisms of sensitization of the response of single dorsal root ganglion cells from adult rat to noxious heat. *European Journal of Neuroscience* 18: 535–541. (b) Adapted from Garraway SM, Petruska JC, and Mendell LM (2003) BDNF sensitizes the response of lamina II neurons to high threshold primary afferent inputs. *European Journal of Neuroscience* 18: 2467–2476. the firing rate of dissociated nociceptors in response to a depolarizing ramp stimulus. This change in firing rate is associated with an increase in Na^+ conductance and a decrease in K^+ conductance elicited by membrane depolarization. This action is in parallel with and independent of NGFs sensitization of the TRPV1 receptor via its effect on the trkA receptor.

Inflammation-Induced Release of NGF into Peripheral Tissues

The role of NGF in hyperalgesia has been demonstrated by showing that the pain induced in various experimental models can be reduced or abolished by delivering an antibody to NGF in conjunction with the sensitizing agent. Another approach is to administer the immunoadhesin trkA-IgG, which binds with endogenous NGF. Both of these reduce or abolish inflammatory hyperalgesia. The implication of these experiments is that NGF is upregulated in inflamed skin, and this has been confirmed by direct measurement. Enhanced NGF levels have also been detected in the inflamed bladder and in the synovial fluid of inflamed joints, suggesting that NGF contributes generally to inflammatory hyperalgesia in peripheral tissues. The release of NGF is mediated by prior release of the cytokines tumor necrosis factor-α and interleukin-1β; keratinocytes as well as mast cells are believed to be important sources of NGF (Figure 4).

Long-Term Effects of NGF on Nociceptive Signaling

As indicated previously, regulation of gene activity is an important consequence of NGF binding to the trkA receptor. The expression of a number of genes has been shown to be upregulated by NGF administration in culture and *in vivo*, and these are considered to be important in mediating the long-term effects of NGF (see below). They include genes for ligand-gated ion channels involved in transducing nociceptive stimuli such as TRPV1 (gated by capsaicin/noxious heat), $P2X_3$ (ATP), and ASIC3 (protons); genes for the neuropeptide transmitters SP and CGRP, important in nociception; and Na^+ channel genes, both TTX sensitive (Nav1.3) and TTX insensitive (Nav1.8 and Nav1.9). Expression of the gene for another neurotrophin, BDNF, is also upregulated, and this is considered to be particularly important for the central effects induced by NGF.

These and other similar changes are instrumental in mediating longer-lasting effects of NGF. The synthesis of additional receptors responsible for transducing nociceptive stimuli (TRPV1, $P2X_3$, and ASIC3), enhances the sensitivity of nociceptors to noxious

Figure 4 Some cellular mechanisms mediating NGF-induced sensitization of nociceptive afferents. NGF levels are upregulated in peripheral tissues after injury as a consequence of activation of inflammatory cells. NGF directly sensitizes nociceptor endings acutely and also contributes indirectly to sensitizing of these endings via the action of other agents released from immunocompetent cells. Direct administration of NGF activates many of these pathways and has virtually immediate sensitizing effects. After injury, the time course of sensitization will depend on the kinetics of NGF release, but it is generally several hours. NGF will also exert slower effects due to upregulation of other channels, such as TRPV1, bradykinin, and Nav1.8.

heat and other stimuli such as ATP and lowered pH. NGF also enhances expression of BK1 receptors, augmenting the effect of the sensitizing agent bradykinin. The elevated level of BDNF in the somata of trkA-expressing nociceptors after long-term exposure to NGF takes several hours to develop *in vivo*. This phenomenon is significant because BDNF has been shown to be released into the dorsal horn and to sensitize the glutamatergic synaptic response of cells in lamina II. This phenomenon is known as central sensitization (Figure 3(b)), to be distinguished from peripheral sensitization of nociceptors themselves (Figure 3(a)). Another long-term effect of NGF is the induction of terminal sprouting of nociceptors in the skin, which could also result in heightened sensitivity of these fibers.

The Effect of Other Neurotrophins and Glial-Derived Neurotrophic Factors on Peripheral Sensitization

BDNF and NT-4, but not NT-3, have also been shown to sensitize the response to capsaicin in isolated DRG cells and noxious heat in the *in vitro* skin–nerve preparation. Interestingly, NT-3 reduces the response of small DRG cells to NGF despite the fact that there are no trkC receptors on small-diameter DRG cells.

Members of the family of GDNFs, consisting of artemin, neurturin, and GDNF, have also been shown to sensitize the response of TRPV1 receptors in nociceptors. The sensitization is elicited at molar concentrations 10–100 times lower than that required for NGF-elicited sensitization of TRPV1-mediated responses of nociceptors. Although all these substances elicit sensitization, artemin appears to be the most significant since it is the only one whose level in the skin is increased by the inflammatory mediator complete Freund's adjuvant, as is its coreceptor GFR-α3. NGF and members of the GDNF family administered individually sensitize the behavioral response to noxious heat for several hours, but the combination of NGF and artemin sensitizes the response for up to 6 days.

Neurotrophins, Central Sensitization, and Neuropathic Pain

Sensitization of AMPA/kainate synapses on lamina II cells by BDNF as described previously is distinct from the sensitization induced by neurotrophins at peripheral nerve endings. There are many examples of central and peripheral synapses whose efficacy is enhanced by neurotrophins. In the case of nociceptor synapses on cells of lamina II, this sensitization does not occur directly but, rather, as a consequence of sensitization of NMDA receptors located on the same neurons (Figure 3(b)), an effect also found in the NT-3/trkC system of spinal motor neurons (Figure 3(c)). PKC has been implicated in the coupling between sensitization of NMDA and AMPA/kainate receptors. As in the case of NGF-induced sensitization of the response of nociceptive neurons to capsaicin or noxious heat, sensitization of synaptic transmission persists for at least several minutes to an hour after removal of the neurotrophin, suggesting that the neurotrophin triggers long-lasting changes in the nociceptive pathway.

BDNF has also been implicated in other mechanisms of central sensitization, specifically in eliciting neuropathic pain via microglia that are brought to an activated state by nerve injury. Nociceptor terminals co-release ATP and glutamate. ATP acts on activated spinal microglia via $P2X_4$ and P2Y receptors to induce BDNF release. BDNF has been shown to inhibit the KCC2 Cl^- transporter in lamina I cells, shifting the Cl^- reversal potential to become positive with respect to the resting potential. This leads to a GABA-induced depolarization (rather than hyperpolarization) of lamina I cells, thereby enhancing

activity in nociceptive pathways. The microglial and synaptic (trkA-expressing sensory neurons sensitized by NGF) sources of BDNF may act in synergy to produce postsynaptic sensitization throughout the superficial dorsal horn.

NGF is an important intermediate in peripheral sensitization in inflammatory pain models (e.g., after complete Freund's adjuvant or carrageenan). In neuropathic pain models (e.g., chronic nerve constriction injury), the evidence for direct NGF involvement is much less convincing. Nonetheless, neurotrophins may participate since there is evidence of increased BDNF expression in neighboring uninjured sensory neurons. Most of these models are essentially partial nerve injuries in that the system being examined involves plexus nerves. This is important because the spared neurons/axons project through a peripheral nerve containing fibers whose processes have been injured resulting in Wallerian degeneration. This degeneration is similar to peripheral tissue inflammation in many ways, not least of which is that denervated Schwann cells release neurotrophins, including NGF. Furthermore, since peripheral axonal injury induces influx of immune cells to the DRG, noninjured neurons resident in the same DRG as injured neurons are exposed to conditions known to induce sensitization (release of NGF by satellite cells, increased levels of immune mediators such as MCP-1, etc.).

Effects of Neurotrophins on Axonal Growth in Adults

The ability of neurotrophins to promote neurite elongation during development as well as in culture has prompted efforts to determine whether they might enhance neurite growth in the adult animal *in vivo*. BDNF enhances regeneration of motor axons, and both NT-3 and BDNF improve elongation of spinal axons in conjunction with different permissive substrates. NGF has not been found to be as effective as BDNF and NT-3 in promoting regeneration of spinal axons, presumably since they express trkB and trkC but not trkA. On the other hand, regeneration of sensory neurons can be enhanced by NGF as well as by NT-3 and GDNF, but not BDNF. Regenerating dorsal root axons normally do not penetrate the spinal cord, but when exposed to neurotrophins, some growth into the spinal cord has been reported. Interestingly, the identity of the regenerating fibers is appropriate for the neurotrophin that was applied (i.e., nociceptors with NGF or GDNF, and spindle afferent fibers with NT-3).

In addition to elongation, neurotrophins play a role in both adaptive and pathologic axonal branching plasticity in the adult. NGF is known to be a key player in the peripheral collateral sprouting of axons from nociceptive DRG neurons and sympathetic neurons, a process by which noninjured neurons extend new axonal branches to innervate denervated skin. A pathologic version of this process may also occur after spinal cord injury where autonomic dysreflexia is associated with new central connections established by trkA-expressing DRG neurons into the sympathetic outflow circuitry. Remodeling of hippocampal neurons as part of memory processes involves BDNF, and BDNF, NGF, and NT-3 are likely involved to some degree in pathologic (e.g., epileptiform) processes. Evidence for significant NT-3-mediated adaptive plasticity is limited to conditions of nerve or spinal cord injury with exogenous NT-3.

Clinical Implications of Neurotrophin Biology

A number of disorders of the peripheral nervous system have been attributed to alterations in NGF metabolism. The importance of neurotrophins as survival factors predicts that their absence during development should deplete specific populations of neurons according to their neurotrophin dependence. This has been advanced as the explanation of the rarely observed hereditary sensory and autonomic neuropathy type IV, in which the insensitivity to pain and reduced sweating are correlated with an absence of the NGF high-affinity receptor trkA. The infectious disease leprosy is characterized by hypoalgesia and reduced sweating from affected skin areas; this is accompanied by diminished NGF levels in skin biopsies from this areas. Diabetic neuropathy results in reduced nociceptive function; the magnitude of the capsaicin-evoked skin axon reflex (a measure of nociceptive function) is correlated with NGF levels in the skin.

In adults in whom NGF acts to sensitize the response to certain nociceptive inputs, treatments that reduce NGF activity have been explored as possible treatment modalities in various pain states. In animal models, this approach has proven useful in models of experimental arthritis, visceral pain (pancreatitis and interstitial cystitis), or metastatic bone pain where more conventional treatments have not proven effective or have significant side effects. A humanized antibody to NGF (RN624) has been developed and is in clinical trials.

The Neuroanatomy of Breathing

Breathing is generated in neural circuits ranging from the telencephalon to the spinal cord. The rhombencephalon (medulla and pons) contains the neurons that generate respiratory rhythm and then sculpt that neural activity to produce respiratory motor output in cranial and spinal motor neurons. Distinct respiratory output patterns (Figure 1) are expressed in cranial motor neurons in the rhombencephalon to regulate airway caliber and in cervical and thoracic spinal motor neurons that generate the rhythmic pumping action of the lungs. Brain stem and spinal motor neurons contribute to other behaviors as well, including chewing, swallowing, vocalization, vomiting, posture, locomotion, defecation, and reproduction.

Sensory inputs that convey information concerning arterial blood gases and status of the lungs and airways modulate respiratory pattern. Forebrain regions modify breathing by providing for voluntary and emotional changes in breathing patterns and induce feed-forward changes anticipating changes in metabolic demand. Important (and sometimes overlooked) elements of respiratory circuits are the ascending respiratory-related sensory pathways that drive adaptive short- and long-term behavioral responses to assure that the individual is maintained in a favorable environment. Perceived difficulties in breathing, termed dyspnea, are potent stimuli for motivating behavior.

Respiratory Neurons

Patterns of activity in respiratory motor and premotor neurons reflect respiratory modulation, characterized by bursts of action potentials during active periods, alternating with periods of little or no activity. These brain stem and spinal neurons mediate the coordinated motions of the airways and chest wall during breathing and are regulated to mediate respiratory reflexes, the preservation of homeostasis, and voluntary changes in respiratory activity. Respiratory neurons are classified as inspiratory (I) or expiratory (E) by the phase of the respiratory cycle in which they are active. These categories are subdivided into incrementing (augmenting; I-Aug or E-Aug), decrementing (I-Dec or E-Dec), or constant (I-Con or E-Con) types. Neurons with activity spanning the inspiratory and expiratory phases (I–E or E–I) are also observed. Preinspiratory (pre-I) neurons typically fire one brief burst of action potentials immediately before the onset of inspiration and a second burst immediately following the end of inspiration. This cell type has been observed mainly in neonatal rodent *in vitro* preparations, but it is of major significance to current models of respiratory rhythm generation. Commonly recognized respiratory neuron categories are summarized in Figure 2.

Respiratory-Related Neurons

In addition to phasic respiratory neurons, there are significant groups of cells that might be classed as respiratory-related in that they are nonphasic cells that, nonetheless, modulate respiration via tonic afferents to brain stem respiratory circuits. This, for example, is probably the case for second-order neurons in the nucleus of the solitary tract (NTS) relaying information from peripheral chemoreceptors in the carotid body.

Brain Stem Respiratory Neuron Groups

Respiratory neurons are concentrated (but not found exclusively) within three regions of the rhombencephalon (Figure 3). The dorsal respiratory group (DRG; Figures 3(a) and 3(b)) is in the dorsomedial medulla in caudal to mid-rostral portions of the NTS. The ventral respiratory column (VRC; Figures 3(a) and 4) forms a continuous field in the ventrolateral medulla extending from around the facial nucleus to the medullary spinal junction (Figure 4). This large aggregate of respiratory neurons encompasses five or more physiologically distinct subregions (Figure 3(b)). The pontine respiratory group (PRG; Figure 3(b)) is in the rostral dorsolateral pons and encompasses portions of the parabrachial complex and the ventrally adjacent Kölliker–Fuse nucleus.

Nucleus of the Solitary Tract and Dorsal Respiratory Group

The NTS is a complex structure that relays visceral afferents ascending in the vagus, glossopharyngeal, and facial nerves. Afferents from the airways, lungs, and peripheral chemoreceptors directly target various NTS subnuclei, largely localized at mid rostrocaudal (corresponding to the length of area postrema) to caudal (posterior to area postrema) NTS levels (including

Figure 1 Patterns of respiratory motor activity on selected spinal (phrenic) and cranial nerves in two rats (a and b). Vertical dotted lines indicate phase transitions between inspiration (I) and expiration (E). Note that the onset of inspiratory activity on the cranial nerves precedes that on the phrenic nerve. The top trace for each nerve is a low-pass filtered version of the raw activity shown in the trace immediately below, showing the nerve's overall discharge pattern. IX, glossopharyngeal nerve; Phr, phrenic nerve; PhX, pharyngeal branch of the vagus nerve; SLN, superior laryngeal branch of the vagus nerve; XII, hypoglossal nerve. Reproduced from Hayashi F and McCrimmon DR (1996) Respiratory responses to cranial nerve afferent stimulation in rats. *American Journal of Physiology* 271: R1054–R1062.

its commissural subdivision). The DRG designates NTS neurons with centrally generated respiratory activity (most commonly inspiratory), thus excluding neurons whose respiratory activity is largely dependent on peripheral afferent inputs. The DRG is a source of input to spinal cord respiratory motor neurons in some species, but is less so in others.

Ventral Respiratory Column

Distinct anatomical compartments within the VRC are inferred from clustering of similar types of respiratory neurons (e.g., inspiratory or expiratory discharge patterns), presence or absence of spinal cord projections, and respiratory responses to chemical stimulation. Specific respiratory neuron types are not restricted to individual compartments but exhibit overlapping distributions with the peak concentrations of particular neuron types centered within given compartments.

The caudal half of the VRC, termed the ventral respiratory group (VRG), contains bulbospinal respiratory premotor neurons (Figure 5) that receive converging inputs from VRC rhythm-generating neurons and other inputs from outside the VRC, sculpting the pattern of motor output distributed to various respiratory motor neurons. The VRG is subdivided into rostral (rVRG) and caudal (cVRG) based on the peak concentrations of inspiratory (rVRG) versus expiratory (cVRG) bulbospinal neurons. Inspiratory bulbospinal neurons provide mainly excitatory input to spinal inspiratory motor pools, including monosynaptic input to phrenic motor neurons. Expiratory bulbospinal neurons in the cVRG are mainly excitatory and project to interneurons innervating thoracic and upper lumbar motor neurons that drive expiratory pump muscles (e.g., internal intercostal muscles and abdominal muscles). Inhibitory expiratory neurons in the vicinity of the Bötzinger complex (BötC) and cVRG contribute to the inhibition of spinal inspiratory motor pools.

Respiratory rhythm generation occurs mainly in the rostral half of the VRC, which contains at least three functionally distinct compartments (Figure 3(b)). The BötC occupies a portion of the VRC adjacent to the caudal surface of the facial nucleus and contains mainly inhibitory glycinergic expiratory neurons. The pre-Bötzinger complex (pre-BötC), an area between the BötC and anterior rVRG, is a key region for rhythm generation and is hypothesized to be essential for inspiratory rhythm. At least in the rat, the majority of respiratory neurons identified within the pre-BötC are excitatory medullary interneurons that project extensively within the ipsilateral and contralateral VRC. Some pre-BötC propriobulbar neurons express neurokinin-1 (NK1) receptors, a feature distinguishing between the pre-BötC and the BötC. NK1 receptor-positive neurons also partially differentiate the pre-BötC from the rVRG, although some large NK1 receptor-positive bulbospinal neurons are found in anterior rVRG.

The retrotrapezoid nucleus (RTN) is located at the rostral end of the VRC, ventral to the rostral BötC and continues rostrally beneath the facial nucleus near the surface of the brain to just caudal to the trapezoid body (Figures 3(b), 3(c), and 4). RTN neurons project to the pons and caudal VRC. The RTN is (part of) a region containing potential central chemosensory cells, an important source of respiratory drive and chemoreflexes. RTN neuronal activity monotonically increases with extracellular acidity (associated with increased CO_2).

The parafacial respiratory group is located ventral to the facial nucleus, at least in neonatal rats (pFRG; Figures 3(b) and 3(c)). Many pFRG neurons have a

Figure 2 Membrane potential and representative discharge patterns of major classes of respiratory neurons found in the medulla and pons. Alternative names remain in common usage for these neurons; some of these are shown in parentheses. Note that a rapid decline in phrenic nerve activity is associated with the inspiratory-to-expiratory transition. Inspiratory and expiratory periods are indicated by the vertical red lines. Expiration is often divided into two phases: E1 and E2. E1 is defined by activity on expiratory-decrementing (E-Dec) (also called postinspiratory (post-I)) neurons and can include residual but declining phrenic nerve activity. Expiratory-augmenting (E-Aug) neuronal activity occurs mainly in E2. Expiratory–inspiratory phase spanning (E–I) neurons begin to depolarize and discharge prior to the onset of inspriation, with their peak depolarization near the transition from expiration to inspiration. Such neurons are concentrated in the pre-BötC, and at least a subset appears to be critical for inspiratory rhythm generation. Inspiratory-augmenting (I-Aug, or I-ramp) neurons start to depolarize at a time approximating the onset of phrenic nerve discharge and then progressively depolarize throughout inspiration, resulting in a graded increase in discharge rate. Late inspiratory (late-I) neurons begin to depolarize and discharge only late in inspiration. Inspiratory-constant (I-Con) neurons discharge at a relatively constant level throughout inspiration. A final group of inspiratory neurons, inspiratory-decrementing (I-Dec) cells, depolarize abruptly at the onset of inspiration and fire at a high rate. As inspiration progresses, these neurons slowly repolarize and decrease their discharge rate. Expiratory neurons can be divided into three predominant groups. Analogous to I-Dec neurons, E-Dec neurons begin to discharge at a high frequency at the onset of expiration. They then progressively repolarize and decrease their discharge rate during expiration. Some investigators distinguish between E-Dec neurons, which discharge at a declining rate throughout expiration, and post-I neurons, which tend to discharge only during the early portion of expiration (the E1, or post-I, interval). E-Aug neurons typically begin to discharge about midway through expiration (i.e., during the late or E2 phase) and, like I-Aug neurons, exhibit a progressive depolarization and a consequent increase in firing rate. A final group of expiratory neurons, termed pre-I neurons, have been identified in neonatal rats and appear to be important in generating expiratory rhythm. These neurons typically depolarize and fire a brief burst of action potentials immediately prior to inspiration onset; they are then hyperpolarized during inspiration and cease firing. Immediately following inspiration termination, they again briefly depolarize and fire a brief burst of action potentials. pre-BötC, pre-Bötzinger complex. Adapted from Feldman JL and McCrimmon DR (1999) In: Zigmond MJ, Bloom FE, Landis SC, Roberts JL, and Squire LR (eds.) *Fundamental Neuroscience*, pp. 1063-1090. London: Academic Press.

pre-I activity pattern. The pFRG is located beneath lateral portions of the facial nucleus in the neonate and may extend caudally beneath the BötC complex. Studies in neonatal and preadolescent juvenile rats have implicated the pFRG in the generation of respiratory rhythm and appear to be critical for active expiratory activity. Whether RTN neurons in the adult rat brain are the same population identified as pre-I neurons in the pFRG of the neonate is not yet known.

Pontine Respiratory Group

The PRG is a group of respiratory neurons in the dorsolateral pons that includes neurons in ventral parts of the medial and lateral parabrachical complex and Kölliker–Fuse nucleus (**Figures 3(b), 3(c) and 4**). The PRG and the VRC are at either end of an essentially continuous column of respiratory and respiratory-related neurons in the lateral pons and medulla (**Figures 3(c), and 4**). It extends rostrally from the medulla, essentially surrounds the facial nucleus, traverses the ventrolateral pons and regions adjacent to both the motor trigeminal and principal sensory trigeminal nuclei before merging ventrally with the PRG. These neurons merge medially with VRC-projecting neurons in the subcoeruleus area.

The lateral pontine column of neurons intervening between the PRG and VRC is inhomogeneous, but it contains neurons with axons that project to the VRC, PRG, and/or DRG, as well as cranial motor neurons (e.g., those innervating airway and orofacial regions,

Figure 3 Respiratory neurons in the rhombencephalon of the rat brain: (a) horizontal view; (b, c) sagittal views. In (a) and (b), functionally distinct brain stem compartments related to breathing are indicated within the shaded columns by different colors. Nearby brain stem structural landmarks are indicated in gray for prominent neuronal nuclei or outlined for major fiber bundles. In (c), neurons are depicted in lateral portions of the pons and medulla that are retrogradely labeled (red dots) following an injection of FluoroGold into the general vicinity of the pre-BötC. Note that the nearly continuous column of propriobulbar neurons occupies regions that have been shown in independent physiological experiments to consist of respiratory neurons or respiratory-related neurons influencing the control of breathing. The column of neurons is interrupted or displaced by the facial nucleus that migrates caudally from the pons in ontogeny to reach its final ventral location at the rostral end of the medulla. Respiratory interneurons are found at the borders of the facial nucleus, most prominently ventrally in the retrotrapezoid nucleus (RTN) in (b). Portions of the RTN, especially caudally, have been associated with central chemoreceptors (sensing CO_2 and pH), providing drive (excitation) to other respiratory brain stem neurons; other neurons in the RTN have been associated with (expiratory) rhythm generation and encompassed by the term parafacial respiratory group (pFRG). The degree to which chemoreception and expiratory rhythm generation are served by independent groups of neurons remains to be determined. It is postulated that pFRG neurons are coupled (reciprocally) to the pre-BötC, a region in the rostral medulla that appears to be essential for the generation of the inspiratory rhythm. Respiratory neurons are most commonly found in the ventral respiratory column of the medulla (VRC) in (a), in the dorsal respiratory group (DRG, in (b)); located within ventrolateral portions of the nucleus of the solitary tract (SolVL), and in the pontine respiratory group (PRG, in (c)) in the dorsolateral pons. Note that, although only the Kölliker–Fuse nucleus and the lateral part of the parabrachial complex are depicted, the term PRG also encompasses respiratory neurons in medial portions of the parabrachial complex. An area termed the ventral respiratory group (VRG; in (a)) is mainly associated with medullary bulbospinal premotor neurons and is subdivided into a rostral aggregate of mainly inspiratory bulbospinal neurons (rVRG) and a more caudal aggregate of mainly expiratory bulbospinal neurons (cVRG). 5n, trigeminal nerve; 7, facial nucleus; 7n, facial nerve; A5, A5 noradrenergic neuronal group; AmbC, compact part of nucleus ambiguus; AP, area postrema; BötC, Bötzinger complex; cVRG, caudal division of ventral respiratory group; DRG, dorsal respiratory group; icp, inferior cerebellar peduncle; ITR, intertrigeminal KF, Kölliker–Fuse nucleus; LPBr, lateral parabrachial region; LRt, lateral reticular nucleus; mcp, medial cerebellar peduncle; Mo5, motor nucleus of the trigeminal nerve; NTS, nucleus of the solitary tract; pFRG, parafacial respiratory group; Pn, basilar pontine nuclei; pre-BötC, pre-Bötzinger complex; RTN, retrotrapezoid nucleus; rVRG, rostral division of ventral respiratory group; scp, superior cerebellar peduncle; SO, superior olive; sol, solitary tract; SolC, commissural subdivision of the nucleus of the solitary tract; SolV, ventral subdivision of the nucleus of the solitary tract; SolVL, ventrolateral subdivision of the nucleus of the solitary tract; sp5, spinal trigeminal tract; vlPons, ventrolateral pontine region; VRC, ventral respiratory column of the medulla; VRG, ventral respiratory group. including the tongue). Although their specific roles in breathing remain incompletely characterized, neurons within this region can be subdivided into distinct compartments (Figures 3(b) and 4). For example, the area between the motor and sensory trigeminal nuclei (the intertrigeminal area), along with portions of the overlying Kölliker–Fuse nucleus, has been implicated in the generation of apneas as part of airway and orofacial protective reflexes.

Mesencephalic Influences on Breathing

Periaqueductal gray Periaqueductal gray (PAG) neurons that project to the parabrachial complex, ventrolateral pons, and VRC modulate breathing. PAG neurons are arranged in rostrocaudally organized columns with individual columns related to emotional coping, pain responses (including pain suppression), autonomic activation and suppression, vocalizations, and reproduction. Neurons in the caudal-lateral and ventrolateral PAG are related to vocalizations

Figure 4 Coronal sections through the rhombencephalon depicting the location of neurons projecting to the ventral respiratory column of the rat. The neurons were retrogradely labeled by a tracer injection (inj) in the rVRG. The retrogradely labeled neurons are shown in white projected against pseudo-colored dark-field images (red) of the brain stem sections. Note that compact aggregates of neurons in the medulla contralateral to the injection site identify the pre-BötC, rVRG, and cVRG. In contrast, areas such as respiratory-related regions of the NTS, the Kölliker–Fuse nucleus, RTN, and BötC, project mainly to the ipsilateral medulla and consequently are only prominently labeled on the same side as the injection. It should be noted that, although the area postrema (AP) appears brightly labeled (last row), this is an artifact resulting from the relatively high amounts of endogenous peroxidase in the area postrema that is demonstrated by the immunoperoxidase procedure used to detect the retrogradely labeled neurons. It is also notable that the AP is a midline structure in small mammals but a bilateral structure in larger mammals such as cats and dogs. Despite this structural difference, respiratory-related NTS neurons are found in similar locations alongside the AP and caudal to it. 7, facial nucleus; 7n, facial nerve; 12, hypoglossal nucleus; A5, A5 noradrenergic neuronal group; AP, area postrema; BötC, Bötzinger complex; cVRG, caudal division of ventral respiratory group; emPBr, external medial parabrachial nucleus; IO, inferior olive; KF, Kölliker–Fuse nucleus; LPBr, lateral parabrachial region; Mo5, motor nucleus of the trigeminal nerve; NTS, nucleus of the solitary tract; PAG, periaqueductal gray; pdx, pyramidal decussation; Pn, basilar pontine nuclei; pre-BötC, pre-Bötzinger complex; RMg, raphe magnus; RTN, retrotrapezoid nucleus; rVRG, rostral division of ventral respiratory group; scp, superior cerebellar peduncle; SO, superior olive; sol, solitary tract; SolC, commissural subdivision of the nucleus of the solitary tract; SolVL, ventrolateral subdivision of the nucleus of the solitary tract; sp5, spinal trigeminal tract; vlPons, ventrolateral pontine region; VRG, ventral respiratory group.

(particularly in response to emotional or sensory inputs) and project to cVRG neurons premotor to laryngeal and abdominal motor neurons. PAG vocalization areas also synapse on vocalization-related neurons in the ventrolateral pons. This latter area integrates afferents from the PAG, cochlea (auditory), and forebrain that modify vocalization/breathing by projections to the VRC (e.g., cVRG) as well as to laryngeal motor neurons. Projections from cortical laryngeal motor areas terminate in the ventrolateral pons, but do not target laryngeal motor neurons directly; an exception is the human brain, in which stimulation of motor cortex directly activates laryngeal motor neurons. Dorsolateral PAG projections to the parabrachial complex appear necessary for orienting responses, such as changes in heart rate, blood pressure, and breathing elicited by novel stimuli.

Forebrain influences on breathing In addition to its role in vocalization, the forebrain affects breathing related to emotions, metabolic and hormonal homeostasis, and sleep–wake cycles. Few of these influences are mediated by direct projections to the VRC. Direct projections arise from posterior hypothalamus, paraventricular hypothalamic nucleus, and perifornical and lateral hypothalamus. These projections are

Figure 5 Bulbospinal neurons in the ventral respiratory column of the rat: (a) inspiratory bulbospinal neurons and their axons; (b) expiratory bulbospinal neurons and their axons. These are depicted on horizontal sections of the rhombencephalon and in transverse sections of the cervical spinal cord (C4–C5) from the level of the phrenic nucleus. As shown in (a), in the rat I-Aug neurons in the rVRG are the main source of excitatory (glutamatergic) inspiratory afferents innervating the phrenic nucleus and driving the diaphragm. Most I-Aug neurons use enkephalin as a co-transmitter. I-Aug neurons project via axons crossing in the medulla that descend both ipsilaterally and contralaterally to the parent cell to terminate in the spinal cord. I-Aug neurons send collaterals to other premotor neurons in the ipsilateral and contralateral ventral respiratory column and to a subset of respiratory-related cranial motor neurons. At least some of the I-Aug axons provide inspiratory input to thoracic inspiratory motor neurons (e.g., external intercostal motor neurons). In the cat, (excitatory) Iβ neurons in the ventrolateral subdivision of the NTS receive an inspiratory respiratory drive as well as excitatory SAR afferent input and project to the phrenic nucleus in the contralateral spinal cord; these cells do not provide local collaterals to respiratory areas of the medulla. Iγ neurons have also been identified in the rat. They receive a central respiratory drive, DAR afferent input, and project to the spinal cord. These neurons are included within the population of RAR/DAR cells depicted in **Figure 6**. As shown in (b), E-Aug neurons in the cVRG provide the excitatory drive to expiratory motor neurons in the thorax and abdomen. These neurons send axons that cross in the medulla and descend in the contralateral spinal cord to innervate thoracic and upper lumbar spinal interneurons and motor neurons, ultimately controlling expiratory pump muscles, such as the internal intercostal muscles of the rib cage and the abdominal muscles. No local medullary collateral axons arise from the cVRG E-Aug neurons, but their axons bifurcate at the level of their target neurons to innervate expiratory motor pools both ipsilateral and contralateral to the parent cell. E-Aug neurons in the BötC send inhibitory (glycinergic) axon collaterals to the ipsilateral VRC and a substantially lower number of branches to the contralateral VRC (see also **Figure 4**). Ascending axonal branches are also provided to the pons, including the PRG. E-Dec neurons are found throughout the VRC, particularly within the BötC and cVRG. Many E-Dec neurons within the VRC are inhibitory (glycinergic) and their axons arborize in the ipsilateral, and to a lesser extent, the contralateral medulla. Some E-Dec neurons, particularly those located caudally in the VRC provide axon collaterals to the ipsilateral spinal cord. Both BötC E-Aug neurons and E-Dec neurons are potential sources of afferents to phrenic motor neurons, which are actively inhibited during expiration. BötC, Bötzinger complex; cVRG, caudal division of ventral respiratory group; DAR, deflation-activated receptor; E-Aug, expiratory-augmenting; E-Dec, expiratory-decrementing; I-Aug, inspiratory-augmenting; I-Dec, inspiratory-decrementing; NTS, nucleus of the solitary tract; RAR, rapidly adapting stretch receptor; rVRG, rostral division of ventral respiratory group; scp, superior cerebellar peduncle; SAR, slowly adapting stretch receptor; VRC, ventral respiratory column of the medulla.

supplemented by telencephalic contributions originating in insular and frontal cortex and in portions of the extended amygdala, such as the central nucleus of the amygdala and the bed nucleus of the stria terminalis. Despite modest direct projections to the VRC, the forebrain substantially engages pontine relay neurons in areas such as the PAG, parabrachial complex, and ventrolateral pons that integrate voluntary, emotional, hormonal, and reflexive motor demands on the respiratory system.

Monoamine systems and breathing In addition to the effects of monoamines on breathing that correspond to its roles in arousal, control of motor tone and behavioral state (waking/sleeping), specific respiratory functions may also be served by select portions of the monoamine systems.

Serotonin. While many serotonin neurons in the caudal brain stem target both the dorsal and ventral spinal cord, serotonergic innervation of the VRC appears to arise from raphe magnus in the rostral

medulla-caudal pons. In victims of sudden infant death syndrome, postmortem serotonin receptor density is decreased, and the area with the most obvious receptor changes is the arcuate nucleus, a medullary nucleus composed of serotonergic and nonserotonergic neurons (a likely homolog of the raphe magnus and nearby parapyramidal neurons described in nonprimate mammals; both regions have mixed serotonergic and nonserotonergic neurons). The arcuate region in the human probably corresponds to one of several CO_2-chemosensitive regions located in the medulla and caudal pons. Medullary serotonin neurons target broad regions of the spinal cord, including respiratory motor neurons. Serotonergic innervation of motor pools appears to play an important role in regulating their excitability and in initiating/orchestrating plasticity in respiratory motor neurons. As with other monoamines, there is a circadian cycle in serotonergic neuronal activity, and this could directly impact the regulation of respiration during sleep–wake cycles.

Catecholamines. Norepinephrine, epinephrine, and dopamine have diverse effects on breathing, including effects on breathing frequency that depend on the adrenergic receptor subtype. The organization of catecholamine input to respiratory-related areas is somewhat confusing because brain stem noradrenergic cell groups vary as a function of developmental age and between species (or even between rat strains).

Noradrenergic neurons (A5 and A6 groups) modulate respiratory motor output at multiple sites, including both brain stem and spinal cord. Activity in catecholaminergic neurons also varies with the circadian cycle, and they probably mediate some changes in respiratory activity characteristic of the sleep–wake cycle. In addition, locus coeruleus neurons may participate in central chemoreception. Noradrenergic neurons, including neurons in the subcoeruleus region, probably project to the VRC. An inhibition of respiration mediated by α_2-adrenergic receptors is observed after central injections of catecholamines, and in *in vitro* preparations pontine noradrenergic afferents suppress breathing. Noradrenergic and adrenergic neurons located in the medial and commissural nuclei of the NTS are also a likely source of afferents to the ventrolateral medulla, but whether these neurons reach respiratory circuits is unclear.

Dopamine neurons in the posterior hypothalamic A11 cell group are a likely source of dopaminergic projections to the VRC and DRG. However, the central effects of dopamine on breathing are not well understood. When the pons is included, dopamine facilitates fictive breathing in brain stem–spinal cord preparations *in vitro*, but depresses respiration when the pons is removed; the depression appears to result in part from the effects of dopamine D4 receptors on a subset of pre-I neurons in the pFRG that depolarize and begin to fire tonically when stimulated with dopamine. Important dopaminergic influences are also found in the NTS, where dopamine (as well as histamine) is released from chemosensory afferent fibers arising in the carotid body.

Respiratory Reflexes

Sensory receptors related to breathing have essential regulatory and airway-protective roles. Coughing, sneezing, mucus secretion, and airway constriction protect the airways from irritants and facilitate the removal of inhaled substances that are potentially harmful to the lungs and airways. Sensory feedback from arterial and central chemoreceptors as well as lung mechanoreceptors modulates the breathing pattern (e.g., tidal volume and breathing frequency) and is essential for matching ventilation to changing metabolic requirements. Feedback is also essential for adapting respiratory motor output to other behaviors such as changes in posture or locomotion.

Receptors in the Nasal Passages and Pharynx

Respiratory reflexes can be evoked from the nasal cavities via receptors in the mucous membrane. Sensory information is transmitted largely via branches of the trigeminal nerve, including the anterior ethmoidal nerve and branches of the maxillary nerve. Nasal receptors respond to inhaled irritants such as ammonia, cigarette smoke, and volatile anesthetics, as well as to cold and decreased pressure associated with respiratory airflow. Irritants elicit various cardiorespiratory reactions, including sneezing, mucus secretion, bradycardia, hypertension, and inhibition of breathing.

Submersion of the face in water elicits a stereotypic response consisting of apnea, bradycardia, and increased peripheral vascular tone (the diving reflex). The diving reflex is elicited by receptors with afferent fibers in the trigeminal nerve that terminate primarily in ventral aspects of the spinal trigeminal nucleus with smaller terminal fields in the NTS, paratrigeminal nucleus, ventrolateral medulla, and PRG. The diving reflex can be anticipatory. This aspect involves higher central nervous system (CNS) processing, probably interacting with the dorsolateral pons. The parabrachial complex relays somatic and visceral sensations to both forebrain and brain stem; conversely, the parabrachial complex and Kölliker–Fuse nucleus relay descending cortical pathways to cardiorespiratory regions in ventolateral pons and medulla.

Laryngeal receptors elicit powerful respiratory reflexes via vagal afferent fibers that course in the

recurrent and superior laryngeal nerves. Receptors are divided into several different subgroups based principally on their activating stimulus. Cold/flow receptors respond to laryngeal cooling, which occurs during inspiration as room temperature air moves through the air passages. Pressure receptors sense laryngeal pressure changes, especially the decreased pressure that exerts a collapsing force on the airway during inspiration. Respiratory drive receptors respond to the magnitude of contraction of airway muscles, especially the sole airway abductor (opener), the posterior cricoarytenoid. Irritant receptors are activated by inhaled irritant chemicals (e.g., ammonia or cigarette smoke) as well as the presence of water (solutions lacking chloride) in the larynx. Finally, C-fiber receptors respond to chemical stimuli; significant percentages (~40% in mouse) express transient receptor potential vanilloid (TRPV1) receptors that are activated by protons, heat, and vanilloid ligands such as capsaicin. The relative inaccessibility of laryngeal receptors to experimental manipulation has limited our understanding of their specific roles in the production of respiratory reflexes. However, given their location at the entry to the trachea, they have the capacity to produce a variety of respiratory protective reflexes, including cough and apnea, as well as reflexes that promote airway patency by activation of upper airway muscles (e.g., genioglossus and posterior cricoarytenoid). Beyond the termination of the primary afferent fibers in the NTS, little is known about the central pathways by which these afferent fibers exert their influence on breathing.

Receptors in the Lower Airways

Generally, three categories of receptors are identified within the airways below the larynx: slowly adapting stretch receptors (SARs), rapidly adapting stretch receptors (RARs), and bronchopulmonary C-fibers. Receptors termed deflation-activated receptors (DARs) are prevalent in small mammals and share some homologies with the RARs in larger mammals – both elicit augmented inspiratory efforts and both are inhibited by γ-aminobutyric acid (GABA)ergic neurons receiving input from SARs. SARs, RARs, and DARs constitute airway mechanoreceptors innervated by rapidly conducting, myelinated, vagal afferent fibers that terminate with distinct topographies in the NTS (Figure 6).

C-fibers are slowly conducting unmyelinated axons constituting the majority (~75%) of pulmonary vagal afferent fibers. They terminate in several caudal NTS subdivisions (Figure 6). They are polymodal and nociceptive, responding to a variety of inflammatory mediators and inhaled irritants. Reflex changes in breathing in response to C-fiber activation involve rapid shallow breathing interspersed with apneas; additional reflex effects include bronchoconstriction, mucus secretion, hypotension, bradycardia, and airway mucosal vasodilation. Beyond the identification

Figure 6 Respiratory-related afferents to the NTS. Vagal afferents to the respiratory-related areas of the rat NTS are shown. SARs, RARs, and C-fibers travel in the vagus nerve to enter the ventrolateral quadrant of the medulla at mid-rostral levels. These axons then travel caudally in the solitary tract to terminate in the NTS. SARs (green axons) terminate ipsilaterally in the ventral, ventrolateral, intermediate, and interstitial NTS subnuclei at the rostrocaudal level of the area postrema (AP). RARs (red vagal axons) terminate in a region beginning near the caudal end of area postrema (also called the calamus scriptorius) and extending across the midline at the commissural subdivision of the NTS. The terminations of vagal C-fibers (blue) are more widely dispersed and terminate bilaterally in the NTS. Inhibitory (GABAergic) SAR second-order neurons (pump cells, orange) in SolV and SolVL project extensively to the ipsilateral VRC and also send ascending axon collaterals to the lateral pons. Excitatory pump cells (green) are also likely to exist and their postulated axonal arborization is depicted as similar to that of GABAergic pump cells. E-Dec neurons are probable targets of excitatory pump cell axons. RAR neurons are less commonly observed in the rat than in the cat. DAR neurons (red), however, are more frequent and are topographically located in NTS regions similar to those inhabited by RAR neurons in the cat. DAR neurons are excitatory and give off extensive collaterals to the ipsilateral VRC and to respiratory related targets in the ipsilateral pons. Some also project to the spinal cord. Iγ and DAR neurons both receive input from deflation-sensitive receptors. Iγ neurons (purple), however, also receive a central respiratory drive and usually project to the spinal cord. AP, area postrema; BötC, Bötzinger complex; DAR, deflation-activated receptor; E-Dec, expiratory-decrementing; GABA, γ-aminobutyric acid; KF, Kölliker–Fuse nucleus; NTS, nucleus of the solitary tract; PBr, parabrachial nucleus; RAR, rapidly adapting stretch receptor; SAR, slowly adapting stretch receptor; SolV, ventral subdivision of the nucleus of the solitary tract; SolVL, ventrolateral subdivision of the nucleus of the solitary tract; VRC, ventral respiratory column of the medulla.

of the regions of C-fiber termination within the NTS, little is known concerning central pathways mediating these responses.

SARs are located in airway smooth muscle, particularly in large airways, and modulate breathing pattern, airway smooth muscle tone, systemic vascular resistance, and heart rate. SAR-reflex effects on breathing pattern are known as the Breuer–Hering reflexes and include alterations of both tidal volume and breathing frequency. Expansion of the lung during inspiration increases SAR activity and leads to inspiratory termination, thereby limiting the tidal volume (i.e., the Breuer–Hering inspiration-inhibiting reflex). If inflation is maintained or lung volume is increased, the expiratory duration is lengthened (i.e., the Breuer–Hering expiratory facilitatory reflex). Breuer–Hering reflexes are active under relaxed breathing conditions in all mammals, although their contribution in adult humans during resting conditions is relatively minor. SAR influences in humans increase during conditions such as physical exercise, when tidal volume is two to three times its resting value.

RARs are arranged circumferentially in airway epithelium and submucosa. They respond to lung inflation and irritant chemicals, but tend to have little activity under normal conditions. RARs fire irregularly with only a few action potentials during lung inflation and give rise to A∂-fibers in the vagus nerve. They are implicated in a number of potent airway protective reflexes, including augmented breaths (sighs), airway constriction, mucus secretion, and laryngeal closure. Coughs appear to be triggered by a select subset of polymodal A∂-fibers (cough receptors).

Second- and Higher-Order Neurons in Respiratory Reflexes

Central Pathways of Slowly Adapting Stretch Receptors

SAR primary afferent fibers have a restricted arborization within the mid to caudal portions of the NTS (Figure 6). Despite diverse autonomic and respiratory motor reflexes elicited by SAR activation, only two functional classes of NTS neurons receive monosynaptic input from SARs (Figure 6). One type, termed Iβ neurons, exhibit inspiratory discharge patterns independent of, but augmented by, SAR inputs. Iβ neurons are bulbospinal premotor neurons that monosynaptically excite phrenic motor neurons, although the extent of this projection may vary among species. This disynaptic activation of phrenic motor neurons represents a positive feedback excitation of phrenic nerve discharge by SAR afferents during lung inflation.

A second group of NTS neurons, termed pump neurons, presumably mediate Breuer–Hering reflex changes in respiratory rhythm. Pump neurons receive monosynaptic SAR input but can be readily distinguished from Iβ neurons by their general lack of inspiratory discharge in the absence of SAR input. Consistent with the broad effects they elicit on respiratory pattern, they have extensive axonal arborizations within the DRG, VRC, and lateral pontine respiratory areas.

Many pump neurons are GABAergic, with a small percentage also containing glycine. Their axons terminate throughout the VRC, where both rhythm-generating neurons (pre-BötC) and bulbospinal premotor neurons (rVRG and cVRG) are potential targets.

In addition to inhibitory pump cells, there is probably a population of excitatory pump neurons. The excitatory and inhibitory pump neurons may both contribute to Breuer–Hering inspiratory-inhibiting and expiratory-facilitatory reflexes. VRC I-Dec and E-Dec (or post-I) neurons (Figure 2) are inhibitory and influence inspiratory and expiratory duration. It appears that I-Dec neurons inhibit expiratory neurons and E-Dec neurons (glycinergic) inhibit inspiratory neurons. Their declining discharge pattern represents a declining inhibition that, when low enough, permits the transition from expiration to inspiration or vice versa. Consequently, the inhibition of I-Dec neurons by pump neurons contributes to a more rapid decline in the discharge of I-Dec neurons and a shortening of inspiratory duration, thereby decreasing tidal volume. In contrast, SAR activation provides strong excitation of E-Dec neurons (probably from excitatory pump neurons), and subsequent E-Dec inhibition of inspiratory neuron activity lengthens expiratory duration.

Central Pathways of Rapidly Adapting Stretch Receptors

RAR afferent fibers monosynaptically activate NTS excitatory neurons termed RAR interneurons (Figure 6). Like pump neurons, these interneurons provide extensive axonal arborizations to VRC and PRG neurons. Despite the extensive arborization pattern of RAR interneurons, the identity of targeted respiratory neuron subtypes is not yet known. These targets presumably include neurons that facilitate inspiration because RAR receptors evoke reflexes that are preceded by large inspirations, such as coughs and augmented breaths (sighs). Sighs are triggered in response to decreased lung compliance caused by alveolar collapse; the ensuing deep inspiration reopens collapsed alveoli.

Deflation-Activated Receptor-Mediated Reflexes

Lung deflation causes expiratory termination and increased inspiratory effort. This reflex is particularly important in young mammals, including human infants, or other small mammals that have highly a compliant chest wall. In the absence of compensating muscular activity, increased chest wall compliance permits greater inward recoil of the lung during passive expiration, leading to low end-expiratory lung volumes. Low lung volumes have potentially negative implications, including the greater likelihood of alveolar collapse and impaired gas exchange. This tendency is offset by slowing expiratory airflow via glottal adduction and/or braking activity (postinspiratory activation) of the diaphragm and earlier onset of the subsequent inspiratory effort. Lung deflation alters the activity of respiratory neurons controlling all these factors, producing appropriate changes in airway caliber as well as decreased expiratory duration and increased peak phrenic nerve activity.

DAR afferent fibers terminate in the NTS, where they activate two general classes of excitatory (glutamatergic) neurons. One type, DAR relay neurons, is analogous to the pump cells in having a discharge pattern determined almost completely by their primary afferent input. They are localized caudally within the commissural subnucleus of the NTS, immediately medial to the solitary tract, and are inhibited by input from GABAergic/glycinergic pump cells. The second class of neurons receiving DAR afferent input is a subset of DRG inspiratory neurons, termed inspiratory-γ (Iγ) neurons. Iγ neurons project to the spinal cord and, although their spinal targets have not yet been identified, their inspiratory facilitatory effect suggests that phrenic motor neurons are the likely targets. Like pump cells and RAR interneurons, DAR relay neurons give rise to axons that arborize extensively in the VRC and PRG, although the target neuron identities are not yet known.

Central Pathways of Peripheral Chemoreceptors

Chemoreceptors in the carotid bodies and aortic arch are sensitive to changes in arterial carbon dioxide, oxygen, and pH. The carotid bodies are generally more important in mediating this response and provide the principal mechanism by which mammals sense lowered levels of oxygen. Afferents from the carotid body travel in the carotid sinus nerve, a branch of the glossopharyngeal cranial nerve. The latter enters the brain stem at the posterior levels of the facial nucleus and travels caudally to join the solitary tract. The afferents terminate in caudal portions of the NTS, mainly within the commissural and medial subdivisions. A variety of transmitters and modulators are found in carotid chemoreceptor afferent fibers, including dopamine, histamine, adenosine, serotonin, and glutamate. Subsequent projections from the NTS to the VRC and particularly to the RTN appear to be glutamatergic.

Summary

From a physiological perspective, the idiom "as easy as breathing" is an oxymoron because breathing is an extraordinarily complex event that requires multiple layers of organization and integration. At odds with this complexity, our individual personal experiences, when healthy, mislead us into thinking it is a simple process because it is so automatic and reliable, leading to a smooth integration of respiratory activity into nearly every facet of our daily lives. To the contrary, the entire process depends on multiple structural systems that have evolved to serve gaseous homeostasis and on the parallel evolution of behavioral systems that avail themselves of voluntary and reflex components of breathing and airway regulation in order to eat, drink, speak, swim, walk, run, copulate, defecate, vomit, and the myriad other activities that require adjustments in respiratory rhythm and pattern so that they may also proceed in a smoothly integrated and coordinated fashion. It is usually only under challenges, such as during sustained physical activity, disease, or emotional stress that we begin to appreciate that breathing is not easy. The consequences of failure at this essential task are devastating.

Neural Cell Adhesion Molecules and Synapse Regulation

M Schachner, I Leshchyns'ka, and V Sytnyk, Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany

The Neural Cell Adhesion Molecule

The neural cell adhesion molecule (N-CAM) was discovered as the first member of the immunoglobulin superfamily in neural cells. It occurs in three major isoforms and minor, often very cell-type-characteristic, alternatively spliced variations. All three major isoforms of N-CAMs share the same extracellular domain encompassing five immunoglobulin-like (Ig-like) domains and two fibronectin type III modules. Two transmembrane isoforms with apparent molecular masses of 180 and 140 kDa (designated N-CAM180 and N-CAM140, respectively) contain a single transmembrane region and intracellular domains of different lengths. The shortest N-CAM isoform, with the apparent molecular mass of 120 kDa (designated N-CAM120), is attached to the plasma membrane via a glycosylphosphatidylinositol anchor, predisposing the localization of N-CAM120 to lipid-enriched microdomains, which are also called lipid rafts and which are distinct from the lipid microenvironment of N-CAM140 and N-CAM180 (Figure 1).

N-CAM is unique in that it carries an unusual carbohydrate, the α-2,8-linked polysialic acid, which has not been found on any other recognition molecule. Polysialylation and isoform expression undergo changes during development. Polysialylation decreases during embryonic progression to the adult stage, but remains prevalent at sites where neurogenesis is active, such as on neural stem cells in the dentate gyrus of the hippocampus and the rostral migratory stream emanating from the subventricular zone of the lateral ventricles and terminating in the olfactory bulb.

N-CAM was discovered as a homophilically interacting (i.e., self-binding) molecule. Reports from different laboratories have shown that homophilic binding between N-CAM molecules is accomplished via antiparallel association of all five immunoglobulin-like domains, the first and the second immunoglobulin-like domains, or only via interaction between the third immunoglobulin-like domains of the molecule. Polysialic acid regulates homophilic interactions of N-CAMs in that it reduces these interactions, supposedly by its highly negatively charged sialic acid residues, in addition to a large hydration volume surrounding the glycan chains. Besides *trans*-interactions (i.e., interactions between molecules located on opposed cell surfaces), *cis*-interactions between N-CAMs located in the plasma membrane of the same cell can also occur. These may modulate *trans* homophilic interactions between N-CAMs.

N-CAM also interacts with non-self-binding partners in so-called heterophilic *cis*- or *trans*-interactions. Among the heterophilic binding partners are the receptors for fibroblast growth factor and the glial cell line-derived neurotropic factor receptor, both of which are involved in N-CAM-dependent signal transduction. N-CAM interacts with other members of the immunoglobulin superfamily, such as L1, with other recognition molecules, such as prion protein, and with extracellular matrix molecules, such as phosphacan.

N-CAM and Synaptic Plasticity

The polysialylated form of N-CAM and the protein isoforms of N-CAM are differentially distributed in cell surface membranes. While N-CAM180 is mainly, if not exclusively, found on postsynaptic membranes in the central nervous system, N-CAM140, the smaller transmembrane isoform, is not only found postsynaptically, but also presynaptically. The glycosylphosphatidylinositol (GPI)-anchored isoform of N-CAM is mainly, if not exclusively, found on glial cells which abut onto the pre- and postsynaptic membranes as potentially homophilic interaction partners, thus providing a molecular basis for a glial influence on synaptic activity. Interestingly, the levels of expression of both N-CAM140 and, in particular, N-CAM180 depend on synaptic activity.

The first observation suggesting that expression of N-CAM180 in postsynaptic densities of some, but not all, synapses between axons of granule cells and Purkinje cell dendrites in the molecular layer of the adult mouse cerebellum pointed to a particular functional distinction between these synapses. Together with the observation that N-CAM180 is less mobile in the surface membrane than N-CAM140 is, this finding gave rise to the idea that N-CAM180 is well poised to immobilize cell surface components at crucially interacting apposing cell surface membranes at the synapse. An increase in the proportion of hippocampal spine synapses expressing N-CAM180 following long-term potentiation in rats verified this conclusion. In chickens, it was also observed that training increased the proportion of synaptic active zones containing N-CAM in the lobus paraolfactorius of the striatum and altered the distribution of N-CAM in synaptic membranes in the hyperstriatum ventrale of chicken forebrain.

Heterophilic binding partners of N-CAM:

Receptors:	FGFR (*a*), GFRα (*a*)
Other recognition molecules:	L1 (*a,b*), RPTPζ/β (*b*), prion protein (*a,b*)
Extracellular matrix molecules:	phosphacan (*c*), heparin (*c*), heparan sulfate proteoglycans (*c*)

Figure 1 Structure and homo- and heterophilic interactions of N-CAMs. (a) The three major N-CAM isoforms are shown. All isoforms share the same extracellular part, composed of five immunoglobulin-like and two fibronectin type III domains. N-CAM140 and N-CAM180 are transmembrane isoforms, with N-CAM180 containing the largest intracellular domain. N-CAM120 is anchored to the plasma membrane via glycosylphosphatidylinositol and is located in lipid-enriched microdomains which are distinct from the lipid microenvironment of N-CAM140 and N-CAM180. (b) A scheme of the homophilic interactions of N-CAM is shown. Homophilic *trans*-interactions of N-CAM (*a*–*d*) can be mediated by all five immunoglobulin-like domains (*a*), the first and the second immunoglobulin-like domains (*b*), or only the third immunoglobulin-like domain (*c*). Polysialic acid (shown in gray) attenuates homophilic interactions of N-CAM (*d*). N-CAM molecules can also interact with each other in a *cis* configuration, being located in the surface plasma membrane of one cell (*e*). (c) A scheme of the heterophilic interactions of N-CAM is shown. N-CAM can associate with heterophilic binding partners located in the same plasma membrane (*a*), on adjacent membranes (*b*), or in the extracellular matrix (*c*). Bottom: Examples of the heterophilic binding partners of N-CAM, with the type of their heterophilic interactions with N-CAM (as described in (c)) indicated in parentheses.

Not only the number of synapses expressing N-CAMs, but also the distribution of N-CAMs, and in particular N-CAM180, within postsynaptic densities is changed in an activity-dependent manner, correlating with changes in localization of the NR2A subunit of the *N*-methyl-D-aspartate (NMDA) receptor subtype of glutamate receptors. This is not the case for the GluR2/3 subunit of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor subtype and the mGluR1 subunit of the metabotropic glutamate receptor: in synaptic membranes of nonstimulated hippocampal spine synapses, N-CAM180 and NR2A accumulated in the center of the postsynaptic density, whereas GluR2/3 and mGluR1 were distributed evenly. Twenty-four hours following induction of long-term potentiation *in vivo*, N-CAM180 and NR2A accumulated at the edges of postsynaptic densities, whereas GluR2/3 localized more centrally.

Functional validation of the importance of N-CAM in synaptic plasticity derived from observations that antibodies against N-CAM interfered with hippocampal long-term potentiation in slice preparations *in vitro*. Recovery of emotional behavior in N-CAM-deficient mice through transgenic expression of N-CAM180 driven by the neurofilament promoter

showed that N-CAM180 is indeed involved in certain types of synaptic interactions. Further functional links between synaptic activity and N-CAM expression were provided by observations on N-CAM-deficient mice which showed increased anxiety and serotonin 1A receptor response. Furthermore, mice constitutively deficient in N-CAM and mice in which N-CAM was conditionally ablated in the second and third postnatal week in excitatory neurons, under the control of calcium/calmodulin kinase IIα (CaMKII) promoter, showed reduced long-term potentiation and long-term depression *in vitro* and abnormalities in behavior. Mice deficient in the two polysialyltransferases responsible for N-CAM polysialylation also showed altered synaptic plasticity *in vitro* and abnormalities in learning and memory.

The combined observations emphasize the importance of N-CAM and its isoform N-CAM180 in synaptic plasticity. The exact mechanisms by which N-CAM participates in the regulation of synaptic efficacy remain poorly understood, but recent findings indicate that N-CAM may play an important role in this scenario by activating signal transduction pathways, remodeling of the cytoskeleton in postsynaptic densities, and/or gene transcription. These findings are discussed in greater detail in the following sections.

N-CAM Is a Signal Transducer

Early findings indicated that N-CAM, like other transmembrane cell surface receptors, is indeed a signal transducer. Activating N-CAM at the cell surface by using N-CAM antibodies or triggering homophilic N-CAM *trans*-interactions produced signaling responses in the N-CAM-expressing cells, including enhanced calcium influx via G-protein-dependent channel activation, pH change, and phosphoinositide turnover, all of which had been suggested to contribute to neurite outgrowth and synapse function. Additional observations that N-CAM180, the largest N-CAM transmembrane isoform, is accumulated at sites of focused signal transduction – namely in the postsynaptic density, where cytoskeletal elements act together with pivotal signal-transducing enzymes – fostered further activities aiming to elucidate signal transduction pathways that were first discovered to influence neuronal migration and neurite outgrowth, but were later found to be pivotal in signal transduction in synapses (Figure 2).

Figure 2 Schematic diagram showing the distribution and multiple functions of N-CAM in synapses and postsynaptic densities. The topography of the distribution of N-CAM140 and N-CAM180 in synapses is indicated in blue and red, respectively. N-CAM140 is present both pre- and postsynaptically, while N-CAM180 is present only postsynaptically. Homophilic and probably heterophilic (not shown) interactions of N-CAM in the synaptic cleft contribute to synapse stabilization and modulation of function. Via the intracellular domain, N-CAM180 associates with spectrin-enriched *trans*-Golgi-derived organelles, and anchors this complex in the postsynaptic density. Homophilic and heterophilic interactions of N-CAM140 and N-CAM180 activate signaling cascades in the postsynaptic density. Two of the most well-studied pathways, including MAP kinase pathway activation via RPTPα/p59fyn (blue arrows) and PKC/GAP43 through N-CAM140 (blue arrows) and N-CAM180 (red arrows), are shown. These pathways result in activation of gene transcription in the nucleus and cytoskeleton remodeling in the postsynaptic density, respectively. PKC, RPTPα, and p59fyn regulate the phosphorylation of other postsynaptic proteins, including NMDA receptors, thus providing additional mechanisms for N-CAM-mediated control of synapse efficacy. Signaling pathways that have been characterized are shown with solid arrows; hypothetical signaling pathways are shown with dashed arrows.

N-CAM Associates with and Reorganizes the Cytoskeleton

A prerequisite for the precise topographic distribution of N-CAM isoforms in the postsynaptic membrane derives from the capacity of N-CAM180 and N-CAM140 to interact with the cytoskeleton. N-CAM binds to the membrane cytoskeleton linker protein spectrin, which is one of the most abundant proteins in the postsynaptic density and an important platform for docking of receptors and ion channels. In initial experiments, N-CAM180, because of its direct interaction with spectrin, was shown to be less mobile than N-CAM140 within the surface membrane. However,

more refined techniques have recently shown that all three isoforms of N-CAM accumulate, co-localize, with and co-immunoprecipitate spectrin. In another recent study, α- and β-tubulin as well as α-actinin were observed to associate with N-CAM180 and N-CAM140. Moreover, N-CAM180, but not N-CAM140, bound to microtubule-associated protein 1a, β-actin, and tropomyosin. These proteins are also associated with the cytoskeleton, particularly in postsynaptic compartments.

Spectrin is a pivotal platform for activation of neuromodulatory receptors at the cell surface. The NMDA glutamate receptor subtype regulating synaptic plasticity in long-term potentiation and depression is cross-linked to N-CAM via spectrin. Furthermore, CaMKIIα, highly enriched in postsynaptic densities and involved in synaptic plasticity, is also bound to the spectrin platform. Clustering of N-CAM induces formation of detergent-insoluble complexes enriched in postsynaptic proteins and resembling postsynaptic densities. Disruption of the N-CAM/spectrin complex in N-CAM-deficient mice or by an interfering spectrin fragment in wild-type cells decreases the size of postsynaptic densities and reduces synaptic targeting of N-CAM/spectrin-associated postsynaptic proteins, not only including spectrin, but also the NMDA receptor and CaMKIIα. Furthermore, N-CAM-deficient neurons are unable to recruit CaMKIIα to synapses in response to NMDA receptor activation. These observations indicate that N-CAM regulates formation of spectrin-based postsynaptic specializations with one of its quantitatively most important ingredients – CaMKIIα – to promote activity-dependent postsynaptic rearrangements leading to long-lasting changes in synaptic strength.

Clustering of N-CAM Induces Signaling through Lipid Rafts

Spectrin plays an important role in the interaction of N-CAM with kinases and phosphatases in lipid rafts, which are lipid-enriched microdomains serving as lipid-based signaling platforms in postsynaptic densities. N-CAM120 redistributes spectrin predominantly to lipid rafts, while N-CAM140 and N-CAM180/βI spectrin complexes do not depend on raft integrity and are located both in rafts and raft-free membrane domains, thus suggesting the possibility of integration of different signal transduction mechanisms. Spectrin acts as a bridge between the transmembrane N-CAM isoforms and protein kinase C β2 (PKCβ2) and the receptor-like protein tyrosine phosphatase α (RPTPα). Clustering of N-CAM enhances the formation of the N-CAM/PKCβ_2 and N-CAM/RPTPα complexes via spectrin. Interestingly, redistribution of PKCβ2 and RPTPα to N-CAM/spectrin complexes is blocked by a specific fibroblast growth factor receptor inhibitor. Activation of N-CAM is accompanied by a redistribution of N-CAM and N-CAM-associated proteins to lipid rafts, where N-CAM interacts with the growth-associated protein 43 (GAP43), which is highly expressed not only in the developing nervous system, but also in synapses in the adult. GAP43 promotes actin reorganization, which is regulated by its phosphorylation through protein kinase C. RPTPα, a known activator of lipid-raft-localized protein tyrosine kinase p59fyn, links N-CAM to this kinase. Association between N-CAM and p59fyn is lost in RPTPα-deficient brains, and is disrupted by dominant-negative RPTPα mutants, showing that RPTPα functions as a link between N-CAM and p59fyn. N-CAM-mediated p59fyn activation is abolished in RPTPα-deficient neurons, implicating RPTPα as a major phosphatase involved in N-CAM-mediated signaling.

p59fyn is an organizer of signal transduction pathways activated by clustering of N-CAM molecules at the cell surface. Phosphorylation of p59fyn activates the focal adhesion kinase (FAK). After activation of p59fyn and FAK by N-CAM, further downstream signaling is induced, resulting in activation of mitogen-activated protein kinases (MAPKs). Activation of the Erk/MAPKs commences at the cell surface also by activation of the small guanosine triphosphate (GTP)-binding protein Ras. From Ras, the signal progresses through sequential activation of the serine/threonine kinases Raf and MAP extracellular kinase (MEK), leading to phosphorylation of Erk/MAPKs. Activation of MEK, the kinase immediately upstream of extracellular signal-regulated kinases ERK-1 and ERK-2, rescues the inhibition of p59fyn. A docking protein, ShcA, has been shown to contribute to p59fyn/FAK-mediated MAPK activation in integrin signaling by recruiting the adaptor protein Grb2, which associates with the GTP exchange factor SOS to induce Ras activation. In addition, MAPK activation by N-CAM may result from an increase in cytoplasmic calcium, which induces activation of MAPK, and/or by PKC, which can activate Raf.

More indirect ways, also probably involving the spectrin cytoskeleton, have become evident by the ability of N-CAM to regulate cell surface delivery of G-protein-activated inwardly rectifying potassium channels via lipid rafts. Mice deficient in N-CAM exhibited a strikingly increased sensitivity to serotonin 1A receptor agonists. Studies of the relationship between N-CAM and serotonin receptor signaling pathways mediating G-protein-activated inwardly rectifying potassium (Kir3) channels showed that delivery of these channels to the cell surface is increased in N-CAM-deficient mice as opposed to wild-type mice.

N-CAM140 and N-CAM180 specifically reduced inwardly rectifying currents generated by neuronal, but not cardiac, channels through impairment of cell surface transport of these channels. Interestingly, mutational and pharmacological disruption of the lipid raft association of N-CAM140, including elimination of palmitoylation-targeted delivery of N-CAM to lipid rafts, normalizes surface delivery of channels. This observation alludes to a novel mechanism controlling long-term excitability of neurons.

These observations indicate a complex interplay between N-CAM function, neurotransmitter and cytokine receptors, ion channels, kinases, and receptor tyrosine phosphatases that themselves act as recognition molecules and impinge on the cytoskeleton and common signaling cascades of the MAP kinase pathway and transcriptional elements.

N-CAM Activates Gene Transcription

Cyclic AMP response element-binding protein (CREB) activates genes that contain regulatory cre-elements, such as the immediate-early gene c-*fos*, and both CREB and the activated genes are important for N-CAM-mediated neurite outgrowth. CREB is activated by the MAPK pathway, leading to its phosphorylation and activation of transcription. Signaling from N-CAM to CREB also proceeds through protein kinase A (PKA), since inhibition of PKA inhibits N-CAM-dependent neurite outgrowth, and neither activation of PKA or MAPK rescues inhibition of N-CAM-mediated neurite outgrowth by expression of a dominant-negative CREB protein. These findings imply that PKA and MAPK signaling converges on CREB activation. It has been suggested that calcium influx is an important ingredient in stimulating cAMP production to activate PKA, which in turn is required for nuclear translocation of MAPK. PKA also induces MAPK activation through the Ras-related small GTP-binding protein Rap1. Implicating yet another N-CAM-related molecule, it has been found that CaMKII, together with PKA, can directly phosphorylate CREB to regulate its activity. CaMKII also regulates the transcriptional activator nuclear factor-kappa B (NF-κB), which has been shown to be activated by N-CAM functions. A link from the MAPK pathway to transcription involves phosphorylation of the transcription factor ELK-1. The genes activated by ELK-1 and NF-κB, as well as those activated by CREB in response to N-CAM triggering in synapses, remain to be identified.

N-CAM Regulates Synapse Formation

N-CAM is not only important in the functioning of mature synapses, but also during synapse development, as observed in cell culture of hippocampal neurons. Time-lapse video recordings in cell cultures of hippocampal neurons showed that N-CAM accumulates at initial contacts between an axon and dendrite within several minutes after contact establishment. These initial contacts then often give rise to synapses, but can be disassembled via retraction of an axon or dendrite, with both neurites separating from each other. Interestingly, absence of N-CAM in cultured neurons from N-CAM-deficient mice leads to an enhanced disassembly of initial contacts within several minutes after contact establishment, when compared to wild-type neurons, indicating that N-CAM is required to stabilize interacting neurites.

Again, the mechanisms of the transformation of a contact between an axon and a dendrite into a fully functional synapse depend on N-CAM. *Trans*-Golgi network organelles that are linked via spectrin to the initially formed clusters of N-CAM in the plasma membrane are vitally important for the transformation of contacts to nascent synapses. The complexes of N-CAM and *trans*-Golgi network organelles are translocated along neurites of cultured hippocampal neurons and are trapped at sites of initial neurite-to-neurite contacts. The accumulation of *trans*-Golgi network organelles at contacts with neurons from N-CAM-deficient mice is reduced when compared to neurons from wild-type mice, confirming that N-CAM mediates the anchoring of intracellular organelles at nascent synapses.

To evaluate the contribution of the pre- versus postsynaptic expression of N-CAM in regulation of synaptic efficacy, dissociated hippocampal cells from N-CAM-deficient and wild-type mice were cultured in homo- and heterogenotypic combinations. Electrophysiological recordings from synaptically coupled neurons showed that synaptic strength of excitatory, but not inhibitory, synapses depends on expression of N-CAM postsynaptically, but not presynaptically, correlating with higher levels of potentiation and synaptic coverage of N-CAM-expressing neurons compared to N-CAM-deficient neurons in these heterogenotypic co-cultures. Synaptic density was the same in homogenotypic cultures of N-CAM-deficient and wild-type neurons as well as in heterogenotypic co-cultures in which several types of glutamate receptors were pharmacologically inhibited. These observations indicate that the relative levels of postsynaptic N-CAM expression controlled synaptic strength in an activity-dependent manner by regulating the number of synapses.

While postsynaptic N-CAM promotes synapse formation, presynaptic N-CAM is involved in organization of the presynaptic machinery as revealed by analysis of neuromuscular junctions (NMJs) in N-CAM-deficient mice. N-CAM-deficient NMJs

show multiple alterations in the presynaptic organization including reduced presynaptic accumulation of Ca^{2+} channels, Rab 3-interacting molecule (RIM) and syntaxin. N-CAM-deficient mice exhibit transmission failures in NMJs, subjected to repetitive stimulation, and locomotor behavioral defects. Presynaptically, N-CAM140 plays the major role as revealed by analysis of primarily N-CAM180-deficient mice. However, deficiency in N-CAM180 also affects molecular organization of the presynaptic terminals.

The role of polysialic acid in the synaptogenic activity of N-CAM was also studied in cell culture. Conveniently, a very specific enzyme removing only polysialic acid, but not other glycan chains, from the N-CAM protein backbone abolished preferential formation of synapses on N-CAM-expressing neurons in heterogenotypic co-cultures of wild-type and N-CAM-deficient hippocampal neurons. Expression of any of the three major isoforms of N-CAM in N-CAM-deficient neurons stimulated preferential synapse formation on N-CAM-expressing neurons. Additionally, removal of heparan sulfates from the cultured neurons and mutation in the heparin-binding domain of N-CAM diminished synaptogenic activity of neuronally expressed N-CAM carrying polysialic acid, suggesting that interaction of N-CAM with heparan sulfate proteoglycans mediates synapse formation. N-CAM-driven synaptogenesis was also inhibited by antagonists to the fibroblast growth factor receptor and the NMDA receptor, but not by blockers of non-NMDA glutamate receptors and by blockers of voltage-dependent sodium channels. Enzymatic removal of polysialic acid and heparan sulfates also inhibited the increase in the number of perforated synapses associated with NMDA receptor-dependent long-term potentiation in the CA1 region of organotypic hippocampal cultures. Thus, neuronally expressed N-CAM, with its associated polysialic acid in complex with heparan sulfate proteoglycans, promotes synaptogenesis and activity-dependent remodeling of synapses.

Dysfunction of N-CAM Leads to Psychiatric Disorders

Disturbances of N-CAM function in forming synapses and at mature synapses, studied both in cell culture and in intact animals with the help of N-CAM-specific mutations, show wider implications, not only in laboratory animals, but also in humans: genetic variations in the N-CAM gene have been shown to confer risks associated with bipolar affective disorders. Furthermore, the hippocampus and prefrontal cortex of patients with schizophrenia and bipolar disorders accumulate the secreted extracellular cleavage products of N-CAMs in tissue and cerebral spinal fluid, most likely interfering with homophilic interactions of N-CAMs. Accordingly, transgenic mice ectopically expressing secreted N-CAM display disturbed synaptic connectivity and abnormal behavior, with abnormalities that are particularly relevant to schizophrenia. Thus, disruption of the many functions of N-CAMs by mutations may affect the structural organization of postsynaptic densities and reduce the efficacy of synapse formation and maintenance, possibly being directly relevant to the etiology of psychiatric disorders. The combined observations establish N-CAM as an important player in the assembly and function of a unique invention: the synapse.

Neural Circuitry in the Somatosensory System

K D Alloway, The Pennsylvania State University, Hershey, PA, USA

Somatosensory Circuits

Cutaneous stimulation evokes neuronal responses in the central nervous system that are tightly coordinated both spatially and temporally. As in other neural systems, the coordination of stimulus-induced neuronal activity in the somatosensory system is dictated primarily by the detailed connections of its neural circuits. Within this context, the main factors that influence neuronal coordination in the somatosensory system include its topographic organization, the morphology and density of its synaptic contacts, and the biophysical properties of the neurons embedded within its neural circuits. Although the coordination of neural activity is constrained by the connectivity of the neuronal substrate, somatosensory circuit operations are dynamic. Consequently, the functional strength of the connections between brain regions or between specific pairs of neurons in the somatosensory system can fluctuate with changes in stimulation, neuronal bursting, corticofugal processing, and other factors.

Ascending Somatosensory Pathways

The somatosensory system consists of the ascending neuronal pathways that convey somesthetic information to the cerebral cortex as well as the descending corticofugal projections from the somatosensory cortex. Hence, awareness of the body and its interactions with the environment requires the transmission of kinesthetic and tactile information through the peripheral nerves and then through a series of brain regions located progressively higher in the neuraxis. Innocuous stimulation of the skin, for example, activates peripheral nerve fibers that, depending on the body part that is stimulated, terminate in one of the following brain stem regions: the nucleus gracilis (leg and lower trunk), the nucleus cuneatus (arm and upper trunk), or the trigeminal nuclei (face and head). Each of these brain stem nuclei gives rise to ascending axons that transmit cutaneous information to neurons in the ventrobasal part of the contralateral thalamus, which includes the ventroposteromedial (VPM) nucleus for the head representation and the ventroposterolateral (VPL) nucleus for the trunk and limbs. In turn, the ventrobasal thalamus transmits cutaneous information to the primary somatosensory cortex and surrounding regions in the parietal lobe.

The somatosensory representations in the brain stem, thalamus, and cortex have a precise somatotopic organization that has important consequences for processing spatial information. Each somatosensory region contains a spatially organized map of the entire body, and within each map, adjacent neuronal populations represent neighboring sites on the body. The ascending connections through successive levels of the neuraxis act as linkages between neuronal populations that represent the same part of the body. For example, the thalamic neurons that represent the thumb have many synaptic contacts on the cortical neurons that represent the thumb, but have few synaptic contacts on cortical neurons that represent the palm or the arm.

Time-Locked Neuronal Responses

Tactile stimulation evokes a time-locked sequence of neuronal activity that reflects the sequential order of the ascending somatosensory pathways. Following punctate stimulation of the hand, for example, microelectrode recordings demonstrate that neurons in the nucleus cuneatus have response latencies (i.e., time delays) that are shorter than those recorded in the ventrobasal thalamus. Likewise, thalamic response latencies are shorter than those recorded in the somatosensory cortex. Therefore, response latencies in the somatosensory system increase both with the length of the axonal route and with the number of intervening synapses that are traversed as stimulus-induced neural activity advances from the periphery to the somatosensory cortex.

Local Inhibitory Circuits

The somatosensory nuclei in the brain stem and thalamus contain elementary circuits in which inhibitory interneurons modulate the transmission properties of the relay neurons. By comparison, the somatosensory cortex contains even more complicated inhibitory circuits that modulate the response properties of the pyramidal neurons. In fact, the majority of synaptic contacts on the pyramidal soma originate from local inhibitory neurons.

In all levels of the somatosensory system, inhibitory connections provide a mechanism for sharpening the temporal and spatial tuning properties of the excitatory neurons. Lateral inhibitory connections, for example, regulate the spatial extent of neuronal responsiveness. This view is based on experiments showing that local blockade of γ-aminobutyric acid (GABAergic) transmission substantially increases the receptive field size of individual neurons in each level of the somatosensory system.

Recurrent inhibition also plays a major role in processing somatosensory information. In the thalamus, for example, projections from the reticular nucleus form recurrent inhibitory connections with the thalamocortical relay neurons in VPM or VPL. Composed exclusively of a slender band of GABAergic neurons along the lateral edge of the thalamus, the output of the reticular nucleus modulates the spatial and temporal activity of the thalamocortical relay neurons. In addition to receiving collateral excitatory inputs from thalamocortical relay neurons, the reticular nucleus also receives collateral inputs from corticothalamic feedback projections. By activating the reticular nucleus, corticothalamic projections indirectly inhibit selective parts of the ventrobasal thalamus while directly activating other parts of the thalamus. Hence, coordinated interactions between the corticothalamic projections and the recurrent inhibitory circuits of the reticular nucleus provide a mechanism for selectively filtering or enhancing transmission of tactile information to the cerebral cortex.

Somatosensory Neuronal Interactions

To characterize neuronal coordination within a neural circuit, neurophysiologists record the action potentials of several neurons simultaneously and then use cross-correlation analysis to identify those neurons that have correlated discharges. When electrodes are placed in brain regions that are anatomically connected, cross-correlation analysis permits inferences about whether specific pairs of neurons are interconnected. Furthermore, if two neurons are synaptically connected or are located in serially connected brain regions, cross-correlation analysis provides a convenient method for measuring the functional strength of these connections during a variety of experimental manipulations.

In essence, a cross-correlogram (CCG) illustrates time-varying fluctuations in the incidence or probability of a target neuron discharge given that a reference neuron discharged at time zero. As shown in Figure 1, two neurons located in different neuronal circuits have coordination patterns that reflect their relative circuit locations and synaptic relationships. For serially connected neurons, the CCG is used to calculate the probability that a reference neuron discharge is associated with a target neuron discharge at a specific time delay. This probability, or efficacy, is calculated as follows: efficacy $= (CE/NR) \times 100$, where CE indicates the number of correlated events in the CCG peak and NR indicates the total number of reference discharges. Hence, the efficacy ratio indicates the proportion of presynaptic reference neuron discharges that are correlated with subsequent time-locked discharges in the postsynaptic target neuron. For neurons that are not serially connected, the correlation coefficient is used to indicate the amount of correlated activity. As shown in Figure 1, the formula for the correlation coefficient is similar to the efficacy ratio.

Feed-Forward Transmission

Simultaneous neuronal recordings in successive levels of the somatosensory system reveal substantial changes in neuronal responsiveness as somesthetic information is transmitted to higher levels of the neuraxis. In general, peripheral afferent nerves transmit information with a high degree of fidelity to their postsynaptic targets in the brain stem, but subsequent transmission to the thalamus and cortex is characterized by a decline in postsynaptic responsiveness.

When afferent nerve fibers and their postsynaptic responses in the nucleus cuneatus are recorded simultaneously, nearly 90% of the axonal discharges in the afferent fiber are associated with a time-locked discharge in the postsynaptic cuneate neuron. In fact, a single impulse in the afferent nerve fiber often produces a burst of two or three discharges in the cuneate neuron. This high degree of synaptic security is related to the morphologic relationship between the central terminals of the afferent nerve fiber and the postsynaptic dendrites of the cuneate neuron. Ultrastructural examination indicates that afferent fibers have massive terminals that are invaginated by the cuneate neuron dendrites, and these synaptic contacts are completely ensheathed by glia. Presumably, this glomerular-like structure enables high-fidelity transmission of somesthetic information.

Comparisons of neuronal responses recorded simultaneously in the nucleus cuneatus and ventrobasal thalamus indicate that the rate of stimulus-induced activity is much lower in the ventrobasal thalamus than in the nucleus cuneatus. Consistent with this decline in responsiveness, cross-correlation analysis indicates that efficacy rates for cuneothalamic interactions reach a maximum of 30%. Hence, cuneothalamic efficacy is much lower than the synaptic efficacy of the primary afferent nerve fibers (see earlier).

Simultaneous neuronal recordings in the ventrobasal thalamus and somatosensory cortex reveal that cortical responsiveness is lower than in the thalamus. Cross-correlation experiments indicate that the maximum thalamocortical efficacy rate is about 20%, but most pairs of thalamic and cortical neurons exhibit efficacy rates well below 10%.

Differences in the efficacy rates for cuneothalamic and thalamocortical interactions are also related to the synaptic morphology of these connections.

Figure 1 Cross-correlation analysis and the measurement of functional connection strength. (a) For neurons that are serially connected, the CCG shows time-varying fluctuations in the probability of a discharge in the target neuron (T) given that a reference neuron (R) discharged at time zero. The height of the CCG peak represents the number of instances in which a discharge in the reference neuron was time-locked to a subsequent discharge in the target neuron. The delay of the peak with respect to time zero reflects the time needed for action potentials to travel along the axon of the reference neuron. The efficacy ratio, which is obtained by dividing the number of coincident events in the CCG peak by the number of reference spikes, represents the probability that a reference spike is associated with a subsequent target neuron discharge at a specific time delay. (b) For neurons that are not serially connected with each other, the amount of correlated activity is determined by calculating a correlation coefficient, $\rho(\tau_0)$, in which A and B represent the number of discharges recorded from neurons *A* and *B* over a time period *T*.

Although not as large as the terminals formed by afferent nerve fibers, cuneothalamic terminals form glomerular-like synapses that are enveloped by a glial sheath. By contrast, thalamocortical synaptic contacts are much smaller, are not invaginated by the postsynaptic dendrites, and are not ensheathed by glial processes. Hence, thalamocortical connections are substantially weaker than the synaptic connections in the earlier stages of the somatosensory system.

Thalamocortical Feed-Forward Interactions

Feed-forward neuronal interactions between the ventrobasal thalamus and somatosensory cortex vary as a function of the laminar structure of the cerebral cortex. Cross-correlation analysis indicates that the incidence and strength of stimulus-induced thalamocortical interactions are highest when thalamic neurons are paired with cortical neurons in layer IV or in the deep part of layer IIIb. In fact, thalamocortical efficacy values above 10% are obtained only when the cortical neuron is in granular layer IV. This is consistent with the fact that neurons in the middle cortical layers receive the highest density of synaptic contacts from thalamocortical relay neurons. Furthermore, stimulus-induced thalamic discharges precede neuronal discharges in the middle cortical layers by 1–2 ms, which corresponds to the time needed for conducting action potentials from the thalamus to the cortex. This tight temporal coordination undoubtedly reflects interactions between neurons that have strong, monosynaptic connections.

Thalamocortical efficacy rarely exceeds 5% for cortical neurons recorded outside the middle cortical layers. Nonetheless, a comparison of thalamic interactions with cortical neurons in the supra- or infragranular layers reveals functional distinctions between these layers. For example, the probability of detecting correlated thalamocortical interactions is twice as great when the target neuron is a supragranular neuron instead of an infragranular neuron. Furthermore, the proportion of time-locked thalamocortical interactions that transpire within a 3 ms interval is much higher for target neurons in the supragranular than in the infragranular layers. These findings suggest that information transmitted from the ventrobasal thalamus must be processed by many synaptic connections before it can influence neurons in the deep cortical layers.

Laminar differences in the strength and relative timing of thalamocortical interactions have prompted

the view that tactile information follows a multisynaptic serial route through somatosensory cortex that commences in granular layer IV and proceeds to the supragranular layers before arriving in the infragranular layers. While this view overlooks many details of cortical connectivity and other aspects of cortical processing, it is consistent with the predominant circuit connections within a column of somatosensory cortex. Thus, most axons arising from granular neurons in layer IV terminate in the supragranular layers, which project to infragranular layer V. In turn, layer V pyramidal neurons send collateral projections to the neurons in infragranular layer VI. Finally, cortical output projections to the thalamus, neostriatum, pons, and spinal cord originate almost exclusively from infragranular layers V and VI.

Somatotopic Influences

The incidence and strength of stimulus-induced neuronal interactions in the somatosensory system are related to the somatotopic properties and other characteristics of the recorded neurons. Cross-correlation analysis indicates that neighboring cortical neurons with similar receptive fields and other response properties show high rates of correlated activity. As the amount of receptive field overlap declines, however, the amount of correlated activity that is produced by a punctate stimulus also declines.

Similar findings have been observed for pairs of neurons that reside in successive levels of the somatosensory system. Thus, in response to a simple punctate stimulus, cuneothalamic or thalamocortical interactions are strongest for those neurons that have identical or highly overlapping receptive fields. Neurons that represent nonoverlapping receptive fields do not exhibit correlated responses to a punctate stimulus. These results are consistent with the precise topographic organization of the ascending somatosensory projections.

Dynamic Interactions

The coordination of stimulus-induced neuronal activity varies substantially with stimulus intensity, location, and other factors that affect the spatiotemporal distribution of neural responsiveness. For example, if two neurons with similar receptive field properties are recorded simultaneously in the thalamus and cortex, their correlated activities can be altered merely by changing the peripheral stimulation site. Even though the synaptic contacts made by the thalamic neuron onto the cortical neuron are constant within a recording session, small shifts in stimulus position effectively activate slightly different populations of thalamic and cortical neurons. Because the two neurons are embedded in a larger network of neuronal connections, any shift in the network distribution of activity can produce a concomitant shift in the correlated activities of the two neurons. Hence, the dynamic operations of a circuit, including the effectiveness of communication between two connected neurons, may fluctuate instantaneously as the distribution of neural activity is altered by changes in the parameters of sensory stimulation.

Functional connection strength in the somatosensory system also varies with changes in the temporal structure of neuronal activity. Simultaneous neuronal recordings in VPM and somatosensory barrel cortex have shown that thalamocortical efficacy depends on the time interval between successive thalamic impulses. Thalamic discharges that occur after a quiet period of several hundred milliseconds are much more effective in evoking a cortical response than are thalamic discharges that occur in the midst of a train of thalamic discharges. Although the exact biophysical mechanism for this effect remains uncertain, activity-dependent depression of the thalamocortical synapse is the likely explanation for this dynamic shift in connection strength.

Neuronal Synchronization

Administration of a punctate stimulus to the skin activates intermingled populations of different types of peripheral receptors and their afferent projections to the central nervous system. Even if a single afferent fiber could be activated by a sensory stimulus, afferent fibers have terminal arborizations that form multiple synaptic contacts on neighboring postsynaptic neurons. This pattern of divergence is repeated at successive levels of the somatosensory system. Hence, the rich innervation of the skin and the divergence of successive ascending projections ensure that populations of neighboring neurons are activated simultaneously within each level of the somatosensory system.

Cross-correlation analysis of neurons located in close proximity consistently reveals the presence of synchronized activity during somatosensory stimulation. Thus, when neighboring neurons are recorded by two separate electrodes during cutaneous stimulation, the CCG exhibits a peak of coincident discharges at time zero (see Figure 1(b)). Such experiments have demonstrated stimulus-induced synchronization in all levels of the somatosensory system, including the brain stem, thalamus, and in primary (SI) and secondary (SII) somatosensory cortex.

The widespread incidence of neuronal synchronization in different brain regions during sensory, motor, and cognitive processing has prompted the

Figure 2 Thalamocortical cooperativity in the somatosensory system. (a) Simple neuron circuit in which a pair of thalamocortical relay neurons converge on a target neuron in somatosensory cortex. (b) The impact of thalamic synchronization on cortical responsiveness is determined by comparing the efficacy values from a series of CCGs that are constructed on specific types of reference events occurring in the spike trains of the two thalamic neurons. For example, individual CCGs are constructed (1) for synchronous thalamic discharges, (2) for short interneuronal interspike intervals (INISIs), or (3) for longer INISIs. (c) Specific reference events are identified by inspecting the thalamic spike trains and identifying INISIs in which a pair of thalamic discharges in the two neurons are isolated from other discharges by a deadtime period.

view that neuronal synchronization facilitates neurotransmission in many neural systems. According to this view, the probability of a postsynaptic neuronal discharge depends on the relative timing of presynaptic inputs and is highest when multiple presynaptic neurons discharge synchronously.

Thalamocortical Cooperativity

The impact of thalamic synchronization on thalamocortical transmission has been analyzed by using conditional cross-correlation analysis to measure cortical responsiveness as a function of the relative timing of thalamic discharges. In this procedure, the probability of a cortical neuron discharge following synchronous thalamic discharges is compared to the probability of a cortical response when each thalamic neuron discharges asynchronously (i.e., alone). If thalamic neurons cooperate with each other to activate a cortical neuron, the efficacy rate of their synchronous thalamic discharges should exceed the efficacy rate that is calculated from the joint probability of their asynchronous thalamic events. For example, if each thalamic neuron has an efficacy rate of only 10% when it discharges by itself, then each thalamic neuron also has a failure rate of 90%. Consequently, when both thalamic neurons discharge simultaneously, the predicted joint failure rate is 81% (the product of $90\% \times 90\%$). Hence, the predicted efficacy rate when both thalamic neurons discharge simultaneously is 19% ($100\% - 81\%$). If the observed efficacy exceeds 19%, then synchronization of these thalamic neurons must represent 'cooperative' rather than independent events.

Conditional cross-correlation analysis of thalamocortical interactions requires that two thalamic neurons with similar somatotopic properties are recorded simultaneously with a cortical neuron that also has similar response properties. As shown by Figure 2, a computer program searches the two thalamic spike trains and sorts those instances in which discharges of the two thalamic neurons are separated by a specific time interval. A set of conditional CCGs is then constructed for each type of reference event. Thus, the first conditional CCG is constructed based only on instances in which both thalamic neurons discharged at exactly the same time. A second CCG is then constructed based on reference events consisting of a discharge in one thalamic neuron followed by a discharge 1 ms later in the other thalamic neuron. A third CCG is constructed based on reference events consisting of a discharge in one thalamic neuron followed by a discharge in the other thalamic neuron 2 ms later. This process is repeated until a set of CCGs has been constructed for the range of discharge intervals across the two thalamic neurons. In each conditional CCG, the reference event at time zero represents the time of the second discharge of the two thalamic neurons.

The computer program also requires the presence of a deadtime period before and after each pair of thalamic neuron discharges. Hence, each reference event for a conditional CCG must represent an instance in which the discharges in the two thalamic neurons occur in isolation of other thalamic discharges. As shown in Figure 2, the deadtime period is at least as long as the interval between the two neuronal discharges. Without a deadtime period, the cortical neuron might discharge because it received a burst of homosynaptic inputs from the same thalamic neuron. Hence, a deadtime period removes cortical responses due to homosynaptic integration of the recorded neurons and ensures that the conditional CCGs are based on cortical responses to their heterosynaptic inputs.

Conditional cross-correlation analysis indicates that synchronized pairs of thalamic neurons have an efficacy rate that is more than twice the efficacy rate that is measured when the thalamic neurons discharge asynchronously (i.e., separated by 10 ms or more). Cortical responsiveness declines rapidly when thalamic discharges are separated by more than 3 ms and reaches an asymptotic level at intervals larger than 10 ms. This suggests that synchronous thalamic discharges represent cooperative events that facilitate the transmission of sensory information to the cerebral cortex.

Cortical Coordination

The presence of stimulus-induced neuronal synchronization in the cerebral cortex has prompted substantial debate and speculation, but its function remains unknown. In contrast to the impact of thalamic synchronization on cortical responsiveness, no studies have shown that cortical synchronization increases the responsiveness of target neurons in other cortical or subcortical regions.

Local populations of neurons in somatosensory cortex exhibit synchronized responses that vary as a function of cortical layer, neuronal proximity, and changes in the pattern of tactile stimulation. In rodent barrel cortex, for example, stimulus-induced synchronization is much more prevalent among infragranular neurons than in the other cortical layers. This finding is consistent with the infragranular location of intrinsically bursting neurons, which have extensive horizontal connections that may synchronize cortical outputs. Nonetheless, many results indicate that neurons in all layers of somatosensory cortex show increases in synchronization during certain experimental paradigms.

Tactile stimulation evokes neuronal synchronization among neighboring neurons in both somatosensory cortical regions SI and SII, but some distinctions between these regions have been reported. During cutaneous stimulation of a focal site, neuronal synchronization is more extensive in SII than in SI, possibly because SII neurons receive more thalamocortical convergence and have larger receptive fields. Neuronal synchronization in SII is also modulated by shifts in selective attention. In monkeys that alternately perform tactile and visual tasks, SII neurons are weakly synchronized during the visual task, but are strongly synchronized during the execution of a tactile discrimination.

Corticocortical Synchronization

Simultaneous neuronal recordings in separate cortical regions demonstrate that tactile stimulation can synchronize neurons that are widely separated from each other. In cats, for example, SI and SII neurons with overlapping receptive fields become synchronized during focal stimulation. This is consistent with the fact that the ventrobasal thalamus sends parallel, somatotopically organized projections to both cortical regions. Presumably, the dense corticocortical interconnections between SI and SII facilitate and reinforce the temporal precision of the synchronization that is observed across these cortical regions.

Direct corticocortical connections are not necessary, however, to synchronize separate cortical areas during tactile stimulation. In monkeys, for example, neuronal populations in Brodmann areas 3b (SI) and 4 (primary motor cortex) become synchronized during manipulative behaviors that require skill and attention, but not during simple repetitive movements. Although these cortical regions are not directly connected, it is conceivable that they become synchronized by subcortical inputs or by multisynaptic corticocortical pathways. While the function of neuronal synchronization across widespread parts of sensorimotor cortex is not clear, the acquisition of skilled movements that rely on somesthetic guidance may require coordination of multiple cortical regions that represent specific tactile sensations related to the control of specific motor actions.

Corticocortical and Corticofugal Interactions

Corticocortical and corticofugal projections play a major role in processing somatosensory information. Somatosensory cortex provides a rich source of projections to motor cortex as well as to other parts of the motor system, including the neostriatum, the pons, and the superior colliculus. The importance of these projections is related to the close interactions that transpire between the somatosensory and motor

systems during motor learning, active touch, and other somesthesis-guided behaviors. In addition, somatosensory cortex provides feedback projections to each level of the somatosensory system, including the spinal cord, brain stem, and thalamus. The ability to make fine tactile discriminations or to ignore somesthetic information in certain situations is facilitated by cortical feedback projections that modulate the feed-forward transmission of tactile information at each level of the somatosensory system.

The influence of the somatosensory cortex on the thalamus has been demonstrated by many physiological studies. Reversible inactivation of somatosensory cortex, for example, produces both suppressive and augmenting responses in the thalamus. Such opposite effects are undoubtedly due to the fact that corticothalamic projections can produce direct excitation or indirect inhibition via the reticular nucleus.

Simultaneous recordings of neuronal activity in SI cortex and the ventrobasal thalamus during different behavioral states suggest that corticothalamic projections have a modulatory influence on the feed-forward transmission of somesthetic information. For example, recordings in SI and VPM of awake rats reveal neuronal oscillations in the range of 7–12 Hz that are initiated in SI and then appear in the thalamus several milliseconds later. This top-down progression of neuronal coordination almost always precedes rhythmic whisker movements at frequencies of 7–12 Hz. Furthermore, SI and VPM responses to repeated electrical stimulation of the infraorbital nerve, which innervates the whiskers, are not constant but vary in magnitude according to whether the animal is actively whisking or is in a state of quiet rest. Although these results are subject to interpretation and may rely on several corticofugal mechanisms, such findings indicate that neuronal responses in the somatosensory system represent the outcome of dynamic circuit operations that entail more than the simple feed-forward transmission of sensory information along the ascending somatosensory pathways.

Neural Coding in Primary Motor Cortex

Introduction

What neural code is conveyed in the discharge of neurons in motor cortex? While it is unlikely that neurons code explicitly some movement parameter, it remains valuable (if not essential) to correlate neural activity to some aspect of sensorimotor performance. The neural code expressed in a given brain region is an important issue since it is closely linked to its function.

This article focuses on neural coding related to primary motor cortex (M1), a region intimately involved in volitional motor function and a region that has received the greatest attention for addressing neural coding in the motor system. The neural code used by M1 is important not only for understanding neural processing in this brain region but also for understanding processing in other regions of the central nervous system. For example, if M1 activity reflects the goals of a motor task, it suggests that the details of motor execution must be performed anatomically downstream from this structure, notably in the spinal cord. Alternatively, if M1 activity codes much of the details about muscle activity patterns, then far less neural processing is required at the spinal cord.

This article begins with two background sections. First, it describes the concept of sensorimotor transformations, a theoretical framework that is implicitly or explicitly assumed by many studies in this field. This is followed by a description of the basic physics of limb movement in order to clarify the types of information that may be coded by the brain.

There are many behaviors and animal models that have been used to explore neural processing in M1. This article focuses predominantly on neural processing in nonhuman primates during reaching movements since these are the most common task and species used to address this issue.

Sensorimotor Transformations and Coordinate Frames

The most common framework for addressing the neural basis of reaching has been based on the problem of sensorimotor transformations. For a task such as reaching to a target, it is supposed that the brain converts visual information on target location into patterns of muscle activity through a series of intermediary coordinate frames. One putative series of transformations is shown in Figure 1, in which spatial target location is sequentially converted into hand motion, joint motion, joint muscle torques, and finally into muscle activation patterns.

These types of variables can be divided into several categories. For example, above the dotted line are kinematic variables that describe motion of the hand and joints, or the spatial goal. In contrast, below the line are kinetic variables that describe the physical forces required to generate movement and muscle activity. The dashed line denotes another common separation of variables into extrinsic variables, related to the global goal of the task (spatial goal or hand motion), and intrinsic variables, related to the details of the motor periphery (joint motion, muscular torques, or muscle activity).

One compelling argument to support the hypothesis that the brain computes intermediate representations to control motor action is based on the observation that humans (and nonhuman primates) make relatively straight hand trajectories with bell-shaped velocity profiles. Novel mechanical loads applied to the limb result in deviations in hand trajectory, but with practice, individuals once again generate relatively straight hand trajectories. This consistency of hand trajectories across different spatial directions and mechanical conditions certainly appears to support the idea that hand motion is computed and controlled by the brain. One could imagine that the discharge patterns of neurons somewhere in the motor system should reflect hand motion. Other representations, such as joint motion, could facilitate the integration of proprioceptive information from muscle afferents into motor commands.

Kinesiology of Reaching Movements

In order to identify what information may be represented in the discharge pattern of neurons in M1, it is important first to understand the physics of limb motion. Figure 2 illustrates how variables change during a reaching movement performed in the horizontal plane where movement is restricted to flexion and extension motions at the shoulder and elbow joints. Parameters related to the spatial goal, hand motion, joint motion, joint muscular forces, and muscle electromyographic (EMG) activity create a rich mix of time-varying signals. There are two basic patterns: tonic signals that shift monotonically during movement and phasic signals that rapidly change with

Figure 1 Putative coordinate transformations performed by the brain to convert information on the spatial location of a target into patterns of muscle activity. The various coordinate frames can be divided in several different ways. The dashed line denotes a separation between extrinsic representations related to the global goal versus intrinsic representations related to the details of the motor periphery. The dotted line denotes a separation between kinematic and kinetic representations.

one or more inflections during movement. In some cases, these patterns, such as hand and joint velocities, look quite similar. Also note that joint acceleration and muscular torque are not identical, due to intersegmental dynamics, because muscular torque generated at a joint can cause motion at other joints.

Across movement directions, the pattern of joint motion, muscular torque, and EMG activity can change dramatically (Figure 3). Movements away and toward the body require the largest motion at the shoulder and elbow joints, whereas movements to the right and left require little motion. This is simply a property of limb geometry, or how the motion of each joint contributes to hand motion for a given movement direction. Variations in muscular torque do not parallel joint motion. Shoulder muscular torque is largest for movements to the left and away (flexor), and to the right and toward the monkey (extensor). Elbow muscular torque is smaller in magnitude compared with that at the shoulder and is maximal for movements in the opposite quadrants. The directions of maximal activity of muscles do not match muscular torque at the spanned joint since muscle activity is influenced by a number of other factors, including muscle length, velocity, and the ways other muscles contribute to a given behavior.

The description of limb movements in Figures 2 and 3 are for planar movements involving only two mechanical degrees-of-freedom (DOF), one at the shoulder and one at the elbow. Free whole-arm movements involve at least two more DOF at the shoulder, abduction–adduction and internal–external rotation. Therefore, the patterns of joint motions, muscular torques, and EMG activities are even richer in this context.

Correlations Based on Single-Cell Activity

One common approach for identifying what information is coded in M1 is to correlate neural activity to variables of movement. Figure 4 illustrates the patterns of activity of four representative neurons observed during reaching to the same target displayed in Figure 2. Cells show tonic and phasic patterns and combinations of these two basic patterns. A given neuron could code any of a number of different parameters or a combination of parameters. How does one choose among all the possible parameters?

Perhaps the most common variable correlated to neural discharge in M1 is related to hand motion. This approach was adopted in the early 1980s in the first studies of whole-arm reaching performed by Apostolos Georgopoulos and colleagues. Only hand motion was recorded because there wasn't any technology readily available to record joint motion or estimate joint torques. Figure 5 illustrates how neural activity is broadly tuned to the direction of hand motion. Cell activity is maximal for movements to the lower right, its preferred direction of movement (PD), and the magnitude of activity is reduced gradually for movements at greater angles from this PD. This broad tuning of activity is a very common characteristic of neurons in M1 and elsewhere in the motor system. Therefore, implicitly this and other studies using this approach illustrate that neural activity in M1 correlates with the direction of hand motion and with other hand-based variables, such as movement speed and distance.

Correlations Based on Population Codes

Another approach for examining neural coding in M1 (and elsewhere) is to consider what parameters are specified at the population level. This seems reasonable since motor function certainly reflects the combined action of large populations of neurons. The basic idea is that a neural code is highly distributed, so a neural code may be observed across the cell population.

While Humphrey in the 1970s first demonstrated that the combined activity of neurons could predict the pattern of muscle EMG activity during a motor task, the most influential study examining population coding in M1 was again provided by the reaching studies by Georgopoulos and colleagues. This approach, developed initially by Ken Johnson, is

Figure 2 Kinesiology of a reaching movement. (a) Hand trajectory for five repeat reaches (dashed lines) and the mean trajectory (solid). Large circles denote the size of the central and peripheral targets. Small circles denote the identified start and finish of hand motion based on 5% of peak hand velocity during each trail. (b) Variables related to the spatial goal including its absolute position (top panel), which shifts from the central to the peripheral target when the latter is illuminated. The position of the hand relative to the goal (bottom panel) abruptly jumps when the peripheral light is illuminated but decreases during hand motion. Dashed and solid line denote *x*- and *y*-parameters, respectively. (c, d) Variation in the position, speed, and acceleration of the hand (c) and joints (d) during reaching. Solid and dashed lines in (d) denote the shoulder and elbow, respectively. (e) Active muscular torque and example muscle activity patterns. EMG, electromyographic activity. EMG scale is in arbitrary units (au).

Figure 3 Kinesiology of reaching in different spatial directions. (a) Mean hand trajectories for reaching movements from a central target to 16 peripheral targets. A, R, T, and L denote directions of movement away, right, toward, and left relative to the monkey's body. (b) Polar plot of peak hand speed. Angle defines the direction of hand motion in Cartesian space, and distance from origin defines the magnitude of the peak hand speed. Thick and thin lines denote mean and standard deviation across repeat trials. (c, d) Polar plots of peak joint speed and joint muscular torque. called the population vector hypothesis, or method (PVM). Each neuron provides a 'vote' along a vector aligned with its PD. For a given movement, the magnitude of a cell's vote is scaled proportional to its firing rate for that movement direction. The population vector is computed by summing vectorially all the individual cell vectors. The key observation is that the population vector tends to point in the direction of hand motion (Figure 6). Several studies have used the PVM or more complex mathematical algorithms to predict movement of the hand during spiral movements, circles, or tracking movements throughout the workspace. Based on the number of

Figure 5 Cell activity in primary motor cortex during reaching. Central panel illustrates the mean hand trajectory for five repeat movements to each spatial target. Corresponding cell activity is adjacent to each peripheral target. Each raster plot shows the discharge rate for five repeat trials; each small vertical tick denotes the time of an action potential. Data are aligned to movement onset. Below each raster is the instantaneous firing rate of the neuron. Vertical lines denote movement onset (time = 0 ms) and mean peak hand velocity. The overlying arrow on the central panel denotes the neurons' preferred direction of hand motion.

studies published in the literature, this hand-based approach is certainly the most popular one for interpreting motor cortical activity. The use of correlations between hand motion and M1 activity is also becoming popular for applied research on neuroprosthetics, with the goal of helping individuals who cannot control their muscles directly.

What is the significance that neural activity in M1 is broadly tuned to the direction of hand movement and that population vectors or other mathematical algorithms can predict the direction of hand movement? It could mean that M1 activity is coding high-level extrinsic information related to the global goal of the task, moving the hand to a spatial target. However, several articles have raised the difficulty of interpreting neural coding based on these correlates of hand motion. In particular, when one examines the physics of limb motion, one finds that many variables are broadly tuned to the direction of hand motion, including joint motion, joint muscular torques, and EMG activity patterns (Figure 3). Further, mathematical algorithms can be used to predict virtually any parameter of movement from M1 activity. The basic problem is that understanding what is coded in M1 (and elsewhere in the motor system) cannot be addressed easily using only correlational techniques at the single-cell or population level. Simply recording only one type of information, such as hand motion, and ignoring all other variables do not resolve this problem.

While population vectors tend to point in the direction of movement when monkeys perform free arm movements, some systematic errors between the population vector and the movement direction have been observed for planar limb movements. For these planar movements, there is a substantial bias in the distribution of preferred directions such that most neurons have PDs that are oriented either away from and to the left, or toward and to the right (Figure 7). The result is that population vectors tend to be skewed in these same spatial directions and rarely predict the direction of hand motion. This nonuniform distribution of PDs is also paralleled by variations in joint power and in the distribution of PDs of the shoulder and elbow muscle activities. One could make the argument that this bias in the distribution of M1 neurons means that neurons code limb mechanics or muscle activities but can be countered by the argument stated above regarding the difficulty of interpreting hand-based codes. At best, these results suggest that the mechanics of the limb has some influence on the patterns of activity in M1 at the population level. They do not resolve what information is expressed at the single-cell level.

Figure 6 Population vectors (dashed line with arrow) for movements in different spatial directions. Each cluster includes population vector and the individual neuron vectors for a given direction of movement (0° is to the right, 90° away, etc.). Each black solid line in a cluster denotes the contribution of an individual neuron; the orientation of the line reflects the neuron's preferred direction, and the length of the line reflects the discharge rate of the neuron for that particular direction of movement. The population vector is the vector summation of all the individual neuron vectors. Reproduced from Georgopoulos AP, Kalaska JF, Caminiti R, and Massey JT (1983) Spatial coding of movement: A hypothesis concerning the coding of movement direction by motor cortical populations. *Experimental Brain Research Supplement* 7: 327–336, with kind permission of Springer Science and Business Media.

Dissociation of Parameters

Given the fact that movement parameters are highly correlated, the best approach to identify which parameters are coded in M1 activity is based on experiments designed to dissociate different types of variables. The key aspect of such studies is that they hold one or more variables constant while systematically manipulating another variable. If neural activity changes between the two conditions, then neural activity reflects, to some degree, the latter variable (or another variable with similar attributes).

This important point was recognized by Ed Evarts in the first study to record single-neuron activity in M1 in awake, behaving monkeys. Monkeys were trained to make wrist flexion and extension movements with loads that either assisted or resisted wrist motion. The key observation is that about half of M1 neurons modified their activity when mechanical loads were varied. However, half of M1 neurons were insensitive to loads, demonstrating that they reflected only kinematic aspects of the task.

A more recent study separated three features of movement (joint motion, target direction, and EMG activity) by training monkeys to make wrist movements involving flexion–extension and/or radial-ulnar deviation, with the forearm in three different orientations: supinated, neutral, and pronated. These different forearm orientations shifted the orientation of the hand so that wrist flexion required vertical motion in the supinated position but downward motion in the pronated position. Movement of the wrist was displayed on a video monitor. If neural activity specified the direction of hand motion, then neural activity would rotate 180° from supination to pronation. If neural activity specified the spatial direction of the target, then neural activity would not rotate between the different forearm orientations. Ultimately, the response of muscles was approximately halfway between these two extremes, rotating ~90°. The investigators found that some neurons rotated their activity similarly to muscles, whereas other neurons showed no rotation (Figure 8). No neurons rotated 180°. This suggests that there are at least two populations of neurons, one related to the spatial goal and/or visual feedback of hand motion and another population related to the motor action of the peripheral muscles.

Many other studies have performed dissociations between other classes of variables: intrinsic versus extrinsic variables, spatial goals versus limb motion, and kinematics versus kinetics. In each study, the same basic observation is usually found: some neurons changed their activity across conditions, and other neurons showed no change. Across all these studies, it appears that neural activity can reflect virtually every class of variable. One must conclude that there is no single, unified, coordinate frame to explain the activity of all neurons in M1. Rather, neural coding in M1 reflects many different classes of movement variables.

Context-Dependent Change in Neural Coding

Recent work suggests that there is an additional level of complexity in neural coding in M1. It appears that neural coding can change abruptly across different types of motor behaviors such as switching from maintaining a constant arm posture to reaching to another spatial location. Specifically, the response of neurons to constant loads applied to a monkey's shoulder, elbow, or both joints was observed prior to, during, and after reaching movements (Figure 9). Planar regression models were used to relate cell discharge at a given period (during posture or during movement) to shoulder and elbow torques. About half of recorded neurons in M1 modulated their discharge for these loads as the monkey maintained its hand at a central target

Figure 7 Neural responses during reaching with the limb in the horizontal plane. (a) Distribution of preferred directions of neurons recorded in M1. Each red dot denotes the preferred direction of movement for an individual neuron, and cells are grouped into 16 equal-size bins (bin size = 22.5°). The *p* value in the panel reflects the statistical level at which the population was found to be not uniform compared with a bimodal distribution. (b) Comparison between population vectors (red) and the direction of hand motion (blue). Population vectors did not point in 13 of the 16 directions of movement. Adapted from Scott SH, Gribble PL, Graham KM, and Cabel DW (2001) Dissociation between hand motion and population vectors from neural activity in motor cortex. *Nature* 413: 161–165.

(postural control). However, just before the monkey made a movement toward another spatial target, half of the neurons modulated by loads during posture lost their load-related activity ('posture only' cell, Figure 9), and half the neurons not influenced by load during posture instantly became modulated by load ('reach only' cell, Figure 9). In addition, neurons that responded to loads across posture and movement epochs often changed the magnitude of their load-related discharge. This change in load-related activity was not evident at the muscular level, where most shoulder and elbow muscles responded to loads during both posture and movement. This dramatic change in central processing of load-related activity suggests that the information represented or coded in M1 is not fixed but can change from one behavioral context to another.

Neural Coding in Premotor Cortex

Neural coding in dorsal and ventral premotor cortex appears to be far less complex with regard to the range of variables expressed in the discharge of individual neurons. Spatial goals and the direction of movement are well represented at the single cell level, with less influence by parameters related to the motor periphery, such as joint motion and forces. Also, far more preparatory activity can be observed when the animal is instructed where it will move to but must wait for a go signal before executing the movement. This suggests that neural processing in these brain regions is related to planning and higher-level aspects of the task rather than the details of motor execution.

Neural processing in these premotor regions also shows several complexities. Neural activity can be observed for movements of the contralateral limb and the ispilateral limb and even for movements generated by other individuals. Neural activity can also be influenced by factors such as where the individual is looking. It is interesting that the magnitude of this influence depends on whether gaze angle is controlled experimentally and maintained at a specific spatial location or allowed to move freely during the motor task: Gaze angle influences neural activity in the former context but minimally in the latter.

Beyond Neural Coding

It is worthwhile to reflect on what has been learned about neural coding in M1. Virtually, every variable displayed in Figure 2 correlates with neural activity in this brain region. Even experiments that specifically dissociate different classes of variables illustrate considerable heterogeneity in the type of information conveyed in the activity of M1 neurons.

Figure 8 (a) Wrist movements made in different spatial directions using different forearm orientations: pronated (Pro), middle (Mid), and supinated (Sup). (b) Wrist movements were performed in eight different spatial directions. The shift in forearm orientation shifted the relationship between wrist motion and spatial direction. Upward movements required wrist extension when the forearm was pronated but required wrist flexion when the forearm was supinated. (c) Discharge pattern of a neuron in M1 for the three different arm orientations. Each row of rasters shows the cell's discharge for the same spatial direction, and data are aligned to movement onset. This neuron showed a shift in its preferred direction across the three forearm orientations similar to that observed for wrist muscles. (d) A neuron that showed minimal changes in its pattern of activity when movements were performed with different forearm orientations. Rad, radial deviation; Ext, extension; Uln, ulnar deviation; Flx, flexion; R, radial deviation; E, extension; U, ulnar deviation; F, flexion; Rt, right; Dn, down; Lf, left. This diversity in M1 activity is difficult to fit with the idea that the brain performs a series of sensorimotor transformations to convert spatial goals into muscle activities. The bias in neurophysiological recording techniques toward sampling larger neurons means that most recorded neurons are likely corticospinal neurons from layer V that project down to the spinal cord. Therefore, signals reflecting extrinsic features of movement are in parallel with signals related to the intrinsic features of movement. A further challenge to the notion of sensorimotor transformations is that the variable expressed by an individual neuron can abruptly switch as soon as one switches behavioral context.

It is not clear that continued focus on identifying which parameter is expressed in the discharge pattern of M1 neurons will provide substantive progress in understanding M1 function. What is needed perhaps is to refocus attention on the basic motor problem, sensorimotor control.

The 1970s saw considerable interest in interpreting M1 activity on the basis of feedback control. M1 is

Figure 9 (a) Discharge pattern of three neurons when a reaching movement is made with and without constant-magnitude loads applied to the shoulder or elbow joints. (a)–(c) Vertical columns show sample neurons expressing load-related activity during posture and movement (both), only during reaching (reach only), or only during posture (posture only). (a) Spike rasters and mean instantaneous firing rate under the nine load conditions, organized in a joint–torque coordinate frame, shoulder flexor (SF), shoulder extensor (SE), elbow flexor (EF), elbow extensor (EE), and no joint–torque (0). Shaded regions denote posture and movement epochs used for plane fits displayed in subsequent panels. (b, c) Plane fits of change in neural activity versus change in joint torque during posture (b) and movement (c). Arrows and coefficients denote significant plane fit and regression values, respectively. known to receive rich sensory information related to limb motion, and several studies illustrated how M1 neurons responded rapidly to transient perturbations, providing a long-latency reflex response that could be modified on the basis of the goal of the task. However, several factors appeared to diminish the utility of this line of research. First, experiments examined single-joint movements, which lack much of the mechanical complexity of whole-limb movements. Feedback control was viewed as simple servocontrol with a fixed mapping between sensory input and motor output (single input–single output). The principles of control for a single joint do not simply scale for more-natural whole-limb tasks. Second, substantial time delays in sensory feedback from the periphery meant that simple servocontrol strategies were untenable.

There was a dramatic shift in experimental paradigms in the 1980s toward experiments that examined open-loop control processes. The introduction of the whole-arm reaching task shifted attention to correlates of hand motion and higher-level features of movement, and studies focused on neural activity prior to the initiation of movement, before feedback arrived in the brain. Conceptually, sensorimotor transformations and putative coordinate frames became and have remained the most popular approach for interpreting M1 activity.

However, several advances in our knowledge again make feedback control a viable approach for

interpreting the role of M1 in motor function. The fatal problem that sensory information from the periphery was transmitted too slowly to support feedback control has been curtailed by the recognition that the brain likely uses forward models to convert motor commands into estimates of limb motion. These estimates of limb motion can be computed with minimal delays and can be adjusted as sensory feedback from the limb and vision arrives in the central nervous system. The rapid conversion of motor commands into estimates of limb motion provides a simple explanation for efferent copy and why there are several internal feedback loops within the motor system.

More-advanced feedback controllers are also being considered for interpreting the neural basis of sensorimotor control, such as optimal feedback control (Figure 10). Instead of a simple one-to-one fixed mapping between sensory feedback and motor output, these controllers can connect all sensory feedback signals to all motor outputs (multiple input, multiple output). How this sensory feedback is connected to motor output depends on the goal of the task. These controllers effectively create smart reflexes so that errors that influence the goal of the task are corrected and errors that do not influence the goal are ignored.

Smooth bell-shaped velocity profiles and relatively straight hand paths have often been used as evidence that the brain directly controls and computes hand motion. An interesting feature of optimal feedback controllers is that such patterns of hand motion can be generated even though hand motion is not computed explicitly. Such controllers can use any set of state variables: hand motion is an emergent property, reflecting the interplay between noise/errors and feedback gains. These gains are set on the basis of the behavioral goal which in many motor tasks is related to the hand.

If one views the brain as behaving like an optimal feedback controller, the problem of neural coding in a brain region like M1 changes dramatically. Vision, proprioceptive signals from muscle, cutaneous receptors in the skin, and even auditory signals can all provide valuable feedback on motor performance. It should not be surprising to see neural activity in a region like M1 related to each of these types of signals. Spatial signals are not higher-level representations of movement as compared to signals related to joint motion, as assumed in the sensorimotor transformation framework. Rather, these signals are parallel when viewed from optimal feedback control since visual and proprioceptive signals both provide feedback to guide motor action.

Behavioral context also plays a crucial role in modifying neural processing in M1 by dictating how sensory information is used to guide action. Changes in the behavioral goal necessarily lead to changes in the use of sensory feedback. During posture, the appropriate motor response to a perturbation is to rapidly return to the same spatial location. This is an inappropriate response during a reaching movement, when one should correct and continue to move toward the new spatial location. Thus, it should not be surprising to see substantial changes in neural processing of variables, such as applied loads, between contexts, as shown in Figure 9. Variations in the experimental paradigm, such as controlling gaze angle during reaching or viewing the arm directly versus using a computer monitor which dissociates proprioceptive and visual alignment of the limb, should also modify neural processing.

In conclusion, the concept of neural coding has been influential for exploring the type of information conveyed in the discharge patterns of M1 neurons in awake, behaving animals. These studies have not found a common code to describe neural processing

Figure 10 Basic principle of optimal feedback control. Feedback gains (control law) are optimized based on the global goal of the task. Feedback of motor performance is based on efferent copy and sensory feedback from the limb and vision. Such systems are particularly well suited for managing noise/errors inherent in the sensorimotor system. in this brain region. Rather, these studies have uncovered a highly heterogeneous mix of signals or codes. This seems perplexing within the framework of sensorimotor transformations but provides a foundation for developing highly flexible control signals as viewed from sophisticated control processes, such as optimal feedback control.

Neural Coding of Spatial Representations

Neuronal Signals That Encode Spatial Location

In mammals, spatial information is derived primarily from three sensory modalities: vision, audition, and somatosensation. In many regions of the neocortex, and across sensory modalities, individual neurons fire action potentials at high rates only when objects to which they are sensitive appear in a particular region of space – the neuron's receptive field. For example, a neuron in the primary visual cortex (V1) responds vigorously only when a stimulus to which it is sensitive stimulates a particular region of the retina of approximately 1° of visual angle. Similarly, in primary somatosensory cortex, neurons respond only when a particular part of the body is touched, and tactile receptive fields on the fingertips are typically only a few millimeters wide. In the auditory system, some neurons respond only when a sound originates at some particular angle in space relative to the head. This case is special, however, because, unlike visual and somatic primary receptors on the eyes and skin, primary receptor neurons in the cochlea are not space-specific; the neurons that become selective for sounds from specific regions in space are constructed in a series of computational steps. In all of these cases, however, spatial information is conveyed basically through a labeled-line code, which means that the stimulus location can be inferred from the identity of the activated neuron or neurons. So, to determine where is the stimulus, one needs to know which neurons are responding.

As these examples illustrate, in general, spatial information is carried by firing rate distributions, and it is widely held that brains rely on such distributions to track object location. Cortical microstimulation experiments have largely corroborated this hypothesis. For instance, eye movements toward specific points in space can be elicited with high reliability by microinjecting electrical current at specific points in the cortex, a manipulation that increases the firing rate of a restricted population of neurons around the electrode. It remains possible, however, that brains also rely on other aspects of neural activity to encode object location, for example, correlations between the activity of different neurons or precise spike-train sequences. That firing rates carry a large amount of spatial information is an important premise on which many of the conclusions discussed here depend.

Receptive Field Properties

Receptive field sizes vary widely across regions of the cortex. Consider, for example, the visual system. From the thalamus, visual information first reaches the cortex in the back of the head, in the occipital lobe, where the V1 is located. Receptive fields in V1 are small, typically covering on the order of 1° of visual angle, and they are topographically arranged, meaning that neighboring neurons have receptive fields that overlap or are close to one another in visual space. From V1, visual information is transmitted to a number of different areas in the parietal, occipital, and temporal lobes. In general, the closer a visual area is to the front of the brain, the larger the receptive fields become and the less ordered their topography. The largest visual receptive fields can be almost as large as the whole visual field, as may be found, for example, in the inferotemporal cortex (IT). In general, receptive fields not only increase in size toward more central structures but also become more complex; for instance, V1 neurons are selective for small oriented bars or gratings (stripes), whereas IT neurons respond most strongly to highly complex images such as faces or whole objects.

Areas That Specialize in Spatial Processing

Cortical visual areas have traditionally been divided into two groups, which lie along the ventral and dorsal pathways. The distinction rests both on anatomical grounds and on functional evidence based on brain-damaged patients and lesioned primates, both of whom show consistent kinds of deficits depending on which pathway is affected. Damage to the ventral pathway, which includes areas V2, V4, and IT, generally leads to problems in object recognition (agnosias), whereas damage to the dorsal pathway, which includes V3, the middle temporal area (MT), and several parietal regions, such as areas 7a and the lateral intraparietal area (LIP), leads to problems in navigation and the perception of space (ataxias and visual neglect). The response properties of neurons in these areas also reflect their differing functional roles. Neurons in the ventral pathway are often highly selective for specific objects, but their responses to those objects are relatively invariant to their color, size, position, or perspective, among other properties. On the other hand, neurons in the dorsal pathway are typically not as selective for object identity, but their

activity often depends on the spatial relation between the viewed object and the organism's body. The general conclusion here is that parts of the brain are specialized for processing spatial information. Why this separation of function has evolved remains unclear. It should also be emphasized that the dorsal pathway is not exclusively involved in vision. Rather, it processes auditory and somatosensory signals in addition to visual signals and appears to be important for spatial processing and movement planning in general.

The Precision of Spatial Representations in the Brain

How precisely can we locate an object in space, and what determines this precision? First, spatial accuracy depends on the modality and the species in question. For example, auditory localization acuity varies tremendously across mammals, from hundreds of degrees in subterranean species to approximately 1° in humans and elephants. Second, acuity can depend on the form of the stimulus itself. For example, a person's ability to discriminate between fine-grained textures or Braille letters through touch depends on whether and how those stimuli move across the skin. Third, accuracy also typically depends on where an object is located. For example, spatial acuity in humans is much lower in the periphery than in the center of the visual field (i.e., the fovea), and somatosensory spatial acuity is much higher on the fingertips than on the palm of the hand. Physiologically, in both cases the differences are due to differences in the densities of primary receptors and cortical neurons dedicated to cover each region of space. Touch mechanoreceptor density is approximately four times higher at the fingertips, where acuity is high, than at the palm, where acuity is lower. Differences in photoreceptor numbers across the retina impose similar limits on acuity across the visual field. Discrimination performance in difficult perceptual tasks is often limited by such fundamental constraints as the density of primary receptors.

Tuning Curve Width and Optimal Sensory Coding

Naively, we might also expect receptive field sizes in a population of cortical neurons to limit the precision with which the population can represent an object's position. After all, if only one neuron is firing, the larger its receptive field, the larger is the uncertainty about the location of the stimulus that triggered the response. This intuition, however, is not always correct. First, information about stimulus location is typically spread out across a population of neurons with overlapping receptive fields, in which case spatial accuracy depends not only on the receptive field width but also on the density of neurons and their variability. An array of narrow tuning curves may be extremely ineffective if they leave gaps between them (a tuning curve here is the mean response of a neuron plotted as a function of stimulus location). On the other hand, an array of neurons with wide and overlapping receptive fields may be highly accurate if their variability is low. Some of these possibilities are illustrated in Figure 1.

A second and more profound factor that affects spatial accuracy was identified by Zhang and Sejnowski. They used a measure of accuracy known as the Fisher information to characterize the efficiency of populations of model cortical neurons with tuning curves of different widths. They found that the relationship between tuning width and Fisher information depends on the dimensionality of the stimulus to be represented. That is, whether narrow or wide curves are better depends crucially on the number of parameters that the neurons are representing. Recent work along similar lines by Brown and Bäcker showed that, when an infinite number of neurons cover one dimension (say, distance to a target) or two dimensions (say, target location on a surface), encoding accuracy always increases with decreasing tuning width – narrower curves are always better. However, for three dimensions or higher, the advantage of narrow curves goes away; there is an optimal tuning width in terms of Fisher information, even though the number of neurons remains infinite.

Another theoretical study, by Pouget and colleagues, demonstrated that whether wide or narrow tuning curves are better also depends on the mechanisms that generate those tuning curves. In many models, tuning curve width is determined by the strength of lateral interactions between neurons in a population, such that stronger interactions are needed to generate narrow tuning than wide tuning. Strong lateral interactions, however, also tend to produce strong noise covariations across neurons; that is, the random response fluctuations of pairs of neurons become more similar to one another. In practice, this may limit information transmission quite severely, and therefore, a population with wide tuning curves may be much more informative than a population with narrow curves if the narrowing involves traditional mechanisms that increase noise covariations. This result suggests that generating arrays of narrow tuning curves from arrays of wide ones is probably a rather inefficient strategy, even if the encoded stimulus is one- or two-dimensional, because narrowing mechanisms effectively increase the noise.

In summary, then, in terms of the accuracy for encoding an object's position, the optimal tuning curve width depends on the number of neurons in

Figure 1 Encoding of spatial location by populations of neurons with Gaussian tuning curves: (a) a population of narrowly tuned neurons, tuning curve width = 0.5; (b) a population of widely tuned neurons, tuning curve width = 2.3; (c) localization error as a function of tuning curve width. In (a), each curve represents the mean response of a neuron as a function of the location of a stimulus x. There are 21 neurons, and x may be between −10 and 10 (arbitrary units). The tuning curves are narrow (width $\sigma = 0.5$), so only one or two neurons fire significantly above the baseline in any trial (a trial is one stimulus presentation). The graphs (a1)–(a3) show the responses of the 21 neurons in three single trials with low (red points), medium (blue points), and high (magenta points) signal-to-noise ratios. Variability across trials was modeled as a Poisson process, so the variance of each response was equal to the mean. The signal-to-noise ratio was controlled by varying the maximum response of the neurons: $r_{max} = 10$, 15, and 30 spikes s^{-1} for the red, blue, and magenta points, respectively. Background firing was constant at 4 spikes s^{-1}. (b) As in (a), but for wide tuning curves (width $\sigma = 2.3$). In this case, approximately eight neurons typically fire above baseline in each trial. (c) Localization error as a function of tuning curve width for the three signal-to-noise ratios in (a) and (b). The error is the average deviation between the true stimulus location, x, and the location that is estimated from the responses of the 21 neurons in each trial, x_{est} (more specifically, $E^2 = <(x - x_{est})^2>$, where E is the localization error and the brackets indicate an average over trials and over all values of x). The width that is optimal for representing stimulus location depends on the signal-to-noise ratio. If it is high (magenta curve), narrow tuning curves are better because they generate smaller localization errors; in contrast, if the signal-to-noise ratio is low (red curve), broader tuning curves are more accurate.

the population, their noise properties, and the number of dimensions of the encoded position vector.

Tuning Curve Width and Motor Constraints

An interesting and perhaps counterintuitive observation about the neural activity that encodes spatial location is that it should not be more accurate than required by the animal's behavior. Just as commuting between home and school in a Formula 1 race car would be costly and inefficient, localizing objects with greater accuracy than necessary would waste resources. A recent theoretical study by Salinas highlighted the crucial role that motor constraints play in determining optimal sensory representations, and an impressive data set collected by Heffner and colleagues illustrated the point. Based on the analysis of more than 30 species of mammals, Heffner and collaborators found that sound localization capacity varies tremendously in this group – discrimination thresholds range from approximately 1°in humans and elephants to approximately 25°in gerbils and horses. Discrimination threshold in this case corresponds to an angular separation between two sound sources, such that a subject can distinguish with 75% accuracy which source generated a short noise burst. According to Heffner's analysis, the measured differences across species are not accounted for by variations in sound environment, interaural distance, or animal lifestyle. Rather, sound localization acuity in mammals seems to depend on the precision required for the visual orienting response to sound. The logic is as follows. The primary function of sound localization is to produce an orienting response, that is, to bring the sound source into the most sensitive part of the field of view (the fovea) for visual inspection. Therefore, species that have small areas of best vision

(e.g., humans and elephants) need to make highly precise movements, whereas species that have large areas or streaks of optimal vision (e.g., gerbils and horses) do not. This is an important observation because it means that when behavior does not require high accuracy, the sensory representation should be correspondingly coarse, even if, in principle, it could be made more precise.

Reference Frames in the Cortex

References for Sensory Responses

Because there are no absolute spatial coordinates, an object's position in space can only be specified relative to a landmark that serves as reference. A crucial question therefore is: relative to which reference or references does the neocortex represent object locations? Experiments suggest that different parts of the cortex use different references, and some neurons seem to combine multiple ones. Those regions of cortex that receive sensory information most directly often use the topography of peripheral sensory organs themselves as references. For example, in the early visual cortex the reference is the retina – V1 neurons are said to encode visual information in retino-centered or eye-centered coordinates. In the early somatosensory cortex, the reference is the skin. Audition is different because firing rate distributions among the inner ear's sensory neurons do not depend in a straightforward way on where in space a sound originates. Thus, early auditory neurons do not represent spatial information in an ear-centered coordinate frame. Further downstream, however, through a series of computations involving the combination of interaural level differences, monaural spectral cues, and interaural time differences, cortical neurons create a representation of sound-source location in a head-centered or eye-centered reference frame.

References for Motor Responses

Just as sensory neurons require a reference for encoding the position of objects that are seen, heard, or touched, the motor system requires one or more references in order to move a limb to a desired position. In more central areas, the reference frames of cortical neurons that contribute to generating behavior are more complex than those of traditional sensory neurons. In a series of landmark papers, Gross, Graziano, and their colleagues showed that in the premotor cortex of monkeys many neurons fire strongly only when an object is seen at a particular place relative to a specific body part; that is, they have body-part-centered reference frames. For example, many premotor neurons are bimodal, in that they respond to both visual and somatosensory stimuli, and their visual receptive field is typically a three-dimensional region of space near the somatosensory receptive field. The key finding is that both of these receptive fields move where the body part moves. Neurons with receptive fields anchored to the arms, upper body, and head are especially prevalent. This multiplicity of reference frames suggests that neurons in the motor system rely on reference points specific to and convenient for the types of behavior they help to generate. Visual receptive fields attached to the foot may be useful for playing soccer, visual receptive fields attached to the mouth may be useful for biting an apple, and so on. Thus, the responses of such neurons may allow a sensory signal to act directly as a motor signal. Another implication is that sensory processing is not limited to sensory cortex, traditionally conceived. In fact, sensory processing seems to occur all over the cortex and to be inseparably intermingled with motor planning.

Changing Reference Frames

That sensory and motor cortical areas exhibit different sets of reference frames indicates that information about object location must be transformed from one set of reference frames to another as it propagates between brain regions. This operation is known as a coordinate transformation. According to the work of Richard Andersen and collaborators, the posterior parietal cortex (part of the dorsal pathway, not surprisingly) is largely responsible for coordinate transformations in the cortex. Many posterior parietal neurons are multimodal, and many represent locations in mixed reference frames, which means that receptive fields are partially anchored to more than one body part. For example, parietal neurons often have receptive fields that are sensitive to the position of the eyes in the orbit as well as to the position of the head relative to the body. Several theoretical studies have demonstrated that such mixed representations can underlie coordinate transformations. Lesion studies also suggest that the parietal cortex is crucial for coordinate transformations. Parietal lesions famously lead to neglect, a condition wherein a person loses awareness of a region of space. The condition consists not merely of blindness or of a failure to locate objects within a region but of a total lack of awareness of the region's existence. Neglect does not have one characteristic reference frame; rather, it depends on the nature of the task at hand (and of the lesion). The neglected region of space may be defined relative to the eye, the arm, the body, or even an object in the environment. These observations support the idea that the parietal cortex represents the location of objects in many different reference frames.

As an example, consider the problem of reaching for an object, say, a teacup. To grasp the teacup, the brain must compute the difference between the position of the hand and the position of the cup (with positions specified by vectors). To compute this motor error, the two positions can be defined with respect to a number of reference frames. It is thought, however, that at some point in the visuomotor cascade the two locations must be encoded in the same reference frame and that the corresponding neural signals should be combined to produce the motor error. Indeed, neurons in a cortical area called the parietal reach region respond to both target and current hand positions in an eye-centered reference frame. Let us call these E neurons. For E cells, there is a special point in the visual field (the preferred target location) such that their activity is strongest when the target is located there; but there is also another point (the preferred hand location) such that their activity is strong when the hand is seen there. When the subject moves his eyes, each E neuron changes its firing rate by some amount, but as a population the E responses still encode the hand and target positions (if these have not changed). In contrast, neurons in another parietal area, area 5, seem to encode the displacement vector explicitly, independently of eye position. We call these M neurons. They have a preferred displacement vector, so their activity can be described as signaling target position in hand coordinates. The key difference it that, when the subject moves his or her eyes, the activities of all M neurons remain unchanged. This resembles much more closely a motor command. There is yet another type of parietal neuron that seems to use a mixed or intermediate representation. The activity of those intermediate cells signals target location and is sensitive to both hand and eye positions, but the dependence is more complicated than for E and M neurons. Their properties are similar to those observed in intermediate layers of artificial network models that are trained to transform object location from one reference frame to another, so they are thought to be an important link for constructing M neurons out of E neurons.

How exactly such coordinate transformations occur remains unclear, but experimental and modeling studies indicate that an important component is a mechanism called gain modulation. Gain modulation is observed when the sensitivity of a neuron to a stimulus changes as a function of another variable or parameter. For example, when the response of a parietal neuron is plotted as a function of the position of a spot of light, the resulting curve typically has a bell shape. For a neuron that is gain modulated by, say, eye position, the amplitude of the curve varies as a function of eye position. Andersen and colleagues documented the modulation of visual responses depending on a variety of parameters, such as eye and head position, arm position, and eye velocity, in many parts of the parietal cortex. This particular way to integrate information from multiple sources is powerful because populations of gain-modulated neurons do not represent spatial information in a fixed reference frame; rather, by combining those responses appropriately, different groups of downstream neurons can extract spatial information in the reference frame that best suits their function.

Keeping Objects Separate

As previously mentioned, evidence suggests that separate parts of the cortex are specialized for processing information about object identity and location. Psychophysics corroborates this idea because brain damage can destroy a person's ability to locate an object in space while leaving relatively intact his ability to identify it, or vice versa. Therefore, it has been suggested that there must be some mechanism by which the brain can keep track of which visual features appear in which parts of visual space; otherwise, it would be impossible for an organism to avoid confusing the attributes of multiple objects in different locations. This is often referred to as the binding problem. Evidence that such a mechanism exists comes from studies of patients with Balint's syndrome, which can occur following bilateral damage to the parietal lobes. A Balint's patient is capable of seeing only one object at a time. When there is more than one object in the visual field, the patient often claims that the object he or she sees has some of the attributes of other objects that he or she does not see, such as color, even though it does not. It is unknown whether such patients actually see objects or just jumbles of features, but it is undeniable that they somehow lose track of the locations of different features in space, suggesting that they have lost some mechanism by which normal brains avoid such problems.

One of the earliest and most influential attempts to explain our ability to keep track of object attributes in space is called feature integration theory, developed by Anne Treisman. The theory posits that, when the brain directs attention to an object, the neural representations of its features and its location are selectively enhanced (the firing rates of responding neurons are increased); this allows these representations to be singled out from those of other features and locations, so that there is no longer an ambiguity regarding which belongs with which. Although this is a powerful theory and it is consistent with known effects of attention on neural activity, a number of objections have been raised over the years. For

example, numerous studies suggest that a person can attend to multiple objects simultaneously, without confusing their attributes. Standard feature integration theory does not specify how the brain resolves location ambiguities in such cases.

Another theory, which was popularized by von der Malsburg, Singer, and Gray, among others, is based on binding by neural synchrony. The idea is that the neurons representing an object's features and location fire spike trains in synchrony with one another and out of synchrony with neurons representing the features and locations of other objects. The synchrony between neurons tags the encoded features as belonging together. Unlike in feature integration theory, in this mechanism features and locations of multiple objects can be simultaneously grouped. Although there is substantial evidence that is consistent with this hypothesis, in recent years important violations of its predictions have also appeared, so its validity remains an open question.

It should also be pointed out that the binding problem may not be quite as difficult as it seems at first. Although it is true that we rely on different areas of the cortex to track object identity and location, those areas are not totally devoid of information regarding their conjunction. For example, inferotemporal neurons, thought previously to be largely insensitive to object location, can be very sensitive to location when the visual field contains multiple objects. However, because the brain does not rely directly on this spatial information to locate an object in space (we know it relies on mechanisms in the dorsal pathway, and the parietal regions in particular), object representations in the ventral pathway may still have to be matched to spatial representations in the dorsal pathway. The conjunction information in IT could provide a basis for this match.

Introduction

The development of the nervous system begins overtly with the formation of the neural plate in the surface ectoderm. Soon after the neural plate forms, it folds in on itself to form neural folds. The dorsal lips of the neural folds subsequently fuse to form the neural tube, a process called primary neurulation. Just before, during, and slightly after the fusion of the neural folds, a population of neuroepithelial cells in the dorsal lips of the neural fold and the dorsal region of the neural tube undergo an epithelial–mesenchyme transition (EMT) and emigrate away from neural tube; this cell population is the neural crest (Figures 1(a) and 1(b)). The formation of the lumbosacral neural tube in birds and mammals, and the entire neural tube in fish, occurs by a different process, known as secondary neurulation. Here, a compact mass of cells forms and then cavitates to form a neural tube. Neural crest cells also form at the dorsal regions of the neural tube, adjacent to the epidermis, during secondary neurulation. The neural crest is a transient structure that only exists around the time of formation of the neural tube. Neural crest cells migrate along particular pathways before settling in many different locations. They give rise to most of the facial skeleton, the peripheral nervous system, melanocytes, and many other derivatives.

The neural crest was first described and recognized as a migratory population in the 1860s. From the 1920s on, many methods have been used to experimentally probe its development, including ablation (removal) of neural crest in living embryos and later observations of deficits, and application of various stains to neural crest cells to follow them. However, the method that has been pivotal in studying the migration pathways and fates of neural crest cells is the quail–chick chimera technique. This method was devised in the late 1960s by Nicole Le Douarin, who saw that the nuclei of quail cells can be distinguished from those of chick cells using histological or immunohistochemical techniques (Figure 2(c)). Segments of neural primordium containing premigratory neural crest cells from specific regions of the neural axis in quails are transplanted into chick embryos (Figures 2(a) and 2(b)), and the location of the quail cells within the chick host embryos can be determined later, thus revealing the migratory pathways and fate of neural crest cells from different axial levels.

The neural crest can be subdivided into three main axial populations – cranial, vagal, and trunk – although the vagal population includes the most caudal cranial and the most rostral trunk neural crest cells (Figure 3). The different axial populations migrate along different pathways and each gives rise to a range of cell types. Some of these cell types are common to several axial levels, whereas some are unique. For example, all neural crest levels give rise to sensory neurons. In contrast, cranial neural crest cells give rise to most of the bone and cartilage of the head and neck, whereas trunk neural crest cells have minimal ability to form skeletal elements. This article discusses the induction of the neural crest and the migratory pathways and derivatives of cranial, vagal, and trunk neural crest cells.

Induction and EMT

The first portents that the neural crest is different from the more medial ectoderm of the neural plate (which produces the central nervous system) and the more lateral epidermis (which produces the skin) are seen in gastrulation, even before neurulation. At this stage, a restricted region of epiblast (surface cell layer) fated to contribute to the neural crest expresses the paired-box transcription factor gene *Pax-7*. This region of epiblast is able to produce cells with neural crest markers when isolated from all inductive influences, and suppression of Pax-7 prevents this.

Later, important signaling processes occur across the border between the neural and epidermal ectoderm to mark this zone as different from the adjacent but contiguous epithelia. Important in this process are secreted growth factors of the Wnt family and of the transforming growth factor family, especially bone morphogenetic proteins such as BMP-4. The lineage-specifying action of BMP-4 in particular has a quantitative nature; high levels specify epidermal lineage and moderate levels promote neural crest characters, whereas low levels permit neural plate character. BMP-4 gene expression is homogenetically induced in the dorsal neural ectoderm, giving a positive feedback capacity. A gradient of BMP-4 activity is sharpened by a countergradient of its secreted inhibitor Noggin. These signals from the epidermis act within the ectodermal layer on the edge (later dorsal) cells of the neural ectoderm. In addition,

Figure 1 (a, b) Primary neurulation, which involves the formation of the neural plate and folds, and subsequent closure of the folds to form the neural tube. Neural crest cells delaminate from the dorsal regions of the neural folds and neural tube. (c) In the trunk region, neural crest cells migrate along two main pathways; first, they migrate along a ventral pathway through and between the somites to form sympathetic ganglia, Schwann cells, and dorsal root ganglia. Later, emigrating cells migrate along a dorsolateral pathway to form melanocytes.

Figure 2 Quail–chick grafting technique devised by Nicole Le Douarin and colleagues. A defined region of the neural tube containing premigratory neural crest cells, in this case sacral neural tube, is removed from chick embryos (a) and replaced with transplanted neural tube from quail embryos (b). Following subsequent development, the location of the quail cells within the chick host embryos can be determined using immunohistochemical methods. CNH, chordoneural hinge; TB, tail bud. (c) Transverse section through the hindgut following quail–chick sacral neural crest grafting. Quail cells, which are stained brown, are found within nerve bundles outside the gut (arrowheads), external (arrows) and internal (open arrowhead) to the circular muscle layer (CM) of the gut, as well as within the circular muscle layer (open arrows). These experiments show that sacral neural crest cells give rise to derivatives both within and outside the hindgut. Reproduced from Burns AJ and Douarin NM (1998) The sacral neural crest contributes neurons and glia to the post-umbilical gut: Spatiotemporal analysis of the development of the enteric nervous system. *Development* 125: 4335–4347, from The Company of Biologists.

fibroblast growth factor signaling from another layer, the underlying mesoderm, is also important for neural crest identity.

The outcome of this signaling is the expression of specific genes in the lateral neural plate border region which includes the dorsal neural tube as well as cells fated for neural crest; these 'border genes' include *Zic3* and *Pax-3*. Expression of other genes such as *Sox-2* in the medial region act to limit the neural crest zone to the neural plate border. On the lateral epidermal side, the high levels of BMP-4 signaling induce genes such as *Dlx* and *Msx* family members, whose products repress a variety of proneural genes such as *Zic3* and *Sox-2*, while promoting expression of epidermis-defining keratins.

Experimental manipulation of these border genes indicates that they control expression of genes that are closely related to neural crest fate and to neural crest behavior such as EMT and migration. Included in this gene repertoire are the zinc finger transcription factors *Snail-1* or *Snail-2* (formerly called *Slug*). These genes have an interesting evolutionary history: the neural crest of fish, amphibians, and mammals expresses *Snail-1*, whereas that of reptiles and birds employs *Snail-2*. In a very short period of time, expression of the forkhead gene *FoxD3*, and the Sry HMG-box genes of the *Sox-E* subfamily (*Sox-8*, *-9*, and *-10*), is induced in the neural crest region. When overexpressed (or suppressed), these genes can induce (or inhibit) neural crestlike behavior such as migration in nonneural crest neural ectoderm, as shown first by Angela Nieto for *Snail2*. These genes are sharply temporally regulated, and with the exception of *Sox-10*, their mRNA levels decline around or just after the time when neural crest migration commences. *Sox-10*, however, continues to be expressed

Figure 3 Axial level of origin of neural crest derivatives in chick embryos. Melanocytes arise from all levels of the neural axis, whereas only cranial neural crest contributes to skeletal elements (the cranial skeleton). Cardiac neural crest, which arises adjacent to somites 1–3 and contributes to the outflow tracts of the heart, is not included in the diagram. AM, adrenomedullary; CNS, central nervous system; CT, connective tissue; ENS, enteric nervous system; FB, forebrain; HB, hindbrain; MB, midbrain; Mel, melanocyte; NC, neural crest; oto, otic vesicle; Para, parasympathetic ganglion; s, somite; Sch, Schwann cell; Sen, sensory neuron; SC, spinal cord; Sym, sympathetic ganglia.

especially in vagal and trunk neural crest and has other functions; including maintenance of an undifferentiated state. *Dlx* and *Sox-9* expression reappears later in postmigratory cranial neural crest-derived cells prior to their formation of skeletal tissues. Work in many species by many authors, particularly Marianne Bronner-Fraser and colleagues, has opened up this field of neural crest induction. Yet the regulatory circuits between these genes are complex and not fully elucidated (Figure 4). Moreover, although these cells are specified as neural crest (since they express many appropriate genes), they are not necessarily committed to this fate. The morphogenetic event of EMT might be thought of as marking a watershed in neural crest cell lineage commitment, yet experimental transplantation back into the neural tube reveals that at least some can still contribute to the neural tube.

The neural crest at any one level produces several different types of differentiated cells, and different axial levels produce some unique types. At any one level, during the premigratory phase, some cells are broadly multipotent within the neural repertoire and differentiation is guided by exposure to instructive cues they encounter later. Others become more restricted; the last cells to commence emigration are more likely to be restricted to a melanocyte lineage, and this is related to prolonged exposure to the neural tube. The intrinsic differences between axial levels of the neural crest are tied to the general positional identity of axial structures. Broadly stated, the cranial neural crest has a less restricted range of potentiality, whereas more caudal neural crest lacks some potentials. This is most notably demonstrated by the inability of trunk neural crest to produce connective tissue derivatives such as cartilage. A similar but less complete restriction is also seen in the limited ability of trunk neural crest to generate an enteric nervous system. This seems to involve the nested expression of *Hox* genes, and there is genetic cross-modulation between these axial position genes and some to the genes previously mentioned that specify the neural crest.

The outcome of this is the EMT and onset of migration of neural crest cells, sometimes termed delamination. This is the archetypal example of a process repeatedly seen in development and which seems to be replicated pathologically in carcinoma invasion. This involves relocation and reduction of the molecules that hold the neural epithelial cells together, most prominently the classic adherens junction molecule, N-cadherin. Experiments indicate that N-cadherin inactivation can trigger migration in neural epithelial cells. Other nonclassic cadherins are induced, and these may be important in maintaining the transient cell–cell adhesions seen between migrating

Figure 4 Putative gene regulatory and signaling interactions in action at the neural plate border of vertebrates. Red arrows, proven direct regulatory interactions; black arrows, genetic interactions suggested by gain- and loss-of-function analyses largely in *Xenopus*; gray lines, repression. neural crest cells. In addition, there are changes in the suite of integrins expressed on the cell surface. The integrins allow new adhesive contacts to develop with extracellular matrix (ECM) molecules, which form the substrate for the first steps of neural crest cell migration. Like other migrating cells, neural crest cells modify their surrounding ECM via expression of several matrix metalloproteases (MMPs). Inhibition of MMPs can prevent neural crest EMT and subsequent migration, and in particular may be required to penetrate the neural tube basal lamina, as seen at the cranial level in rodents. In addition, the actin-based cytoskeleton of these cells is reorganized from the apico-basal polarity typical of neural epithelial cells to the more flexible network arrangement which allows cell motility. The transient expression of the *RhoB* gene immediately prior to EMT may be involved in this.

The timing of neural crest EMT is stereotyped but not precisely related to other morphogenetic events in the neural epithelium. Sometimes, the newly mesenchymal neural crest cells individually crawl out of the neural epithelium before neural tube closure (cranial level of rodents), but this event occurs after neural tube closure in birds and in the trunk of rodents. In amphibians, the neural crest separates as a coherent population from the neural tube and only commences migration later, when permissive ECM changes occur.

Cranial Neural Crest

Cranial neural crest cells contribute to much of the bone, cartilage, and connective tissue in the head, including most of the head skeleton and parts of the teeth. Many congenital craniofacial deformations are due to defects in the development of cranial neural crest cells. Cranial neural crest cells also give rise to some smooth muscle in the head, melanocytes, all cranial parasympathetic neurons and their support

cells, and all glia and some, but not all, neurons in cranial sensory ganglia (Figure 3). Sensory neurons in cranial ganglia that do not arise from the neural crest arise from placodes, which are specialized regions of the ectoderm. Some cells within the thyroid, parathyroid, and thymus glands also arise from the cranial neural crest.

In the hindbrain, the segmental rhombomeres not only play a vital role in the patterning of branchiomotor nerves and cranial ganglia but also influence neural crest cell migratory pathways in this region. Hindbrain neural crest cells migrate in three distinct streams adjacent to rhombomeres 2, 4, and 6 and populate the first, second, and third branchial arches, respectively (Figures 5(a) and 5(b)). The regions adjacent to rhombomeres 3 and 5 are therefore neural crest cell-free zones. Some studies attributed the absence of neural crest cells adjacent to rhombomeres 3 and 5 to apoptosis of premigratory neural crest cells at these axial levels induced by signals derived from the even-numbered rhombomeres. However, subsequent studies by Peter Farlie, Paul Kulesa, Scott Fraser, Paul Trainor, and Rob Krumlauf have shown that neural crest cells are generated at odd-numbered segments but migrate anteriorly and posteriorly to join the streams of neural crest cells migrating from the even-numbered rhombomeres. The authors of these studies have proposed that the environment adjacent to the neural tube determines the behavior of cranial neural crest cells – inhibitory signals present adjacent to rhombomere 3 induce neural crest cells at this level to migrate anteriorly and posteriorly and limit their generation, whereas the otic vesicle provides a physical barrier to neural crest cells generated at rhombomere 5.

Cranial neural crest cells, through their interactions with facial epithelium and neuroectoderm, contribute to the development of most craniofacial structures in vertebrates (Figure 6). Different species have different facial morphologies. To examine whether species-specific facial patterning is intrinsic to neural crest cells or determined by cues from the facial ectoderm, neural crest cells destined to form the upper beak from duck were transplanted into quail embryos and vice versa. The resultant chimeric 'qucks' (duck embryos containing quail frontonasal neural crest cells) had short beaks typical of quail, and 'duails'

Figure 5 (a) Diagram showing migration of hindbrain neural crest cells in three streams. Neural crest cells from rhombomeres 1 and 2 (r1, r2) colonize branchial arch 1 (ba1). Only a small number of neural crest cells are generated in rhombomere 3 (r3), and those that are generated migrate anteriorly or posteriorly to join the streams lateral to r2 and rhombomere (r4), respectively. Neural crest cells from r4 colonize branchial arch 2 (ba2). The otic vesicle (OV) forms a physical barrier to neural crest cells from rhombomere 5 (r5) and they consequently migrate anteriorly or posteriorly to join the streams lateral to r4 and rhombomere 6 (r6), respectively. Neural crest cells from rhombomeres 6 and 7 colonize branchial 3 (ba3). Cranial motor nerves are shown on the left-hand side: V, trigeminal; VII, facial; IX, glossopharyngeal. (b) Head of an 8.5-day-old mouse embryo that had been processed for immunohistochemistry using an antibody to the neurotrophin receptor p75, which labels neural crest cells; p75-immunoreactive cells are stained red. There are three streams of neural crest cells (arrows) migrating from the hindbrain into the branchial arches (ba). At this developmental stage, crest cells from r1 and r2 are already colonizing ba1, but migration of neural crest cells caudal to the OV from r6 has just commenced. (a) Reproduced from Trainor PA, Sobieszczuk D, Wilkinson D, and Krumlauf R (2002) Signalling between the hindbrain and paraxial tissues dictates neural crest migration pathways. *Development* 129: 433–442, from The Company of Biologists. (b) Adapted from Anderson RB, Stewart AL, and Young HM (2006) The phenotypes of neural crest-derived cells in vagal and sacral pathways. *Cell Tissue Research* 323: 11–25, from Springer-Verlag.

(quail embryos containing duck neural crest cells) possessed flattened ducklike beaks (Figure 7). These transplantation experiments showed that neural crest cells intrinsically contain species-specific information, which is a major determinant of facial morphology. The genes involved in facial patterning are well conserved between species, and different facial morphologies are probably in part generated by differences in the temporal patterns of expression of these genes. Quail cranial neural crest cells transplanted into duck not only retained their own temporal pattern of gene expression but also altered the pattern of gene expression in nonneural crest-derived host tissue.

Figure 6 Lateral view of an avian skull showing the contribution of cranial neural crest (red), cephalic mesenchyme (blue), and somitic mesoderm (green). Adapted from Le Douarin NM and Kalcheim C (1999) *The Neural Crest*, 2nd edn. Cambridge, UK: Cambridge University Press.

Studies have also examined whether cranial neural crest cells at different rostrocaudal levels are prespecified to a particular fate prior to emigration from the neural tube. For example, neural crest cells destined to give rise to first branchial arch skeletal derivatives have been transplanted to a more posterior location in the hindbrain. In the 1970s, Drew Noden found that such embryos possessed duplicate first arch derivatives, such as two upper jaws, suggesting that cranial neural crest cells are prespecified prior to emigration. Studies by Paul Trainor and colleagues have shown that if the transplanted tissue excludes the mid-hindbrain isthmus, the transplanted neural crest cells show considerable plasticity. Because the isthmus was included in Noden's experiments, and because it expresses high levels of fibroblast growth factor 8 (fgf-8), it appears to act as a patterning center. Our current understanding is that cranial neural crest cells are not preprogrammed to a particular fate prior to emigration, nor is their fate determined solely by the environment into which they migrate but, rather, cranial neural crest cell fate depends on

Figure 7 Differences in morphology of duck (a) and quail (b) beaks; the duck beak is flat and broad, whereas the quail beak is short and narrow. When neural crest cells of the presumptive beak region from duck embryos are removed and replaced with equivalent tissue from quail embryos, the 'quck' embryo has a beak that resembles a quail beak (c). Conversely, when neural crest cells of the presumptive beak region from ducks are transplanted into quail embryos ('duail'), the embryo has a beak that resembles a duck beak (d). Adapted from Schneider RA and Helms JA (2003) The cellular and molecular origins of beak morphology. *Science* 299: 565–568, from the American Association for the Advancement of Science.

a combination of signals from the hindbrain and from the branchial arch environment, as well as interactions between neural crest cells.

Vagal Neural Crest

Vagal neural crest cells are defined as neural crest cells that originate adjacent to somites 1–7 (Figure 3). The head–neck boundary corresponds approximately to somite 5, and thus vagal neural crest cells include the most caudal cranial neural crest cells and the most rostral trunk crest cells. Vagal neural crest cells give rise to two well-characterized derivatives – the cardiac outflow tracts and the enteric nervous system.

Cardiac Neural Crest

In the 1980s, using the quail–chick transplantation method described previously, Margaret Kirby showed that neural crest cells that emigrate adjacent to somites 1–3 contribute to the aorticopulmonary septation complex within the cardiac outflow tract of the heart and to smooth muscle (tunica media) of the aortic arch and its major branches; thus, these neural crest cells are known as the cardiac neural crest. Studies using a number of different strains of transgenic mice have largely confirmed the cardiac neural crest derivatives first identified in birds (Figure 8). However, some extra cardiovascular derivatives have also been reported in transgenic mice, including a neural crest contribution to the epicardium, but it is unclear whether these represent ectopic transgene expression or actual neural crest contribution to the cardiovascular system in mice.

A large number of genes and signaling pathways are now known to be involved in cardiac neural crest development in mice. The molecules include growth factors including fgf-8, transforming growth factor-β2, bone morphogenetic proteins, neurotrophin-3, Wnt1, and vascular endothelial growth factor; adhesion molecules including NCam, N-cadherin, and connexin-43; transcription factors including Pax3, Nkx2.6, FoxD3, Tbx1, Sox9 and Snail-1/Snail-2; and guidance cues including semaphorin 3C and notch signaling. Many of the aforementioned genes were identified from mouse models of congenital heart defects, but only a small number (e.g., Notch ligands and Tbx1) have been implicated in congenital heart anomalies in humans.

Enteric Nervous System

Within the wall of the gastrointestinal tract there is a vast network of neurons and glial cells called the enteric nervous system. Pioneering ablation experiments performed by Chester Yntema and Warner Hammond in the 1950s, and subsequent chick–quail transplantation studies performed by Nicole Le Douarin and colleagues in the 1970s, showed that all enteric neurons and glial cells arise from the neural crest, and the vast majority arise from vagal neural crest cells. Vagal neural crest cells migrate toward the gut along a pathway that is later followed by the vagus nerve (Figure 9). After

Figure 8 The heart and nearby blood vessels of transgenic mice in which cardiac neural crest cells express green fluorescent protein (GFP) (a) or the reporter gene, *lacZ*, and thus appear blue after histochemical processing (b). Cranial neural crest cells contribute to the aortic arch and great vessels. Reproduced from Stoller JZ and Epstein JA (2005) Cardiac neural crest. *Seminars in Cell and Developmental Biology* 16: 704–715, with permission from Elsevier.

Figure 9 Lateral view of a 10.5-day-old transgenic mouse embryo in which cells expressing the receptor tyrosine kinase, Ret, also express green fluorescent protein (GFP). The epithelium had been removed to reveal the developing organs. Ret (and thus GFP) is expressed by vagal (including cardiac) and trunk neural crest cells. There is a stream of GFP+ cells that migrate from the hindbrain caudal to the otic vesicle (OV), adjacent to somites 1–7, into the gut along the pathway that will later be followed by the vagus nerve (X). At this developmental stage, GFP+ vagal neural crest cells have colonized the stomach and part of the midgut but not the caecum or hindgut; the neural crest cells within the gut will form the enteric nervous system. Vagal neural crest cells also give rise to ganglia of cranial nerves IX and X, and those arising from somites 1–3 contribute to the cardiac outflow tracts (asterisk). Trunk neural crest cells forming sympathetic chain ganglia (symp chain) also express GFP+. Reproduced from Anderson RB, Stewart AL, and Young HM (2006) The phenotypes of neural crest-derived cells in vagal and sacral pathways. *Cell Tissue Research* 323: 11–25, from Springer-Verlag.

entering the foregut, they migrate caudally through the gut mesenchyme to colonize the entire gastrointestinal tract.

A congenital disease called Hirschsprung's disease, or congenital megacolon, occurs in humans when neural crest cells fail to colonize the most distal regions of the gastrointestinal tract. Genetic studies in humans with Hirschsprung's disease and a variety of transgenic or mutant mice with defects in the enteric nervous system have been pivotal in identifying the genes required for the development of the enteric nervous system. Mutations in the genes encoding members of two signaling pathways account for approximately 50% of the cases of Hirschsprung's disease – these are glial cell line-derived neurotrophic factor acting through the receptor tyrosine kinase, Ret, and endothelin-3 acting through endothelin receptor B (EDNRB). Other signaling pathways involving neurotrophin-3, BMPs, hedgehog proteins, netrins/DCC (deleted in colorectal cancer), Slit/Robo, the cell adhesion molecule L1, and a number of transcription factors, including Sox8 and 10, Phox2b, Mash1, and Sip1, are also involved in the development of the enteric nervous system.

Trunk Neural Crest

Trunk neural crest cells give rise to dorsal root (sensory or spinal) ganglia, sympathetic postganglionic neurons, Schwann cells, adrenal chromaffin cells, and melanocytes. After emigrating from the neural tube, trunk neural crest cells follow two main pathways: neural crest cells destined to give rise to dorsal root ganglia, sympathetic ganglia, Schwann cells, and adrenal chromaffin cells follow a ventromedial pathway between the somites and the neural tube, within

the rostal half of each somite and in the intersomitic spaces, whereas melanocyte precursors follow a dorsolateral pathway, immediately under the ectoderm (Figure 1(c)). Neural crest cells that follow a ventral pathway emigrate from the neural tube prior to the cells that follow a dorsolateral pathway. Migration pathways are defined as a complex spatial array of guidance molecules, both attractive and repulsive. The substrates for migration include both extracellular matrix and cell surfaces.

Ventral Pathway

Early migrating neural crest cells follow a ventral pathway and appear to be prevented from entering a dorsolateral pathway by repulsive cues (Figure 10(a)). Ephrins and Slits are expressed in the dorsal regions of the developing somites (the dermamyotome), and their receptors – EphBs and Robos, respectively – are expressed by early migrating trunk neural crest cells; these guidance cues appear to repel early emigrating neural crest cells from the dorsolateral pathway. As they move ventrally, the crest cells diverge laterally due to repulsive signals from the medially placed notochord. These signals are mediated in part by the lectican (large chondroitin sulfate proteoglycan) aggrecan.

Neural crest cells migrate through the rostral halves of the somites and between somites but avoid the caudal half of each somite (Figure 10a). The development of segmental dorsal root ganglia is linked to the segmentation of the mesoderm. In particular, the selective migration of neural crest cells through the rostral half of each somite is essential for establishing the segmental organization of dorsal root ganglia; if the caudal halves of somites are replaced with rostral halves prior to the emigration of neural crest cells from the neural tube, a single continuous 'polyganglion' develops instead of segmental ganglia (Figure 11). A number of molecules are differentially expressed by the rostral and caudal halves of somites. Some molecules that were initially identified as repulsive axon guidance cues, including semaphorin 3A (Sema3A) and ephrin-B1, are expressed by the caudal, but not rostral, half of each somite, and the receptors for Sema3A and ephrin-B1 are expressed by migrating neural crest cells. *In vivo* and *in vitro* experiments have shown that Sema3A and ephrin-B1 are repulsive to migratory trunk neural crest cells, and thus trunk neural crest cells are channeled into the rostral half of each somite by the presence of repulsive cues in the caudal regions of the somites (Figure 10). Some ECM molecules such as F-spondin, tenascin-C, and lecticans that are selectively expressed in the caudal half of each somite are inhibitory to migrating crest cells and most likely contribute to the exclusion of neural crest cells from the caudal half of each somite.

Figure 10 Pathway of trunk neural crest cells that migrate along a ventral pathway and the molecules that influence their pathways. Neural crest cells in the dorsolateral pathway are not shown. (a) Neural crest cells delaminate all along the neural tube and are then channeled into streams of cells through the rostral half of each somite by repulsive cues expressed exclusively in the caudal half of each somite; the repulsive cues include Ephrin-Bs, semaphorin 3A (Sema3A), and F-spondin. (b) The migration of cells to form sympathetic ganglia is influenced by repulsive cues in the dermamyotome and notochord and in tissue dorsal to the gut which prevents trunk neural crest cells from entering the gut. DRG, dorsal root ganglia. Reproduced from Young HM, Anderson RB, and Anderson CR (2004) Guidance cues involved in the development of the peripheral autonomic nervous system. *Autonomic Neuroscience* 112: 1–14, with permission from Elsevier.

Some trunk neural crest cells coalesce to form dorsal root ganglia adjacent to the neural tube, whereas others migrate further ventrally and coalesce into sympathetic ganglia adjacent to the dorsal aorta (Figure 10(b)). In fact, the first trunk neural crest cells that emigrate from the neural tube migrate directly to the dorsal aorta and form sympathetic ganglia, whereas dorsal root ganglia arises from crest cells

Figure 11 Three-dimensional reconstructions of the neural tube and dorsal root ganglia (DRG) from an embryo in which the caudal halves of each somite were replaced with rostral halves on one side of the embryo only. (a) On the control side of the embryo, DRG are segmental and the location of each ganglion corresponds to the rostral half of each somite. (b) On the experimental side, which contains only rostral halves of somites, there is a 'polyganglion' instead of individual segmental ganglia. Reproduced from Le Douarin NM and Kalcheim C (1999) *The Neural Crest*, 2nd edn., Cambridge, UK: Cambridge University Press.

that migrate slightly later. The general rule seems to be that for any locus of the neural crest, the first cells to migrate tend to disperse the farthest. Neuregulin, a growth factor whose effects are mediated by members of the ErbB family of receptor tyrosine kinases, is required for the migration of cells ventral to the neural tube to form sympathetic ganglia but not for the formation of dorsal root ganglia. Guidance cues expressed by the dermamyotome, notochord, and tissue dorsal to the gut are also thought to influence the migration of sympathetic ganglion precursors.

Dorsal root ganglion neurons and sympathetic postganglionic neurons have different phenotypes and use different neurotransmitters. Sympathetic postganglionic neurons are induced to express the appropriate phenotype by bone morphogenetic proteins produced by the dorsal aorta.

Dorsolateral Pathway

The last neural crest cells that emigrate from the neural tube follow a dorsolateral pathway, just beneath the ectoderm, and give rise to melanocytes (pigment cells) (Figure 1(c)). Emigration of neural crest cells along a dorsolateral pathway commences as migration along a ventromedial pathway is ceasing – late migrating neural crest cells seem to express different molecules from the early migrating cells that enable them to overcome the repulsive cues in the dermamyotomes. Melanocytes probably arise from all axial levels of the neural crest, but their development has been most extensively studied from trunk neural crest cells.

Two signaling pathways are known to be essential for the development of melanocytes. Endothelin-3 acting at EDNRB receptors on neural crest cells promotes the proliferation and migration, and delays the differentiation, of melanocyte precursors. Stem cell factor is produced by the dermamyotome and acts at Kit tyrosine kinase receptors on neural crest cells. This signaling pathway is required for the survival of melanocyte precursors until the late stages of differentiation in the skin, and it may direct their migration dorsolaterally. The transcription factor Mitf (microphthalmia-associated transcription factor) is also required for melanocyte development. Mitf has been shown to regulate genes required for pigmentation. However, since melanocyte precursors undergo apoptosis or adopt an alternative cell fate in the absence of Mitf protein, Mitf must also regulate genes required for the survival and proliferation of melanocyte precursors and the maintenance of melanocyte identity.

Sacral Neural Crest Cells

The location of the sacral region of the neural axis varies between species. Sacral neural crest cells are those that emigrate caudal to somite 28 in chick embryos and caudal to somite 24 in embryonic mice. Sacral neural crest cells give rise to neurons and glial cells in pelvic parasympathetic ganglia and to some enteric neurons, mostly in the hindgut (Figures 2 and 12). They are also thought to give rise to melanocytes and Schwann cells.

Plasticity of Trunk Neural Crest Cells

Like cranial neural crest cells, a large number of studies have examined whether trunk neural crest cells are predetermined or biased to a particular fate prior to emigration from the neural tube. Studies by Le Douarin and colleagues, in which premigratory neural crest cells from one axial level were transplanted to different axial levels, showed that at least some neural crest cells show considerable plasticity, and their fate was largely dependent on the environment. Experiments by Marianne Bronner-Fraser, Scott Fraser, and colleagues, in which individual premigratory neural crest cells were labeled, showed

Figure 12 Colon and nearby reproductive organs from a 4-day-old transgenic mouse in which many vagal, trunk, and sacral neural crest cell derivatives express the reporter gene, *lacZ*, and so appear blue after histochemical processing. A dense network of stained neurons is present in the gut (open arrows) – most of these will have arisen from vagal neural crest cells, but some sacral crest cells also colonize the hindgut (**Figure 2(c)**). There are also stained cells (closed arrows) associated with the seminiferous vesicles – these are pelvic ganglion neuron precursors.

that individual premigratory neural crest cells could give rise to a variety of derivatives. For example, one labeled crest cell gave rise to melanocytes and Schwann cells as well as cells in dorsal root ganglia and the adrenal medulla. However, other labeled cells gave rise to only a single derivative. There is also evidence, particularly for melanocyte precursors, that some neural crest cells are prespecified, or at least biased to a particular fate, prior to emigrating from the neural tube. For example, melanocyte precursors express cell type-specific markers while still within the dorsal neural tube. Evidence suggests that some premigratory trunk neural crest cells are multipotent and their fate is probably determined by the environment through which they migrate or by tissue they colonize, whereas other premigratory trunk neural crest cells are biased or perhaps even prespecified prior to emigration. That the early migrating cohort includes multipotent cells and the late emigrating cohort comprises determined cells may indicate that restrictive lineage decisions are time regulated without regard to the morphogenetic decision of migration onset.

Conclusion

The neural crest is a transitory, migratory population of cells that gives rise to a remarkable diversity of cell types. It only occurs in vertebrates, and because of its role in craniofacial development, it is thought to have played a pivotal role in the evolution of vertebrates.

Neural Crest Cell Diversification and Specification: ErbB Role

The peripheral nervous system (PNS) mainly derives from the neural crest and develops in a process of highly organized migration of pluripotent precursor cells that become progressively committed to fully differentiated cell types, including neurons and glia cells. The main glial cell type in the PNS are two types of Schwann cells (SCs) that serve distinct functions. Remak (or nonmyelinating) SCs engulf several small caliber C-fiber axons without enwrapping them. This ensheathment is nevertheless required for long-term axonal integrity. Myelinating SCs form compact myelin sheaths around single axons of large-caliber motor and sensory neurons, an essential prerequisite for rapid and precise impulse conduction. Myelination critically depends on reciprocal molecular interactions between neurons and glia cells. In the PNS, signaling of a neuronal growth factor, Neuregulin-1 (NRG1), to glial receptor tyrosine kinases of the ErbB family has emerged as a central regulator of SC development and myelination. This is in addition to other presumed roles of NRG1–ErbB signaling in the mammalian nervous system, such as neuronal migration, synaptogenesis, and synaptic plasticity.

Components of the NRG–ErbB Signaling System

Neuregulins (NRGs) are a family of membrane-associated growth factors with an extracellular epidermal growth factor (EGF)-like signaling domain. The term neuregulin derives from neu differentiation factor (NDF) and heregulin, the first cloned ligands for the oncogene ErbB2 (a.k.a., neu and HER2). Four genes (*Nrg1–Nrg4*) are present in mammals, but only *Nrg1* has been studied in detail. Due to alternative promoter usage and mRNA splicing, multiple (>16) NRG1 isoforms are produced that are subgrouped by their distinct N-terminal domains (Figure 1(a)). NRG1 type I (also known as heregulin, NDF, or acetylcholine receptor-inducing activity) and NRG1 type II (also known as glial growth factor (GGF)) have N-terminal immunoglobulin-like domains. Transmembrane forms of NRG1 undergo proteolytic cleavage by metalloproteinases, including tumor necrosis factor-α converting enzyme and BACE1 (β-site amyloid precursor protein–cleaving enzyme 1), a type I transmembrane aspartyl protease. As a consequence, NRG1 types I and II are shed from the neuronal cell surface and act as paracrine signaling molecules. NRG1 type III is defined by its cysteine-rich domain, which functions as a second transmembrane domain. Consequently, type III is thought to remain tethered to the cell surface after cleavage and to act as a juxtacrine signal (Figure 1(a)). In addition, exons encoding shorter amino termini of NRG1 have been identified (referred to as types IV–VI), but these isoforms have not been further characterized.

The EGF-like domain (contained in all NRG1 isoforms) is necessary and sufficient for binding and activation of transmembrane receptor tyrosine kinases of the ErbB family. The term ErbB originally derived from its homology to the erythroblastoma viral gene product, v-erbB. The basic structure of all four members of the ErbB receptor family (ErbB1–4) includes two extracellular cysteine-rich ligand binding domains, a transmembrane region, the tyrosine kinase domain (inactive in ErbB3), and a C-terminal domain (Figure 1(b)). NRG1 directly binds to ErbB3 and ErbB4. ErbB2, which is devoid of an activating ligand binding site, is the preferred dimerization partner. ErbB receptors dimerize not by virtue of a bridging effect of NRG1 but, rather, following a ligand-activated conformational change in the ectodomain of ErbB3 or ErbB4. Crystallographic data indicate that ErbB2 constitutively exposes a dimerization loop and can form heterodimers with ligand-activated ErbB3 or ErbB4 receptors. NRG1 binding induces homodimer (ErbB4/ErbB4) or heterodimer formation (ErbB2/ErbB3, ErbB2/ErbB4, and ErbB3/ErbB4), which leads to receptor cross-phosphorylation, recruitment of SH3-containing adapter molecules, and activation of downstream signaling pathways. Complexity of NRG1–ErbB signaling emerges from isoform-specific receptor affinity and dimer-dependent stimulation of signaling pathways. Moreover, several observations suggest that NRG1–ErbB signaling is bidirectional. Upon binding to an ErbB receptor and/or following neuronal depolarization, the C-terminal intracellular domain (ICD) of NRG1 is proteolytically cleaved off in a γ-secretase-dependent process and subsequently translocated to the cell nucleus. Here, depending on cell type and interactions with other transcription factors, the ICD might act as an enhancer or repressor of gene expression, resulting, for instance, in increased neuronal survival or enhanced synaptic plasticity. ErbB receptors have also been identified to be translocated to the nucleus, either the entire protein or its cytoplasmic domain. In particular, γ-secretase-dependent proteolysis (after NRG1 binding) and nuclear translocation have been observed for the cytoplasmic domain of

Figure 1 Structure of NRG1/ErbB signaling components. (a) NRG1 types I and II are synthesized as single pass transmembrane proteins; type III has two transmembrane domains. With metalloproteinase (MP) cleavage, types I and II are shed as paracrine signals, type III remains tethered through its cysteine-rich domain (CRD) and is a juxtacrine signal. The cytoplasmic domain might undergo further cleavage stimulated by binding of ErbB receptors to NRG1, followed by translocation to the nucleus. (b) Proposed mechanism of NRG1-induced ErbB2/ErbB3 heterodimer activation. Extracellular ErbB receptor domains are represented by two CRDs (S1 and S2) and two cysteine-free, ligand-binding domains (L1 and L2). ErbB3 (blue) lacks a functional intracellular tyrosine kinase domain and exists on the cell surface in an autoinhibited conformation (resulting from the interactions between the S1 and S2 domains). Bivalent binding of NRG1 (NRG, red dumbbell) to the L1 and L2 domains of ErbB3 rearranges the conformation of the extracellular domain, leading to heterodimer formation with ErbB2, which is devoid of a functional ligand binding site. Dimerization between a ligand-bound ErbB3 and an ErbB2 molecule results in receptor auto-phosphorylation and activation of downstream signaling pathways. ErbB4, suggesting that both ErbB receptors and their ligands can function as regulators of gene expression.

NRG1–ErbB Signaling Regulates SC Lineage Development

In rodents, development of SCs from pluripotent neural crest cells progresses through two intermediate cell types, SC precursors (SCPs) and immature SCs, which proliferate and migrate along preexisting axons. Early migratory neural crest cells and mesenchymal cells express NRG1, ErbB2, and ErbB3, but not ErbB4. Before embryonic day (E) 10, only type I isoforms of NRG1 are expressed. Later, NRG1 type III becomes the predominant isoform in spinal cord motor neurons and

sensory neurons of dorsal root ganglia (DRG). In contrast, ErbB2 and ErbB3 are strongly expressed in SCPs and immature SCs but are mostly absent from sensory and motor neurons, at least during embryogenesis.

Multiple studies in which a recombinant EGF domain (derived from NRG1) was added to cultured SCs or injected into rodent sciatic nerves have demonstrated that ErbB signaling operates during all stages of SC development and has potent effects on SC survival, proliferation, migration, differentiation, and myelination.

The essential requirement of NRG1–ErbB signaling for the development of the SC lineage *in vivo* was demonstrated through gene targeting in mice. Mouse mutants lacking NRG1, ErbB2, or ErbB4 die at midgestation (E10.5) due to heart malformation. Most ErbB3 null mutants die between E11.5 and E13.5 (also due to defective heart development), but some embryos develop to term. In NRG1, ErbB2, and ErbB3 (but not ErbB4) null mutants, the number of SCPs that line peripheral axons is severely diminished already at E10.5, as evidenced by the reduced expression of several SC markers (e.g., ErbB3, p75, Sox10, and S100). The severity of SCP loss, however, depends on the axial level. Likewise, glial cells in the enteric nervous system are absent in the mutants. Analysis of ErbB3-deficient mice at later embryonic stages revealed not only loss of SCPs along peripheral nerves but also a reduction of up to 80% of motor and sensory neurons, again depending on the axial level. Neuronal death is likely to be a secondary effect and may be attributed to the absence of SC-derived neurotrophic factors (e.g., nerve growth factor, ciliary neurotrophic factor, or glial cell line-derived neurotrophic factor) that support neuronal survival.

The importance of ErbB2 signaling at later stages of prenatal SC development became apparent through transgenic rescue of the heart defect. Rescued ErbB2 mutants die at birth and completely lack SCPs and immature SCs in peripheral nerves at this time. In contrast, SCPs are present, albeit at reduced numbers, in DRG (at E12). This observation was attributed to the compromised ability of mutant SCPs to migrate out of the DRG and into peripheral nerves. However, the true lineage relationship between SCs in dorsal and ventral nerve roots, DRG, and peripheral nerves is not fully understood. Thus, the presence of some SCs in DRG of ErbB2 (and ErbB3) mutants could also reflect a differential dependency on ErbB2 signaling of certain SCP subpopulations, such as satellite SCs in DRG.

Do different NRG1 isoforms serve distinct functions during PNS development? Several lines of evidence strongly suggest that signaling of a membrane-tethered type III isoform of NRG1 is most critical for SC maturation (and myelination). Mouse mutants selectively lacking NRG1 isoforms with an Ig-like domain (affecting types I and II) die at E10.5 and display abnormalities in heart and cranial ganglia, which are very similar to those observed in pan NRG1 mutants. In contrast, SCPs that line spinal nerves are unaffected. The generation of mice that specifically lack NRG1 type III variants allowed researchers to directly address the role of this isoform in SC development. NRG1 type III mutants die at birth due to an inability to breathe. Interestingly, the consequences of type III-restricted gene targeting on SC development appear milder than those in ErbB2 or ErbB3 mutants. SCPs (defined by ErbB3 expression) are present along peripheral nerves already at E11.5, albeit at reduced numbers. At E14.5, immature SCs (Sox10/ErbB3/S100+), although dramatically reduced, are still present close to dorsal and ventral roots and along peripheral nerves. Nevertheless, S100+ cells are completely absent from nerve terminals. DRG explants from type III mutants prepared at E14.5 display a marked SC deficiency at first but are partially repopulated by endogenous SCs during the course of several weeks. However, many of these SCs fail to attach and ensheathe neurites properly. Thus, NRG1 type III isoforms are essential for the peripheral migration and/or survival of SCs, but signaling by other NRG1 isoforms is sufficient to also allow the initial generation and early differentiation of SCs.

Taken together, neuronal NRG1 type III signaling to SCs is mediated through an ErbB2/3 heterodimer and critically important for multiple aspects of SCP and premature SC development, including migration, differentiation, and survival.

NRG1–ErbB Signaling as a Master Regulator of Myelination in the Peripheral Nervous System

Immature SCs, which are generated from SCPs (between E13 and E15 in late embryonic nerves), first communally ensheathe large groups of axons. Subsequently, by radial sorting, individual SCs associate either with large-diameter axons in a 1:1 ratio or with several small-diameter (<1 μm) axons. During this process, the emergence of SC polarity, reflected by the asymmetric distribution of molecules (e.g., the polarity protein Par-3), is a prerequisite for focal deposition of myelin components. Early postnatally, SCs engulfing a large-diameter axon are selectively activated to differentiate into myelinating SCs that wrap multiple layers of myelin membrane around this axon. In contrast, SCs associated with small-diameter axons mature into 'nonmyelinating' SCs that ensheathe 5–25 (up to 50) small-caliber axons (in a so-called Remak bundle) without forming compact myelin sheaths. Since SC proliferation and survival both depend on axonal signals, limited axonal contact provides a

means by which the number of SCs and axons are matched.

In contrast to the control of myelination, the role of NRG1–ErbB signaling in radial sorting, SC polarity, timing of myelination onset, and the survival of SCs in postnatal nerves has not been determined *in vivo*. Several studies, however, support involvement of NRG1 in some of these processes. For instance, rescue of axotomy-induced SC death by exogenous NRG1 suggests that it is a component of an axon-derived survival signal at perinatal stages. The role of NRG1 in timing the onset of myelination through a phosphatidylinositol 3-kinase (PI3K)-dependent pathway is supported by the observation that treatment of rat SC cultures with recombinant NRG1 (similar to axonal contact) activates PI3K and mitogen-activated protein kinase (MAPK). In early SC–DRG neuron cocultures, elongation of SCs and subsequent myelination can be blocked by inhibition of PI3K (but not MAPK), whereas PI3K stimulation promotes myelination. In contrast, the maintenance of myelin sheaths in mature cocultures does not critically depend on PI3K activity. In agreement with this observation, pharmacologic inhibitors of ErbB receptors demonstrate a requirement of NRG1 signaling for the initiation of myelination also in zebra fish.

The first demonstration that NRG1–ErbB signaling plays a direct role in myelination came from the analysis of mouse mutants with a conditional deletion of the *ErbB2* gene in myelinating SCs. ErbB2 deficiency causes abnormally thin myelin sheaths, containing fewer myelin wraps. Similarly, mice that overexpress a dominant negative ErbB receptor in SCs (under control of the CNPase promoter) are hypomyelinated.

The level of NRG1 type III on the axonal surface, rather than axon diameter *per se*, has been identified to act as an instructive signal to induce myelination *in vitro*. Expression of NRG1 type III on the axon correlates with the ensheathment fate of axons *in vivo*: Unmyelinated, autonomic neurons express low levels of NRG1 type III on the axon surface, whereas BDNF/NT3-dependent DRG neurons, whose axons are heavily myelinated, express high levels. DRG axons from NRG1 type III null mice are not myelinated by SCs in cocultures and do not induce myelin-specific structural proteins or transcription factors, thus demonstrating that axonal NRG1 type III is essential for myelination (**Figure 2(A)**). Furthermore, mice haploinsufficient for NRG1 type III have a significantly higher proportion of axons that are persistently unmyelinated. In contrast, forced expression of NRG1 type III in the postganglionic fibers of sympathetic neurons converts these normally unmyelinated fibers to myelination *in vitro* (**Figure 2(B)**). Importantly, and despite addition of a soluble NRG1 type III ectodomain, cocultures of DRG neurons from type III null mutants and wild-type SCs fail to myelinate. Also, juxtacrine signaling (from heterologous cells stably expressing NRG1 type III) is not sufficient to induce myelin protein expression in cocultured SCs, demonstrating that NRG1 type III requires additional signals present on the axon to induce SC myelination. Together, these results suggest that threshold levels of axonal NRG1 type III provide the long-sought instructive signal that triggers SC myelination, at least *in vitro* (**Figure 3**).

Finally, NRG1–ErbB signaling has also been recruited for the regulation of the final stage of SC differentiation: the quantitative control of myelin sheath thickness (**Figures 2(C) and 2(D)**). Rapid impulse propagation is a function of axon caliber and myelination, and the optimal myelin thickness is reached when the 'g-ratio' is close to 0.68 (i.e., the numeric ratio between the diameter of the axon cylinder and that of the myelinated axon), a ratio remarkably well maintained for peripheral axons. Thus, axon size is monitored by myelinating SCs in order to assemble the correct number of myelin wraps. Mouse mutants with altered expression levels of NRG1 demonstrated that this information is encoded, at least in part, by the amount of membrane-associated NRG1 type III on the axon surface. Heterozygous NRG1 type III null mutant mice, which display approximately 50% NRG1, are hypomyelinated and exhibit reduced nerve conduction velocity. In contrast, transgenic mice that overexpress NRG1 type III in DRG sensory neurons and spinal cord motor neurons (under control of the neuronal Thy1 promoter) become hypermyelinated (**Figures 2(C) and 2(D)**). This effect appears to be specific to NRG1 type III because transgenic mice that overexpress the secreted NRG1 type I are not hypermyelinated. NRG1 has emerged as the rate-limiting factor of myelin growth control but not SC survival since SC numbers are unaltered in NRG1 +/− sciatic nerves. ErbB2 and ErbB3 are expressed by SCs at saturating levels. Only a dramatic reduction in number disrupts myelination (i.e., in a conditional mouse mutant with an SC-specific null mutation of the ErbB2 gene).

Whereas the requirement of the type III isoform for myelination is well established, the role of posttranslational modifications of NRG1 during myelination is only beginning to be addressed. First insight into the importance of proteolytic processing came from mouse mutants expressing only 'noncleavable' NRG1 variants. These mice display a phenotype analogous to NRG1 null mice (impaired heart development),

Figure 2 NRG1 type III is a master regulator of peripheral myelination. (A) Myelination by Schwann cells is completely blocked in the absence of NRG1 type III. Co-cultures of wild-type rat Schwann cells and sensory neurons from wild-type mice (+/+) or NRG1 type III null mutants (–/–) were maintained *in vitro* for 3 weeks, fixed, and stained for myelin (protein P0, red) and axons (neurofilament, green). Numerous myelin segments are evident in wild-type co-cultures, in contrast, no myelin is formed in co-cultures containing sensory neurons derived from NRG1 type III mutants. (B) Ectopic expression of NRG1 type III induces myelination of normally unmyelinated sympathetic neurons. Co-cultures of Schwann cells and control (left) or superior servical ganglion (SCG) neurons infected with NRG1 type III lentivirus (right) were stained for MBP (red) and neurofilament (green). (C) The level of axonal NRG1 type III determines myelin sheath thickness. Semithin cross sections (0.5 μm) of the sciatic nerve comparing transgenic NRG1 overexpressing mice with a wild-type control at age 5 months. Type III transgenics are hypermyelinated (Nrg1 type III tg), but not the type I transgenics (Nrg1 type I tg). The specific function of NRG1 type III is confirmed by a corresponding hypomyelination of mice with a type III isoform-specific null allele (Nrg1 type III +/–). (D) The ultrastructure and periodicity of compact myelin in hypermyelinated fibers, prepared from NRG1 type III transgenic mice (left), is indistinguishable from myelin prepared from wild-type mice (right). This demonstrates that hypermyelination is a consequence of additional membrane wraps. The two axons shown are of about equal diameter. Scale bar = 100 μm (B). (A, B) Reproduced from Tavegia C, Zanazze G, petrylak A, et al. (2005) Neuregulin-1 type III determines the ensheathment fate of axons. *Neuron* 47: 681–694. (C, D) Reproduced from Michailov GV, Sereda MW, et al. (2004) Axonal neuregulin-1 regulates myelin sheath thickness. *Science* 304: 700–703.

indicating that cleavage of NRG1 is critical for its function. Studies have identified BACE1 as essential for normal peripheral (and central) myelination. BACE1 is coexpressed with NRG1 in motor and sensory neurons at postnatal stages. BACE1 deficiency in mouse mutants results in the accumulation of unprocessed NRG1, hypomyelination of peripheral nerves, and aberrant segregation of small-diameter axons by SCs. The exact number and sequence of proteolytic cuts, the participation of other proteases, and the mechanisms that regulate proteolysis remain to be determined.

Taken together, the published studies support a model in which a threshold level of NRG1 type III is required to trigger myelination. At higher levels, the amount of myelin formed is a function of the amount of NRG1 type III presented by the axon to the SCs. This model also suggests a mechanism by which axons, via differing levels of NRG1 type III, coordinate SC numbers as they adopt alternative phenotypes. For example, axons expressing higher levels of NRG1 type III generate the additional SCs required to establish the one-to-one relationship characteristic of myelinated fibers. Open questions include the regulation of

Figure 3 Axonal NRG1 regulates successive steps of Schwann cell differentiation. (a) Schwann cells (in blue) arise from neural crest precursor cells (in green) and interact with both large and small caliber axons of spinal motor and sensory neurons. During embryogenesis, NRG1 on the axon regulates Schwann cell development by activating ErbB signaling cascades, thereby promoting Schwann cell differentiation and expansion. The amount of NRG1 type III on the axon detected by committed Schwann cells, which is a function of axon size and NRG1 levels, then drives them either into segregating single axons and myelination (top), or into a nonmyelinating phenotype and formation of a Remak bundle (bottom). Above threshold levels, NRG1 type III signals axon size to Schwann cells to optimize myelin sheath thickness. (b) In mouse mutants lacking NRG1 type III (–/–), heterozygous NRG1 type III mutants (+/–) and transgenic NRG1 type III overexpressing mice, the amount of myelin made by Schwann cells varies directly as a function of axonal NRG1 type III levels (indicated by yellow dots) rather than as a function of axon diameter. Reproduced from Nave KA and Salzer JL (2006) Axonal regulation of Mylination by neuregulin 1. *Current Opinion in Neurobiology* 16: 492–500.

NRG1 expression in individual neurons to match NRG1 steady-state levels to axon caliber and length.

ErbB Signaling in the Mature Peripheral Nervous System and in Pathological Conditions

Adult sensory (DRG) and spinal motor neurons continue to express NRG1 type III. Likewise, expression of ErbB2 and ErbB3 is maintained in mature SCs, albeit at reduced levels. Moreover, differentiated SCs, at least in culture, express several NRG1 isoforms, and autocrine NRG1 signaling in SCs may explain why SCs become progressively less dependent on neuronal NRG1 signaling during development. Indeed, expression of ErbB receptors has also been reported in adult motor and sensory neurons. Thus, NRG1-expressing SCs might signal to neurons that they myelinate. Moreover, ErbB2 expression is induced in SCs upon sciatic nerve transection in adult rats. SC proliferation in Wallerian degeneration follows a fixed time course, and the expression of NRG1 and ErbB2 is coordinately induced, implicating this pathway in SC mitogenesis and remyelination after axotomy.

Surprisingly, conditional inactivation of ErbB2 in adult myelinating SCs (induced at 2.5 months of age) does not impair normal myelin sheath maintenance or the proliferation of SCs after nerve axotomy. Whether remyelination is unaffected in these mutants awaits further analysis. Thus, the molecular control of SC function differs significantly between development and regeneration.

In contrast to myelinated motor axons, sustained ErbB signaling is required for nonmyelinating SCs and small axons (C-fibers) in the mature nerve. Disruption of ErbB signaling in adult nonmyelinating SCs by expression of a dominant negative ErbB receptor causes cell death and proliferation of nonmyelinating SCs and, indirectly, loss of unmyelinated axons in transgenic mice.

Aberrant ErbB receptor activity contributes to the development of many human cancers. Receptor

overexpression, kinase domain mutations, and autocrine ligand production can cause ErbB activation in tumors. Since SCs express various forms of NRG1 and autocrine NRG1–ErbB signaling has been implicated in their proliferation, it is plausible that NRG1/ErbB2 may be involved in the pathogenesis of human nerve sheath tumors and Schwannomas. This is also supported by the development of nerve sheath tumors in transgenic mice that overexpress a soluble NRG1 type II variant (GGFβ3) in myelinating SCs. Overexpression of ErbB2 and ErbB3 by SCs has been noted in nerves from patients with Charcot–Marie–Tooth disease type 1A, the most common hereditary peripheral neuropathy. The upregulation of these receptors may correlate with the generation of supernumerary SCs ('onion bulbs') or play a role in the inhibition of myelination or demyelination.

Aberrant signaling through the ErbB2 receptor is also a cause of demyelination in leprosy. *Mycobacterium leprae*, the causative agent of leprosy, directly binds and activates ErbB2 on the surface of myelinating SCs without the usual dimerization with ErbB3. The subsequent activation of MAPK1/2 by phosphorylation results in demyelination. This process can be blocked at the receptor activation stage by Herceptin, a monoclonal antibody directed against the ectodomain of ErbB2 (Figure 4).

Taken together, these studies have demonstrated that ligand-independent ErbB activation does not necessarily recapitulate NRG1 signaling but, rather, orchestrates a distinct spectrum of potentially pathological cellular responses.

Future Research

Although principal mechanisms of myelination control by NRG1–ErbB signaling have been defined, a number of gaps remain in our understanding of the molecular details. For example, the relevance of intracellular processing, transport, and localization for isoform-specific functions (e.g., myelination versus neuromuscular junction formation) remains poorly defined, and the exact composition and localization along the axon of the core NRG1 type III–ErbB2/3

Figure 4 Leprosy induced peripheral demyelination is mediated by ErbB2, *Mycobacterium leprae,* the causative agent of leprosy, activates ErbB2 receptors on the surface of myelinating Schwann cells. This leads to their activation by phosphorylation (P) without the usual dimerization with ErbB3. The subsequent activation of the extracellular signal-regulated kinases (Erk) 1/2 by phosphorylation, a mitogen-activated protein kinase kinase (MAPKK)-dependent event, results in demyelination. The process can be blocked at the receptor activation stage by Herceptin (a monoclonal antibody directed against ErbB2) or at the Erk1/2 phosphorylation stage using a MAPKK inhibitor (UO126). signaling complex are unknown. It will be of particular interest to determine whether the C-terminal fragment of NRG1, after proteolytic cleavage by BACE1 (or other proteases), remains associated with the N-terminal EGFL domain-containing fragment or whether, upon γ-secretase cleavage, it mediates back-signaling by nuclear translocation. The N-terminal fragment might be further proteolytically processed such that the EGFL domain is released into the adaxonal space. Because the activity of the core NRG1 type III–ErbB2/3 signaling complex is most likely modulated by multiple interactions with other molecules on the axonal and glial surface and the extracellular matrix, the identification of interacting partner molecules is another important task. Finally, the downstream signaling pathways that transmit information provided by the activated ErbB2/3 heterodimer from the growing myelin membrane to the SC nucleus and the set of target genes which is transcriptionally regulated by those pathways have yet to be identified.

Neural Crest Cell Diversification and Specification: Melanocytes

K Bismuth and H Arnheiter, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

Melanocytes are pigment-producing cells of vertebrates. They are found in the integument, the eye, the inner ear, and, depending on the species, also in a variety of other inner organs, such as the lung, the heart, and around the aorta. Their pigment, termed melanin, is a biopolymer that is synthesized through a series of catalytic steps starting with the conversion of the amino acid tyrosine to dihydroxyphenylalanine (DOPA) by a copper-binding enzyme called tyrosinase. There are two types of melanin : eumelanin, which is black, and pheomelanin, which is yellow. Both types are made in membrane-bound intracellular organelles, called melanosomes, in which they can be found in pure form or mixed. Not every cell that contains melanosomes is a melanocyte, however, because melanocytes can transfer their melanosomes to other cell types that are not capable of producing melanin. In human skin, for instance, melanosomes are transferred from melanocytes to keratinocytes and into hair shafts, and in birds they are found in feathers. Clearly, a major role of melanocytes is to provide a body's visible pigmentation and so to aid in camouflage, display, and sun protection.

However, melanocytes are also critical for other organs. In the eye, for instance, they are found in the iris, which serves as an aperture that controls the depth of focus and regulates the amount of light that enters the eye. They are also found in the choroid behind the retina, where they serve as a light screen, blocking the passage of light to deeper tissues. In the inner ear of mammals, they are found in a portion of the wall of the cochlear duct, called the stria vascularis, where they regulate the ionic composition of the endolymph and ensure that auditory hair cells function properly. In fact, diminished numbers of strial melanocytes can lead to hearing impairment, as is likely the case in human Waardenburg syndromes, which are characterized by pigmentary abnormalities in skin, hair, and eyes and by varying degrees of deafness. Importantly, the function of melanocytes in hearing is independent of their pigmentation because mammals that lack melanin but retain melanocytes usually have normal hearing. Hence, melanocytes have important roles beyond fashioning the variety and beauty of an organism's coloration.

Development of Melanocytes

Melanocytes are generated from the neural crest, which is an embryonic population of cells that forms at the border between the neural plate and the adjacent surface ectoderm. Neural crest cells are induced by extracellular signals such as bone morphogenic proteins (BMPs), the Wingless/Int family of proteins (WNTs), and fibroblast growth factors (FGFs). These ligands induce transcription factors that hierarchically serve to specify the neural plate border, the neural crest, and, finally, a variety of cellular derivatives. In addition to melanocytes, these include the glial cells and neurons of the peripheral nervous system, smooth muscle cells, and bone and cartilage of the head.

The precursors to melanocytes, called melanoblasts, emerge at all axial levels between the region of the diencephalon and the tail end of the neural tube. This is in contrast to other crest derivatives, which are usually made at more restricted sites. Soon after their generation, neural crest cells accumulate in an area, called the migration staging area, close to the dorsal lip of the neural tube. From there, they migrate to their ultimate destinations, first leaving from the head region and then progressively from regions further toward the tail. In many vertebrates, melanoblasts migrate only after other crest derivatives have left. In regions where somites are present, melanoblasts travel between the somites and the surface ectoderm, with a major direction from back to belly but also longitudinally from head to tail and tail to head. This pathway is called the dorsolateral pathway and is different from the pathway taken by nonmelanoblastic crest derivatives, which migrate between the somites and the neural tube. In regions where no somites are present, particularly in the area of the otic vesicle, melanoblasts travel close to the neural tube as well as laterally toward the surface ectoderm. The majority of melanoblasts enter the dermis and then cross the basal membrane to take up residence in the epidermis, feather buds, or hair follicles. Others migrate toward the developing inner ear, the choroid, the ciliary body, the iris, and other inner organs. While traveling, melanoblasts begin to express a series of proteins, including the melanin-synthetic enzymes dopachrome tautomerase (DCT), tyrosinase-related protein-1, and tyrosinase, and the melanosomal protein pMEL17. In mice, expression of these proteins follows a characteristic sequence over several days. This sequence culminates with the induction of tyrosinase, which is the rate-limiting enzyme in melanin synthesis. Importantly, both cell proliferation and migration can continue even after

melanin has accumulated in the cells. The principal stages of melanoblast development in mouse embryos are shown in Figure 1.

This brief description of melanocyte development leaves us with a number of specific questions. What molecular signals specify melanoblasts and segregate them from other crest derivatives? Is specification irreversible, and if so, when does irreversibility occur – before migration or only later when the cells are closer to their final destination? How many cells are specified as melanoblasts, and how much do they have to proliferate to populate an entire body? What are the mechanisms that control melanoblast proliferation, guide them to their destinations, and control the progression toward their differentiation? What are the mechanisms that replenish melanocytes that are lost in adults, for instance, during hair and feather molting, when there is no recourse to the embryonic neural crest? We briefly discuss our current knowledge on these questions.

Melanoblast Specification: The Interplay between Signaling Pathways and Transcription Regulation

The analysis of both *in vivo* genetic models and *in vitro* culture systems made it possible to identify a number of factors involved in melanoblast specification. Three common notions have emerged from these studies. First, many of the factors involved in

Figure 1 Melanoblast development and migration from the neural crest in mouse embryos. The left side shows schematic drawings of sections through the trunk and head areas as well as the respective migration pathways of melanoblasts and other neural crest derivatives. (a–g) Represent cryostat sections prepared from albino embryos or newborns that were labeled by nonradioactive *in situ* hybridization using riboprobes. Hence, the label marks gene expression, not pigmentation. (a, b, and e) Expression of the transcription factor gene *Mitf* is, together with KIT expression (not shown), one of the first signs of melanoblast specification in the neural crest. In the trunk area, *Mitf*-expressing cells are first found in the region of the roof plate of the neural tube (arrows in a). Then they migrate on a dorsolateral pathway underneath the surface ectoderm (b, and magnification of boxed area in b). (c and d) At later stages, the *Mitf* marker becomes progressively weaker and melanoblasts can best be labeled by expression of the melanogenic gene *Dct*. (c) Shows *Dct*-positive cells that have entered the epidermis and developing hair buds, and (d) shows *Dct*-positive cells in hair follicles of newborns. (e) In the head region, neural crest cells express *Mitf* only after they have migrated away from the crest. They are found underneath the surface ectoderm and on a pathway toward the otic vesicle. (f) *Dct*-positive melanoblasts have entered the lateral wall of the cochlear duct at E16.5. (g) Other melanoblasts have migrated close to the optic cup and start to populate the region behind the retinal pigment epithelium (RPE). This region will form the pigmented choroid. Neural crest-derived melanoblasts have also migrated close to the ciliary margin zone (CMZ), that will form the ciliary body and the iris of the eye. Note that the RPE is also positive for *Dct* but is derived directly from the optic neuroepithelium, not the neural crest. (h) H&E-stained section through the choroid and RPE of an adult eye of a pigmented mouse. Only the choroidal pigment cells are neural crest derived.

early specification operate not at a single stage but during several phases of melanocyte development. Second, many of the factors can either promote or inhibit melanocyte formation, depending on the conditions. Third, many of these factors also operate in other organ systems, and their mutations can lead to disorders unrelated to melanocyte function, including embryonic or adult lethality.

A list of factors currently implicated in melanocyte development is shown in Table 1. The factors are arranged by functional groups and alphabetically within groups, starting with a group of factors operating from outside the cells and ending with a group functioning inside. Not listed are the typical differentiation (pigmentation) genes, and we refer the reader to other reviews for more detailed information on the factors not specifically covered here.

Numerous genetic and expression studies as well as biochemical and cell-biological analyses have demonstrated that among the early effectors of melanoblast development, the cell surface receptor KIT and the transcription factor MITF mark melanoblasts selectively in the neural crest and are the ones most specifically involved in their development. KIT is a receptor tyrosine kinase that binds a single ligand, KIT ligand (KITL), and activates the mitogen-activated protein (MAP) kinase pathway and the phosphoinositide-3 (PI3) kinase pathway. Based on natural and genetically engineered mouse mutants, the MAP kinase pathway is critical for melanocyte development, but the PI3 kinase pathway is dispensable. MITF is a basic–helix–loop–helix–leucine zipper transcription factor that was originally identified in mice with transgenic insertional mutations at the microphthalmia locus (hence its name, microphthalmia-associated transcription factor). Such mice are entirely white and deaf because their melanoblasts do not develop properly, and they have small eyes (microphthalmia) because the development of the pigmented epithelium of the retina, a neuroepithelial derivative, also depends on MITF. MITF has several isoforms, one of which, the M-MITF isoform, is under the control of its own specific promoter, the M-promoter, and is the major isoform of melanoblasts.

There is *in vitro* evidence that KIT and MITF engage in cross-talk. The KIT-mediated activation of the MAP kinase pathway leads to serine phosphorylation of MITF, which regulates MITF's transcriptional activity and stability. Conversely, MITF is needed for KIT to accumulate in melanoblasts. KIT and MITF are thus part of a feedback loop. This feedback loop intersects with a second signaling pathway that also acts early in melanoblast development and involves the ligand endothelin-3 (EDN3) and the G-coupled endothelin receptor-B (EDNRB). Consistent with the observation that EDNRB signaling stimulates melanoblast proliferation *in vitro*, EDNRB-deficient mouse embryos have few melanoblasts, and after birth melanocytes are largely missing except in spots around the neck and the base of the tail. Although EDNRB is expressed in melanoblasts where it acts cell autonomously, it is also expressed in other cell types, notably in cells of the neural tube. Interestingly, co-cultured, EDNRB wild-type neural tube or nonmelanoblastic neural crest cells can rescue the proliferation of EDNRB-deficient melanoblasts and let them develop at least to the tyrosinase-positive stage, but similar cells genetically deficient in KITL cannot. Because KITL alone can rescue EDNRB-deficient melanoblasts *in vitro*, it is conceivable that EDNRB signaling also helps melanoblast development in a cell nonautonomous manner by stimulating KITL production or secretion in other cells. Hence, it appears that all three factors – EDNRB, KIT, and MITF – are functionally linked during the early stages of melanoblast development.

What, then, induces these key factors? Much work has gone into the identification of transcription factors that directly stimulate the M-MITF promoter. They include SOX10, a member of the SRY-box-containing high-mobility group of transcription factors; PAX3, a paired domain transcription factor; LEF1/TCF, another high-mobility group protein; and CREB, a basic–leucine zipper protein. None of these are specific to melanoblasts, however. Thus, much as with many other promoters, it is likely the combinatorial network of these and other factors, each with its own specific transcriptional activities, that regulates the M-MITF promoter. Similar reasoning applies to KIT and EDNRB even though much less is known about their transcriptional regulation in melanoblasts.

On the next level up, extracellular ligands have been identified that regulate the regulators of MITF. Among them are WNT proteins, which are cysteine-rich secreted proteins that bind members of the G-coupled receptor family called Frizzled receptors (FZD) and receptors related to low-density lipoprotein receptor (LPR; particularly LPR5 and LPR6). The coactivation of these two types of receptors induces the so-called canonical WNT signaling pathway, whose hallmark is the accumulation of β-catenin and its transfer to the cell nucleus, where it interacts with LEF/TCF to stimulate the transcription of specific target genes. Together with BMPs and FGFs, WNTs are critical in specifying the neural crest by operating upstream of a series of transcription factors, including PAX3, SOX9, SOX10, SLUG/SNAIL, AP-2, and FOXD3 (Table 1). Many of these factors are also engaged in extensive yet species-specific cross-regulatory networks. Interestingly, after its early role in neural

Table 1 Factors implicated in melanocyte specification and development

Functional group	*Symbol*	*Name*	*Function*	*Human neural crest-related disorders (OMIM No.)*[a]
Extracellular matrix and cell adhesion	ADAMTS20	Adamts20 metalloprotease	Involved in ECM remodeling	
	ECM	Extracellular matrix (collagen, fibronectin, laminin)	Migration of melanoblasts

Figure 2 Simplified schematic representation of the interplay between signaling pathways and transcription factors involved in melanocyte development. For abbreviations, see Table 1. Biochemical evidence shows that the MAPK pathway regulates MITF activity and stability through phosphorylation. Genetic evidence suggests that EDNRB signals through Gnaq and Gna11, two members of the Gαq family of G-proteins, as well as through Gα12/13.

crest specification, canonical WNT signaling is also critical in promoting the melanoblast fate. For instance, in mouse embryos, elimination of β-catenin in neural crest stem cells leads to a lack of melanoblasts and sensory neuronal lineages but not other crest derivatives. In zebra fish, overexpression of β-catenin in premigratory neural crest cells leads to excess pigment cell formation through the stimulation of MITF. In transgenic mice, however, stimulation of MITF by stably active, nuclear β-catenin can also lead to inhibition of melanoblast proliferation, illustrating that potent factors such as β-catenin need to be finely tuned with respect to their levels and specific time points of expression. This is all the more important because β-catenin also acts downstream of cadherins, which together with integrins regulate cell adhesion and migration. A simplified scheme of the interactions of the extracellular ligands and transcription factors involved in melanoblast development is shown in Figure 2.

Melanoblast Specification: Cell Number and Location

In previous decades, the existence of melanoblasts could be assumed only indirectly from the existence of their descendents, the melanocytes. Using pigmentation as the readout, two types of studies have suggested that in mice, melanocytes must arise from a very small number of precursors. Mintz produced chimeras of embryos of pigmented and unpigmented, tyrosinase-deficient (albino) mice. From the width and arrangement of the pigmentation stripes that appear in adults, she concluded that there are precisely 34 melanocyte precursors, 17 equally spaced on either side of the embryo – three for the head, six for the body, and eight for the tail. Support for a small number of melanocyte precursors, although not exactly 34, came from the infection of albino embryos with retroviral vectors expressing wild-type tyrosinase. The resulting mice had small pigmented stripes whose widths were reminiscent of those observed in Mintz's chimeras. In later studies, the use of *in situ* hybridization or antibody probes specific for melanoblasts indicated that the number of initially specified melanoblasts is indeed small, particularly in the trunk region. These studies showed, however, that melanoblasts are unevenly distributed between head and tail. The use of a line of transgenic mice in which the bacterial *lacZ* gene is expressed under control of the promoter of the early melanogenic gene *Dct*

also showed an uneven head-to-tail distribution of melanoblasts. However, the *Dct–lacZ* marked melanoblasts were found to mix extensively along the head-to-tail axis and to be considerably more numerous than suggested from the earlier studies. Each study has to be considered with caution, however. The first assumes that one stripe represents a clone derived from a single cell, which is only true if the cells are thoroughly mixed early in the chimeric embryos but their descendents do not mix later in development. The second may not reflect the marking of the earliest melanoblasts because cells could be infected at different stages during lineage development. The third is limited by the sensitivity of the *in situ* probes, and the fourth may overestimate the number of melanoblasts because it cannot be excluded that *lacZ*-marked cells may give rise to other cells besides melanocytes. Thus, the truth may well lie somewhere in between: more than 34 melanoblasts in mice but less than 1000.

The question of where and when melanoblasts are committed to the melanocyte lineage has also not been answered definitively. On the one hand, the coexpression of KIT and MITF in premigratory mouse neural crest cells strongly argues for an early commitment of melanoblasts. On the other hand, there is *in vitro* evidence that *Dct*-positive neural crest cells, usually considered to be melanoblasts, are capable of generating both melanocytes and smooth muscle cells. In the quail, even epidermal melanocytes have been observed to switch their fate and become Schwann cells, the myelin-forming cells of the peripheral nervous system (and vice versa, Schwann cells have been seen to become melanocytes). In fact, the question of commitment cannot be answered universally for all vertebrate species, and probably not even universally for all axial levels in the same species. In the head region of mouse embryos, for instance, *Kit*-positive cells, identified by expression of a knock-in Kit^{lacZ} allele, are first observed at the dorsal midline of the neural tube, but MITF expression, detected by antibody labeling or *in situ* hybridization, is usually seen only in postmigratory melanoblasts. In contrast, at the trunk level, both KIT and MITF are first expressed together in cells at the top of the neural tube (**Figures 1(a) and 1(e)**).

Although there are thus arguments for both premigratory and postmigratory commitment, the proof of a true restriction in a melanoblast's developmental potential requires systematic challenges with conditions permissive for alternative fates: Fate maps are not indicative of fate restrictions. For instance, it is not known whether MITF/KIT double-positive melanoblasts of mice, which normally develop only into melanocytes, are entirely incapable *in vivo* of developing into other cell types. This point is not of mere academic interest because a prolonged retention of a broader developmental potential in one cell lineage may provide an embryo with the means to correct developmental aberrations in another, and thus still yield a healthy adult.

Melanoblast Survival, Proliferation, and Migration

The developing population of melanoblasts is regulated by the parameters of cell survival, cell proliferation, and cell migration. The molecular dissection of these parameters has indicated a series of important players. Recent evidence suggests, for instance, that Notch signaling, which is involved in many developmental processes, is also critical for melanoblast survival. Notch receptors represent a family of conserved transmembrane proteins that are activated by specific ligands, Delta and Jagged, through direct cell–cell interactions. In fact, Notch signaling, acting through the downstream target gene *Hes1*, plays a critical role in preventing apoptosis of melanoblasts. Moreover, the previously mentioned extracellular factors WNT, EDN3, and KITL, are critical for cell survival and for promoting cell proliferation. As alluded to previously, the actions of these factors converge on MITF, the all-purpose melanoblast transcription factor, which has been shown to regulate cell survival and proliferation. *In vitro* experiments in melanoma cells suggest, for instance, that MITF stimulates the expression of the antiapoptotic genes *Bcl2* and hypoxia-inducible factor-1α (*Hif1α*), but a C-terminal fragment of MITF, liberated by the proapoptotic, activated caspase-3, enhances apoptosis. MITF also seems to have both positive and negative effects on cell proliferation. It promotes cell proliferation by stimulating the transcription of the gene encoding cyclin-dependent kinase-2 (CDK2), which promotes the G_1-to-S transition during the cell cycle. MITF also stimulates the transcription factor TBX2, which represses the expression of p21, a protein inducing growth arrest. Furthermore, MITF appears to be essential, and in fact is increasingly expressed, in highly aggressive, metastasizing melanoma cells, earning it the name 'lineage addiction oncogen.' On the other hand, MITF is also clearly antiproliferative: it activates the gene encoding INK4a, which promotes cell cycle exit, and it directly stimulates the gene encoding p21, which induces G_1 arrest. What controls the net result of these opposing actions is not entirely clear but may rest in part on the balance of expression of distinct MITF isoforms. For instance, when expressed *in vitro*, isoforms that lack certain subexons are less antiproliferative, or may even promote proliferation, compared to isoforms

that contain these subexons. Hypothetically, then, distinct MITF isoforms might be expressed at different developmental time points or during different phases of the cell cycle and may regulate different subsets of cell cycle regulators. This might occur either at the transcriptional level or by direct interactions at the protein level. MITF and cell cycle regulators may hence be integrated at multiple levels.

While melanoblasts proliferate, they also migrate, but proliferation and migration are not synchronized because there are spurts of growth that alternate with spurts of migration. Migration is controlled in part by cell adhesion and the extracellular matrix. Cadherins form a family of glycoproteins involved in calcium-dependent cell adhesion, regulation of the cytoskeleton, and cell signaling. Melanoblasts express distinct cadherins very dynamically during development. For instance, when neural crest cells delaminate from the epithelium, they express cadherin 6 but only low levels of N-cadherin. In migrating melanoblasts, E- and P-cadherins are weakly upregulated, but upon arrival in the dermis, neither is expressed. E-cadherin increases 200-fold when the cells enter the epidermis and interact with E-cadherin-expressing keratinocytes. Melanoblasts that enter hair follicles, however, downregulate E-cadherin again and exclusively express P-cadherin. The few melanocytes remaining in the epidermis continue to express E-cadherin, and those in the dermis express N-cadherin. These dynamic changes in cadherin expression seem to adapt the cells to their local environment, a hypothesis that has been tested by both gain-of-function and loss-of-function mutations in select cadherins. Because cadherins have wide-ranging actions in other tissues, however, specific effects on melanoblasts are not always easy to discern.

The parameters of cell migration have also been explored in heterologous cell grafting experiments using unrelated cell types, such as tumor cells or embryonic stem cells. These experiments point out the importance of β_1 integrin, a member of a family of transmembrane proteins that assemble in heterodimers and serve as major binding partners for extracellular matrix components, but their relevance to melanoblast migration is unclear. Support for the importance of the extracellular matrix in melanoblast migration comes from genetic observations on the role of proteases known to remodel the extracellular matrix. The mouse coat color mutation *belted*, for instance, is due to a mutation in the metalloprotease gene *Adamts20*. This gene is homologous to *Gon-1* of *Caenorhabditis elegans*, which encodes a metalloprotease required for cell migration. In summary, the regulation of cell migration involves a variety of partners that all collaborate to ensure that the cells end up on the right tracks and in the right locations.

Melanoblast Differentiation

Melanoblast differentiation, characterized by melanization and the acquisition of a dendritic phenotype, relies heavily on MITF, whose targets include many of the genes involved in melanin biosynthesis (such as the previously mentioned *Dct*, tyrosinase-related protein-1, and tyrosinase). A common *cis* element in the promoters of these genes is the so-called M-box, which in its core contains an Ephrussi (E) box of the sequence 5'CATGTG3'. E boxes are widespread in the genome and bound by a wide array of basic–leucine zipper, basic–helix–loop–helix, and basic–helix–loop–helix–leucine zipper transcription factors. Although flanking sequences influence the efficiency with which specific factors bind a given E box, they are insufficient to explain the restriction of the melanogenic genes to the melanocyte lineage. Again, it is likely the combination of several distinct transcription factors that is critical for this regulation. As alluded to previously, the activity of MITF is also regulated by post-translational modifications such as phosphorylation. Moreover, it has been described that MITF is dynamically modified by small ubiquitin-like modifier (SUMO) side chains, which are proteins of approximately 100 residues that are added to two lysines of MITF. Sumoylation, as the modification is called, reduces MITF's activity on promoters with multiple E boxes, but not on those with single E boxes, and thus may influence target gene specificity. Furthermore, both *in vitro* and *in vivo* tests show that some melanogenic genes are stimulated not only by MITF but also directly by SOX10, a regulator of MITF, suggesting the existence of feed-forward loops between SOX10 and MITF target genes. By regulating genes involved in the dynamics of the actin cytoskeleton, MITF also modulates cell shape. Nevertheless, although MITF is expressed at high levels in melanoblasts as they differentiate into melanocytes, it soon fades away in most differentiated cells; thus, it is conceivable that maintenance transcription of melanogenic genes in mature melanocytes, and possibly the maintenance of cell shape, is controlled by other E-box binding factors expressed in mature melanocytes. Without functional MITF, however, melanocytes can never mature and become pigmented, but when they remain unpigmented because they have mutations in the melanin biosynthetic genes, they stay alive and thrive.

Adult Melanocyte Stem Cells

Tissue injury, be it the result of physical or metabolic processes, is a common feature of life, and hence the mechanisms of tissue repair are of great importance for the maintenance of health. Much excitement has

been created by the recognition that adult mammals contain stem cells capable of regenerating lesioned tissues. Stem cells are usually defined as undifferentiated cells capable of self-renewal and of generating a variety of differentiated cells. Many stem cells reside in a particular compartment, called the niche, that provides the necessary environment for their maintenance. An example of such a niche is the bulge region of hair follicles which lies between the hair bulb and the sebaceous gland. As the hair goes through its cycles of loss and regrowth (technically, the phases are know as catagen, telogen, and anagen), multipotent stem cells from the bulge replenish all types of epithelial cells of the hair structure. A particular slow-cycling cell, marked in mouse transgenic studies by the previously mentioned *lacZ* reporter under the control of the *Dct* promoter, is capable of self-renewal and returning to a quiescent stage; of populating neighboring, vacant bulges; and of giving rise to melanocytes. These cells share many features with developmental melanoblasts but have been dubbed melanocyte stem cells. However, the usual stem cell feature, multipotentiality, has not been shown to be among their traits, and their relationship to multipotent stem cells in the niche is unclear.

Major questions in stem cell biology concern the mechanisms of stem cell maintenance and the distinction between self-renewal and differentiation. Interestingly, several of the signaling pathways and transcription factors mentioned previously in the context of melanoblast development are also involved in melanocyte stem cell regulation. For instance, Notch signaling is required for the maintenance of melanocyte stem cells in the hair follicle, and PAX3, SOX10, and MITF, together with WNT signaling, are involved in regulating differentiation. Whereas SOX10 and MITF collaborate to stimulate *Dct* transcription, PAX3 represses *Dct* transcription. It does so by recruiting the Groucho corepressor GRG4 and by interacting with LEF/TCF, whose binding to the *Dct* promoter competes with MITF binding, resulting in low *Dct* expression. What can flip the switch is extracellular signaling, particularly the activation of the canonical WNT signaling pathway and its concomitant β-catenin activation. Activated β-catenin interferes with the binding of PAX3 to LEF/TCF and GRG4 and dislodges PAX3 from the *Dct* promoter. This relieves repression of the *Dct* promoter and frees PAX3 to stimulate MITF expression to higher levels, which in turn activates the *Dct* promoter and sends the cells on the way to differentiation. Of course, this process is not allowed to act indiscriminately in all melanocyte stem cells, lest there would be no stem cell left for the next hair cycle. How some cells of the niche escape the effects of WNT signaling is not yet known, however. Intriguingly, premature differentiation and concomitant loss of stem cells seem to be a feature of a mutant allele of *Mitf*, $Mitf^{vit}$, which leads to premature graying. This and other mutants in MITF and in other factors underscore the importance of the mentioned pathways not only for development but also for tissue regeneration.

In summary, the biology of melanocytes and their regulation from birth to death has provided us with many mechanistic insights that are not readily attainable in other systems. Melanocytes, in fact, are highly suitable to elucidate basic principles of cell lineage determination in the neural crest.

Neural Crest Diversification and Specification: Transcriptional Control of Schwann Cell Differentiation

M Wegner, Universität Erlangen-Nürnberg, Erlangen, Germany

The Role of Transcription Factors in the Schwann Cell Lineage

Schwann cells and satellite glia are the two main glial cell types of the peripheral nervous system (PNS). Whereas satellite glia are found within ganglia in close association with neuronal somata, Schwann cells are found in close contact with axons in the peripheral nerves. Both Schwann cells and satellite glia arise from neural crest stem cells. Following their specification, Schwann cells go through several consecutive developmental stages, including the Schwann cell precursor and the immature Schwann cell, before they finally undergo terminal differentiation and become myelinating or nonmyelinating Schwann cells of the adult PNS. Each developmental stage is characterized by specific patterns of gene expression, and progression from one stage into the next requires corresponding changes. Taking the role of transcription factors as regulators of gene expression into account, each stage of Schwann cell development and each transition from one stage into the next must be brought about by changes in transcription factor occurrence or activities.

Transcriptional Control of Schwann Cell Specification

Transcription factors with importance for Schwann cell development are already present in pluripotent neural crest stem cells. This includes the α isoform of transcription factor AP2, the forkhead protein FoxD3, the paired domain protein Pax3, and the high-mobility-group domain containing protein Sox10. Because all these transcription factors are expressed during the specification event, their presence must at least be compatible with the transformation of a neural crest stem cell into a Schwann cell precursor. Except for Sox10, whether these transcription factors are also required for specification has not been rigorously tested.

In neural crest stem cells, Sox10 is important for survival and for the maintenance of pluripotency; trunk neural crest stem cells show a reduced survival rate in mice deficient for Sox10. However, enough neural crest stem cells survive to aggregate to dorsal root ganglia and populate roots and proximal portions of peripheral nerves. Whereas neuronal specification in the dorsal root ganglia is initially undisturbed in the absence of Sox10, neural crest cells fail to undergo specification to glia. These loss-of-function studies show that Sox10 is indeed required for the specification of Schwann cell precursors as well as satellite glia precursors, both of which can be distinguished from neural crest stem cells by the expression of B-FABP. Schwann cell precursors also start to express low levels of the myelin protein zero (MPZ) as a marker. This basal level of MPZ expression is probably due to a the direct activation of the MPZ promoter by Sox10 and is orders of magnitude below the level attained later during active myelination.

Because the specification of both Schwann cells and satellite glia is under control of Sox10, Sox10 alone cannot account for the difference between both glial cell types. Rather, different transcription factors must be present in presumptive glia along nerves and in dorsal root ganglia, so that cooperation of these transcription factors with Sox10 leads to different glia, depending on their localization. This model fits the general perception of Sox proteins as transcription factors that function mainly in combination with partner proteins. Although this limits the intrinsic impact of Sox proteins on developmental processes, it also endows them with functional versatility. Sox10, for example, exerts many additional functions at later stages of Schwann cell development with changing partner proteins.

Hooked on Neuregulins: The Schwann Cell Precursor

Newly formed Schwann cell precursors depend for survival and proliferation on neuregulin 1 signaling. In particular, the membrane-bound isoform III of neuregulin 1 is strongly expressed on axons at this time, thus making survival of Schwann cell precursors dependent on axonal contact. Schwann cells recognize the neuregulin 1 signal with a heterodimeric receptor consisting of ErbB2 and ErbB3. In the absence of Sox10, the expression of ErbB3 is strongly reduced in neural crest-derived cells along the nerve, proving that Sox10 is genetically upstream of ErbB3 expression. Ectopic expression of Sox10 in a neural cell line, furthermore, leads to a rapid induction of ErbB3 expression, arguing that ErbB3 transcription may be

directly dependent on Sox10 in neural cells. Sox10 may, thus, also ensure the survival of Schwann cell precursors by making them responsive to neuregulin 1.

Neuregulin 1 continues to be important for Schwann cells and promotes both the transition of Schwann cell precursors to immature Schwann cells and myelin formation. Neuregulin 1 signals seem predominantly transduced through the mitogen-activated protein kinase (MAPK) pathway in Schwann cells and through Ets proteins as their nuclear effectors. Accordingly, several Ets proteins, in particular Net and GA binding protein (GABP-)α, are prominently expressed in Schwann cell precursors, immature Schwann cells, and throughout myelination.

Neuregulin 1 also stimulates the expression of the transcription factor cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) and induces sustained phosphorylation of CREB on its serine residue 133 in Schwann cells. Signaling through CREB appears to contribute to Schwann cell proliferation during the early stages of lineage development.

Molting into an Immature Schwann Cell

Several days after specification, Schwann cell precursors develop further into immature Schwann cells. In the mouse, this transition occurs around 13 days postcoitum, requires continued neuregulin signaling, and is characterized by changes in gene expression. Most important, from this stage onward Schwann cells establish an autocrine signaling mechanism that makes them less dependent on axonal signals for survival and proliferation. It is not yet known which transcription factor or which combination of transcription factors is needed to drive Schwann cell precursors into the immature Schwann cell stage. However, evidence exists to implicate AP2-α as a negative regulator of this process. As already mentioned, AP2-α expression has continued in Schwann cell precursors from the neural crest cell stage. Immature Schwann cells normally arise once AP2-α expression is extinguished. Reciprocally, prolonged expression of AP2-α interferes with the timely progression from the Schwann cell precursor to the immature Schwann cell stage. Taking into account that endothelins exert a similar effect on Schwann cell development through the endothelin B receptor, a link may exist between AP2-α and endothelin signaling in Schwann cell precursors.

Maintaining the Immature State

In contrast to AP2-α, Sox10 continues to be expressed in immature Schwann cells, possibly ensuring continued ErbB3 expression during this stage of Schwann cell development. The same continued expression from neural crest stem cells into the immature Schwann cell stage is also observed for FoxD3 and Pax3.

In addition, immature Schwann cells start to express transcription factors that are undetectable at earlier stages of their development. This includes the two related POU homeodomain transcription factors – Oct6 (also known as SCIP and Tst-1) and Brn2 – as well as the zinc finger protein Krox20 (also known as Egr2). Initial expression of these transcription factors in immature Schwann cells is at a low basal level, orders of magnitudes below the maximal levels achieved at later times of Schwann cell development. Expression of Krox20 is, furthermore, inversely correlated to the expression of its close relative Krox24 (also known as Egr1), which is expressed at highest levels in Krox20-negative Schwann cell precursors and is completely absent later in myelinating Schwann cells which exhibit maximal Krox20 levels.

More prominently expressed than Oct6 and Krox20 in immature Schwann cells is the high-mobility-group domain protein Sox2. In contrast to its distant relative Sox10, it is specifically turned on in the Schwann cell lineage and not expressed in neural crest stem cells. In fact, forced expression of Sox2 in the presumptive neural crest at the time of neurulation leads to a fate switch and causes these cells to become part of the neuroepithelium. Sox2 expression is important to maintaining Schwann cells in the immature state. Similarly, this appears to be the case for Pax3 and FoxD3, as well as for the bZip transcription factor cJun. Similar to phosphorylated CREB, these transcription factors all stimulate Schwann cell proliferation. They also appear to repress terminal differentiation.

Schwann cell proliferation is also enhanced by glucocorticoids, indicating that immature Schwann cells express the glucocorticoid receptor. Glucocorticoid receptor is not the only nuclear hormone receptor in Schwann cells. Thyroid hormone receptor and progesterone receptor have also been detected, as well as several members of the p160 coactivator family of steroid receptor coactivators (SRC1–SRC3) as crucial mediators of nuclear hormone receptor effects. Interestingly, Schwann cells also have the capacity to synthesize progesterone, indicating that progesterone signaling may be part of the autocrine loop that exists in Schwann cells from the immature state onward.

Choosing between Two Alternative Fates during Terminal Differentiation

Progesterone and thyroid hormone have also been reported to promote myelin gene expression in Schwann cells and may thus be involved in triggering

terminal differentiation at the end of embryogenesis. During terminal differentiation, Schwann cells choose between two mutually exclusive pathways. Schwann cells in contact with small-caliber axons ensheath these axons as nonmyelinating Schwann cells. These cells no longer actively divide, but are not permanently withdrawn from the cell cycle. They, furthermore, continue to express many of the same transcription factors that were already expressed in the immature Schwann cells. Myelinating Schwann cells, on the other hand, exit the cell cycle, establish a one-to-one relationship with large-caliber axons and form myelin sheaths around an axonal segment. Myelin formation, in addition, requires dramatic changes in the expression pattern of myelinating Schwann cells as lipid biosynthesis and the production of myelin proteins (such as MPZ, MBP, PMP-22, and Connexin-32) and the synthesis of specific glycolipids are steeply increased.

Triggering Myelination by Axonal Signals

Of all the steps in Schwann cell development, transition from the immature Schwann cell to the myelinating Schwann cell is best understood. It is critically dependent on at least three groups of transcription factors, the first being nuclear factor (NF)-κB proteins, in particular p65/relA. NF-κB is already present in Schwann cells before myelination, and it is mainly localized during this stage in a complex with I-κB proteins in the cytoplasm and, thus, in an inactive state. At the onset of terminal differentiation, an axonal signal activates the low-affinity nerve growth factor (NGF) receptor p75 and thereby leads to nuclear translocation of NF-κB and induction of its transcriptional activity. In the mouse, blockade of NF-κB activity or the genetic deletion of p65 attenuates peripheral myelination significantly.

NF-κB also stimulates Oct6 expression in Schwann cells and is thus part of the strong axon-dependent upregulation of Oct6 gene expression immediately prior to myelination. Axonal signals influence Oct6 gene expression also through increased intracellular cAMP levels. This inducibility by cAMP has, in fact, led to the designation of Oct6 as suppressed cAMP-inducible POU (SCIP) protein.

Escorting Schwann Cells into the Myelinating Stage

Maximal Oct6 levels coincide with the phase during which Schwann cells in contact with large-diameter axons, establish a one-to-one relationship, and prepare for myelination. Oct6 is, therefore, strongly associated with this promyelinating stage. Schwann cells in Oct6-deficient mice become arrested in their development at the promyelinating stage, supporting the notion that Oct6 mediates the progression from the promyelinating into the myelinating stage. However, the arrest is only transient, so that Schwann cells eventually overcome this block in Oct6-deficient mice and form myelin sheaths with a delay of approximately 2 weeks.

The transient nature of this developmental defect can probably be attributed to the closely related POU protein Brn2, which is co-expressed with Oct6 in Schwann cells. During normal development, Brn2 is expressed at lower levels than Oct6 in Schwann cells. As a result, the loss of Brn2 does not lead to a noticeable change in pattern or timing of Schwann cell differentiation. Once Oct6 is experimentally deleted, a compensatory upregulation of Brn2 occurs, and these increased Brn2 levels may now be able to overcome the arrest of Schwann cell development in Oct6-deficient mice.

In agreement with functional redundancy between Oct6 and Brn2, the overexpression of a Brn2 transgene rescues the developmental delay of Oct6-deficient Schwann cells. Simultaneous loss of Oct6 and Brn2, on the other hand, causes affected Schwann cells to persist in the promyelinating stage much longer than if they were only Oct6-deficient. Accordingly, compound mutant mice show a myelination delay of more than 8 weeks, compared to the 2 weeks in Oct6-deficient mice. Nevertheless, some residual capacity to enter the myelination stage is retained. At present, it is unclear why that is, but Oct-1, a ubiquitously expressed POU homeodomain protein distantly related to Oct6 and Brn2, could be responsible. In contrast, Brn-5, another POU homeodomain protein that is expressed in the Schwann cell lineage, was excluded as a compensating factor because it is predominantly expressed in myelinating Schwann cells and was unable to rescue the Oct6 phenotype when overexpressed as a transgene in Oct6-deficient Schwann cells.

It has long been controversial whether Oct6 (and by analogy Brn2) functions as a transcriptional activator or repressor. Differential display studies on the sciatic nerves of wild-type and Oct6-deficient mice have preferentially identified genes that are downregulated in the absence of Oct6, thus pointing to a primarily activating role of Oct6 in Schwann cells, although it has not been established that the identified genes (including the genes for the fatty acid transporter P2, the amino acid transporter tramdorin1, and the LIM domain protein cysteine-rich protein (CRP)2) are directly activated by Oct6.

There is very good evidence that the Krox20 transcription factor is under the direct positive control of Oct6. Studies in transgenic mice have identified an

enhancer 35 kb upstream of the transcriptional start site of the mouse Krox20 gene that is responsible for Krox20 expression in Schwann cells and that at the same time depends for its activation on Oct6 binding. Interestingly, Oct6 is not the only transcription factor that binds to the enhancer. There also are several recognition elements for Sox10, which is still strongly expressed in Schwann cells during the promyelinating stage. The enhancer is cooperatively activated by Oct6 and Sox10, and it is likely that *in vivo* cooperative activation is responsible for the dramatic upregulation of Krox20 expression in promyelinating Schwann cells.

It is also assumed that Oct6 is not only needed for the progression from the promyelinating to the myelinating stage but has additional, possibly repressive, functions during the early phases of myelination. This assumption is supported by the continued Oct6 expression in young myelinating Schwann cells. However, proof of these additional functions in myelinating Schwann cells is difficult to obtain in the currently available mouse models. In older myelinating Schwann cells, Oct6 is eventually downregulated. Interestingly, Oct6 itself is involved in its downregulation, pointing to the existence of a negative autoregulatory loop.

Finalizing Myelination

The dramatic upregulation of Krox20 in promyelinating Schwann cells follows that of Oct6, in accord with the epistatic relationship between both transcription factors. One of the functions of Krox20 is to suppress the immature state. It inactivates the proliferative response of Schwann cells toward their major axonal mitogen neuregulin 1. At the same time, Krox20 makes the cells less susceptible to cell death. To achieve this, Krox20 prevents the c-Jun N-terminal kinase (JNK)-dependent phosphorylation of cJun which is required for both the proliferative and the apopotic response of immature Schwann cells. As a consequence, Krox20-deficient Schwann cells are arrested in the promyelinating stage, but in contrast to Oct6-deficient Schwann cells, the block is permanent. There is additional evidence that Krox20 is involved in the downregulation of its activator Oct6 because Oct6 expression continues in Krox20-deficient Schwann cells.

Krox20 is also actively involved in establishing the myelinating stage. As is evident from gene expression profiling, most myelin genes and lipid biosynthetic enzymes are under direct or indirect control of Krox20. Confirming the link between Krox20 and myelin gene expression, several human patients have been identified with heterozygous mutations in Krox20. These heterozygous mutations manifest themselves as congenital hypomyelinating neuropathies or peripheral neuropathies of the Charcot–Marie–Tooth type 1 and Dejerine-Sottas syndrome, which are more frequently observed for genetic disturbances of myelin genes, including MPZ, PMP22, and Connexin-32. The patients' phenotype is thus compatible with a function of Krox20 during terminal differentiation of myelinating Schwann cells.

Regulating Myelin Gene Expression

In myelinating Schwann cells, Krox20 directly binds to the Nab1 and Nab2 cofactors. This cofactor interaction is crucially important for Krox20 function because mice deficient for Nab1 and Nab2 show defects in peripheral myelination similar to Krox20-deficient mice. Although Nab1 and Nab2 have been shown to function as repressors of Krox20 *in vitro*, the observed phenotype in Nab1/Nab2-deficient mice suggests that *in vivo* they are coactivators as well as corepressors.

It is unlikely that the Krox20–Nab1/Nab2 complex alone is responsible for the activation of all myelin genes and key enzymes in lipid metabolism. Thus, Schwann cells express transcription factors that have been associated with the transcriptional regulation of lipid metabolism in other tissues, including sterol regulatory element binding protein (SREBP)1 and SREBP2, the δ isoform of C/EBP, and the δ isoform of peroxisome proliferator-activated receptor (PPAR). Their increasing expression levels during myelination is compatible with a similar role in Schwann cells. Several SREBP target genes have been shown to be synergistically activated by SREBPs and Krox20 in tissue culture.

Another transcription factor with potential relevance for the myelinating stage of Schwann cells is the still expressed Sox10. Although a role of Sox10 during peripheral myelination has not been formally proven *in vivo*, there are several lines of evidence to implicate Sox10 in the process. The first comes again from the analysis of myelin gene expression in tissue culture. Thus, Schwann-cell specific regulatory regions of the MPZ, MBP, and Connexin-32 genes are all activated by Sox10. In case of the MPZ gene, an intronic enhancer appears to mediate this activation and is synergistically activated by Sox10 and Krox20. The Connexin-32 promoter is likewise synergistically activated by Sox10 and Krox20. Sox10 and Krox20 may thus cooperate in the activation of many genes during myelination, just as Sox10 cooperated during earlier phases of Schwann cell development with other transcription factors such as Oct6 during Krox20 activation in promyelinating Schwann cells.

The second piece of evidence for a role of Sox10 in peripheral myelination comes from patients with peripheral myelinopaties. Some carry heterozygous mutations in Sox10. Others have been found to carry mutations in a region of the Connexin-32 promoter that binds Sox10 and mediates Sox10-dependent activation. A role in myelination has already been proven for Sox10 in the oligodendrocytes of the central nervous system. Similar to Schwann cells, oligodendrocytes express Sox10 from earliest time, but in contrast to Schwann cells, they do not depend on Sox10 until terminal differentiation because of the additional presence of the closely related and functionally redundant Sox9. When Sox9 is downregulated in oligodendrocytes immediately before terminal differentiation, Sox10 function becomes evident and myelination is disrupted in the central nervous system of Sox10-deficient mice.

Open Questions

Although many transcription factors have been identified over the last years that contribute to Schwann cell development, there are still obvious gaps in our knowledge. Transcription factors that drive the transition from the Schwann cell precursor to the immature Schwann cell are, for instance, still unknown. In addition, several transcription factor families with important roles as developmental regulators in other neural cell types are missing from the list of Schwann cell regulators. The most conspicuous example concerns cell-specific (class B) basic helix-loop-helix (bHLH) proteins which, as proneural proteins, influence fate decisions in central and peripheral neurons as well as central glia. Because both Id proteins as the negative regulators of bHLH proteins and class A proteins as the heterodimerization partners for class B bHLH proteins have already been detected in Schwann cells, it is only a matter of time before a Schwann-cell-specific bHLH protein is identified. Many transcription factors thus remain to be discovered to complete the picture.

More and more findings point to functional interactions between already identified transcription factors, as exemplified by the cooperative activation of myelin genes by Sox10 and Krox20. Such interactions and cross-regulatory activities are probably essential for Schwann cell development. It is highly unlikely that the regulation of Schwann cell development can be explained by the isolated actions of a handful of cell- and stage-specific transcription factors; rather, their combination and cross-talk with more widely expressed transcription factors drive Schwann cell development. A second challenge thus is to find out how Schwann cell transcription factors influence one another's activity and to establish an integrated picture of the transcriptional network in Schwann cells.

Given the fact that lineage progression in other cell types is strongly associated with changes in chromatin structure, it can be safely assumed that such epigenetic changes are also relevant to Schwann cell development. Up until now, the question of how transcription factors influence chromatin structure has been barely addressed in Schwann cells and will certainly be an issue in the future.

Last, transcriptional regulation of Schwann cell development is thought to reflect many of the principles that are active during remyelination following nerve injury. Several transcription factors have indeed been shown to contribute to both processes. However, whether transcriptional control of remyelination is indeed a recapitulation of the regulatory events during Schwann cell development still requires rigorous testing.

Introduction – Neural Induction as a Complex Process

Embryonic development involves the progressive restriction of the fates of initially pluripotent cells to different cell types, arising at the correct locations in the embryo and at the right time. Surprisingly, only a few signaling pathways (as few as seven or eight different classes) appear to be involved in all of these cell fate choices. As in music, where an infinite number of tunes can be played by arranging only a few different notes in precise combination, order, and duration, the timing of the sequence of signaling events is critical in directing cells to their ultimate fates.

Over the past two decades, we have learned considerably about the roles of these different signaling pathways, in large part due to research on embryos of the South African clawed toad frog, *Xenopus laevis*. This species lays large eggs which do not change in volume during early development, permitting genes to be misexpressed or their function inhibited in the entire embryo or a part thereof. This is done by injection of RNAs encoding a gene product of interest, or inhibitory, mutant versions of it (including antisense morpholino oligonucleotides), into one of the cells (blastomeres) arising during the first few cell divisions, and studying the consequences at a later stage of development. This approach has been particularly powerful in identifying the critical signaling pathways that influence cell fate choices in the early embryo. However, because all signaling pathways are used repeatedly during development, the usefulness of the misexpression approach is limited to the study of the very earliest developmental events. It was this approach that led to the identification of fibroblast growth factors (FGFs) and Nodal (a member of the transforming growth factor-β family) as critical players in the induction of the mesoderm, when misexpression and loss of function approaches were combined with the 'animal cap assay' designed by Pieter Nieuwkoop to study this particular inductive event in the late 1960s. The animal cap assay involves isolation of the animal pole of the blastula-stage embryo (which does not normally contribute to mesoderm), which is then cultured in a neutral medium – the cap can be cut from embryos injected with control RNAs or with experimental constructs, or can be treated with protein factors added to the medium.

Although the animal cap assay was designed specifically to study mesoderm induction (precisely because it does not normally contribute to this tissue), it has also been extended to study neural induction and to other, somewhat later developmental events. This approach, along with other experiments (summarized in Figure 1), led to the influential 'default model,' which proposes that inhibition of bone morphogenetic protein (BMP; another member of the transforming growth factor-β family) signaling is sufficient to cause animal pole cells to adopt a neural fate. However, BMP signaling is also critical for other patterning and inductive events that take place either earlier than or at the same time as neural induction, making it rather difficult to separate these processes from a direct role purely in neural induction. In particular, inhibition of BMP is first required to specify the 'dorsal' side of the whole embryo (where gastrulation will begin) and where Spemann's organizer will arise. Then, different levels of BMP specify different types of mesoderm: the higher the level, the more ventral the mesoderm. The mesoderm arises from the equatorial region of the embryo. Therefore, treatments that alter the levels of BMP signals from the earliest stages of development will affect all of these processes and the assay will reveal the cumulative effects of the treatment on all of the intervening events as well as any indirect consequences.

An additional problem with studying neural induction using this approach is that the animal cap does contain cells whose normal fate is to contribute to part of the nervous system (especially neural crest, but also some central nervous system, depending on the size of the cap excised). It is therefore impossible to exclude the possibility that by the time it is isolated, the cap has already received some of the signals required by cells to be specified as neural. Thus, the animal cap assay makes it impossible to distinguish a truly 'instructive' induction from a merely 'permissive' event that is part of a more complex cascade.

It is therefore not surprising that, although there is considerable evidence consistent with the proposals of the default model (summarized in Figure 1), some experiments in both the chick and in the frog (especially those that do not rely exclusively on early misexpression and on the animal cap assay) are not so consistent and reveal more complexity (summarized in Figure 2). In *Xenopus*, inhibition of BMP signaling in one early blastomere (A4) whose progeny does not include any part of the nervous system is not sufficient to induce expression of neural markers. In addition, when the FGF pathway is inhibited with a dominant-negative FGF receptor or with a chemical

Figure 1 Experimental evidence consistent with the default model. Control animal caps (a) will develop as epidermis; neural markers (+, expressed; –, not expressed; na, not applicable) are expressed when caps are excised from embryos injected with constructs encoding bone morphogenetic protein (BMP) inhibitors (b), or when a BMP antagonist is added to the medium in which caps are cultured (c). Dissociation followed by reaggregation of animal cap cells causes neural differentiation (d), while addition of BMP proteins to the culture medium reverts this effect (e). In whole embryos, the neural plate (blue) develops from the dorsal side (f); when BMP inhibitor constructs are injected into one of the blastomeres at the two-cell stage, the neural plate is expanded in the injected side (g), while injection of BMP at the same stage leads to a drastic reduction in the size of the neural plate (h). Early depletion of BMP antagonists, by injection of antisense morpholinos against Noggin, Chordin, and Follistatin in the whole embryo, leads to expression of BMP molecules in the neural territory and causes severe ventralization of the whole embryo and almost complete abrogation of the neural plate (i). The opposite experiment (j), depletion of three BMPs (BMP2, BMP4, and BMP7), which effectively eliminates BMP signaling in the whole embryo, produces dorsalized radial embryos expressing neural markers throughout the ectoderm.

inhibitor (SU5402), animal caps from embryos injected with a BMP antagonist no longer form neural tissue, suggesting that FGF signals are required in addition to BMP inhibition to specify neural fates. Interestingly, in the ascidian *Ciona intestinalis* (a basal chordate), it is FGF rather than BMP inhibition that is responsible for inducing neural fates, suggesting that a requirement for FGF in neural induction is an ancestral feature of this process.

In the chick embryo it is possible to introduce DNA constructs or morpholinos at virtually any chosen stage of development and in precisely selected groups of cells. In addition, the chick embryo contains a very large region which never contributes to any part of the nervous system in normal embryos, although it is competent to do so in response to grafts of the organizer (Hensen's node, at the tip of the primitive streak, which is analogous to the amphibian dorsal lip of the blastopore). Experiments (Figure 2) combining grafts of the organizer with a time-course analysis of gene expression at intervals following the graft first revealed that neural induction is a relatively long process: if an organizer is grafted and then removed after different periods of time, it can be shown that a period of contact as long as 13 h is required before the cells that had been exposed to organizer signals express definitive central nervous system (CNS) markers (such as the transcription factor Sox2). Within a shorter time, the organizer does induce transient expression of some markers, such as Sox3 (which appears after about 3 h) and the 'early response to neural induction' marker (ERNI; which is induced after just 1 h). Despite the induction of these markers, however, cells expressing them revert to a nonneural fate and do not express Sox2 or form a neural plate if the organizer is removed. Inhibition of BMP after 5 h of contact with the organizer can, however, stabilize the expression of Sox3, but is still not sufficient for induction of either Sox2 or of a neural plate.

The evidence suggesting that BMP inhibition is not sufficient for neural induction in the chick embryo also includes the fact that the timing of expression of the BMP antagonists implicated in this process in the frog (such as Chordin, Noggin, and Follistatin) does not entirely fit with the period during which the chick organizer is able to induce neural markers: Chordin is expressed in the organizer at a stage when this tissue can no longer induce, while Noggin and Follistatin are not present at all at the inducing stages and appear only in nonorganizer tissue at later stages. Likewise BMP4 and BMP7 (the BMPs implicated as the inhibitors of neural fate in the frog) are not ubiquitously present

Figure 2 Experimental evidence inconsistent with the default model. Analysis of the time course of neural induction, after grafts of the organizer (Hensen's node), shows that while 13 h of contact between the organizer and the host ectoderm is required for full neural induction (a), 5 h of contact induces transient expression of early neural markers (e.g., Sox3 and ERNI) (b). Contact for 5 h is also required to sensitize the ectoderm to bone morphogenetic protein (BMP) inhibitors such as Chordin (c). Manipulation of BMP levels at the border of the neural plate affects the size of the neural plate: when Chordin (BMP antagonist) is expressed at this border, the neural plate is expanded (d); misexpression of BMP4 at this site causes narrowing of the neural plate (e). Overexpression of BMP in the neural plate territory does not affect the expression of early neural markers (f) (although it does abolish Sox2 expression at a later stage), while inhibition of BMP in the nonneural ectoderm does not induce neural markers (g). Dissociation of either chick epiblast (h) or of zebra fish animal caps (i) does not lead to neural differentiation. In *Xenopus*, injection of BMP antagonists at the 32-cell stage into a blastomere (A4) that is fated to give rise predominantly to ventral epidermis is not sufficient to trigger neural marker expression in the progeny of the injected cell (j). Animal caps excised from embryos injected with both a dominant-negative fibroblast growth factor (dnFGF) receptor and BMP antagonists (Chordin or Noggin) do not express neural markers. *, Expression of only early neural markers; **, expression of early and definitive neural markers; ***, induction of a neural plate; na, not applicable.

throughout the early embryo before neural induction as they are in *Xenopus*. Finally, inhibition of BMP (by Chordin, Noggin, or intracellular antagonists) is not sufficient to induce any neural marker in the chick, even when combined with or preceded by application of FGFs to the same cells. However, inhibition of BMP is undoubtedly required for neural induction, since when BMP4 is misexpressed in the prospective neural plate it prevents expression of Sox2 (but not Sox3). Moreover, when BMP levels are manipulated at the border of the neural plate (prospective neural crest/placode territory, somewhat equivalent to the animal cap of *Xenopus*) the size of the neural plate is affected: higher levels of BMP narrow the neural plate, while lower levels expand it.

Experiments using explants of prospective neural plate or prospective epidermis from pregastrula-stage embryos, either cultured alone or in the presence of various peptide growth factors, suggested that in addition to FGF and BMP inhibition, inhibition of Wnt signaling may also be important. However, in whole embryos, it is still impossible to impart neural identity to competent cells even with a combination of all three of these signals.

These results suggest that neural induction is likely to be the result of a more complex and relatively long cascade of sequential signaling events, involving both FGF signals and inhibition of BMP, but also other signals which are still unknown. They also suggest that cells at the anterior and lateral borders of the neural plate are particularly sensitive to the level of BMP signaling.

The Timing of Neural Induction

The classical experiments of Spemann and Mangold (published in 1924) and subsequent studies in various species suggested that neural induction probably occurs at the gastrula stage, after the mesoderm has been specified and patterned to some extent. However, experiments in the chick using explanted tissues as well as studies of the expression patterns of very early 'preneural' markers suggested that cells are already started along the cascade that will lead to the acquisition of neural fates at much earlier stages, even preceding gastrulation and before the organizer forms. ERNI and Sox3 are two such markers. Both are induced by, and require, FGF, but neither this

Figure 3 A model for the sequence of events that initiate neural induction in the chick embryo. (a) Before gastrulation, the epiblast (upper disk) is induced to express the early, 'preneural' markers ERNI and Sox3 by fibroblast growth factor (FGF) secreted by the extraembryonic endoderm (hypoblast; lower gray disk). At this time the posterior (right) margin of the epiblast expresses Nodal, but its activity is blocked by its inhibitor Cerberus, which is also produced by the hypoblast. (b) Gastrulation begins when the hypoblast (and Cerberus expression) moves away from the Nodal-expressing region: this releases Nodal signaling, which cooperates with FGF to induce the formation of the primitive streak. Cells ingress from the surface of the epiblast into the primitive streak to form mesoderm and endoderm. (c) Continued exposure of the epiblast that still remains on the surface to FGF from the hypoblast now induces expression of the zinc finger transcription factor Churchill. (d) A target gene activated by Churchill is *Sip1*, which encodes another zinc finger transcription factor that blocks two genes (*Brachyury* and *Tbx6L*) required for ingression of cells into the primitive streak. This effectively ends the process of gastrulation next to the anterior parts of the primitive streak and therefore causes *Churchill*$^{+}$/*Sip1*$^{+}$ cells to remain on the surface and become committed to a neural plate fate.

signal nor the expression of these early markers is sufficient for neural plate formation (Figure 3). At this early stage, FGF8 (the most likely candidate for an initial inducing signal) is expressed in an extraembryonic tissue (called the hypoblast in chick, rabbit, and human embryos, the equivalent of which is the anterior visceral endoderm (AVE) in the mouse); this tissue can induce the expression of these early preneural markers when grafted to an ectopic site, even though neither the chick hypoblast nor the mouse AVE can induce a neural plate in the same assay. It is therefore likely that neural induction is initiated by signals from the hypoblast/AVE but that acquisition of a neural plate fate occurs only after the initial induction has been reinforced and completed by signals from other tissues, most likely to be the organizer itself and its derivatives (such as the notochord, prechordal mesendoderm, and perhaps paraxial mesoderm). Importantly however, the early organizer contains both the early and the later signals (or the cells that are a source of the latter), explaining why grafts of the organizer are sufficient to induce a complete nervous system even if it does not normally do all this in the embryo.

FGF8 can induce expression of ERNI, Sox3, and Churchill (a zinc finger transcription factor, which in normal embryos is expressed in the forming neural plate from the end of gastrulation) in a competent

region of the chick embryo that is not fated to contribute to the neural plate. However, these three markers are induced at different times following exposure to FGF: ERNI is induced after 1–2 h and Sox3 after 3 h, and Churchill induction requires 4–5 h. Loss-of-function experiments suggest that both Sox3 and Churchill are functionally required for neural induction to produce a neural plate expressing Sox2. These findings suggest that even a single initial signal can trigger events that follow each other in time. Although we do not yet understand the mechanisms that regulate the timing of onset of expression of these different markers, this is likely to involve complex interactions and feedback mechanisms within the responding cells. It may well turn out that, as in music, the duration of each signal is just as important as the sequence in which they are experienced by cells.

Not Just a Decision between Neural Plate and Epidermis

In the experiments of Spemann and Mangold and those that followed them, the organizer was usually grafted ventrally, adjacent to a region of the embryo whose fate is normally to give rise to epidermis. This led to the generally assumed view that neural induction is a decision between these two fates: skin as opposed to nervous system. However, a study of the expression and functions of early 'preneural' markers suggested that, in addition, neural induction also requires cells to decide between mesodermal and neural fates, close to the midline of the embryo. Functional studies of transcription factor Churchill suggested that it encodes a transcriptional activator, the target of which is another zinc finger transcription factor called Sip1 (Smad-interacting protein-1), which in turn inhibits expression of the primitive streak gene *Brachyury*, required for ingression of cells to form mesoderm. Therefore the onset of Churchill expression marks cells that will no longer ingress to form mesoderm and which will therefore remain on the surface of the embryo, where they can form a neural plate if they receive the remaining signals required to complete the process. Interestingly, Sip1 was originally isolated as a direct partner of Smad-1, a critical effector of BMP signaling, suggesting perhaps that Churchill/Sip1 are part of a mechanism required to sensitize cells to levels of BMP signals, perhaps explaining why cells that have not been exposed either to an organizer or to FGF signals for at least 5 h do not appear to be responsive to BMPs or their antagonists. Thus, neural induction comprises not only a decision between neural plate and epidermis at its lateral boundary, but also the decision to stop ingressing (gastrulation) so that cells can remain on the surface to give rise to neural plate, at the midline. These results are summarized as a model in Figure 3.

Importantly, exposure to FGF and absence (or low levels) of BMP are both required along with Nodal signaling to initiate gastrulation and for specifying the organizer. Although the hypoblast/AVE do produce FGF8 and BMP antagonists, both of these tissues paradoxically inhibits primitive streak formation in both chick and mouse embryos. This is due to their expression of Cerberus and Lefty-1, which inhibit Nodal. Thus, FGF signals are required in parallel to specify mesendoderm and for the initiation of neural induction, but different cells within the epiblast are destined to form mesendoderm and neural plate. It is the duration and timing of these signals as well as the position of the cells when they receive them that determine which of these fates (mesendoderm, neural plate, or epidermis) they will adopt.

Taken together, these findings reveal several distinct stages in the neural induction process: first, an FGF signal induces, sequentially, expression of ERNI, Sox3, and Churchill. Then, Churchill (via Sip1) inhibits ingression of cells, preventing them from forming mesendoderm and causing them to stay on the surface. These surface cells become sensitive to both BMP inhibition and to other signals required for formation of a Sox2-expressing, mature neural plate. BMP inhibition stabilizes the expression of early markers (Sox3) but is not sufficient to induce Sox2.

Conclusions – Neural Induction Is Not Yet a Solved Problem

The experimental findings discussed here reveal that neural induction is likely to be the result of a sequence of signaling events rather than a single signal. Although BMP inhibition is required for cells to acquire a neural plate fate, this is insufficient, and other signals, including FGF (but not only this factor), are also required. Moreover, formation of a neural plate also requires mechanisms that cause cells to remain superficial in the embryo and prevent them from gastrulating. While some of these signals are starting to be uncovered, it is becoming clear that there are several other pathways that must be involved. These other pathways still remain to be found, as are the precise interactions between these different pathways, which are likely to be very complex.

The timing and spatial pattern of expression of the earliest marker, ERNI – which is initially expressed in a large territory, including the entire future neural plate, and is downregulated just before the appearance of Sox2 expression – raise the possibility that ERNI might act as an antagonist of commitment to neural plate identity. However, BMP inhibitors and Wnt

antagonists (either alone or when combined with each other and with FGF) are not sufficient to downregulate ERNI expression. Among the many questions that still remain open about neural induction, it will be particularly interesting to explore whether the signals that cause the downregulation of ERNI expression are the missing signals required alongside FGF and BMP inhibition to commit cells to a neural plate fate, and which trigger initial expression of Sox2.

Introduction

Since the 1906 publication of Charles Sherrington's *The Integrative Action of the Nervous System*, the concept of neurons as integrators of synaptic inputs has become a central tenet of neuroscience. Neural circuits integrate information in various ways: summating spatially, receiving converging inputs from different sensory modalities, bridging sensory and motor pathways, combining reward and cognitive signals, and so forth. Integration of information in the temporal domain, the topic of this article, has been increasingly recognized in recent years to be important for a variety of brain functions. Time integration is defined as the mathematical accumulation of an input signal so that the resulting output reflects the running total of the input. Networks in the nervous system can exhibit a great diversity in the 'integration time' during which they compute and store this running total. Typically, neurons are leaky devices with an integration time of tens of milliseconds. However, some neurons or neural networks can have a very short integration time constant (a few milliseconds or less); such 'coincidence detectors' can be activated only by synaptic events that are precisely synchronized. At the other extreme, neurons of certain brain areas behave as if their characteristic time constant was effectively infinite. Not only do they perform time integration of inputs without noticeable leak during stimulation but also they maintain the memory of the integrated signal after the stimulus is withdrawn, in the form of self-sustained persistent activity.

The first neural integrators were discovered in the oculomotor system in the 1960s when it was realized that motor command neurons signaled the velocity of eye movement, whereas downstream motor neurons encoded the eye position (Figure 1(a)). Therefore, an integration operation is required to convert velocity signals into position signals. Functionally, such neural integrators are well suited to implement oculomotor control, just like integrators commonly used in feedback control systems by engineers. Similarly, in the head direction system, which is part of the spatial navigation system and signals the animal's directional heading, the inputs from the semicircular canals encode the head velocity, which is integrated by head direction cells into the positional signal that conveys the orientation of an animal's head in space (Figure 1(b)). When the head is still, head direction cells show elevated and directionally tuned persistent activity in the absence of external inputs.

These examples illustrate two encoding schemes of neural integrators – 'rate code' and 'location code.' In a rate code, exemplified by the oculomotor system (Figure 1(a)), the integrator accumulates the signal in the firing rate of the neurons and the persistent firing rate of each neuron varies monotonically with the encoded feature. By contrast, in a location code as used in the head direction system (Figure 1(b)), each neuron exhibits a bell-shaped tuning curve of an encoded feature with peak response at a particular 'preferred' feature. When a particular value of the encoded feature (e.g., a particular head direction) is being stored, neurons with preferred features similar to this value will be highly excited and neurons with more dissimilar preferred features will be less excited. This creates a localized activity profile across the population known as a 'bump' of neural activity, and the encoded feature (e.g., the current direction of the head) can be read out from the peak location of this bump. If velocity signals smoothly move this bump of activity around the neural population, then the location of the bump can represent the integral of the velocity input. In other words, the stimulus feature is specified by 'which neurons are active' in a location code and by 'how high the neural activities are' in a rate code. Mathematically, a perfect integrator is described by $dX/dt = I(t)$, where $I(t)$ is the input, and X is either the peak locus of network activity (in a location code) or the neural firing activity level (in a rate code).

Based on the mathematical properties of integrals in the sense of calculus, neural integrators are expected to be capable of certain computations of special importance to higher cognitive functions. For example, if a signal suddenly vanishes, its integral remains at exactly the same level as that before disappearing. This is suggestive of a memory system. Indeed, in a delayed discrimination task in which a monkey is required to actively remember the frequency of a vibrotactile stimulus during a memory period of a few seconds, neurons in the prefrontal cortex (a cortical area known to play a critical role in working memory) have been found to exhibit graded persistent activity that changes monotonically with the intensity of the transient somatosensory stimulus (Figure 1c). As another example, the integral

Figure 1 Experimental evidence for neural integrators in various systems reveals two principal coding schemes: 'rate code' and 'location code.' (a) In the oculomotor system, eye velocity-encoding motor commands from neurons in brain stem nuclei occur in the form of bursts at the time of each saccade but not during gaze fixation. However, neurons downstream fire tonically during fixations to maintain the eye muscles' tension and, thereby, the eye position (a.2). The neural integrator of the oculomotor system was hypothesized to explain how transient inputs as in a.1 (bottom) result in sustained responses as in a.2. Neurons in the oculomotor neural integrator show a rate code: The eye position is encoded in their average rate of sustained firing (a.3). (b) Input to head direction (HD) neurons comes from neurons in the brain stem that fire at the time of head rotations, with the firing rate encoding the angular velocity of head rotations. (b.1). HD neurons encode the integral of this signal and fire maximally only when the head points in a specific direction (b.2). The ensuing code, when plotting the average rate of the cell as a function of the HD, is a location code where neurons firing maximally encode the current HD (b.3). (c) In a task in which the vibration frequency f_1 of a tactile stimulus needs to be remembered over a delay period in order to compare it with another frequency f_2 (c.1), neurons in the prefrontal cortex present sustained firing during the delay period, which depends on f_1 (c.2; colors correspond to different values of f_1 as indicated in c.3). Using a rate code, these cells encode in their average delay firing rate the frequency f_1 (c.3). of a constant signal is a linearly increasing function. A neural integrator will thus be able to accumulate evidence in favor of alternative propositions in a decision process. When alternatives with a barely discernible difference in their sensory inputs are presented over an extended period of time, an integrator can accumulate the small differences over time until it can eventually discriminate the alternatives through

its ever growing output. This accumulation dynamics is at the heart of the 'drift diffusion' model for reaction time decisions in the psychological literature. Neurophysiological studies using behaving monkeys have found single neuron activity in the posterior parietal cortex that is correlated with accumulation of sensory information during perceptual decisions. Also, drawing on the response of a neural integrator to a constant input, a clock can be built. If the neural integrator is reset each time it reaches a prespecified value, the resets will occur at uniform intervals as the ticks of a clock. Some authors have hypothesized that this scenario represents a candidate neural mechanism by which time intervals can be estimated.

This body of experimental evidence reveals that integration is a fundamental neural computation in the brain, and quantitative neural models have begun to yield clues as to what likely mechanisms underlie this operation in neural circuits and what theoretical concepts need to be explored experimentally. In this article, we present an overview of the computational models of neural integrators. We first define and discuss key concepts that underlie the construction of these models, and then we present some representative models that operate through several specific mechanisms. Finally, we discuss challenges and perspectives for future research on neural integrators.

From Concepts to Cellular Mechanisms

Time integration involves two basic operations. First, during stimulation, a neural integrator needs to additively increase or decrease its output in response to excitatory or inhibitory input signals, respectively. Second, a neural integrator should have a memory capability to store the running total of inputs. Neither integration over a long timescale nor memory of the running total is obvious from a neurophysiological standpoint because leakage of neuronal currents out of the membrane tends to make a neuron forgetful. As a result, the duration over which a neuron can temporally sum incoming synaptic potentials is limited by its membrane time constant. To achieve long integration times, most models therefore incorporate tuned positive feedback that serves to offset the intrinsic leakage of membrane currents. This positive feedback is most often in the form of synaptic feedback in a recurrently connected network, but it has also been implemented as feedback loops in the intracellular signal transduction pathways within a single neuron.

To illustrate how positive feedback can lead to integration, consider a simple model of a neuronal pool with a mean firing rate r and a synaptic connection to itself of weight w (Figure 2a). A pulse of external input to the neuronal pool leads to an immediate change of firing rate. When the input terminates, the induced change in firing rate is sustained by reverberating input arriving through the recurrent synaptic connection. In this manner, the network both summates and stores external signals.

Quantitatively, integration by this simple network can be described by the firing rate equation:

$$\tau_{\text{neuron}} \frac{\mathrm{d}r}{\mathrm{d}t} = -r + wr + I(t) \qquad [1]$$

where r represents the mean firing rate of the neuronal pool, w is the strength of the synaptic connection, $I(t)$ is the external input to be integrated, and τ_{neuron} is the intrinsic decay time constant of neurons in the pool. The first term on the right-hand side represents the intrinsic neuronal 'leak' processes which, in the absence of feedback ($w = 0$), lead to rate decay with time constant τ_{neuron}. The second term, wr, gives the total positive feedback, which is proportional to the strength of the feedback connection and increases with the neural activity level. The effective time constant of the network is given by

$$\tau_{\text{integrator}} = \frac{\tau_{\text{neuron}}}{|1 - w|} \qquad [2]$$

For instance, when a constant external input is presented, activity in this model exponentially approaches a steady-state level (given by $I/(1-w)$) with time constant $\tau_{\text{integrator}}$. This means that the system cannot integrate an input I for a time much longer than $\tau_{\text{integrator}}$, beyond which the neural activity level becomes insensitive to the duration of the stimulus presentation. Moreover, after the input is turned off, the system decays back to zero, and hence the memory about the input is lost, with the same time constant. The system's integration time is fairly short in the absence of positive feedback (when $\tau_{\text{integrator}} = \tau_{\text{neuron}}$), but the integration time can be increased with stronger positive feedback (a larger w).

Perfect integration is achieved when the positive feedback balances the intrinsic neuronal leak processes (Figure 2a, $w = 1$) so that

$$\tau_{\text{neuron}} \frac{\mathrm{d}r}{\mathrm{d}t} = I(t) \Rightarrow r = \frac{1}{\tau_{\text{neuron}}} \int I(t)\mathrm{d}t \qquad [3]$$

This balancing of feedback and leak implies that such models require fine-tuning in order to achieve perfect integration. The tuning criterion can be viewed graphically by plotting the magnitude of the leak term (r) and the feedback term (wr) on the same set of axes (Figure 2, top row). For firing rates at which these terms balance, the network performs perfect integration. When feedback is less than leak, the stored total

Figure 2 Positive feedback as a mechanism for neural integration. (a) Simple model of a neuronal population with positive feedback onto itself carried by a synaptic connection of weight *w*. (Top) When properly tuned, the feedback at any firing rate offsets the intrinsic leak processes that pull the firing rate back toward zero. Dashed red line, intrinsic leak; solid blue line, synaptic feedback. (Middle) The integrated total of external inputs can be conceptually represented by the location of a block along a surface. External inputs that are accumulated by the integrator move the block along the surface. When well tuned, the integrator can stably maintain any accumulated value, corresponding to the block not slipping along the flat surface. (Bottom) Accumulation of pulsed excitatory or inhibitory inputs into sustained firing rates. (b, Top) Model in which the synaptic weight is decreased so that the positive feedback is less than the intrinsic leak at all firing rates. Firing rate drift is proportional to the difference between the feedback and leak traces. (Middle) The model firing rate behavior can be represented by the location of a block on a curved surface, where the curvature is proportional to the firing rate drift in the absence of input. (Bottom) Decrease in the synaptic weight leads to exponential decay of firing rates in the absence of input. (c) A model in which feedback is too large leads to exponential growth of firing rates.

in the integrator leaks away at a rate proportional to the difference between the leak and feedback. In the absence of input, this leads to exponential decay on a timescale $\tau_{\text{integrator}}$ (leaky integrator; Figure 2(b)). Similarly, when feedback is greater than leak, activity exponentially increases with a time constant given by the same formula (unstable integrator; Figure 2(c)).

In a useful conceptual description, the network's output can be represented by the location of a block being pushed along a surface, with the movement of this block representing the dynamics of the network. External inputs slide the block with a velocity proportional to the size of the input. For a flat and level surface (Figure 2(a)), corresponding to a well-tuned network, the position of the block thus represents the integral of the external input. In the absence of input, the block stays in place, corresponding to successful maintenance of the accumulated input. For a mistuned network, the slope of the surface is given by the degree of mistuning – that is, by the difference between the feedback and leak. In this case, even in the absence of input, the position of the block drifts with a velocity proportional to the mistuning. For the leaky network, the mistuning brings the activity back to the origin (Figure 2(b), bottom), whereas for the unstable network, the mistuning leads to unbounded increase in activity (Figure 2(c), bottom).

Although the previously discussed model is highly simplified, it captures the essence of the positive feedback mechanism used by more biologically detailed network models. Because of the strong coupling between neurons that mediates the positive feedback in such networks, only certain activity patterns can be stably maintained internally in the absence of external inputs. These activity patterns are typically assumed to form a continuous, one-dimensional line in the high-dimensional space of all possible firing

patterns; the distance along this line (analogous to the distance of the block along the surface in Figure 2) represents the accumulated total of inputs being stored by the integrator. Activity patterns not along the line decay rapidly to a nearby point along the line so that the line is said to be an 'attractor,' or 'line attractor,' of the networks dynamics.

Specific biological networks differ in their implementation of positive feedback, which may be through excitatory pathways or disinhibitory (hence, effectively excitatory) pathways. They also differ in the topographic organization of the pathways conveying this feedback and in the means by which tuning of this feedback is accomplished: in networks utilizing a rate code, the positive feedback provided to each neuron typically changes monotonically as input is accumulated, and the magnitude of feedback connections is tuned to ensure that activity does not leak or exhibit unstable growth. In networks that utilize a location code, the pathways that mediate the positive feedback are spatially structured to allow a localized bump of activity to be maintained, and tuning of the network is typically accomplished by making symmetric connections between neurons so that the bump of activity can be maintained equally well at any location. Finally, the biophysical substrate of the positive feedback can differ between models, from synaptic feedback in network models to feedback between intracellular variables such as intracellular calcium concentration, membrane potential, and conductance levels in single neuron integrator models. Next, we discuss each of these specific mechanisms and their applications to neural integrators.

Diversity of Model Scenarios

Network Integrator Models

Rate code It is often observed in neural integrator networks that two opposing populations of cells are responsible for accumulating the input. Inputs to these populations are typically arranged in a 'push–pull' manner such that when one population is excited (pushed) by the external input, the other population is inhibited (pulled). Both the oculomotor integrator, which is located in the brain stem, and neocortical integrator networks display such a push–pull organization. In the oculomotor neural integrator, external commands that encode the velocity of an intended eye movement are sent through excitatory connections to one cell population and through inhibitory connections to the opposing population. The network integrates these inputs into sustained differences in firing rate between the two populations, with the excited population exhibiting above-background firing rates and the inhibited population exhibiting below-background firing rates.

Such networks contain two potential synaptic pathways to mediate positive feedback. Excitation between neurons within a population could provide a source of excitatory positive feedback. Inhibition between opposing populations could provide a source of mutual-inhibitory positive feedback whereby the excited population inhibits the opposing population and thereby disinhibits itself.

In the simplest models of this circuit, two neurons representing the opposing populations are assumed to be connected by mutual inhibition that provides a disinhibitory positive feedback loop (Figure 3a, middle). Such a circuit requires tonic excitation to drive neuronal activity. Thus, external inputs (of vestibular origin) consist of two components: a tonic component responsible for the background firing rate of neurons and a modulated component that is excitatory to one population and inhibitory to the opposing population. Common, same-direction changes in the tonic background input to each population lead to a corresponding change in the background firing rates of the two populations but are not integrated over time (Figure 3(a), first step in inputs). Because the eye position in this system is determined by the difference in the outputs of the two populations, such inputs do not lead to a change in eye position. By contrast, oppositely directed changes in inputs to the two populations about this tonic level do lead to an integrated response. The population that receives increased external input exhibits an upward ramp in activity, whereas the opposing population exhibits a downward ramp (Figure 3(a), second step in inputs). The difference between these two outputs, which is a ramp of twice the slope of either individual population, represents the integral of the difference between the commands received by either population. An advantage of this network is that it properly integrates such differences while remaining robust against same-direction perturbations in input rates that might be caused by global changes in background rates. In linear network theory, the integration of input differences and nonintegration of common inputs are termed 'differential mode' integration and 'common mode' rejection, respectively.

Alternatively, integration in the oculomotor neural integrator could be instantiated by excitatory feedback within each population, as illustrated in Figure 2. This idea has been quantitatively examined using realistic conductance-based spiking neurons and synaptic connections. Figures 3(b) and 3(c) show a model of a single population of the goldfish oculomotor neural integrator network, based on finely tuned recurrent excitatory positive feedback. Neurons were

Figure 3 Rate code models of the oculomotor neural integrator. (a) Network model based on recurrent inhibition. Two neurons connected by mutual inhibition receive external inputs from ipsilateral and contralateral sources. Positive feedback is provided by each neuron inhibiting its neighbor and therefore disinhibiting itself. External inputs to the network consist of two components – a 'common' background input that is identical for each of the two neurons and a 'differential' command input that is excitatory to one neuron and inhibitory to the other. Changes in the common component (bottom, first step in inputs) lead to a change in background output levels but are not integrated (top traces). Differences in inputs (bottom, second step in inputs) are integrated by the network, in this case from a step into a ramp. In the oculomotor system on which this model was based, eye position is controlled by a difference between the outputs of two populations represented by these cells. Thus, the network output is robust to common changes in background inputs but is sensitive to differential inputs. (b, c) Integration by a network based on recurrent excitation. (b) Model network consisting of a population of neurons with recurrent excitatory synaptic connections. External commands from excitatory and inhibitory bursting neurons provide the velocity-encoding input for saccades, and vestibular signals provide tonic background input. Eye position is decoded from the network via a first-order model of the motor neurons and oculomotor plant. (c) Integration of bursts into steps of firing rate and eye position by the tuned network. Steps of firing rate in the absence of external command inputs are maintained by recurrent excitation. Different neurons begin firing at different eye positions due to differences in their background input levels. (a) Adapted from Cannon SC, Robinson DA, and Shamma S (1983) A proposed neural network for the integrator of the oculomotor system. *Biological Cybernetics* 49: 127–136. (b, c) Adapted from Seung HS, Lee DD, Reis BY, and Tank DW (2000) Stability of the memory of eye position in a recurrent network of conductance-based model neurons. *Neuron* 26: 259–271.

connected in an all-to-all manner, with each neuron receiving excitatory and inhibitory command inputs to be integrated as well as tonic vestibular background inputs that differed from neuron to neuron (Figures 3(b) and 3(c)). As in Figure 2, active neurons exchanged positive feedback through recurrent synaptic excitation, allowing them to persistently maintain changes in firing rate in response to transient command inputs. However, unlike the simple model of Figure 2, the size of the active population also changed in response to inputs because neurons were sequentially recruited into the network with increasing network activity (with recruitment order determined by the amount of background input each neuron received). To offset the extra source of positive feedback that newly recruited neurons provided to their neighbors, the model assumed that synaptic transmission saturates as presynaptic firing rates increase. This idea of synaptic saturation balancing recruitment of neurons represented a significant step in the realistic modeling of rate-code integrators because it demonstrated how linear accumulation of inputs could occur even in systems with realistic nonlinearities. Experimentally, studies of the goldfish

oculomotor integrator have suggested that integration in this system is generated within each population of the integrator and not through recurrent inhibition between populations. This result is consistent with the idea of integration through excitatory positive feedback, but it is unknown whether single neurons in the system are endowed with intrinsic properties that could also contribute to the integration.

Location code Figure 4 shows schematically a typical neural integrator model in which the encoded feature is specified by the peak location of the network activity profile (location code). Neural networks that show this type of encoding has been used to model many neurobiological computations, from encoding of spatial location by place cells in the hippocampus to spatial working memory in dorsolateral prefrontal cortex. The realization of a neural integrator that utilizes a location code requires two ingredients. First, a continuous family of localized persistent activity patterns (bumps; Figure 4(b)) must be generated, each representing the graded value of the accumulated signal. Such localized activity profiles can be sustained by excitatory reverberation among neighboring neurons as the positive feedback mechanism (Figure 4(a)) or, alternatively, using tonic excitation combined with structured synaptic inhibition that sculpts the network activity profile. Second, a shifting mechanism must enable transient inputs to smoothly move the bump in such a way that the moving speed is linearly proportional to the input amplitude so that the final location of the bump accurately represents the time integral of the input (Figure 4(c)). The head direction (HD) system captures especially well these two aspects of neural integrators using a location code. When an animal turns its head, the angular velocity signal carried by vestibular inputs (Figure 1(b.1)) is integrated over time by HD cells into a positional signal, and the latter is sustained internally when the animal keeps the HD fixed (Figure 1(b.2)). HD cells are selective for angular HD according to a Gaussian (bell-shaped) tuning curve (Figure 1(b.3)).

Interestingly, evidence indicates that HD cells are generated in a neural circuit characterized by a paucity of local excitatory connections. Consistent with this observation, Figure 5 shows a model of HD neurons based on a mechanism without recurrent excitation in which the most active neurons push down their neighbors' activities through cross-directional inhibition rather than lifting up their own activities through isodirectional excitation. Baseline neuronal activities in this model are provided by constant-rate excitatory background inputs, and the direction-selective 'bump of persistent activity' reflects inhibition-driven decreases in activity below these externally driven levels. Moreover, the model surmises that this bump of activity is shifted around the network by 'rotation cells' consisting of two inhibitory cell populations (Figure 5(a)). When the HD is fixed, the inputs from the two inhibitory neural populations are balanced with each other, and the bump of activity in the excitatory neural population is maintained fixed (Figure 5(b), time epochs between input pulses). As the head turns, the angular velocity signal increases the firing of one inhibitory population while decreasing the firing of the other. The resulting asymmetric inhibitory inputs induce the activity pattern in the excitatory neural population to move at a constant speed proportional to the input amplitude (angular velocity) (Figure 5(b), time epochs during input pulses).

Figure 4 A bump attractor ring model as the substrate for a location code integrator. (a) Example of connectivity between neurons in a ring model attractor network. Recurrent excitation among near neighbors underlies positive feedback in the network, whereas growth of firing rates is controlled by nonselective feedback inhibition. When neurons at either end of the network (top) are made to coincide, a ring model network is obtained (bottom). (b) Given appropriate connectivity strengths, the network shows a whole family of stable neural activity states in the absence of external input ('bump' states, in different colors), each of which peaks at a different location on the network. The *x*-axis represents different neurons in the population, labeled by their preferred feature. For each curve, the *y*-axis values represent a possible distribution of firing rates across the population. (c) Bump states remain stably at their locations but can be shifted along the network smoothly by a 'push.' The final location of the shifting bump will be a read-out of the integral of this push force over the time during which it acts on the bump.

Figure 5 Time integration by a bump attractor network. (a) Model scheme. An excitatory neural network, encoding a directional angle (0–360°), receives inputs from two inhibitory neural populations that are balanced with each other when there is no input. A velocity signal increases input to one of the inhibitory populations (+I) and decreases input to the other (−I), leading to a bias for the excitatory network. (b) Network firing pattern (top) in response to a series of input signal steps (bottom). Neurons in the network are aligned along the *y*-axis, labeled by their preferred directional angles. The *x*-axis represents time. Each dot is a spike. The network activity pattern has the form of a bell-shaped profile (top right), with peak location encoding the directional angle (white line). In the absence of an external input, the directional information is maintained by a persistent firing pattern. An input induces the bump of activity to move at a speed proportional to the stimulus amplitude; hence, the network performs a time integral of the input. Simulation by P Song using the model published in Song P and Wang X-J (2005) Angular path integration by moving 'hill of activity': A spiking neuron model without recurrent excitation of the head-direction system. *Journal of Neuroscience* 25: 1002–1014.

Computation performed by the model is quite similar to an integral operation in calculus. When the input intensity is doubled (second vs. first input pulse), the hill of activity moves twice as fast. Moreover, the network can integrate both positive (first and second pulses) and negative (third pulse) inputs. In fact, with the third input of an amplitude half that of the second input, but lasting twice as long, the bump of activity moves back to the position before the second pulse, as expected by perfect integration.

Single Neuron Integrator Models

Neural integrators can also reside in the internal biochemical machinery of a single neuron. Experimental evidence that single cells can exhibit a range of graded persistent activity has been based on recordings in an *in vitro* preparation of rat entorhinal cortical slices (Figure 6(a)). A number of computational models have been built to explore the mechanistic basis of this activity (Figures 6(b)–6(d)). All of these alternative models implicate two principal actors: the muscarinically activated calcium-dependent nonselective cation current (I_{CaN}) and the concentration of calcium in the cytoplasm. The interaction between these two substrates can subserve integration through a positive feedback loop. During neural activity intracellular calcium increases because of the influx of calcium ions through high-threshold calcium channels, increased

Figure 6 Mechanisms of integration in single neurons. (a) When activated cholinergically, synaptically isolated neurons of the entorhinal cortex integrate successive, brief pulses of current injection (I_{inj}; bottom left) into stable graded firing rate levels (top left). This also corresponds to a rate code, where the average rate of the neuron is linearly related to the number of stimuli applied (right). (b) Positive feedback (thick arrows indicated with a + sign) between intracellular calcium entering through high-threshold calcium channels (pink) and calcium-dependent nonspecific cation channels (purple). (Lower panels) Linearly increasing neural response (up to integrator saturation limit) for three distinct step pulse currents. (c) Positive feedback (thick arrows indicated with a + sign) between intracellular calcium and calcium release from internal stores (orange). (Middle) With uniform distribution of these feedback units along a dendrite, stable localization of the calcium front (color code in dendrite) determines the total amount of current I_{CaN} (channels open on the dendrite) summated at the soma. (Bottom) Stable neural firing rate after three consecutive pulses of current. (d) During external stimulation, phosphorylation/dephosphorylation of I_{CaN} channels modifies the balance of intrinsic currents in the neuron and its spontaneous firing rate. No positive feedback is involved in this mechanism. (Lower panels) A computational model based on this mechanism reproduces faithfully the experimental results in (a) (top graph, injected current; bottom graph, neural output). (d) Adapted from Fransén E, Tahvildari B, Egorov AV, Hasselmo ME, and Alonso AA (2006) Mechanism of graded persistent cellular activity of entorhinal cortex layer V neurons. *Neuron* 49: 735–746.

intracellular calcium activates the I_{CaN} current, which in turn admits cations into the neuron, depolarizing it and generating further neural activity (Figure 6(b)). Hence, this is a positive feedback mechanism similar to that of Figure 2, but it is realized at the single cell level rather than by a synaptically interconnected circuit. It has been proposed that a learning algorithm can be used to dynamically adjust the parameters of such a mechanism to generate linearly increasing responses to step current pulses of varying intensity (Figure 6(b)). Alternatively, the fundamental positive feedback loop could be established between the intracellular calcium and intracellular stores of calcium (e.g., the endoplasmic reticulum). The positive feedback occurs because intracellular stores of calcium have been found to release calcium to the cytoplasm upon increases in intracellular calcium (calcium-induced calcium release). In this scenario, I_{CaN} is not part of the positive feedback loop but, rather, serves to translate the calcium level into neuronal activity by providing calcium-dependent depolarizing currents (Figure 6(c)). Models of neural integrators built around this

scenario require a spatial distribution of the positive feedback units in order to generate graded levels of activity. One possibility would be to distribute them continuously along the neural dendrites so that a front between high- and low-calcium regions stabilizes at arbitrary locations on the dendrite (which again requires fine-tuning). Strong bursts of action potentials would progressively move this front toward the soma, enhancing the total amount of I_{CaN} and the stable firing rate of the cell (Figure 6(c)).

The two mechanisms described previously (Figures 6(b) and 6(c)) rely on a biochemical feedback loop that is highly sensitive to small modifications of the neuronal properties (fine-tuning). However, experiments on isolated, cholinergically activated entorhinal cortex neurons (Figure 6(a)) have challenged this modeling framework. In these neurons, both the careful matching of membrane currents and the release of calcium from internal stores do not seem to be necessary for neural integration. This has prompted another mechanistic explanation that does not rely on a positive feedback loop. Instead, a computational model was built based on the hypothesis that phosphorylation or dephosphorylation of I_{CaN} channels is triggered by excessively high or low concentrations of intracellular calcium, respectively. During normal, autonomous neural function it was assumed that intracellular calcium levels do not reach the extreme values required to trigger phosphorylation or dephosphorylation in the model. However, during the long pulses of external current injection tested experimentally, the phosphorylation states of the I_{CaN} channels could be changed. Because the two forms of the I_{CaN} channel have significantly different maximal conductances, these changes permanently modify the balance of currents present in the neuron and thus the basal firing rate (Figure 6d). Furthermore, because the associated basal calcium concentrations are far from the thresholds for phosphorylation or dephosphorylation of the I_{CaN} channel, the normal positive feedback loop between voltage activity, calcium concentration, and I_{CaN} conductance state is broken and the firing rates remain perfectly robust against small fluctuations. However, it is unclear whether it is biologically plausible to assume that at high calcium levels phosphorylation is not counteracted by dephosphorylation so that effectively there is no 'biochemical leak.' Moreover, the robustness does occur at a cost relative to positive feedback models because it also implies that the network is incapable of integrating small inputs. This trade-off between robustness against small fluctuations and insensitivity to small inputs is a feature of several models of neural integrators that attempt to solve the fine-tuning problem.

Hybrid Models Incorporating Synaptic Feedback and Intrinsic Bistability

Integrator models based solely on network mechanisms require fine-tuning of synaptic connection weights in order to perform accurate integration over long timescales. Some models have demonstrated that this need for fine-tuning can be reduced if neurons contain one or more digital elements that only turn on when their inputs are sufficiently large and only turn off again when their inputs are sufficiently small. In the simplest realization of this scheme, an integrator network could be made from N 'bistable' neurons that can exist in either of two stable states for a given level of input – an 'on' (active) state and an 'off' (inactive) state. If external inputs sequentially turn neurons on or off at a rate proportional to the size of the input, then the number of active units at any given time reflect an integral of the external input.

Unfortunately for this simple scheme, experimentally observed integrator neurons have not been found to exhibit such discrete on or off neuronal firing. However, this observation does not preclude the possibility that some fraction of a neuron's inputs are transmitted through bistable elements such as dendritic plateau potentials. For example, Figure 7 shows a network in which a conventional recurrent excitatory positive feedback model was modified to include multicompartmental neurons that each contain multiple bistable dendrites (Figure 7(a)). Dendritic compartments were assumed to generate plateau potentials that turn on when synaptic input exceeds a value s_{on} but do not turn off until the input falls below a lower value s_{off} (Figure 7(b)). The firing rate of each neuron reflects the number of its dendrites that are active, in addition to background and external command inputs. Because the dendrites operate in a digital manner, stored activity in the integrator network can be maintained stably even if synaptic inputs are altered by moderate amounts. As shown in Figure 7(d), the network integrates pulses of inputs into steps of firing rate even when synaptic weights (and hence recurrent synaptic inputs) are altered by an amount that would cause gross decay in firing rates in fine-tuned networks (compare to Figure 2(b)). Conceptually, the effect of the bistability in this model is to add ridges to the bottom of the energy surfaces described in Figure 2 (Figure 7(c)). External inputs to the network, which can be represented by (large) tiltings of the surface, slide the block to a location representing the new accumulated value. Imprecision in tuning of the network corresponds to (smaller) warping of the surface. Unlike the fine-tuned network, this warping does not cause the network's

Figure 7 A hybrid intrinsic network mechanism of integration. (a) Network of multicompartment model neurons. Each neuron projects recurrent excitation of weight W to a single bistable dendrite of each of its neighboring neurons. Neurons also receive external background and command inputs at the soma. (b) Dendrites have a bistable input–output relationship characteristic of a plateau potential. Dendrites are activated when synaptic input exceeds a value s_{on} and deactivated when input falls back below a value s_{off}. (c) The bistable nature of the dendrites can be conceptualized as creating ridges in the surface along which the ball representing the state of the system moves (see **Figure 2**). These ridges make the network output resistant to drift that otherwise would be caused by small perturbations in synaptic connection strength that correspond to warping and tilting of the surface. (d) Robust maintenance of activity in the network. Pulses of input are accumulated into different levels of stable output (rate code). Firing rates can be maintained in the absence of command inputs even when weights are changed by an amount that would cause severe drift in a network without bistable elements (right; compare to **Figure 2b**). (a, b, d) Adapted from Goldman MS, Levine JH, Major G, Tank DW, and Seung HS (2003) Robust persistent neural activity in a model integrator with multiple hysteretic dendrites per neuron. *Cerebral Cortex* 13: 1185–1195. (c) Adapted from Pouget A and Latham P (2002) Digitized neural networks: Long-term stability from forgetful neurons. *Nature Neuroscience* 5: 709–710 (comment on Koulakov AA, Raghavachari S, Kepecs A, and Lisman JE (2002) Model for a robust neural integrator. *Nature Neuroscience* 5: 775–782).

representation of its integrated input to slip as long as the warping is insufficiently large to knock the block out of the divots. However, this robustness against imprecise tuning also implies that the network is unresponsive to small inputs that do not tilt the surface enough to cause the block to slide. A challenge for future models incorporating bistability is to overcome this inherent trade-off between robustness to imperfect tuning and inability to integrate small external inputs.

Accumulation of Information versus Graded Memory

So far, our discussion has focused on perfect time integration in the sense of calculus, which is exemplified by oculomotor neural integrators and HD cells. However, it is important to note that different components of the nervous system are likely to exhibit different types of temporal integration, some less perfect than others, to satisfy a variety of computational demands. In particular, it is useful to distinguish two types of time integration: approximately linear summation of inputs during stimulation (e.g., slow ramping activity in response to a prolonged constant input) and parametric working memory (graded conversion of pulse-like input to plateau-like persistent activity). Figure 8(a) shows a line attractor network model of parametric working memory, which was developed to simulate the monkey delayed somatosensory comparison experiment (Figure 1(c)). Like the prefrontal neuron shown in Figure 1(c), this model produces graded persistent activity, which is approximately proportional to the strength of a transient input pulse and is self-sustained after the stimulus offset. The mechanism underlying graded persistent activity is precisely the tuned positive feedback described in Figure 2 but implemented with a realistic circuit model of spiking neurons. Positive feedback in the model was mediated by NMDA receptors, which have a relatively slow decay time constant of 50–100 ms, reducing the requirement for fine-tuning of synaptic weights. Such a line attractor network can sum inputs in the sense of calculus. However, working together with other neural circuits, or using additional gating input signals, such a network has been shown to be capable of encoding the intensity rather than the duration of a stimulus; that is, the graded persistent activity is proportional to the input amplitude, but if the stimulus is prolonged for increasingly longer durations, the level of neural firing would not grow linearly with time, contrary to a neural integrator. In the somatosensory delayed discrimination task the subject has to encode and remember across a delay the frequency of a somatosensory vibration, not the number of vibrations applied on a fingertip. Thus, the behavioral task requires parametric working memory but not strict time integration of input during stimulation.

Conversely, a neural circuit capable of nearly perfect integration of inputs during stimulation does not necessarily exhibit graded self-sustained persistent activity when the stimulus is withdrawn. This is illustrated in a neural circuit model of decision making (Figure 8(b)). In simulations of a two-alternative forced choice task, firing activity of neurons increases quasi-linearly over time (up to a point) in response to a constant and long-lasting stimulus. Such ramping activity gradually accumulates information about the evidence in favor of one of the two alternative choices, and the rate of ramping activity increases with the input amplitude (corresponding to the quality of sensory evidence) (Figure 8(b)). Later in time, however, competition between neural populations representing the two alternatives ultimately leads to a categorical choice that is manifested by the divergence in the neural activity of the two neural populations. One of them increases while the other decays. Thus, if a decision-based motor response must be delayed, persistent activity during working memory maintenance would be binary. The mnemonic neural firing pattern would not depend on the strength of input in a graded manner but reflect only the categorical choice made during stimulation. This was exactly what was found in lateral intraparietal area neurons in the two-alternative forced-choice version of a visual motion discrimination task and in a discrete attractor network model of decision making and working memory. Graded time integration during stimulation and binary persistent activity during a memory period are not incompatible with each other because the former is a property of neural responses to external inputs, whereas the latter reflects stable states in the absence of inputs. Thus, time integration in decision making does not necessarily require line attractors. Of course, some decision tasks require graded integration of information across temporal gaps, which engage both time integration and parametric working memory. Novel task designs are required to identify the neural activity underlying such decision processes.

Challenges and Future Directions

How neural integrators can be realized robustly by plausible biophysical mechanisms remains a topic of active current research. Current models are based on three ideas. First, positive feedback can create long time constants from much faster decaying biophysical processes. This scenario requires a need for

Figure 8 Graded memory and accumulation of information. (a) Graded memory in a network that converts a pulse-like input into persistent activity. The transient input is presented with a range of amplitudes, and the induced persistent activity after the stimulus offset increases approximately linearly with the input strength. The simulations are from a line attractor model of spiking neurons for the somatosensory delayed discrimination experiment (**Figure 1(c)**). (b) Linear ramping activity during stimulus presentation. Neural activity increases quasi-linearly in time, and it varies stochastically from trial to trial (three trials are shown for each input amplitude). The ramping rate increases with the input amplitude. Such 'ramping-to-threshold' probabilistic neural activity can serve to accumulate information for decision making, or can be used to estimate a time interval. The simulation results are from a discrete attractor network model of perceptual decision making and working memory. fine-tuning that seems unreasonably strict. For neural integrators using a rate code, fine-tuning amounts to adjustment of synaptic weights in the networks, whereas for neural integrators using a location code, fine-tuning implies symmetry of connections and homogeneity of neuronal properties in networks. Moreover, such systems typically display random drifts of neural activity in the absence of external inputs, which would be functionally detrimental. Second, very slow biophysical and biochemical processes naturally provide long time constants. However, systems that are built on processes with very slow kinetics, such as the single neuron integrator cells of entorhinal cortex, suffer from a sluggish response to inputs that does not match the rapid accumulation of inputs exhibited in other systems. Third, nonlinearities such as plateau potentials or thresholds have been used to provide robust behavior in some models but also place constraints on the types of functions that can be integrated. Further progress depends on new experiments that place more constraints on, and establish a firmer mechanistic basis for, computational modeling in this area. What types of inputs a given system does or does not integrate may provide a guide to future models because different mechanisms may be tailored to the system's specific needs. Nevertheless, certain overarching themes, such as positive feedback and analog memory storage of accumulated input levels, are likely to provide a common framework in which to view many systems.

Although most of the current research on modeling of integrators has focused on neural dynamics and robustness to perturbations on fast timescales, an open question concerns what learning rules can assemble and maintain the tuning of such circuits. Experimental evidence for plasticity rules in neural integrators is lacking, and modeling offers the opportunity to suggest appropriate experiments to address this question. Work in the oculomotor system has shown that with altered visual feedback, the oculomotor integrator can be tuned to become leaky or unstable. This suggests that reinforcement learning signals, such as retinal slip for the oculomotor system, can be utilized to tune integrator dynamics. In addition, theoretical work on this system has suggested how spike timing-dependent plasticity could be used in an unsupervised manner to maintain stable firing in the absence of external inputs. In networks utilizing a location code, where proper performance depends on homogeneity across the network so that a bump of activity can be stably maintained at any location, theoretical work has shown how a homeostatic synaptic plasticity rule (synaptic scaling) can effectively create this homogeneity in a network of neurons with diverse intrinsic parameters. Moreover, a modeling study has proposed that line attractors using a rate code can be realized using a symmetry principle for the construction of the network connectivity. If so, homeostatic regulation mechanisms may also offer a possible solution to the fine-tuning

problem for neural integrators using a rate code. Other theoretical work has noted that the higher order statistics of neuronal voltage fluctuations can exhibit special properties when networks are tuned to a line attractor, and has suggested how a learning mechanism that monitors such fluctuations could be used to tune the integrator dynamics. Close collaboration between theory and experiments will be needed to test and further develop such hypotheses at both the single neuron and the systems levels.

Neural Oscillators and Dynamical Systems Models

Introduction

Suppose that a synaptically isolated neuron is injected with a constant current. As the amount of current increases, the neuron might begin to fire action potentials. Or perhaps it will fire a burst of action potentials and then stop firing. Or, if it was already firing, maybe the spikes will stop. On the other hand, consider what happens as a walking horse speeds up: he switches first to a trot and then to a gallop. In both of these cases, some qualitative change in behavior has occurred as some parameter (current in the first case, frequency in the second) changes. How can we put these wildly different phenomena at wildly different spatial and temporal scales on a common footing? Nonlinear dynamics or dynamical systems theory is an area of mathematics which attempts to classify the qualitative differences between systems as their initial states or their parameters change.

Most modeling of neurons, circuits, and systems depends on the simulation of large systems of coupled differential equations: rates of change for voltages, synaptic strengths, etc., are given in terms of the variables themselves. Thus, in this article, we focus on how nonlinear dynamics can help us understand the behavior of the kinds of differential equations that occur in computational neuroscience.

To gain an intuitive feel for the concepts that are introduced in this article, it helps to think of some simple physical systems. A familiar example is a damped pendulum, that is, a solid rod with a weight at the end and with friction. If you move the pendulum, it will rock back and forth several times, eventually returning to the downward position. This position is called an attractor, since perturbations of the pendulum end up back in the downward state. Let us consider a more complicated example. Place a flexible plastic ruler narrow edge down, and place your finger along the top edge. As long as you do not apply too much pressure, the ruler will remain completely straight. If you transiently bend the ruler from the side, keeping the same pressure on it, it will return to a the straight position. Now, apply more pressure on the top of the ruler. Once the pressure becomes too great, the ruler will buckle (bend) to one side or the other. The physical system has gone to a new attractor as the parameter (the applied pressure) changes. The plastic ruler and the pendulum are governed by sets of nonlinear equations, and the goal of dynamical systems theory is to understand their behavior both qualitatively and quantitatively.

Equilibria

We start with a very simple example, a model for a passive membrane:

$$\frac{dV}{dt} = (-g_L(V - E_L) + I)/C \qquad [1]$$

Here, $1/g_L$ is the input resistance, E_L is the resting potential, I is the applied current, and C is the capacitance. We divided by the capacitance because it is traditional to put just the derivatives of variables on the left-hand side of the equation. This is a linear differential equation, and we can find a closed form solution, or, even easier, we could pop this onto a computer and solve it. However, to do this, we need one more piece of information: the voltage at a particular point in time, for example, $t = 0$. Thus, we specify $V(0) = V_0$, which is called the initial condition. Rather than solve the equation exactly, we will, instead, introduce the concept of state space and use this to deduce what solutions look like.

In Figure 1 is a graph showing dV/dt on the y-axis and V on the x-axis. The x-axis represents all possible voltages and is called the state space for this system. The y-axis tells us how fast and, more importantly, which direction the voltage goes – to the left means it is decreasing and to the right, increasing. For example, if the initial voltage is to the left of the solid black circle, then $dV/dt > 0$ and the voltage increases. Note that as it approaches the filled circle, its rate, dV/dt, gets smaller so that it decelerates as it gets closer to the filled circle. Initial conditions to the right will decrease until the filled circle is reached. An initial condition starting exactly on the filled circle will stay there forever. For this reason, we call this particular voltage an equilibrium point for eqn [1]. Other terms which are commonly used are steady state and fixed point. Note that all initial conditions move to this unique equilibrium. Thus, we say that it is globally asymptotically stable or that it is a global attractor. No matter what the current injected, there will always be one and only one equilibrium point and it is always stable. In fact, we can write it down explicitly:

$$V_{eq} = \frac{I + g_L E_L}{g_L}$$

Thus, for this simple linear model, if we call $V(t) = \phi(t; V_0)$ the solution to eqn [1] given the initial condition, $V(0) = V_0$, we see that $V(t) \to V_{eq}$ as $t \to \infty$

Figure 1 One-dimensional dynamical system showing stable (black) and unstable (gray) equilibria.

for any initial condition. (Note that the function ϕ is introduced to make explicit that the solution depends on the initial value.)

This graphical method may at first seem to be of little use since we can write an explicit solution to the differential equation. However, suppose that in addition to a leak conductance, our membrane has an instantaneous inward current:

$$\frac{dV}{dt} = (-g_L(V - E_L) - g_{Na}m(V)(V - E_{Na}) + I)/C \equiv f(V, I) \qquad [2]$$

where

$$m(V) = 1/(1 + \exp[-(V - V_1)/V_2])$$

(see **Figure 1(b)**). If the inward conductance is large enough, then dV/dt has the form shown in **Figure 1(c)**. It is no longer possible to write down a solution to the differential equation! However, we can use the graphical method to completely understand it. Unlike the left-hand figure, there are now three equilibria. Looking at the arrows on the x-axis, it is clear that initial conditions starting near V_1, V_3 will be driven to respectively, V_1, V_3 while initial conditions near V_2 will be pushed away from V_2. Thus, there are two asymptotically stable equilibria and there is one unstable equilibrium point. Physically, we would never be able to reach the unstable equilibrium, but we would be able to sense it in an experiment. For any initial condition $V(0) > V_2$ will tend to V_3 as time increases, and any initial condition $V(0) < V_2$ will go to V_1. Thus, eqn [2] is bistable; it has two asymptotically stable states and V_2 serves as a separatrix or threshold between the two stable equilibria. Suppose the neuron is resting at V_1 and a brief current stimulus is applied. If the stimulus is small, $V(t)$ will not cross V_2 and will relax back to V_1. If the stimulus is large enough to cause $V(t)$ to cross V_2, then the neuron will tend to the depolarized state, $V = V_3$. All we need now is some sort of delayed outward current and we will have an action potential. Nonlinear dynamics provides a geometric description for the threshold for an active neuron.

More generally, consider a set of n differential equations in n variables:

$$\frac{dx_j}{dt} = f_j(x_1, \ldots, x_n) \quad j = 1, \ldots, n \qquad [3]$$

with initial conditions $x_j(0) = x_{j,0}$. Under fairly general conditions on the functions f_j there is a solution to this which we write in vector form as $X(t) = \Phi(t; X_0)$. In this case the state space is R^n, the set of all n-dimensional vectors, and eqn [3] defines an n-dimensional dynamical system which we can write concisely as

$$\frac{dX}{dt} = F(X) \qquad [4]$$

We call X_{eq} and equilibrium solution to eqn [4] if $F(X_{eq}) = 0$. In our simple example, above, $n = 1$. The familiar space-clamped Hodgkin–Huxley equation consists of four variables, V, m, h, n, and forms a four-dimensional dynamical system. In absence of an applied current, the nerve membrane sits at rest, which is an equilibrium point. We say that an equilibrium point, X_{eq}, is asymptotically stable if all the solutions to eqn [4] with initial conditions that are close to the equilibrium point decay back to the equilibrium point as t increases. The nice geometric picture in **Figure 1(c)** does not help us for higher dimensional systems.

Suppose that A is an $n \times n$-dimensional matrix and that $F(X) = AX$. Then we call this a linear dynamical system. The study of linear dynamical systems is insightful, for, except in special cases (see below), the behavior of any nonlinear system in eqn [4] near an equilibrium point is the same as that of an associated linear system. Consider the following linear dynamical system:

$$\frac{dX}{dt} = AX \qquad [5]$$

Clearly $X = 0$ is an equilibrium point. The general solution to a linear differential equation is a sum of terms of the form:

$$Y(t) = Ve^{at}t^m(\cos bt - c) \qquad [6]$$

where m is a nonnegative integer, a, b, c are real numbers, and V is a constant vector. If $a < 0$, then

$Y(t)$ decays to zero as $t \to \infty$; if $a > 0$, then $Y(t)$ grows exponentially; and if $a = 0$, then the $Y(t)$ grows when $m > 0$ and oscillates when $m = 0$ and $b > 0$. The numbers $\lambda = a \pm ib$ are the eigenvalues of the matrix, A, that is, there is a constant vector, V, such that

$$AV = \lambda V$$

For an $n \times n$ matrix, there are n eigenvalues, roots of the nth order characteristic polynomial

$$pA(\lambda) \equiv \det(\lambda I - A)$$

Combining this fact with eqn [6], we see that all solutions to eqn [5] will decay to the equilibrium point at 0 if $a < 0$ for every eigenvalue of A and that if 'any' $a > 0$, then at least some solutions to eqn [5] will exponentially grow. In the former case, when all the a's are negative, we say that system in eqn [5] is linearly asymptotically stable, and in the latter case when at least one $a > 0$, the system is unstable. The special case $a = 0$ will play an important role later in this article.

Let X_{eq} be an equilibrium solution of eqn [3] or equivalently eqn [4]. Form the following $n \times n$ matrix:

$$B = \begin{pmatrix} \frac{\partial f_1(x_1,\ldots,x_n)}{\partial x_1} & \cdots & \frac{\partial f_1(x_1,\ldots,x_n)}{\partial x_n} \\ \vdots & \ddots & \vdots \\ \frac{\partial f_n(x_1,\ldots,x_n)}{\partial x_1} & \cdots & \frac{\partial f_n(x_1,\ldots,x_n)}{\partial x_n} \end{pmatrix} \qquad [7]$$

and evaluate it at the equilibrium point, X_{eq}. This matrix is called the Jacobi matrix for eqn [4] about the equilibrium point (also often called the Jacobian), and the system $Y' = BY$ is called the 'linearization.' One of the most important results in dynamical systems states that if the linear system defined by the matrix $B(X_{eq})$ is linearly asymptotically stable (all eigenvalues have negative real parts), then the equilibrium point X_{eq} is asymptotically stable as a solution to eqn [4]. This theorem provides a simple way to test the stability of any equilibrium point: form the matrix B and look at its eigenvalues. If all have negative real parts, then the equilibrium is stable; if any have positive real parts, then it is unstable.

Returning to Figure 1, the Jacobian is just the slope of dV/dt at the equilibrium point. Thus, if dV/dt has a positive slope through the equilibrium, it is unstable, and if it has a negative slope, the equilibrium is stable. Let us continue to analyze eqn [2] and Figure 1(c), but now we will change the applied current, I. Changing the current just lifts the curve in Figure 1(c) up or down. This is shown in Figure 2 on the left. For large positive or negative currents, there is only one equilibrium point. However, if we start at $I = 0$ where there are three equilibria and hyperpolarize the membrane (decrease I), then the right-most pair of equilibria will move closer to each other (compare blue with black line). As we continue to decrease the current, there is a current value, $I = I_*$, in which both equilibria come together (cyan curve, green circle), and for $I < I_*$, they no longer exist. Unlike the situation when $I = 0$, when $I < I_*$, there is only one equilibrium point (magenta curve, magenta circle). This is qualitatively different from three equilibria. A similar phenomenon occurs when we raise the current; the left-most equilibria merge when $I = I^*$ (red curve, gold circle). In dynamical systems, any time that a qualitative change in behavior occurs as a parameter varies, we say that a bifurcation has occurred. Specifically, when two equilibria merge and disappear, we say that there is a saddle-node bifurcation. This is often called a limit point or turning point bifurcation. Clearly the left-hand picture is useful for a one-dimensional equation, but obviously, if the function $f(V,I)$ is more complicated, we will run out of space and have to draw many different curves for many different values of I. A concise summary of the behavior of this nonlinear system as a parameter varies is shown in the right side of Figure 2. A plot is made of the equilibrium values of one of the variables on the y-axis, and the parameter is shown on the x-axis. This curve is called a bifurcation diagram. Traditionally, stable equilibria and unstable equilibria are distinguished by changing the color or line type of the curve. In our figure, stable equilibria are solid and unstable are dashed. The diagram should be read as follows. Pick a value of I and mentally draw a vertical

Figure 2 Behavior of nonlinear membrane as the current changes. (Left) Phase space picture. (Right) Bifurcation diagram. Special points are colored green and gold.

line through this value of I. Intersections with the bifurcation diagram correspond to equilibria. Saddle nodes are points where the diagram turns around (hence the name turning point); here, they are at I_* and I^*. Figure 2, right, shows that there will be bistability for all currents between I_* and I^*. Suppose that we do the following experiment. Starting at $I = 0$, we gradually increase the current. As soon as it exceeds I^*, the voltage will jump up to the top part of the diagram. Now, we reduce the current. The voltage stays at the upper part of the diagram until the current falls below I_*. Thus, it jumps down at a different current than it jumped up. This phenomenon is called hysteresis, and our neuron has now been endowed with 'memory.' Once in the 'up' state, it will remain there even when the current is brought to zero. Bistability between states (here, equilibria) plays a central role in almost every aspect of the dynamics of single cells and networks of coupled cells.

Before turning to more complex dynamical systems, we close this discussion with an important point. Looking again to Figure 2, left, observe that when $I = 0$, the slope through the gray circle is positive while that through the black circle is negative. The linearized system for our model is

$$y' = f'(\bar{V})y$$

where $\bar{V}$ is an equilibrium. If the slope (f') is negative, the equilibrium is stable, and if it is positive it is unstable. At $I = I_*$, the slope at the equilibrium is zero and the linearized system is

$$y' = 0$$

which tells us nothing about stability of the nonlinear system. However, whenever a linearized system has a zero eigenvalue, this is the signature for a possible bifurcation for the nonlinear system. This is true no matter what the dimension of the system.

The methods for finding equilibria and their stability, as well as looking for bifurcations, are not confined to one-dimensional models. Nor are they restricted to single neuron models. As an example of a bifurcation with symmetry, let us consider a mutually inhibitory neural network (Figure 3, left):

$$\frac{du_1}{dt} = -u_1 + F(I - gu_2)$$
$$\frac{du_2}{dt} = -u_2 + F(I - gu_1)$$

u_1, u_2 represent the firing rates of two different populations of neurons which are receiving equal inputs, I. The strength of the inhibition is g, and the function $F(u)$ increases with increasing values of u. The reader can imagine this as representing two objects competing for the attention of the network. Since the two populations are identical, there is a symmetric equilibrium point in which $u_1 = u_2 = \bar{u}$. The stability is determined by looking at the linearized system:

$$\frac{dy_1}{dt} = -y_1 - \alpha g y_2$$
$$\frac{dy_2}{dt} = -y_2 - \alpha g y_1$$

where $\alpha = F'(I - g\bar{u})$. Notice that $\alpha > 0$. The Jacobian matrix for this linear system is

$$A = \begin{pmatrix} -1 & -\alpha g \\ -\alpha g & -1 \end{pmatrix}$$

Two-variable systems (also called planar systems) are easy to analyze for stability. Let T be the sum of the diagonal entries of A (called the trace of a matrix) and let Δ be the determinant of the matrix. Then the linear system (and therefore the nonlinear system) will be stable provided that $T < 0$ and $\Delta > 0$. For this example, $T = -2 < 0$ and $\Delta = 1 - g^2\alpha^2$. If the mutual inhibition g is small, or the inputs are small (so that α is

Figure 3 Mutually inhibitory network. (Right) Bifurcation diagram as the input, I, increases.

small), then $\Delta > 0$. If the inputs increase, then Δ could become negative. The equilibrium point is no longer stable. In fact, when the determinant is negative for a planar system, it means that there is one positive eigenvalue and one negative eigenvalue and the equilibrium is called a saddle point. Because of the symmetry of our example, the eigenvalues and corresponding eigenvectors of A are easy to write down:

$$\{\lambda_1 = -1 - g\alpha, \mathbf{v}_1 = [1, 1]^T\}$$

$$\{\lambda_2 = -1 + g\alpha, \mathbf{v}_2 = [1, -1]^T\}$$

λ_1 is always negative, but λ_2 becomes positive when αg exceeds 1. This means that there will be growth along the vector $\mathbf{v}_2$ and decay along the vector $\mathbf{v}_1$. For this reason, $\mathbf{v}_1$ is called the stable set or the stable manifold for the saddle point and $\mathbf{v}_2$ is called the unstable set or unstable manifold. Amazingly, if the linearized system has a saddle point and stable and unstable sets, then the nonlinear system does as well. However, they will not be straight lines.

When the input reaches a critical value so that $\alpha g = 1$, then the determinant is zero and we see that $\lambda_2 = 0$. From the previous discussion, this means that we can expect a bifurcation. Figure 3 shows the bifurcation diagram for this system. This is very different from the diagram shown in Figure 2. Rather than losing solutions as the parameter changes, a solution becomes unstable and two new 'stable' solutions appear. Because of its shape, this is known as a pitchfork bifurcation. It occurs only in systems which have some kind of intrinsic symmetry, but, as this is very common in many physical and biological problems, the pitchfork is a familiar bifurcation. The central line corresponds to the equilibrium point $u_1 = u_2$. As the input increases, when it reaches approximately 1, the symmetric equilibrium point becomes unstable – symmetry is broken. The new equilibria have the form $u_1 = a$, $u_2 = b$ and $u_1 = b$, $u_2 = a$ where $a > b$. A network like this is called winner-take-all since one of the two objects dominates the other. Notice that when $I = 2$, the value a is about ten times larger than the value b.

Planar systems have another advantage over high-dimensional models. Like the one-dimensional models in Figure 1, it is possible to sketch the complete behavior of the differential equation. Instead of plotting u_1 or u_2 versus time, plot one against the other. The resulting diagram is called a phase-plane. Figure 4 shows the phase-plane for the network. Representative solutions (called trajectories; black) appear as curves moving toward the stable equilibrium points, which are filled circles. The advantage of the phase-plane is that it is possible to infer qualitative behavior without actually solving the equations. At each point in the (u_1, u_2) plane, the equations tell us the derivatives, du_1/dt and du_2/dt. These derivatives are tangent to the solutions, so that they show the direction of trajectories. Magenta arrows are drawn at various points in the plane to show the direction. These arrows are called direction fields. Often only a crude approximation of the direction fields is enough: just the eight points on a compass. For example, northeast corresponds to both u_1 and u_2 increasing in time. To determine where u_1 is increasing or decreasing, we only need to determine where u_1 is not changing at all. The graph $du_1/dt = 0$ is called the u_1-nullcline. For our network, $du_1/dt = 0$ when $u_1 = F(I - gu_2)$. This curve is plotted as in red in the phase-plane. The u_2-nullcline, $du_2/dt = 0$ is plotted in green. The nullclines break the phase-plane into regions where the direction fields are similar and their intersections are the equilibria. Thus, much can be gained without ever solving the differential equations. In the right phase-plane, there are two stable equilibrium points separated by an unstable

Figure 4 Phase-plane for mutual inhibitory network. Direction fields (magenta arrows) and trajectories (black) are shown. The u_1 nullcline is in red and the u_2 nullcline is in green. For stronger inputs, there are three equilibria. Two (black circles) are stable. Stable (blue) sets for the saddle point (black square) are shown.

saddle point. The stable set of the saddle point (drawn in blue) divides the plane in two. All initial values of (u_1, u_2) above the stable set will end up at the equilibrium point where u_2 wins and u_1 loses, labeled a. The opposite occurs when below the line. The upper triangular region of the plane is called the 'basin of attraction' for the equilibrium point a.

Limit Cycles

When a neuron is injected with current, it begins to fire repetitively. If the interspike interval is constant, then this pattern of firing is periodic and, in dynamical systems language, is called a limit cycle. A limit cycle is an isolated periodic solution to eqn [4]. All autonomous rhythmic phenomena seen in biology are limit cycles ranging in scales from the 24 h circadian oscillation in the suprachiasmatic nucleus to the 200 Hz ripple in hippocampus. There are several ways in which limit cycles can appear in nonlinear systems. To illustrate these, we will use the simple membrane model of Morris and Lecar:

$$C\frac{\mathrm{d}V}{\mathrm{d}t} = I - g_L(V - E_L) - g_k n(V - E_k) - gcam_\infty(V)(V - E_{\mathrm{Ca}})$$

$$\frac{\mathrm{d}n}{\mathrm{d}t} = a_n(V)(1 - n) - b_n(V)n$$

Depending on the parameters of the model, as the current increases, rhythmic firing appears in three different ways: (1) Hopf, (2) SNIC, and (3) homoclinic. These three possibilities have been found in almost all published simulations, and there is strong evidence that they are also observed in real neurons.

The best-known mechanism by which a neuron begins to fire periodically is via the Hopf or Andronov bifurcation. Recall that an equilibrium point is stable as long as the real parts of the eigenvalues of the linearized system are all negative. There are two ways in which the real part can switch to positive: (1) a real negative eigenvalue becomes a positive eigenvalue through a zero eigenvalue and (2) the real part of a complex eigenvalue changes sign, leading to an imaginary eigenvalue, $\pm i w_0$. In the former case, saddle node and pitchfork bifurcations occur – the number of equilibria changes. In the latter, there is no change in the number of equilibria, but instead, limit cycles appear. Figure 5 shows the bifurcation diagram for the Morris–Lecar model as the applied current increases. There is a single equilibrium point, and it changes from stable to unstable as the current increases past about 95. The magenta and green curves plotted in this figure correspond to limit cycles. They depict the maximum and minimum amplitude of the voltage. Like equilibria, the notion of stability can be defined for limit cycles. The magenta curves correspond to unstable and the green to stable limit cycles. The point HB denotes the point of the Hopf bifurcation. Models which undergo Hopf bifurcations have a limited frequency band and a nonzero minimum frequency (often close to w_0). For this model, the frequency ranges from 8 to 14 Hz. The small figures labeled a, b, and c are the phase-planes corresponding to points along the bifurcation diagram. At point (a) there is only a stable equilibrium and the neuron always returns to rest. In point (b), taken between the currents I_1 and I_2, there are two stable states: a stable

Figure 5 Hopf bifurcation formation of limit cycle. HB, Hopf bifurcation; FLC, fold of limit cycles.

equilibrium and a stable limit cycle. The unstable limit cycle (magenta) separates the plane into two regions. Everything outside of the unstable cycle ends up on the stable cycle and everything inside ends up at the equilibrium. The well-known Hodgkin–Huxley model behaves exactly like this. As the current approaches the value I_1 from the right, the magenta limit cycle and the green limit cycle collide and annihilate. This is called a fold of limit cycles (FLC) and is very much like the saddle-node bifurcation for equilibria: instead of losing two equilibria, two limit cycles are lost. In the transition from (b) to (c), the unstable magenta limit cycle shrinks to the equilibrium and renders it unstable, leaving only the stable limit cycle. There is compelling evidence that fast-spike interneurons in the cortex have this type of bifurcation.

A less well-known, but very important bifurcation to limit cycles is called the saddle-node invariant cycle (SNIC) bifurcation. Most computational models for cortical neurons make the transition from rest to repetitive firing via this bifurcation. An example is shown in Figure 6. Unlike the Hopf case, there is never bistability. Rather, there is a smooth transition from rest to rhythmicity. At the point of bifurcation, the frequency of the oscillation goes to zero. Note the huge dynamic range: 0–25 Hz for the simple model. For subthreshold currents, there are three equilibria; two are unstable and one, the rest state, is stable. Phase-plane (a) shows the big picture. The turquoise equilibrium serves as a threshold. If the potential crosses this, then a spike will be emitted before the cell returns to rest. As the current increases, the threshold and the rest state merge (phase-plane (b)) and at larger currents, these two equilibria disappear, leaving just the stable limit cycle and the unstable equilibrium. Comparing phase-plane (c) in the Hopf and SNIC shows that for large enough currents, they cannot be distinguished. However, most neurons (at least in cortex) operate near rest so that the bifurcation matters. We note that near the critical current, I^*, the frequency grows like:

$$\omega = K\sqrt{I - I^*}$$

A key difference between the SNIC and the Hopf is that the Hopf has a much more restricted frequency range and thus is very sensitive to the frequency of the inputs, while the SNIC has a very broad frequency range and no preferred input frequencies. These differences could have important computational consequences: SNIC neurons respond to the total number of inputs (integrators), while Hopf neurons are more sensitive to timing.

The third way in which a limit cycle can appear also involves an arbitrarily low frequency but with a different scaling from the SNIC. The bifurcation diagram is shown in Figure 7, and it is more complex than the other two. The frequency also has a large dynamic range, between 0 and 50 Hz. At point (a), there are three equilibria, one stable and two unstable. In phase-plane (a) the unstable set (gold) from the saddle point (turquoise) lies on the outside of the stable set (magenta). As the current approaches the value denoted (b) in the bifurcation diagram, the stable and unstable sets merge to form the red loop in phase-plane (b). This is called a 'homoclinic' solution. Just past the bifurcation point, the homoclinic becomes a stable limit cycle, at point (c) and depicted by the green cycle in phase-plane (c). Note that there is both a stable

Figure 6 Saddle-node formation of limit cycle.

Figure 7 Homoclinic formation of limit cycle.

Figure 8 Bifurcation type determines synchronization properties. (a) Two Hopf neurons synchronize with excitatory coupling; (b) SNIC neurons fire in antiphase. (c) Frequency matters as well – if the frequency is halved, a pair of SNIC neurons switch from antiphase to a nonsymmetric rhythm.

limit cycle and a stable equilibrium (black circle). The stable set of the saddle point (magenta) separates the phase-plane into regions which tend to either the limit cycle or the equilibrium. Finally, as the current increases, the stable equilibrium and the saddle point merge (a saddle-node bifurcation), leaving only the limit cycle and the unstable equilibrium.

The reader may well wonder if these differences matter. Indeed, there seems to be little difference in the shapes of the spikes between the SNIC and the Hopf cases when the neuron is driven to fire at, say, 12 Hz. However, the mechanism by which a neuron makes the transition from rest to firing makes a large difference in how it responds to inputs. This fact is illustrated when two neurons are synaptically coupled into a network. Networks of coupled neural oscillators play a central role in many motor pattern circuits and may be important in sensory perception as well. Figure 8 demonstrates that the type of bifurcation matters. In (a), the neurons use parameters like those in Figure 5 and are driven to 12 Hz. Two identical cells are coupled via a synaptic current and, no matter what the initial state, will eventually synchronize. In (b), the parameters are as in Figure 6, driven also to 12 Hz. However, no matter what is the initial state, the two neurons will fire alternately in 'antiphase,' a half-cycle apart. Not only does the type of bifurcation matter, but also the frequency Panel (c) shows what happens to a pair as the frequency is halved from 12 to 6 Hz. Instead of firing in a perfect antiphase pattern, there is a switch so that the neurons fire with a short time between respective spikes followed by a long silent period. In the context of the questions posed at the beginning of this article, one can view the frequency-dependent switch shown in Figure 8(c) as analogous to a gait switch as an animal speeds up or slows down.

Summary

Nonlinear dynamics provides a means of characterizing the temporal behavior of neurons and networks of neurons. Transitions between different qualitative behaviors as parameters change occur in only a few different ways. Despite differences in timescales and dimensions of the problem, these bifurcations share common features which provide insight into how neurons react to stimuli and the number and variety of states that networks can achieve.

Neural Patterning: Arealization of the Cortex

Introduction

The cerebral cortex is the largest and most complex component of the brain, and more so than any other brain component has been affected by evolutionary processes resulting in a tremendous increase in size and complexity, exhibited by primates, including humans, by cetaceans (e.g., dolphins, whales), and by elephants, which have the largest brains among all species. The neocortex is the largest region of the cerebral cortex; it exhibits the most substantial increase in size and complexity in more advanced species, disproportionately so compared to the midbrain and hindbrain, and also exhibits arguably the most significant phylogenetically distinct specializations.

Early in embryonic development of mammals, the neural plate differentiates into the neural tube, and during this process the rostral end of the neural tube develops three vesicles, the forebrain, midbrain, and hindbrain, that ultimately give rise to the brain. Soon thereafter, the dorsolateral aspects of the forebrain evaginate to generate the telencephalic vesicles, and the remainder of the forebrain becomes the diencephalon. The expression of individual transcription factors (TFs) or combinations of TFs correlates with morphologic boundaries within the telencepahlon and has important roles in telencepahlon patterning into two major subdivisions – the ventral telencephalon, which gives rise to the striatum and basal ganglia, and the dorsal telencephalon, which gives rise to the cerebral cortex. The diencephalon differentiates into several components, the major ones including the dorsally positioned epithalamus (habenula) and dorsal thalamus, which reciprocally connect with the neocortex, and the ventrally positioned hypothalamus.

Putting the Neocortex in Its Place

Although the focus here is on mechanisms that control area patterning of the neocortex, it is important to place the neocortex into some context. Within the cerebral cortex, the neocortex is sandwiched between what have classically been considered the more primitive archicortex (including entorhinal cortex, retrosplenial cortex, subiculum, and hippocampus) and paleocortex (olfactory piriform cortex). The neocortex is the most highly differentiated and intricately organized region of the cerebral cortex, and its laminar patterning is distinct from that of the other cortical regions, having the largest number of layers: six major, radially stacked, stratified layers, each containing a heterogeneous population of neurons that are morphologically, connectionally, and functionally distinct from those of other layers.

In its tangential dimension, the neocortex is organized into subdivisions referred to as cortical 'fields' by some authors, but more commonly as cortical 'areas.' Areas are distinguished from one another by major differences in their cytoarchitecture and chemoarchitecture, input and output connections, and patterns of gene expression. In the adult, the transition from one neocortical area to another is typically, but not always, abrupt, with borders that can be sharply defined by area differences in cytoarchitecture and chemoarchitecture, and in some instances by the distributions of projection neurons, input projections, or gene expression patterns. These attributes form a specific combination of properties that is unique for each area, and together with unique combinations of gene expression, determine the functional specializations that characterize and distinguish areas in the adult.

The neocortex has four 'primary' areas. In addition, scores of higher-order areas are positioned between the primary areas, serving as higher-order processing centers focused on a particular modality – for example, particularly features of vision, movement, or attention related to the visual field; many higher-order areas are multimodal. Three of the primary areas are sensory: the primary visual (V1), somatosensory (S1), and auditory (A1), which process primary information received from the eye/retina (vision), body (somatosensation), and inner ear/cochlea (audition), respectively. The only major sense not processed by the neocortex is smell. Distinct orders are sensed by olfactory and vomeronasal receptors in the nose and related peripheral organs and are processed in the olfactory piriform cortex, positioned within the cerebral cortex, usually ventrolateral to more rostral parts of neocortex. The fourth primary area of the neocortex is the motor (M1) area, which controls voluntary movement of body parts.

These primary sensory and motor areas are conserved among all mammals, as is the general spatial relationship between them: V1 is positioned caudally; M1 is positioned rostrally, and S1 is located between them; A1 is located caudolaterally to S1. However, some animals with unusual or large and atypical peripheral appendages/sense organs (e.g., the platypus' bill or the echo-location system in bats) have modifications on this general geometrical scheme of area patterning.

The relationships between a primary cortical area and nuclei in dorsal thalamus are critical both for

adult function and for development and differentiation of areas. Dorsal thalamus has four principal thalamic nuclei that functionally and connectionally parallel the four primary cortical areas. Each primary cortical area sends outputs from layer 6 neurons to a principal thalamic nucleus, and receives, from the same nucleus, thalamocortical afferent (TCA) inputs that terminate primarily in layer 4, thereby generating the reciprocal area- and nuclei-specific connections between cortex and thalamus. Like cortical areas, individual nuclei are responsible for processing modality-specific sensory information. The four principal thalamic nuclei receive modality-specific sensory information from peripheral sense organs or receptors and form reciprocal projections with their related primary cortical areas. A simplified wiring circuit has the ventroposterior (VP) nucleus of dorsal thalamus reciprocally connecting with S1, the dorsal lateral geniculate nucleus connecting with V1, the ventral part of the medial geniculate nucleus connecting with A1, and the ventrolateral nucleus connecting with M1. Thus, the modality of a primary cortical area is determined by the modality of the principal thalamic nucleus with which it is reciprocally connected. Higher-order areas are often multimodal and their modalities are determined largely by the modality of the inputs that they receive from other areas – primary as well as higher-order areas, through intracortical axonal projections.

Corticogenesis

Areas of the neocortex differentiate within an earlier, more or less uniform structure composed of postmitotic neurons, termed the cortical plate (CP) (**Figure 1**). Most neocortical neurons, including all projection neurons and glutamatergic neurons, are generated in the ventricular zone (VZ) of the dorsal aspect of the lateral ventricle, or, at later stages, in a second germinal zone, the subventricular zone (SVZ). The VZ generates deeper layer neurons, including the subplate (SP) and the major classes of layer 6 and layer 5 projection neurons, whereas the SVZ is the primary source of superficial layer neurons. In primates, the SVZ is substantially larger than in other mammals (e.g., mice). In addition, the primate SVZ shows substantial differences in mitotic activity in caudal cortex (and possibly elsewhere); these differences may underlie the major increase in the numbers of neurons in the upper layers in V1 compared to adjacent higher-order visual areas (e.g., V2), which in turn likely contributes to the substantial differences in cytoarchitecture between V1 and V2.

The first postmitotic neurons accumulate on the top of the VZ, forming the preplate (PP), positioned just beneath the pial surface. PP neurons are derived not only from the VZ, but also from the cortical hem or other sources external to the neocortex. Neurons subsequently generated in the VZ migrate along the processes of radial glia, which are actually the VZ progenitor cells, then aggregate within the PP, thereby forming the CP, which splits the PP into a superficial marginal zone (MZ) (future layer 1) and a deep SP. The CP gradually differentiates in a deep to superficial pattern, and layers 6 through 2 emerge. The MZ contains Cajal–Retzius neurons that express reelin, a large, secreted protein required for the proper radial migration of CP neurons and their formation of layers. Cajal–Retzius neurons are generated in multiple sites external to the cortical VZ, primarily within the cortical hem. SP neurons have been proposed to serve a number of critical roles in cortical development, including the pioneering of the internal capsule, the path of the major input and output projections between the cortex and the rest of the central nervous system (CNS).

A majority of cortical interneurons, which are γ-aminobutyric acid (GABA)ergic and also typically express a distinct neuropeptide (e.g., somatostatin, substance P, or neuropeptide Y), are generated primarily within the medial and caudal ganglionic eminences. These interneurons migrate along multiple pathways to reach the cortex, and migrate within the cortex along tangentially aligned pathways, being directed by many molecules, including members of the slit, semaphorin, and neuregulin families. Once interneurons reach an appropriate position, they migrate perpendicular to their original migratory plane and migrate radially into the CP.

Areas Differentiate within a 'Uniform' Cortical Plate Characterized by Exuberant Distribution of Projection Neurons and a Lack of Other Area-Specific Features Except Area-Specific Thalamocortical Afferent Input

It has been assumed that the specification and differentiation processes of neocortical areas are controlled by interplay between intrinsic mechanisms (i.e., genetic mechanisms that operate within the cortex) and extrinsic mechanisms (TCA input or information relayed by it, for example). However, only in the present millennium has compelling evidence emerged for the genetic regulation of arealization, including

Figure 1 Basics of corticogenesis. (a) Organization of the neocortex into areas. (1) Areas of the human cerebral cortex as defined by Brodmann. View of the lateral surface of the human cerebral hemisphere shows a number of cytoarchitectonically distinct areas, such as the primary visual area (area 17, also termed V1) at the caudal pole, the primary somatosensory area (area 3, also termed S1) in the middle, and, just rostral to it, the primary motor area (area 3, also termed M1). (2) Selected areas of the rat neocortex from Kaas and colleagues showing sensory areas (V1, primary visual; V2, secondary visual; S1, primary somatosensory; S2, secondary somatosensory; A1, primary auditory) as well as the primary and secondary motor areas (M1, M2) and the olfactory bulb (OB). (3) An example of abrupt borders between areas (from an 8-month human fetus), showing the V1–V2 cytoarchitectonic border, revealed using a Nissl stain. Each area has six primary layers, but their architecture and internal sublayering differ. (b) Generation, migration, and lamination of neocortical neurons. (1) Most neocortical neurons, including all glutamatergic and projection neurons, are generated in the neocortical ventricular zone (VZ) and later in the subventricular zone (not shown). Most cortical plate (CP) neurons (SP, subplate) migrate radially on radial glial fibers from the VZ, through the intermediate zone (IZ), and aggregate in the CP. The radial glia are also the progenitors in the VZ that give rise to cortical neurons. (2) Layer development of the rodent neocortex. The first neurons generated in the VZ, as well as neurons that migrate tangentially into the marginal zone (MZ) from external germinal zones, such as the cortical hem, aggregate on top of the VZ and form the preplate (PP), which is later split into MZ and SP by the later generated CP neurons (WM, white matter). (3) Most neocortical interneurons (i.e., GABAergic interneurons of various peptide phenotypes) are generated in the medial ganglionic eminence (MGE, pathway 1) and caudal ganglionic eminence (CGE, pathway 2) and migrate tangentially through the intermediate zone and marginal zone to distribute across the neocortex, and then turn perpendicular to their tangential path and migrate radially into the cortical plate (CTX, cortex). The lateral ganglionic eminence (LGE) is the source of GABAergic interneurons that migrate into the piriform cortex (pathway 3) and to the olfactory bulb (pathway 4). Cortical plate neurons are generated in an inside-out fashion, and layers differentiate from the cortical plate in the same pattern: earlier born neurons form the deeper layers, while later born neurons migrate past them and form the more superficial layers. Interestingly, interneurons generated external to the cortex also become distributed in an inside-out gradient dependent upon their birth date. (b3) Adapted from Corbin JG, Nery S, and Fishell G (2001) Telencephallic cells take a tangent: Non-radial migration in the mammalian forebrain. *Nature Neuroscience* 4(supplement): 1177–1182.

the first demonstration of regulatory genes that control area specification and evidence for patterning centers and signaling molecules that establish the initial patterning of these genes.

Cytoarchitecture and Exuberant Projection Neurons

The CP lacks the many features that distinguish areas in the adult cortex, even after all CP neurons have been generated and layers begin to differentiate within it. The sharp cytoarchitectonic borders evident between areas in the adult cortex are lacking; indeed, other than differences in thickness, CP cytoarchitecture is uniform across its tangential extent. Also absent are the restricted, area-specific distributions of distinct types of projection neurons characteristic of the functional specializations of different cortical areas in adults. Instead, cortical projection neurons have widespread distributions early on that include parts of areas, and even entire areas, in which they are not found in the adult cortex, and their restricted adult cortical distributions come about by the elimination of functionally inappropriate axon segments and branches. This mechanism is used to generate the characteristic patterning of callosal, intracortical, and subcortical projections of the mammalian neocortex. Although the area-specific

adult distributions of projection neurons are sculpted primarily through selective axon elimination, areal differences in the initial distribution of projection neurons have been reported. For example, the adult M1 has a higher density of layer 5 corticospinal neurons than does S1; prior to the phase of axon elimination this difference is present but not to the same degree. Therefore, even in this situation, selective axon elimination contributes to the generation of the distribution and density of projection neurons found in adult brains.

Area-Specific Thalamocortical Afferent Input and Potential Roles in Area Patterning

To sum, all classes of projection neurons initially exhibit an 'exuberant' distribution far broader than that found in the adult brain. In contrast to this lack of area specificity in the early distribution of projection neurons, the area-specific projection of TCAs originating in the principal sensory nuclei of dorsal thalamus is evident even at the early stages in their development. Progress has been made in defining mechanisms of TCA pathfinding, particularly subcortically from dorsal thalamus to the neocortex, but the molecular control of TCA targeting of specific areas remains poorly defined relative to mapping in other systems, such as retinal projections. As in the visual system, area-specific TCA targeting is likely primarily controlled intracortically by guidance molecules, and influenced by neural activity. SP neurons and their axons have also been implicated in the development of area-specific TCA targeting, but their role and the molecular basis are vague.

TCAs form the major input to the neocortex, and relay visual, auditory, and somatic sensations to the primary sensory areas of the neocortex in an area-specific manner. Since TCAs are the sole source of modality-specific sensory information to the neocortex, the functional specializations of the primary sensory areas are defined by, and dependent upon, TCA input. The differentiation of anatomical features that distinguish cortical areas, including architecture and distributions of output projection neurons, depends to a large extent upon TCA input. Consistent with this role, the TCA projection exhibits area specificity throughout its development, and the gradual differentiation of areas within the CP parallels the elaboration of the TCA projection within it. In addition, a variety of manipulations, including peripheral manipulations and transplantation experiments, have demonstrated that the CP exhibits considerable plasticity in the development of area-specific features, and that diverse parts of the CP initially have similar potentials to develop features unique to a specific area. Again, TCA input has been implicated as a major influence controlling this plasticity in the differentiation of area-specific features.

The role of TCAs in shaping cortical architecture is not limited to these later events in the differentiating CP. *In vitro* experiments suggest that TCAs release a diffusible mitogenic activity that promotes the production of both glia and neurons by explants of the cortical VZ. If a similar mechanism operates *in vivo*, such an early influence of TCAs on corticogenesis could contribute to reported areal differences in neuronal production in the SVZ in occipital areas (V1 vs. V2), and therefore, as previously described, to the cytoarchitectural differences between areas that become evident later in development.

Indirect Evidence for Intrinsic Genetic Regulation of Area Identity

Evidence for the genetic control of arealization is recent and limited, but compelling. The initial evidence was indirect and based upon the differential expression patterns of numerous genes, ranging from TFs, cell adhesion molecules, and axon guidance receptors and ligands, within cortical progenitors in the VZ or their progeny in the CP. These patterns, which were typically graded across the anteroposterior (AP) and dorsoventral (DV) cortical axes, were shown to develop independently of TCA input by analyses of mutant mice with targeted deletion of TFs (Gbx2 or Mash1, neither of which is expressed in the cortex but which are required for TCAs to reach the cortex). However, the most dramatic areal changes in gene expression, and changes that match expression patterns to cortical areas or their borders, occur postnatally, coincident with the development of patterned TCA input to the CP. Thus, although the early differential expression of many genes may be independent of TCA input, TCAs may later influence the differentiation of more complex patterns.

Roles for Morphogens and Transcription Factors in Control of Area Identity

Two different major forms of gene products influence the intrinsic generation of positional or area identity in the developing neocortex. These two forms of proteins are TFs, which are typically localized to the nucleus of the producing cell, and secreted morphogens, which are secreted by the producing cells. TFs are expressed by neocortical progenitors and directly regulate the positional or area identity that is inherited by their progeny, whether these progeny are additional progenitors or are neurons that form the CP and SP. Secreted morphogens are produced in discrete signaling centers and are believed to be secreted and to diffuse from their source, forming gradients across the dorsal telencephalon (neocortical) VZ that are highly

concentrated at the site of production and progressively diminish in concentration distal to their source. Here we first consider TFs that impart area identities to cortical progenitors, then in the subsequent sections consider roles for morphogens in area patterning.

Intrinsic Control of Area Identity by Differential Expression of Transcription Factors in Cortical Progenitors

The key criteria for a gene that specifies area identity in cortical progenitors is straightforward: it must be expressed by progenitors in the VZ and/or SVZ and must function in a differential manner across the cortical axes, either through differential expression or expression of cofactors or other mechanisms that differentially influence its function, and must impart areal properties. Functionally, genes that regulate arealization, in principle, could have a range of effects – for example, from conferring the complete set of properties that comprise the area identity of a cortical neuron, to a subset of these properties, to regulating the expression of axon guidance molecules that control the area-specific targeting of TCAs. Scores of genes meet the differential expression criteria to be the source of TFs that regulate area patterning, but as of this writing, only four TFs have been shown to function in regulating arealization: Emx2, Pax6, COUP-TFI, and Sp8. Emx2 is a homeodomain TF related to the *Drosophila* gene *empty spiracles* (*ems*), Pax6 is a paired box domain TF, COUP-TFI is an orphan nuclear receptor, and Sp8 is a zinc-finger TF related to the *Drosophila* gene *buttonhead* (*btd*).

Within the cortex, all TFs but COUP-TFI have their expression almost exclusively limited to progenitors in the embryonic VZ. COUP-TFI is expressed in a high caudolateral to low rostromedial gradient both in progenitors and in their CP progeny. Emx2 is expressed in a low rostrolateral to high caudomedial gradient, and Pax6 is expressed in an opposing pattern, a high rostrolateral to low caudomedial gradient across the VZ of embryonic cortex. All three of these TFs are expressed in progenitors throughout embryonic cortical neurogenesis. In contrast, Sp8 is expressed only during the early phase of neurogenesis, and is expressed in a high rostromedial to low caudolateral gradient. Loss-of-function studies have been done in mice for each of the four genes, and gain-of-function studies have been reported for all but the gene encoding COUP-TFI.

Emx2 To date, of the four TFs that function in regulating arealization, Emx2 has been most extensively studied. Genetic manipulations that change the levels of Emx2 expression in cortical progenitors result in disproportionate changes in the sizes of the primary sensory and motor cortical areas. For example, increasing Emx2 expression in neocortical progenitors has no effect on overall cortical size, but results in a significant decrease in the sizes of rostral cortical areas, including S1 and motor areas, and a significant increase in caudal areas, including V1. Decreasing levels of Emx2 expression has the opposing effect on area sizes. Changes in the levels of Emx2 in cortical progenitors appear to result in a complete change in the area identity of their neuronal progeny, to match the contracted or expanded areas.

COUP-TFI Cortical deletion of COUP-TFI results in a massive expansion of anterior areas, including motor, to occupy most of parietal and occipital (sensory) cortex, paralleled by substantial reduction in the sizes of the three primary sensory areas that become compressed and aligned mediolaterally along the caudal pole of the cortical hemisphere. Thus, COUP-TFI is required to balance the patterning of neocortex into motor and sensory areas, and appears to operate through a novel genetic pathway to repress the identities of rostral cortical areas, such as motor, allowing for appropriate specification of the sensory cortical areas. COUP-TFI might also have a role in specifying the identities of sensory areas.

Pax6 Roles for Pax6 in area patterning are presently vague. The initial studies that implicated Pax6 in area patterning depended upon marker analyses of the small eye mutant mouse; these mice are deficient for functional Pax6 protein and die at birth, before cortical areas differentiate, and in addition lack TCA input. Nonetheless, these marker analyses implicated Pax6 in specifying anterior area identities associated with motor areas, consistent with its highest expression in progenitors that give rise to anterior areas. However, a recent gain-of-function study of Pax6 that used a yak transgenic approach to overexpress Pax6 severalfold in cortical progenitors reports minimal or no changes in area patterning. This discrepancy could be explained in several ways. One appealing way is that another gene, for example, that for COUP-TFI, normally represses, in the cortical fields, Pax6 function that would give rise to sensory areas, and therefore represses the effect of Pax6 overexpression. In any case, additional work must be done to properly define the role for Pax6 in the regulation of area patterning.

Sp8 Sp8 has been recently shown to have multiple distinct roles in area patterning, one by its influence on the expression of the morphogen fibroblast growth factor 8 (FGF8) within the commissural plate (CoP), and the other through its expression directly

in cortical progenitors. Sp8 is expressed in a high to low, anteromedial to posterolateral, gradient across the VZ, and is also transiently expressed in the CoP coincident with the expression domain of FGF8, a morphogen implicated in area patterning of the neocortex. Sp8 and FGF8 exhibit reciprocal induction in the embryonic telencephalon, but ectopic expression of Sp8 and FGF8 in anterior dorsal telencepahlon around the normal FGF8 expression domain in the CoP has opposing effects on area patterning, with ectopic expression of FGF8 inducing a posterior shift of cortical areas and ectopic expression of Sp8 inducing an anterior shift – suggesting that in parallel to regulating FGF8 expression, Sp8 also activates a distinct signaling pathway for cortical area patterning. Further, deletion of Sp8 from cortical progenitors results in a reduction of anterior cortical areas, such as motor areas.

Interactions between regulatory genes in controlling area patterning Other TFs are likely involved as primary regulators of area patterning and cooperate with Emx2, Pax6, COUP-TFI, and Sp8. In addition, Emx2, Pax6, COUP-TFI, and Sp8 have inductive or repressive effects upon one another that affect their influence, their level of expression, and even their domain of expression. For example, Sp8 is a direct transcriptional activator of FGF8, and Sp8 induction of FGF8 is repressed by Emx2, which binds Sp8. This provides a mechanism to limit FGF8 expression to the CoP. In addition, many of these TFs influence the expression of one another. For example, Emx2 and COUP-TFI appear to repress Pax6, and Pax6 appears to repress Emx2. Further, as described in the following sections, FGF8 influences the expression of many of these TFs. In summary, gradients of TFs expressed within cortical progenitors in the VZ/SVZ impart area identities, and cooperate with one another, and with as yet unidentified TFs, to activate signaling pathways that control area patterning of the neocortex.

Morphogens/Signaling Molecules Establish Graded Patterns of Transcription Factor Expression in Cortical Progenitors

Current evidence indicates that morphogens secreted by signaling centers located at the perimeter of the developing dorsal telencephalon (dTel) establish gradients of TFs across the dTel VZ, which in turn determine the area fate of cortical progenitors and their progeny. These morphogens include FGF8 expressed by the anterior neural ridge (ANR), which later becomes the CoP, located at the anterior midline of the dTel, and also members of the wingless-int (Wnt) and bone morphogenetic protein (BMP) families, expressed by the cortical hem and choroid plexus epithelium (CPe), located at the dorsal midline of more posterior dTel (**Figure 2**).

Recent studies have begun to better define these patterning centers and, early in development, the action of their signaling molecules to establish and maintain across the neocortical VZ the graded expression of TFs that directly impart area identity to cortical progenitors. The initial domain of FGF8 expression in the ANR/CoP is located at the rostral edge of the prospective neocortex, and later this expression domain extends caudally along the dorsal midline toward diencephalon. Bone morphogenetic proteins (BMP2, BMP4, BMP5, BMP6, and BMP7) and Wnts (Wnt2b, Wnt3a, and Wnt5a) are expressed in the cortical hem, a midline structure adjacent to the hippocampal anlage.

FGF8 FGF8 is the intensively studied member of the FGF family that is expressed in the ANR/CoP. At the neural tube stage, approximately embryonic day 8.5 (E8.5) to E9.5 in mouse, the FGF8-expressing domain is positioned in a discrete dorsomedial domain. After invagination of the neural tube (~E10.5), the FGF8 expression domain is positioned in a small domain in the medial wall of the two cortical hemispheres called the ANR, with the highest expression of FGF8 localized in the anterior region of the cortex. FGF8 expression continues robustly through E12.5 in mouse and then tapers off significantly. Experimental evidence shows that the high rostromedial expression of FGF8 establishes, at least in part, the graded expression of Emx2 and COUP-TFI through repression. Further, changes in levels of FGF8 in embryonic mice result in area shifts that mimic those expected by decreasing or increasing the graded expression of Emx2 across the neocortical VZ, and are likely due to such an effect on Emx2 levels (**Figure 3**).

Wnts and BMPs A second signaling center is the cortical hem that expresses members of the Wnt and BMP families of ligands. These factors begin to be expressed slightly later than FGF8 (~E9.5) and are expressed immediately lateral to the FGF8 domain during the neural tube stage. After invagination of the neural tube, Wnts and BMPs are localized within a domain called the cortical hem, which is positioned just immediately dorsal to the FGF8 expression domain. Along the anteroposterior axis of the dTel, the cortical hem shares a similar anterior boundary with FGF8 but extends significantly further caudally within the medial cortical wall. Expression of signaling molecules from the cortical hem appears to be active until slightly later in development, as expression of Wnts and BMPs remains

Figure 2 Mechanisms of specification and differentiation of neocortical areas. The initial, tangential gradients of transcription factors in the ventricular zone (VZ) are likely established by signaling molecules/morphogens secreted from patterning centers, such as fibroblast growth factor 8 (FGF8) from anterior neural ridge (ANR), which later becomes the commissural plate (CoP), and Wnts and bone morphogenetic proteins (BMPs) from the cortical hem. The graded expression of certain transcription factors, such as Pax6, Emx2, COUP-TFI, and Sp8, imparts positional or area identities to cortical progenitors, which is imparted to their neuronal progeny that form the cortical plate (CP). The CP also initially exhibits gradients of gene expression that are gradually converted to distinct patterns with sharp borders. Coincident with this process, distinct cortical layers (2–6), and the anatomically and functionally distinct areas seen in the adult (M1, motor; S1, somatosensory; A1, auditory; V1, visual), differentiate from the CP. Genes that are differentially expressed across the cortex are often expressed in different patterns in different layers, suggesting that area-specific regulation of such genes is modulated by layer-specific properties, raising questions about the definition of area identity. Although the initial establishment of the graded gene expression in the embryonic CP is controlled by mechanisms intrinsic to the telencephalon, the much more complex differentiation patterns established postnatally, often both spatially and temporally in parallel with the development of thalamocortical afferent input, suggest that these later events might well be regulated influences that arise extrinsic to the cortex, such as thalamocortical afferents. Future studies are required to determine and clarify these mechanisms. Adapted from O'Leary DDM and Nakagawa Y (2002) Patterning centers, regulatory genes and extrinsic mechanisms controlling arealization of the neocortex. *Current Opinion in Neurobiology* 12: 14–25.

strong until approximately E13.5, after which the cortical hem shrinks in size, develops into the fimbria (an axonal tract of the hippocampal formation), and slowly downregulates its expression of these signaling molecules. Although Wnts have been shown to enhance proliferation of cortical progenitors, little evidence implicates Wnts and BMPs in regulating area patterning.

Anteroposterior Patterning of the Cerebral Cortex: Are Arealization and Regionalization Related?

For TFs that exhibit low to high AP graded expression patterns in the neocortex, their graded expression patterns often continue beyond the posterior extent of the neocortex and into other regions of the cerebral hemisphere and through the hippocampal fields. Examples of TFs that function in neocortical arealization and exhibit this form of continuing graded expression include Emx2 and COUP-TFI. These continuous, graded expression patterns suggest a relationship between arealization of the neocortex and arealization of other regions of the cerebral cortex, as well as a relationship between arealization and regionalization of the cerebral cortex. This observation warrants further investigation into these potential relationships.

Translation of Graded Expression of TFs by Cortical Progenitors and Their CP Progeny into Sharp Borders Exhibited by Cortical Areas

The graded expression of TFs expressed by cortical progenitors in the VZ/SVZ, and early on by their neuronal progeny in the CP, eventually transforms into sharply bordered patterns of gene expression that often relate to borders of cortical areas. Studies in *Drosophila* embryos have suggested mechanisms that might operate in the mammalian cortex to accomplish this change. For example, the graded distribution of dorsal, a regulatory protein, generates (through concentration-dependent differences in binding efficacy to promoter and repressor elements) expression patterns of downstream genes with sharp borders that align with the boundaries of different embryonic tissues and related patterns of gene expression. A different example is the development of the sharply patterned expression of the *even-skipped* gene through the combined

Figure 3 The *Emx2* gene imparts area identities to cortical progenitors and their progeny: levels of *Emx2* expression control sizes of cortical areas. Top panel shows relative levels of graded *Emx2* expression in cortical progenitors in four genotypes: wild type (wt), with normal levels of *Emx2*; *ne-Emx2* transgenic mice, in which an *Emx2* transgene is driven by a nestin promoter in cortical progenitors and results in about a 50% increase in overall *Emx2* levels; *Emx2* heterozygous mice ($Emx2^{+/-}$) with only one wt *Emx2* allele, resulting in about a 50% decrease in overall *Emx2* levels; and *ne*-Emx2; $Emx2^{+/-}$ mice with overall levels of *Emx2* being essentially normal due to the combination of endogenous *Emx2* and the *Emx2* transgene. The arrows show the predicted and observed shifts in area patterning. The bottom panel shows area patterning using a schematic of the four primary areas, motor (M), somatosensory (S1), auditory (A1), and visual (V1). The *ne-Emx2* transgenic mice exhibit decreased sizes of S1 and M, an increase in V1, and a rostral shift in all areas. The $Emx2^{+/-}$ mice exhibit increased sizes of S1 and M and decreased size of V1. The sizes of the primary cortical areas in the *ne-Emx2*; $Emx2^{+/-}$ mice revert toward their normal sizes observed in wt. Therefore, the sizes of the areas depend on the overall level of graded *Emx2* expression, and changes in area sizes due to increases or decreases in *Emx2* can be rescued by restoring *Emx2* to wild-type levels in cortical progenitors. Adapted from Hamasaki T, Leingartner A, Ringstedt T, et al. (2004) EMX2 regulates sizes and positioning of the primary sensory and motor areas in neocortex by direct specification of cortical progenitors. *Neuron* 43: 359–372; and from Leingartner A, Thuret S, Kroll TT, et al. (2007) Sizes of somatosensory and motor cortical areas determine proficiency at tactile and motor behaviors. *Proceedings of the National Academy of Sciences of the United States of America* 104: 4153–4158, Copyright (2007) National Academy of Sciences, USA.

action of multiple activators and repressors of its transcription; *even-skipped* is expressed in stripes perpendicular to the AP axis of the *Drosophila* axis where expression of repressors is subthreshold and that of activators is suprathreshold.

Similar mechanisms appear to operate in the developing spinal cord, where sonic hedgehog (shh), a gene product secreted by the notocord and floorplate, represses or induces the expression of different classes of TFs in the VZ of ventral spinal cord. Initially, these TFs have graded, overlapping expression patterns which progressively sharpen through mutual repression, to generate sharply bordered patterns of expression. This mechanism generates genetically distinct domains of progenitors defined by their expression of unique subsets of TFs, which in turn generate unique classes of spinal interneurons and motor neurons.

Similar mechanisms likely operate in the neocortex to generate areas, but important differences are evident. For example, at no time during neocortical neurogenesis are sharply bordered patterns of regulatory genes observed in the neocortical VZ; all have graded expression patterns. Initially, even expression in the CP is graded, but at later stages of development many genes acquire expression patterns with an abrupt border that, in some instances, matches the border between areas.

What Is 'Area Identity'?

The findings and issues discussed in the preceding sections lead directly to a major issue that remains unsettled: the extent to which areas are genetically distinct. Area-specific genes *per se* either do not exist or are very rare at the developmental stages when area identities are being genetically specified, and perhaps even later, when the anatomical features that distinguish areas begin to differentiate within the CP. Thus, in terms of gene expression, a neocortical area is not defined by the expression of a specific set of genes restricted to that area. Instead, a neocortical area is defined by the expression of a unique subset of genes, each of which is also expressed in other areas. However, the actual scenario is even more complex, since each layer has a unique profile of gene expression. Each gene differentially expressed in the neocortex, and expressed in more than one layer, has different expression patterns in each layer. An excellent example is *MDGA1*: this gene encodes a protein that is an immunoglobulin cell adhesion molecule. It is expressed in layers 2/3 through the neocortex,

>and is also expressed in layers 4 and 6 within S1. Thus, it has both layer- and area-specific patterns of expression, and can be used to define an area, S1, but its expression is not limited to that area. Thus, the term 'area identity' in the strictest sense might not truly exist for neurons across layers, and uniquely marks neurons with the specific identity of a given area.

Neural Patterning: Eye Fields

Introduction

Patterning of the central nervous system (CNS) has a crucial role in shaping functional organization. Owing to its external position in the embryo, the eye is often used as a model to study CNS patterning. Establishment of the anteroposterior (A-P) and dorsoventral (D-V) axes constitutes a fundamental step in retinal development. Several morphogens and transcription factors expressed asymmetrically in the early retina play key roles in the establishment of the A-P and D-V axes of the retina. The neural retina is a highly organized sensory organ that receives, integrates, and transmits visual information. Light is captured by the photoreceptor cells, and its information is converted into chemical signals to be sent through a series of interneurons to the projection neurons of the retina, the retinal ganglion cells (RGCs).

During embryonic development, the axons of RGCs grow from the eye to the contralateral optic tectum (OT), the primary visual center in lower vertebrates, or the superior colliculus (SC) in mammals and form a topographic map of visual space. RGC axons emanating from the anterior (nasal) retina project to the posterior OT/SC, while those from the posterior (temporal) retina project to the anterior OT/SC. Likewise, axons from the dorsal retina project to the lateral (L, or ventral) OT/SC, while those from the ventral retina project to the medial (M, or dorsal) OT/SC. For the formation of topographic maps, molecular gradients in origins and targets are essential, as predicted by Sperry in the classical chemoaffinity hypothesis. The family of Eph receptor tyrosine kinases and their ligands, the ephrins, have been shown to fulfill these criteria and control topographic map development.

Members of the EphA family expressed with a temporal high-nasal low gradient in the retina and of the ephrinA family expressed with a posterior high-anterior low gradient in the OT/SC determine the retinotectal projection along the A-P axis. The receptors of the EphB family expressed with a ventral high-dorsal low gradient in the retina, and the ephrinB ligands expressed with a medial high-lateral low gradient in the OT/SC control the mapping of retinal axons along the M-L axis. Recent advances in the study of the molecular mechanisms for retinal patterning are discussed below, and the molecular cascade controlling the events in the chick are highlighted. It is not yet clear whether the patterning mechanism revealed in the chick retina is wholly valid for mammals.

Retinal Patterning along the A-P Axis

When is the A-P axis determined in the developing retina? Fate mappings of the avian anterior forebrain have revealed that there is a distinct area for the presumptive retina in the neural plate, and the A-P axis of the presumptive territory in the neural plate corresponds to the A-P axis of the retina. In the A-P subdivision during the brain's development, boundaries are established at the zona limitans intrathalamica and between the forebrain and midbrain and the midbrain and hindbrain by mutual repression between *Six3* and *Irx3*, *Pax6* and *Pax2*/*En1*, and *Otx2* and *Gbx2*, respectively. Fibroblast growth factor-8 (*FGF-8*) is expressed at the anterior neural ridge and the midbrain–hindbrain boundary and helps to further subdivide the brain. The homeobox genes modulate the response to FGF-8 in their territories – within the *Six3* territory in the anterior forebrain, FGF-8 can induce the expression of *FoxG1*, a winged-helix/forkhead (Fox) transcription factor, whereas in the *Irx3* domain, FGF-8 in the midbrain–hindbrain boundary activates *En1*.

The forebrain is further subdivided by the mutual repression between *FoxG1* (also referred to as Brain Factor 1, *BF1*) and the related gene *FoxD1* (Brain Factor 2, *BF2*). These two *Fox* transcription factors are expressed in adjacent domains in the prospective eye region at the time the optic vesicle evaginates. It is thus considered that the establishment of the retinal polarity along the A-P axis is triggered by FGF signaling. In the chick embryo, misexpression of *FGF-8* upregulates the expression of *FoxG1* and downregulates that of *FoxD1* in the optic vesicle. After the formation of the optic cup, *FoxG1* is expressed in the nasal retina and *FoxD1* is expressed in the temporal retina in a complementary pattern by counteracting each other. Because surgical manipulations of the chick optic vesicle begin to induce severe disturbances to the visual projection map from Hamburger–Hamilton (HH) stage 11/12 (on E1.5), retinotopic specification along the A-P axis of the retina is considered to be determined at or prior to the optic vesicle stage. Ectopic misexpression of *FoxG1* or *FoxD1* in the chick retina reversed the topographic map in the retinotectal projection along the A-P axis. These factors are thus supposed to play a key role in

the initiation of retinal regional specification along the A-P axis.

Subsequently, two homeobox transcription factors, *GH6* and *SOHo1*, are known to be expressed specifically in the nasal region of the developing chick retina. Both *GH6* and *SOHo1* are downstream targets of the Fox genes. Misexpression of *FoxG1* induces the expression of *GH6* and *SOHo1* in the temporal retina. In contrast, *FoxD1* inhibits the expression of these two homeobox genes in the retina. Misexpression of *GH6* or *SOHo1* in the retina results in errors in the projection of retinal axons to the OT along the A-P axis, due to the repression of *EphA3* expression in the temporal retina.

In contrast to *EphA3*, four EphA receptors (*EphA4*, *EphA5*, *EphA6*, and *EphA7*) are uniformly expressed in the chick retina. On the other hand, *ephrinA2* (see below) and *ephrinA5* are also expressed with a nasal high-temporal low gradient in the retina. Overexpression of ephrinAs in temporal axons leads to errors in the topographic targeting of temporal axons, suggesting a role for retinal ephrinAs in the formation of topographic projections. Thus, EphAs uniformly expressed in the retina are also thought to be involved in the topographic projection along the A-P axis, with the help of ephrinAs expressed with a gradient in the retina.

It has been revealed that *FoxG1* controls the expression of all the molecules distributed asymmetrically along the A-P axis through multiple mechanisms in the chick. *FoxG1* is known to act as a transcriptional repressor. The expression of downstream targets of *FoxG1* in the retina is affected by the misexpression of a chimeric protein that consists of a *Drosophila* even-skipped repression domain and a winged-helix (WH) DNA-binding domain of FoxG1. The repressing construct of FoxG1 regulates the expression of *SOHo1*, *GH6*, *EphA3*, *FoxD1*, and *ephrinA5*, similar to the wild type, but not the expression of *ephrinA2*. On the other hand, mutant FoxG1 deficient in DNA-binding ability exerts similar effects on the expression of *SOHo1*, *GH6*, *EphA3*, *FoxD1*, and *ephrinA2* as the wild-type FoxG1, but not on the expression of *ephrinA5*. These results suggest that *FoxG1* controls *ephrinA5* by a DNA-binding-dependent mechanism, *ephrinA2* by a DNA-binding-independent mechanism, and *FoxD1*, *SOHo1*, *GH6*, and EphA3 by dual mechanisms. It is important to note that FoxG1 interferes in bone morphogenetic protein 2 (BMP2) signaling and thereby induces oblique-gradient expression of ephrinA2. The BMP2 signal resultantly plays a pivotal role in the topographic projection along both axes (see below).

What would be the point of using two distinct mechanisms, DNA binding-dependent and DNA binding-independent, to regulate the expression of topographic molecules? One answer is for security to maintain regulation of the EphA/ephrinA system. For instance, if the DNA binding-dependent mechanism is lost because of a mutation in the WH domain, FoxG1 can still regulate the asymmetrical distribution of *EphA3* and *ephrinA2* through the remaining DNA binding-independent mechanism. On the other hand, if the DNA binding-independent mechanism is lost, FoxG1 can still regulate the asymmetrical distribution of *EphA3* and *ephrinA5* through the DNA binding-dependent mechanism. Gene knockout of *ephrinA2* and *ephrinA5* in mice suggests the importance of this redundancy: in the single knockout mice, a substantial proportion of the retinal axons projected normally onto the SC. Since the total EphA/ephrinA system plays an essential role in the formation of the retinotectal map, this dual regulatory system might have evolved during the evolution of the visual system.

In *FoxD1*-deficient mice, ephrinA(s) is highly expressed in both halves of the retina. Misexpression of *FoxD1* inhibits the expression of *ephrinA5* in the chick nasal retina. These results suggest that *FoxD1* is essential for the establishment of the temporal regional specificity in the retina. To reveal the function of *FoxD1* in detail, further experiments are needed. In addition, there is the possibility that yet unknown factors, which are expressed specifically in the temporal retina as the counterpart of *SOHo1* and *GH6*, regulate the regional specification of the temporal retina. *FoxG1* and *FoxD1* are thus thought to be located at the top of the gene cascade for the regional specification along the A-P axis and determine the nasal or temporal specificity in the retina through multiple mechanisms. The cascade of control genes for the formation of the A-P axis of the chick retina is shown in **Figure 1**.

Mouse *FoxD1* plays a role in the specification of the ventrotemporal (VT) retina. In the chick, ipsilateral projection of retinal axons is not observed. In contrast, in mammals, ipsilaterally projecting axons arise from the VT region. The decision of RGCs from the VT retina to project ipsilaterally at the optic chiasma is controlled by the zinc-finger transcription factor *Zic2*. The VT axons are positive for EphB1 and repelled by ephrinB2 expressed in the midline glial cells at the optic chiasma. Conversely, an LIM homeodomain transcription factor, *Islet2*, is expressed in a pattern complementary to *Zic2*, repressing *Zic2* expression in the retina. In the *FoxD1*-deficient mice, the VT axons aberrantly project contralaterally because the expression of *Zic2* and *EphB1* is missing. It is not clear whether *FoxD1* also regulates the ipsilateral projection in other species such as *Xenopus*, in which ipsilateral projections develop after metamorphosis.

Figure 1 Molecular control of anteroposterior (A-P) patterning. FGF-8 derived from the anterior neural ridge induces *FoxG1* expression in the retina. The counteraction between *FoxG1* on the nasal side and *FoxD1* on the temporal side governs the retinal patterning along the A-P axis early on in development. Subsequently, the transcription factors GH6 and SOHo1 in the nasal retina begin to be expressed under the control of *FoxG1*. *GH6* and *SOHo1* inhibit the expression of *EphA3*. *FoxG1* and *FoxD1* also counteract each other to determine the expression pattern of *ephrinA5*. *FoxG1* induces the expression of *ephrinA2*. Arrows and T-bars indicate positive and negative effects, respectively. These effects are not necessarily induced by direct action. Nasal (N; anterior, A) is left, and temporal (T; posterior, P) is right.

Figure 2 Molecular control of dorsoventral (D-V) patterning early in development. The counteraction between *BMP4* on the dorsal side and *Ventroptin* on the ventral side governs the retinal patterning along the D-V axis early in the developmental process. Subsequently, transcription factors Tbx5 in the dorsal retina and cVax in the ventral retina begin to be expressed under the control of the BMP4 signal. *Tbx5* and *cVax* counteract each other to determine the expression pattern of EphB receptors and their ligands, ephrinBs. Sonic hedgehog (Shh) derived from the ventral midline presumably induces expression of *Ventroptin* in the retina. Arrows and T-bars indicate positive and negative effects, respectively. These effects are not necessarily induced by direct action. Dorsal (D) is upwards, and ventral (V) is downwards.

Retinal Patterning along the D-V Axis at the Early Stages

Soon after A-P polarity is determined, initial D-V patterning also develops through the actions of morphogens and transcription factors. Figure 2 shows the schema for the establishment of the D-V axis of the chick retina early on. BMP signaling is required for the D-V patterning of the CNS in vertebrates. The retinal patterning along the D-V axis also appears to be controlled by a gradient of BMP4 signaling, emanating from the dorsal retina. Ventroptin, a BMP antagonist, in the ventral retina counteracts BMP4. Overexpression of *BMP4* in the chick retina upregulates a dorsally expressed T-box transcription factor, *Tbx5*, and downregulates a ventrally expressed *Emx* homeobox gene, *cVax* and *Ventroptin*. In the *BMP4* knockout mouse, the expression of *Tbx5* is lost. Overexpression of *Ventroptin* in the chick retina leads to a downregulation of *BMP4* and *Tbx5* expression and to upregulation of *cVax* expression. The counteraction between *BMP4* and *Ventroptin* thus governs the regional specification along the D-V axis in the retina by controlling the expression of the downstream transcription factors, *Tbx5* and *cVax*.

Sonic hedgehog (*Shh*) is a ventralizing morphogen in many areas of the CNS. Shh expression in the ventral neural tube and the underlying axial mesendoderm extends to the neural and mesodermal tissue located between the two eyes. Therefore, it has been suggested that Shh acts as a long-range morphogen and controls the D-V patterning in the retina, although it is not expressed in the retina. Consistent with this view, misexpression of *Shh* in the chick and *Xenopus* retina suppresses the expression of *BMP4* and *Tbx5* and enhances the expression of *cVax/Vax2*. Because *Ventroptin* also controls the expression of these molecules, Shh supposedly ventralizes the retina through induction of *Ventroptin* expression.

Tbx5 begins to be expressed in the dorsal retina at the early optic cup stages. Misexpression of *Tbx5* in the chick retina enhances the dorsal expression of *ephrinB1* and *ephrinB2* and represses the ventral expression of *EphB2*, *EphB3*, and *cVax*. Additionally, ectopic expression of *Tbx5* causes ventral retinal axons to exhibit defects in topographic mapping. As the optic cup invaginates, *cVax* expression commences in the ventral regions of the retina. Overexpression of *cVax* downregulates the expression of the dorsalizing factors, *BMP4* and *Tbx5*, and upregulates that of the ventral markers, *EphB2* and *EphB3*. When *cVax* is misexpressed in the chick retina, the dorsal axons do not project to their correct target zones, whereas ventral axonal projections appear to be normal.

Thus, *cVax* is sufficient for retinal ventralization. *Tbx5* and *cVax* counteract each other similar to the relation between *BMP4* and *Ventroptin*. Although they are located downstream of *BMP4* and *Ventroptin*, their expression domains have a gap of significant width, in which neither of them is expressed. Two other members of the T-box gene family, *Tbx2* and *Tbx3*, are expressed with a dorsal high-ventral low gradient the same as *Tbx5*, but they cover the gap region. They are also involved in the D-V patterning of the retina. Therefore, a combination of these transcription factors may control the retinal patterning and retinotectal projection along the D-V axis.

Retinoic acid (RA) is also asymmetrically distributed along the D-V axis in the developing retina. The presence of dorsal and ventral zones of RA activity in the retina separated by an RA-free middle zone is conserved among vertebrate species such as zebra fish, chick, and mouse. The two zones of RA activity are sculptured by the expression of two different RA-synthesizing enzymes, RALDH1 in the dorsal retina and RALDH3 in the ventral retina. The presence of a mid-zone free of RA is due to the expression of multiple members of the Cyp26 family of RA-degrading enzymes. RA has been proposed to control the D-V patterning in the retina. In support of this hypothesis, mice deficient in some retinoid receptors show marked defects in development of the ventral eye. Addition of RA to zebra fish embryos during the eye's development results in ventral retinal duplication, while addition of an inhibitor of the ventral RA-synthetic enzyme causes deletion of the ventral retina. These results indicate that RA is essential for proper development of the ventral eye. When analyzed by gene expression, RA treatment of *Xenopus* embryos causes a reduction of *Tbx5* expression and expansion of *Vax2* expression, suggesting that RA has ventralizing activity. However, inhibition of RA signaling in chick or mouse embryos by overexpression of dominant-negative RA receptors or a double knockout of *RALDH1* and *RALDH3* does not significantly alter the expression of *Tbx5* and *cVax/Vax2*, indicating that RA is not involved in the early D-V patterning of the retina in these species. The role of RA in retinal D-V patterning should be clarified by further studies.

Retinal Patterning along the D-V Axis at the Later Stages

The counteraction between *BMP4* on the dorsal side and *Ventroptin* on the ventral side governs the regional specification in the chick retina along the D-V axis early on in the developmental process (HH stage 11 to E5), as described above. At later stages (from E5 onward), in proportion to the disappearance of *BMP4* expression from the dorsal retina, *Ventroptin* begins to be expressed with both a nasal high-temporal low and a ventral high-dorsal low gradient (oblique gradient) in the chick retina, or V/N-high pattern. At the same time, *BMP2* begins to be expressed with an oblique-gradient pattern complementary to that of *Ventroptin* along the two axes, or D/T-high pattern. Thus, the counteraction between *BMP4* and *Ventroptin* is relieved by that between *BMP2* and *Ventroptin*. *FoxG1* represses *BMP2* expression through inhibition of the BMP signaling, and thereby the oblique-gradient expression patterns of *BMP2* and *Ventroptin* are induced. Expectedly, misexpression of *Ventroptin* in the developing chick retina alters the retinotectal projection not only along the M-L axis but also along the A-P axis, owing to the induction of *ephrinA2* expression. It has been long believed that the A-P and D-V axes in the developing retina are determined independently, and also that the retinotectal projection along the two axes is controlled independently. However, these findings indicate that the retinal patterning and topographic mapping along both the A-P and D-V axes are determined in a coordinated manner.

BMP2 knockdown and *BMP2* misexpression in the chick retina at later stages alter the expression of the topographic molecules so far reported to have a gradient only along the D-V axis and that of *ephrinA2* so far only along the A-P axis. Furthermore, these molecules are expressed with an oblique gradient at the later stages, similarly to *BMP2* and *Ventroptin*. Although the axis along the fissure is defined as the D-V axis early on in development, these findings indicate that the D-V axis is tilted to the posterior side at around E5 through the switch from *BMP4* to *BMP2*, along with the corresponding change in the expression pattern of the downstream topographic molecules: the revised oblique D-V axis (D/T-V/N axis) is no longer perpendicular to the A-P axis from E6 onward, when retinal axons begin to project to the tectum in chick embryos. The polarity along the D-V axis was assumed to be determined between HH stage 8 and 14 in the chick retina based on transplant experiments. However, our findings indicate that the plasticity of the regional specificity along the first (orthogonal) and second (tilted) D-V axes is long maintained by BMP signaling and that *BMP2* is responsible for the maintenance of the second D-V axis at the later stages in the retina.

The presence of oblique-gradient molecules in the retina was not recognized until the discovery of Ventroptin. EphrinA2 has long been believed to be a topographic molecule only along the A-P axis. Presumably, this was because previous studies of retinal patterning and retinotectal projection focused on

Figure 3 Developmental expression of topographic molecules in the chick retina. The counteraction between *FoxG1* and *FoxD1* determines the regional specificity along the anteroposterior (A-P) axis in the retina. *FoxG1* controls *ephrinA5* by a DNA binding-dependent mechanism, *ephrinA2* by a DNA binding-independent mechanism, and *FoxD1*, *SOHo1*, *GH6*, and *EphA3* by dual mechanisms. The counteraction between bone morphogenetic protein 4 (*BMP4*) and *Ventroptin* (VOPT) governs the regional specification in the retina along the dorsoventral (D-V) axis early in development (Hamburger–Hamilton stage 11 to E5). At around E5, BMP4 expression in the dorsal retina rapidly begins to disappear, and Ventroptin comes to be expressed in an oblique-gradient manner from E6 onward (in a ventral/nasal-high) gradient). Concomitantly, *BMP2* begins to be expressed in a pattern complementary to that of *Ventroptin* (in a dorsal/temporal-high gradient). The inhibitory action of FoxG1 on BMP signaling is attributable to the change in the expression of *Ventroptin* and *BMP2* to the oblique-gradient pattern. The counteraction between *Ventroptin* and *BMP2* determines the expression of the formerly dorsoventrally asymmetric molecules and *ephrinA2* in an oblique-gradient fashion and resultantly governs the retinal patterning and retinotectal projection along both the A-P and D-V axes. *EphrinA2* begins to be expressed much later than does *ephrinA5* from E6 in an oblique-gradient manner from the beginning under the control of the BMP2 signal. Development proceeds from left to right. Reproduced from Sakuta H, Takahashi H, Shintani T, et al. (2006) Role of BMP2 in retinal patterning and retinotectal projection. *Journal of Neuroscience* 26: 10868–10878.

only the A-P or the D-V axis individually. However, the oblique-gradient expression appears not to be specific to the chick, because *Vax2* is also reported to be expressed with an oblique-gradient (V/N-high) pattern in the mouse retina. Phenotypic defects in topographic mapping along the M-L axis are often accompanied by those along the A-P axis, and vice versa. That the revised D-V axis is not perpendicular to the A-P axis should explain why misexpression or knockdown of the topographic molecules along the revised D-V axis induces changes in the topographic mapping along the two axes in the OT/SC. In support of this view, *ephrinA2* and *Ventroptin* misexpression and *BMP2* knockdown in the developing chick retina all induce phenotypic defects in the topographic mapping along both axes. Moreover, overexpression of *BMP2* in the mouse eye apparently leads to topographic errors among ventral axons along the A-P axis in addition to the M-L axis in the SC. Thus, all the topographic molecules with the oblique-gradient expression probably affect the topographic mapping along both axes. The gene cascades of topographic molecules for the retinal patterning and retinotectal projection in the chick are shown in Figure 3.

Other Aspects of Retinal Patterning

The establishment of retinal polarity is the basis for both the topographic expression of the axon guidance molecules and the formation of the retinotectal map as described above. In addition, many retinal cells are asymmetrically organized within the retina. For instance, chick RGCs and rod photoreceptor cells show an asymmetric distribution along the D-V and A-P axes. Moreover, melanopsin-containing RGCs involved in the circadian photoentrainment show a D/T-concentrated distribution in the rat retina. The distribution of these cells in the retina is also thought to be determined by the topographic transcription factors. This view is supported by the observation that the V/N-concentrated distribution of rod photoreceptor

cells is severely disturbed by the ectopic expression of *cVax* and a dominant-negative form of *Tbx5*.

The distribution of photoreceptor cells is organized differently in the retina among the vertebrate species. Cone cells are asymmetrically distributed along both the D-V and A-P axes in the mouse retina, but only along the D-V axis in the rabbit retina. This appears to be the result of adaptations to the life style of each species during evolution and must be precisely controlled by a set of genes during development. The degree of inclination of the D-V axis may vary between species, leading to a species-specific distribution of particular retinal neuronal types.

Neural Patterning: Midbrain–Hindbrain Boundary

Neural Induction and Posteriorization

The nervous system arises from the neural plate, which is induced during gastrulation (neural induction). Initially, the whole neural plate is of anterior character, and later it acquires posterior values leading to the formation of forebrain, midbrain, hindbrain, and spinal cord (posteriorization). Neural identity is induced by the interplay of antagonists of the bone morphogenetic proteins (BMPs) and the direct inducing activity of fibroblast growth factors (FGFs). In addition to FGFs, other signaling molecules, such as Wnts, retinoic acid (RA), and Nodals, are among the signaling molecules that have been proposed to elicit caudalizing activity. In frog and fish, high levels of BMP activity suppress anterior neural development and conversely, abrogation of BMP activity can promote neural specification. However, evidence from chick suggests that suppression of BMP activity is not sufficient to induce neural identity and that earlier signals, most likely FGFs, promote a 'prospective' state which is followed by maintenance of neural identity by BMP antagonists. Data suggest a model in which inhibition of BMP signaling promotes induction of anterior neural ectoderm, whereas in addition to its function in posteriorization, FGF signaling is necessary for specification of posterior neural ectoderm independent of BMP activity. This model links the two concepts of 'neural induction' and 'posteriorization' of neural tissue closely together by the combinatorial role of FGF signaling.

Positioning of the Brain Primordia

Identification of posteriorizing factors has been difficult because the various signaling pathways that modulate early from anterior to posterior (AP) pattern are often involved in many other events by influencing each other. Wnt molecules have been studied extensively and have been found to be good candidates for involvement in AP regionalization. Neural ectoderm is first induced with anterior character, and the most rostral cells retain this. The cells of the anterior border of the neural plate (ANB) in fish or anterior neural ridge (ANR) in chicken and mouse, located at the rostralmost tip of the neural ectoderm, have been identified as a signaling source promoting anterior forebrain gene expression. In fish, one of the secreted proteins responsible for the activity of the ANB is Tlc, a member of the secreted Frizzled related protein (sFRP) family generally considered as Wnt antagonists. Implanted Tlc-releasing cells are able to restore anterior forebrain identity in embryos lacking endogenous ANB cells. In mouse, Fgf8 has been shown to be required in the ANR for induction of Foxg1 expression and influences cell survival, and in zebra fish Fgf8 is required for patterning anterior commissural territories derived from the anterior neural plate. In general, anterior neural identity is reflected by the ubiquitous expression of *otx2*, a later marker of the forebrain and midbrain primordia. Following the induction of anterior neural tissue, Wnt signaling has been shown to directly repress the anterior expression domain of *otx2* and induces the expression of the posterior marker *gbx1* (the functional homologue of *Gbx2* in fish) without Fgf or Nodal signaling from the adjacent germ layers – respectively the endoderm and the mesendoderm. The signal is Wnt8 emanating from the posterior end of the neural plate, the margin of the embryo. Regionalized expression of the posterior neural markers *gbx1* and *gbx2* positions the boundary between midbrain and hindbrain by mutual repression of *otx2*. Following the establishment of the Otx2–Gbx interface, an MHB-specific cassette of markers is induced around the MHB: Pax2 and Wnt1 anterior to the MHB in the Otx2-positive midbrain domain, Fgf8 posterior to the MHB in the Gbx-positive hindbrain domain, and Engrailed 1 and 2 spanning the whole midbrain–hindbrain territory (Figure 1).

Similar to the interface between *Otx2* and *Gbx* at the MHB, a mechanism for the formation of the prospective ZLI has been proposed during mid-somitogenesis. The interface between the anterior Six3 expression domain and a posterior Irx3 domain should determine the future position of the ZLI. Chick explant culture experiments have suggested that the position of this interface is also controlled by Wnt signaling. Wnt3a induces expression of Irx3 and represses Six3. In addition, in *Six3-/-* mice, the prosencephalon is severely truncated, and ectopic expression of Six3 in chick and fish embryos shows that Six3 is a direct negative regulator of Wnt1 expression. Nevertheless, the role of Six3 in positioning the ZLI is still debatable due to the subsequent rapid retreat of its expression domain to the most anterior part of the forebrain prior to *shh* expression in the ZLI. In addition, there are no *in vivo* data supporting this mechanism, and genetic loss-of-function phenotypes have yet to prove this

Figure 1 Positioning of organizing centers during development of the neural tube. (a and b) Comparative brain anatomy of a fish embryo (32hpf) and a chicken embryo (HH26) at the pharyngula stage. The two organizing centers, the ZLI (red) and the MHB (yellow), are located at morphological outstanding places (arrows). At gastrulation stages, mutual repression of Otx and Gbx positions the principal signal of the MHB organizer, Fgf8 (yellow wings in c). During the segmentation period (d), Anteriorly to the MHB, Fgf8 pattern the midbrain and posteriorly Fgf8 induces cerebellar fate via activation of Irx2 (shown in the left half of the embryo). At the same time, the forebrain organizer is positioned anteriorly to Irx3 in chick or Irx1 in mouse and fish. At the pharyngula stage (e), Fgf8 maintains the characteristics of the midbrain and cerebellum and sets the anterior border of the midbrain via repression of pax6. At the same time (shown in the right half of the embryo), Hh signaling from the ZLI induces the proneural genes in the forebrain (Dlx2 and Dbx1a). The range of the principal signals is shown in the columns located to the left and right of the schematic neural tube. Cer, cerebellum; Hb, hindbrain; HTh, hypothalamus; MB, midbrain; MHB midbrain–hindbrain boundary; PTh, prethalamus; Tec, tectum; Teg, Tectum; Tel, telencephalon; Th, thalamus; ZLI, zona limitans intrathalamica.

concept. Evidence from work done in mouse and fish suggests a rather different mechanism: The transcription factors Fez/Fezl in the prethalamic anlage form an interface with Otx1/2, which is expressed in the anlagen of the ZLI and thalamus. This interface coincides exactly with the anterior boundary of the presumptive ZLI. Subsequently, the expression of the thalamic Irx genes, such as Irx1b in fish, represses the ZLI territory and therefore sets the posterior boundary and gives the ZLI its characteristic tapering shape.

In contrast to the induction of Fgf8 at the MHB, sonic hedgehog (Shh) expression in the ZLI is gradually recruited from ventral to dorsal. Cell movement provides a limited contribution in the dorsal extension of *shh* expression as the ZLI matures. Our understanding is limited with regard to the mechanisms leading to this dorsoventral induction of Shh expression in the ZLI. Induction via ventral Hh signaling or via AP signaling takes center stage in these arguments. In a chick explant approach, it was suggested that Shh from the basal plate is required for the formation of the ZLI. However, induction of Hh expression is independent of Hh signaling, or indeed any ventral signaling, as shown by *in vivo* studies in fish. By taking advantage of zebra fish mutants that lack the entire basal plate of the neural tube and therefore lack ventral *Shh* expression in the midline, namely the one-eyed pinhead and cyclops mutants, establishment of the ZLI was observed as an independent process. Furthermore, all Hh signaling is dispensable for the formation of the ZLI, as shown by the slow muscle omitted mutant embryo (*smu*), which carries a mutation in the coreceptor Smoothened, lacking any Hh signaling. Although the ZLI appears narrower in *smu* mutant embryos compared with wild-type siblings, grafting of wild-type cells in an *smu* mutant background shows that Hh signaling from the ZLI still has the ability to regionalize the territory appropriately. One possible explanation for the differences between the results observed in fish and chick is that in the latter, experimentally induced reduction of ventral Hh signaling causes the ZLI to mature more

slowly. Alternatively, the positive feedback autoregulatory mechanism for *hh* expression, a plausible mechanism in chick, is less evident in fish. The persistence of *shh* expression in the ZLI in *smu* mutant embryos indicates that a positive feedback autoregulation is indeed of little importance in zebra fish.

Function of Local Organizers

As mentioned previously, posteriorization of the neural tube sets the rough position of the brain primordia. To build such a complex structure as the brain, further regionalization processes are required. Indeed, following the coarse AP organization set up during gastrulation, local organizers refine the neural plate. The concept of 'local organizers' describes specific groups of cells that can direct development of the surrounding tissue by signaling molecules. To define a cell population as an 'organizer,' the tissue has to fulfill defined characteristics:

1. The activity resides in a defined population of cells.
2. Removal of these leads to the lack of specific structures.
3. Translocation of an organizer population to an ectopic competent location such as by grafting causes the induction of an ectopic structure.
4. Organizers refine simple spatial organizations into a more elaborate pattern of subregions – a complex spatial diversification of fields. Solely ectopic provision of its organizing or so-called principal signal is able to mimic the function of an organizer population.
5. The efficiency range of organizers depends on the timing of their appearance, how their effective signaling molecules spread, and how signals are translated into specific values at the target sites.

The isthmic organizer forms at the boundary between midbrain and hindbrain and is the best understood local signaling center in the developing central nervous system. Its inductive properties were first described in chicken by grafting isthmic tissue into ectopic locations in the neural tube, resulting in the respecification of the neural tissue to ectopic midbrain and/or cerebellum. Implanted beads soaked with Fgf8 protein can mimic these effects and show that it is therefore the principal signaling molecule secreted by the MHB organizer. A requirement for Fgf8 in MHB development was demonstrated in zebra fish and mouse. The global knockout of Fgf8 in mouse fails to gastrulate and dies very early. In contrast, the zebra fish mutant *acerebellar* (*ace*) overcomes the gastrulation defect and allows the study of specific late functions of Fgf8, supported by antisense studies in fish and conditional knockout in mice. The lack of functional Fgf8 results in loss of the isthmic organizer and subsequently in a loss of the cerebellum. Fgf8 is required to maintain marker gene expression in the midbrain and isthmus but not to induce midbrain, which has already been set up during gastrulation stages. Moreover, the analysis of the midbrain in *ace* mutant fish shows that the MHB is required for AP polarization of the tectum, including the graded expression of ephrin ligands in the midbrain neuroepithelium, and for proper retinotectal map formation. In fish and mouse, Fgf8, together with Engrailed 2, is also necessary to maintain the position of the boundary between the diencephalon and the mesencephalon (DMB) by repressing the expression of *pax6*, a key regulator of forebrain development. Fgf8 secreted from the MHB organizer is also involved in patterning the anterior hindbrain. The most anterior hindbrain segment, namely rhombomere 1, which lies closest to the MHB, does not express any *Hox* genes. However, after transplantation to an ectopic location, within the hindbrain, rhombomere 1 tissue starts to express *Hox* genes. Consistent with this observation, it has been shown that both isthmic tissue and Fgf8 can inhibit expression of *Hox* genes in chick. It has also been shown that alternative splicing of Fgf8 accounts for the higher receptor-binding affinity of Fgf8b relative to Fgf8a, and for the unique ability of Fgf8b to transform midbrain into cerebellum. Taken together, these observations suggest that Fgf signaling from the MHB is required for repression of diencephalic fate, correct midbrain patterning, cerebellum induction, and anterior hindbrain patterning.

Initially, another secreted factor, Wnt1, is broadly expressed throughout the midbrain until its expression becomes restricted to the dorsal midline and a narrow band anterior to the MHB, abutting the expression domain of Fgf8 anteriorly. Wnt1 mutant mice show severe midbrain defects. In fish, Wnt1, Wnt10b, and Wnt3a are partially redundant in their capacity to regulate gene expression at the MHB, and they are required to maintain *pax2* and *fgf8*. In addition, Wnt1 is dependent on proper expression of Fgf8 and Lmx1b as well as Pax2 and Engrailed function during mid-somitogenesis and serves therefore as an example of cross-regulation of different signaling pathways in fish and chicken. However, ectopic application of Wnt1 protein does not show inductive effects comparable to those of Fgfs, suggesting a permissive role for Wnt signaling in pattern formation at the MHB and an important role in cell survival and proliferation.

The function of a further local organizer, the ZLI, has been studied in various species. Similar to the

MHB organizer, the ZLI is located at a boundary between the prethalamus and the thalamus, and members of various signaling families such as Fgfs, Wnts, and Hh are expressed at these structures. This organizing center has been characterized and it was found that ZLI exerts its function by releasing signaling molecules from the hedgehog family, sonic hedgehog-a (Shh-a), and additionally in fish Shh-b (formerly known as tiggy-winkle hedgehog). Hh signaling from the ZLI directly regulates the acquisition of the cellular identity in the diencephalon, namely the acquisition of prethalamic neuronal fate anterior to the ZLI and thalamic fate posterior to the ZLI. Lack of Hh signaling results in a loss of the expression domains and therefore in the loss of cellular identity.

As described previously, a definitive characteristic of an organizer is its ability to induce ectopic cell fate in host tissue following heterotopic transplantation. This capability has been shown for the MHB organizer, which can induce ectopic tectal and/or cerebellar structures according to the place where the organizer is grafted provided it is competent. The ZLI has yet to be confirmed as a true organizer in this way.

Boundaries and Lineage Restriction

The position of organizers often correlates with the position of constrictions in the neural plate. These constrictions are mainly manifestations of gene expression boundaries. To regulate organizer activity, a mechanism must exist that not only ensures the position of the organizer but also defines the actual number and position of cells contributing to the signaling center. One control mechanism is to restrict cell movement across boundaries, which subsequently results in the polyclonal formation of lineage restriction compartments.

A study that followed the fate of hundreds of cells in the developing MHB territory in fish showed a cell lineage restriction boundary between midbrain and anterior hindbrain that corresponds to the Otx–Gbx boundary. A study using an inducible transgenic marker in mice also indicates restricted mixing behavior between the midbrain, isthmic area, and the forming cerebellum. Therefore, the isthmus might show the characteristics of a compartment rather than a single boundary, at least on the dorsal aspects of the neural tube. Eventually, the dorsal part of the midbrain–isthmus boundary seems to allow a small number of cells to cross, although the mouse study could not exclude initiation of the lineage marker prior to the establishment of lineage restriction. Late morphological cell movement at the MHB has also been addressed in chicken. Cells from the dorsal isthmus populate the dorsal midline of the midbrain as well as the cerebellum, and application of Fgf8 protein triggers cell movement and expression of roof plate marker ectopically in, for example, the diencephalon. In summary, there is evidence for restricted cell movement at the MHB in the ventricular zone, and the isthmus may therefore form a separate compartment, but lineage restriction is not absolute and allows cell movement under certain conditions and at specific stages, such as matured neurons in the mantel zone.

Compartmentalization in the forebrain territory has been analyzed for the past 15 years mostly in chick. Various models have been proposed, correlating morphological data and gene expression domains. Analysis of boundaries in the forebrain revealed that there are only three true lineage restriction boundaries: the boundary between pallium and subpallium within the telencephalon, the boundary between the forebrain and midbrain, and the interface between the presumptive prethalamus and the thalamus – the ZLI. Interestingly, the boundary between the prethalamus and the ZLI as well as the boundary between the ZLI and the thalamus are lineage restrictive and, thus, the ZLI is a true compartment. In chick, the presumptive ZLI territory is flanked by the expression domain of lunatic-fringe (Lfng), a glycosyl transferase that modulates the activity of the Notch receptor. The wedge-shaped Lfng-free territory later narrows to a band marking the definitive ZLI territory. Whether horizontal intercalation of cells or differential growth of the adjacent territories causes this phenomenon is unclear.

First Step in Competence: Integration of the Signal by the Surrounding Tissue

The ability of a tissue to respond to signals from an organizer is called competence. With regard to signaling molecules, competence is first defined by availability of their receptors and connected downstream pathway. For the MHB organizer, Fgf receptors (FgfRs) are expressed in the presumptive territory of the midbrain and hindbrain, and ligand activation triggers the intracellular signal transduction cascade of the MAP kinase (MAPK). High levels of expression of FgfR1 can be detected directly around the boundary. Consequently, knockdown of the FgfR1 and downstream players of the MAPK pathway such as the MAPK and Erk2 causes defects in gene expression at the boundary and a loss of the MHB structure. In parallel, Fgf signaling activates a number of repressors that act in a negative feedback loop, such as the coreceptor Sef and the intracellular inhibitors Spry and MKP3. Functional studies in fish have shown that membrane-bound Sef acts as an inhibitor *in vivo*. This repressive activity is elicited by direct binding

to FgfR1 *in vitro,* resulting in prevention of autophosphorylation of the receptor, which is necessary for signal transduction. Sprouty was originally described in *Drosophila* as an inhibitor of growth factor signaling, and experiments in vertebrates confirmed this function with regard to Fgf signaling. Misexpression of Spry4 inhibits the MAPK pathway and consequently leads to the loss of the MHB territory – a phenotype comparable to the Fgf8 mutant *acerebellar.* At the level of the nucleus, competence to respond to Fgf8 signaling is specifically regulated in the neuroectoderm by the zebra fish *spiel-ohne-grenzen* gene encoding the zebra fish oct4 homologue.

For the Hh family of signaling molecules, expressed at the ZLI, the situation is more complex. The ligand-binding component of the receptor of the morphogen is Patched (Ptc), which, being induced by Hh, is a bona fide target gene of Hh signaling. After binding of Hh to Ptc, the signal-transducing component Smoothened mediates the Hh response, presumably via activation of the Gli genes. Loss of Hh signaling can be achieved by interfering with different players of the signaling pathway: by misexpression of a dominant negative form of Patched construct, lacking an extracellular binding site for Hh; analysis of the *smu* mutant embryos; or analysis of embryos treated by the Hh pathway inhibitor cyclopamine. In fish and chick, these approaches revealed a direct dependency of prethalamic as well as thalamic development on functional Hh signaling from the ZLI. Dlx2-positive neuronal precursors in the prethalamic territory as well as Dbx1a- and Gbx2-positive neuronal progenitors in the thalamus do not appear in the absence of Hh signaling, suggesting a definitive requirement for the signal.

A Further Aspect of Competence: Predetermination of Cellular Fate

The definitive fate of the competent tissue is defined less by the principal signal than by the set of transcription factors exerting this function upon activation by the signal. The homeobox transcription factor Pou2/Oct4 is expressed in the early MHB anlage and is disrupted in the zebra fish mutant *spiel-ohne-grenzen*. Besides an early role for regulation of MHB genes, Pou2/Oct4 has a permissive role in mediating hindbrain competence to respond to FGF signaling and therefore restricts influence of the organizer posterior to the MHB.

For Hox gene-mediated positional information, it has been shown that Pbx proteins are necessary and sufficient, and a further facet of its role as competence factor has been revealed: Engrailed, together with Pbx, is required for proper establishment of the midbrain territory. Similar to the Hox genes, Pbx binds to Engrailed and its absence leads to comparable phenotype with the Engrailed knockdown: down-regulation of Fgf8 and caudal shift of the posterior forebrain into the presumptive midbrain territory (Figure 2).

Interestingly, a family of molecules that are able to modulate the response to signaling molecules and are asymmetrically expressed at boundaries has been identified: the Iroquois genes, which are involved in establishing neuronal prepattern in *Drosophila*. Irx2 is expressed posterior to the MHB in the presumptive hindbrain before the onset of Fgf8 expression and has been shown to mediate the competence of this region to form the cerebellum in response to Fgf signaling. Fgf8 via MAPK signaling is required to convert Irx2 from a transcriptional repressor to an activator: Thus, an activated form of Irx2 can convert presumptive tectum into cerebellum in the absence of FGF signaling. Irx2 fused to the engrailed repressive domain has the opposite effect when electroporated into the hindbrain: The entire cerebellum is transformed into

Figure 2 Function of the organizing centers. The lateral view of a schematic fish brain shows the influencing range and function of the two organizers: the ZLI organizer releases Shh (red), which binds to its receptor Ptc (light red; competence). In addition, the tissue around the organizer is already prepatterned (prethalamus, purple; thalamus, beige) and awaits the activation by Hh signaling to switch on the prethalamic program, induction of Dex2 expression, or thalamic program, induction of Dbx1a or Gbx2. Similarly, the tissue around the Fgf8-releasing center (yellow) is prepatterned and competent by the expression of the Fgf receptor 1. Anteriorly, in the tectum Fgf8 induces EphA2/A5, whereas posteriorly Irx2 and Pou2 (green) are needed to induce cerebellar fate.

midbrain tectum. This suggests that the midbrain/rhombomere 1 region has a tectal default state. The Irx2-related gene Irx3 is expressed exclusively posterior to the ZLI in the presumptive thalamus, and its ectopic misexpression anteriorly endows the prethalamus with thalamus-specific expression. This indicates that the Iroquois genes mediate positional competence on either side of signaling centers such as the MHB organizer and the ZLI organizer. Interestingly, the expression pattern of the Iroquois genes is independently induced of the principal signal and is more likely directly established by the early Wnt gradient in the neural plate. Further confirmation of this model derives from the finding that in fish, when wild-type cells are transplanted into a *smu* mutant embryo, they start to activate autonomously the proper gene expression with regard to the position of the ZLI, suggesting a correct prepattern independent of Hh signaling. Thus, principal signals from the organizers trigger the timing of the initiation of the downstream cascade rather than determination of the definitive fate of the surrounding tissue.

Functional Range of Organizers Is Determined by the Receiving Field

Apart from accurately controlling expression of the signaling molecule, a further way to control the functional range of signaling molecules has been identified. The receiving tissue actively regulates the range and the steepness of gradients from molecules released from source tissue. These mechanisms are the facilitation of signal spreading by modulation of extracellular matrix components, uptake of the signal molecule and direct degradation by 'restrictive clearance,' or uptake and re-release of signaling molecules by 'planar transcytosis.'

For signaling molecules in general, it has been shown that components of the extracellular matrix, such as the heparan sulfate proteoglycans (HSPGs), influence signaling range. For Fgf signaling, HSPGs function as coreceptors in the receptor complex and facilitate spreading of Fgf molecules through the extracellular space (ECS) in *Drosophila*. Consistently, enzymes involved in the biogenesis of heparan sulfate chains were found to be important for FGF signaling in flies and in mice. In mouse, a conditional knockout of Ext1, a glycosyltransferase involved in chain elongation of HSPGs, causes defects in the inferior colliculi and the cerebellum, a phenotype reminiscent of a loss of Fgf-dependent MHB function. A mutation in the heparan sulfate copolymerase *tout velu* and a mutation in the cell surface HSPG *dally* cause a decrease of movement of Hh molecules from their site of production. Furthermore, digestion of HSPGs by heparinase treatment strongly reduces the level of Shh signaling range in mice.

Advances have been made in understanding how signaling factors spread dynamically in embryos on a subcellular level. Identification of cellular components involved in signaling will yield a full understanding of the inductive mechanisms involved. The direct observation of tagged versions of signaling molecules has been correlated with the indirect evidence of the induction of gene expression. For Fgf8, an increase in internalization through activating Rab5-dependent endocytosis leads to a shortened functional range of the signaling factor. Conversely, reduced Fgf8 uptake by downregulation of Rab5 activity causes a wider signaling range of Fgf8 and subsequently a broader induction of target genes, such as Spry4 or the Ets transcription factors Erm and Pea3, a mechanism referred to as 'restrictive clearance' (Figure 3).

In the *Drosophila* wing, similar observations were made for wingless, for which different internalization rates operate posterior and anterior to the signaling center, which leads to different signaling ranges and creates an asymmetric response. By analogy, endocytosis might regulate the difference between

Figure 3 Influence of the competent tissue on the range of a signaling center. During gastrulation, in zebra fish, the range of Fgf8 is directly influenced by the capacity of internalization: Low internalization leads to a broader activation of the target gene (blue), whereas enhanced uptake leads to a restriction of target gene activation (c). Internalization is linked to degradation and restrictive clearance of the principal signal. In *Drosophila*, in wing imaginal discs, the signaling factor decapentapledgic (Dpp) behaves exactly the opposite: Low uptake restricts very strongly the induction of the target gene shown in yellow (d and e), whereas a higher level of internalization leads to a broad activation of target genes (f). Internalization is therefore linked to the propagation of the signaling factor and called planar transcytosis.

long-range activity of Fgf8 anterior to the MHB and short-range function in cerebellar induction and Hox gene repression. A further concept for signal spreading is provided by studies of the signaling molecule Dpp in the *Drosophila* wing imaginal disk. A higher rate of internalization led to a further distribution due to the fact that Dpp is only partially internalized for degradation, but a significant amount of the factor is released again. Thus, a planar transcytosis model allows the possibility that tight control of signaling range by the balance between degradation and release is determined by the receiving tissue as well as by the level of signal. It will be interesting to determine whether planar transcytosis exists in vertebrate embryos and whether this mechanism is employed in organizer signaling.

In this article, we described the formation and the function of two organizing centers in the early neural plate, the MHB organizer and the ZLI organizer. Apparently independent of organizer activity, the neural tube shows an initial expression pattern of modulating and determining factors, anticipating the actual fate of the regions. The organizers define the exact time points when these fates are going to be realized. Subsequently, the surrounding tissue reacts to the signal and initiates the downstream program. Furthermore, the surrounding tissue can influence the signaling range directly. The elaborate interplay between modulating factors and organizer activity sets the stage for the next level of complexity during brain development. It is obvious that this is only a next step and that many more have to follow to build as complex a structure as the human brain. Nevertheless, the prime importance of the exact timing of organizer activity is manifest, and alteration in these early events leads to gross malformation of the brain.

Neural Prostheses for Reaching

H Scherberger, University and ETH Zürich, Zürich, Switzerland

© 2009 Elsevier Ltd. All rights reserved.

Introduction

During the past 40 years, much progress has been made on prosthetics for the functional stimulation of muscles and of sensory pathways. In particular, cochlear prostheses for the hearing impaired have been tremendously successful, and promise has been shown for the restoration of vision with the stimulation of cortex, lateral geniculate nucleus, and the retina. These stimulation devices can help visually or auditory impaired people by transmitting meaningful sensory information into the brain. Paralyzed patients, in contrast, require a neural prosthesis of the opposite kind. They need a brain–computer interface (BCI) that can read motor plans originating from the brain and send them to external effectors such as computer screens or robotic arms. Ideally, of course, such BCIs can read the patient's brain noninvasively, that is, without the need to implant electrodes inside the skull.

This has been pursued using electroencephalographic (EEG) signals. For example, the group of Birbaumer used EEG slow cortical potentials to control an electronic spelling device that allows quadriplegic patients to write messages on a computer screen, and Wolpaw and colleagues achieved two-dimensional control of a cursor on a computer screen using EEG mu (8–12 Hz) and beta rhythms (18–26 Hz). Although this technique is noninvasive, major disadvantages are that it requires extensive training of the subjects and that the amount of information transmitted through the device is limited to approximately two characters or a few movements per minute. This is probably attributable to the fact that EEG decoding is more closely related to unspecific biofeedback than to reading out the movement intentions of the brain for specific actions. For these reasons, several researchers have been trying to access motor and premotor signals more directly, namely by placing bundles of microelectrodes into specific premotor, motor, and parietal brain areas of nonhuman primates and human patients.

Progress in Neural Prostheses

Using chronically implanted electrodes in motor cortex and thalamus of rats, Chapin and colleagues reliably recorded multiple action potentials of many neurons, or multiunit activity, simultaneously over days and weeks. The rat was trained to position a one-dimensional robot arm to obtain water by pressing a lever. The real-time signals of the recorded neurons were analyzed by an artificial neuronal network that was configured to estimate the robot arm trajectory. This population readout was used to control the position of the robot arm, and in some cases the animals could position the lever even without moving their own forelimbs. This result was a first proof-of-concept that cortical multiunit recordings can be used to read out movement intentions for controlling a robotic device, and a follow-up study of the same group could link the outcome of a learning behavior in a motor task with the predictability of the animal's response from the neural ensemble activity in motor cortex.

Following this success, similar attempts to read out movement plans have been made from motor cortex of nonhuman primates. Nicolelis and colleagues predicted arm trajectories in three-dimensional space from ensembles of cells in motor cortex using a decoding algorithm that was based on a neural network approach. At the same time, Schwartz and colleagues implanted arrays of microwire electrodes permanently in monkey primary motor cortex and recorded multiple single-unit activity over weeks and months. During arm-reaching trials, Taylor and colleagues found the time-varying speed and direction of the animal's arm to be encoded in motor cortex and the population vector approach was successfully applied to decode three-dimensional arm movement trajectories from the neuronal signals. Using principal component analysis, the temporal modulation of the neuronal ensemble was utilized to improve the movement prediction accuracy and the three-dimensional endpoint position of a robot arm could be controlled online. Similar results were also reported by Serruya and colleagues from the lab of Donoghue, who employed silicone-based electrode arrays. Finally, more cognitive brain areas involved in motor control have also been investigated for their suitability to control a motor prosthesis, which is highlighted in the following section.

Decoding Cognitive Motor Signals

Cortical areas such as the parietal reach region (PRR) in the posterior parietal cortex and the dorsal premotor area (PMd) in premotor cortex play an important role in the sensorimotor transformation of visual and other sensory information for the generation of arm-reach signals. Such high-level planning areas might represent reach intentions in a particularly simple

manner, for example, if they encode the movement goal and not the details of the movement trajectory or the movement dynamics. The group of Andersen at Caltech is developing a neural prosthesis for reach movements that is based on signals from PRR. In their decoding experiments, Musallam and colleagues trained macaque monkeys first in a delayed reach task and then in a brain control task after microelectrode arrays had been implanted permanently in PRR and PMd (Figure 1(a)). In the reach task, animals first touched and looked at a central fixation spot before a visual cue was presented for a few hundred milliseconds on a touch-sensitive screen in one of eight possible locations. In the following memory period, the animal could plan the upcoming reach movement but had to withhold its execution until a 'go' signal was given that instructed the animal to reach to the peripheral target, which was rewarded with a small amount of water or juice.

During brain control trials, single- and multiunit activity was recorded simultaneously from many electrodes during the memory period and used to decode the intended reach location. As a feedback to the animal, a visual target was placed on the screen reflecting the decoded target location. Importantly, the animal was not obliged to reach with its own arm and was rewarded if the 'decoded' location matched the required location target (cue). Interestingly, animals quickly adopted a strategy in which they planned, but did not execute, their intended reach movement.

Figure 1(b) shows an example neuron during the brain control task with a preferred direction upward and to the right. Activity increased from baseline after cue onset and remained elevated throughout the memory period (interval delineated by vertical dotted lines). However, trials in which the animal knew in advance it would receive a preferred reward (orange juice) produced a significantly stronger response (black curves and tick marks) than in trials in which the animal received a less preferred reward (water; red curves and tick marks). Similar findings were made when the expected amount of reward or the reward probability was varied instead of the reward type. This suggests that individual cells in PRR represent not only the target location but also the expected value of the intended action.

The decode performance in the brain control task steadily improved over the weeks and months of the experiment. Figure 1(c) shows the overall success rate for predicting the correct target position (one out of four possible positions) in approximately 70 daily sessions in two animals (different colors). Although

(b) Example neuron during the brain control task with instructions to the up, right, left, and down direction that were rewarded either with 'orange juice' (black) or 'water' (red). Clearly, this neuron was more strongly active for trials with the preferred reward 'orange juice.' (c) Overall success rate for decoding the intended movement from four possible targets in subsequent recording sessions in two animals (black and blue dots). Dotted line, chance level (25%). (d) Success rate in off-line simultaneous decoding of the reach direction (one of four) and the expected value (preferred or nonpreferred reward) in subsequent sessions of one animal. Adapted from Musallam S, Corneil BD, Greger B, et al. (2004) Cognitive control signals for neural prosthetics. *Science* 305: 258–262, with permission from AAAS.

performance was only slightly above chance in the beginning (25%, dashed line), it steadily increased to levels of approximately 55% in the first and 35% in the second animal. Similarly, Figure 1(d) depicts the success rate of the simultaneous (off-line) prediction of the movement direction (one out of four) and the expected value (high or low) for one animal (dashed line: chance level, 12.5%). These results indicate that the target goal, as well as the expected value of the action can be decoded simultaneously from the neural activity in PRR and suggest that cognitive signals from PRR could be a viable source for controlling a motor prosthetic.

Undoubtedly, it is important to identify the brain areas most suitable for the decoding of a specific action, particularly if the goal is to restore a lost motor function without interfering with other, still intact motor modalities. Second to this goal is the speed by which information can be transmitted in a BCI, and in this case it holds: the faster the better.

Fast Decoding

As stated previously, human-operated noninvasive decoding methods (e.g., EEG-based) can only transmit a few letters per minute (in the order of 1 bit s^{-1}), whereas for invasive methods the transmission rate can be substantially higher. At Stanford University, Santhanam and colleagues from the group of Shenoy have developed a high-performance BCI using a 96-channel silicon electrode array that was implanted in the premotor arm area PMd. Macaque monkeys were first trained in the previously mentioned delayed reach movement task, from which a statistical description of the tuning properties of the recorded neurons was obtained. For speed decoding, three or more prosthetic cursor trials followed in quick succession (Figure 2(a)). In all prosthetic trials, the animal continuously touched and looked at the central fixation spot, while a visual cue appeared in the periphery to indicate the target (yellow circle). The following delay period was then subdivided into a first epoch of 150 ms that was ignored and a second epoch of variable duration (10–300 ms), during which the neural activity of the electrode array was acquired and subsequently decoded. After that, the cue disappeared and the decoded target location was presented on the screen (dashed circle), resulting in a total trial duration of approximately 200–400 ms. Immediately after, either another prosthetic trial was started or the trial sequence was completed with a delayed reach trial and the animal was rewarded (not shown).

The selection of the optimal trial duration was found to be critical for maximizing the BCI performance. Decoding from longer trials led to more

Figure 2 Single trial accuracy and information transfer rate capacity during fast prosthetic cursor trials. (a) Sequence of three prosthetic cursor trials. After the animal has placed its hand on the board, a target (solid circle) appears, the intended reach movement is decoded, and a cursor is placed on the screen at the predicted location (dashed circle in the following trial). If the predicted location was correct, the next cursor trial started immediately. After three or more cursor trials, a standard real reach trial followed and the animal was rewarded (not shown). (b) Decode accuracy (black curve) and information transfer rate capacity (ITRC) (red solid curve) for different trial lengths, as assessed from an eight-target control experiment. Whereas decoding accuracy steadily increased with trial length, ITRC was maximal for a trial length of approximately 260 ms and then declined. Red dotted line, theoretical ITRC assuming 100% accuracy independent of trial length. Reprinted by permission from Macmillan Publishers Ltd: *Nature* (Santhanam G, Ryu SI, Yu BM, et al. (2006) A high-performance brain–computer interface. *Nature* 442: 195–198), copyright (2006).

accurate predictions because of the reduced noise in the integrated signal. On the other hand, longer trial durations also reduced the number of possible trials per second, thus leading to a decreased BCI performance. Figure 2(b) illustrates this fundamental speed–accuracy trade-off using data from the standard delayed reach task. Decode accuracy (measured in percentage of correctly decoded trials) increased with trial duration but saturated for trials longer than 250 ms (black curve). As a second performance measure, the information transfer rate capacity (ITRC) gives the rate at which information is transmitted. It is defined as the information per trial (which depends on the decode accuracy and the number of possible targets) divided by the trial duration. ITRC

did not increase monotonically with trial duration (red solid curve) but showed a peak of 7.7 bit s^{-1} at 260 ms. This was expectedly lower than the theoretical maximal ITRC that assumes 100% decode accuracy regardless of the trial duration (red dotted curve).

Using sequences of prosthetic trials with variable number of possible targets (2, 4, 8, or 16), the authors found in two animals a maximal ITRC of 6.5 and 5.3 bit/s, respectively (using the 8-target task), which by far exceeded current noninvasive (e.g., EEG-based) methods. These results highlight the superior performance of systems with implanted electrodes and suggest that invasive BCIs could be very beneficial for paralyzed patients.

Clinical Applications

The group of Kennedy was the first to report the restoration of neural output in a patient using a single, chronically implanted neurotrophic electrode. The electrode was inserted in primary motor cortex of a 'locked-in' patient who was completely paralyzed. Several weeks after implantation, activity from a single neuron that had grown into the cone electrode could be recorded and the patient was trained to control the firing rate of that neuron using visual and aural feedback.

Building on this initial success and their own experience with multielectrode recordings in monkeys, Patil and colleagues from the group of Nicolelis recorded intraoperatively from neurons in the subthalamic nucleus and thalamic motor centers using a 32-microwire array in patients undergoing deep brain stimulator surgery. Neural activity was recorded while patients performed intraoperatively a hand-gripping task with visual feedback, and subsequent off-line analysis revealed the viability of such neural signals to drive a human BCI. These findings were encouraging; however, there was concern that the recorded signals were largely somatosensory and would not correlate well with the movement intentions of paralyzed patients who are unable to move their arms.

These shortcomings, as well as the inherent risk of subcortical hemorrhages were avoided in the most advanced demonstration of a functional neural prosthesis using signals from human primary motor cortex. Hochberg and colleagues from the group of Donoghue recorded ensembles of motor neurons in a tetraplegic patient who was chronically implanted with a silicone-based electrode array (**Figure 3(a)**) 3 years after suffering a massive spinal cord injury. Intended hand motion of the patient modulated the recorded motor cortical activity, and using suitable decoding algorithms, the patient was able to control a cursor on a computer screen, open and close a prosthetic hand, and perform rudimentary actions with a robotic arm. Notably, these actions were possible for the patient with relatively little effort and

even while conversing. This ease of operation is most likely related to the inherent cortical plasticity that constantly keeps numerous sensory and motor systems in register and that might be involved in the fine-tuning of the recorded signals from visual feedback. Although more such patient studies are needed before final conclusions can be drawn, the existing evidence suggests a clear advantage for using highly localized brain activity for decoding, instead of the spatially more blurred signals to which noninvasive methods are currently confined.

The main difficulty of using BCIs with chronically implanted electrodes is the progressively deteriorating signal quality of the recorded spiking activity, which restricts the lifetime of the implanted electrodes to often less than 1 year. A better understanding of the physiological and biochemical nature of this signal degradation, as well as effective countermeasures, is therefore necessary before human patients can benefit in the long term from implantable BCIs that rely on spiking activity.

Electrode Design and Biocompatibility

Recording electrodes for chronic implantation in the brain have been manufactured from various materials and a number of protocols exist for their insertion into cortical and subcortical areas. Electrode arrays have been made from metal wires out of tungsten, stainless steel, or platinum/iridium with electrode shafts electrically isolated using varnish, parylene, or other coatings and with tips that are either left blunt or sharpened. Individual electrodes are arranged to bundles or arrays in a multitude of lengths and spacings. Figure 3(c) shows an example of such a multielectrode array, in which electrodes are rigidly attached to a connector. This ensemble is fixed to the skull after being slowly inserted into the brain using speeds of approximately 0.1 mm min^{-1}. Such designs have been extensively used and produced a wealth of neural data. However, since electrodes fixed to the skull cannot follow the intracranial movements of the brain due to respiration, circulation, and shock, these designs, although successful, have always been considered imperfect.

In a different approach, electrodes have been micromachined from a solid block of silicon (Figure 3(a)). This electrode array, originally developed by the group of Norman in Utah, consists of a 10×10 array of sharp electrodes that is cut and etched with electrode lengths of 1–1.5 mm and is implanted into the cortical surface with a pneumatic inserter at speeds of approximately 8 m s^{-1}. It is electrically connected with a flexible wire bundle to a connector that is fixed on the skull. This floating design allows the electrode array to follow the movements of the brain. It has been successfully used for targeting brain areas on the cortical surface, particularly motor and premotor cortex in monkeys and humans. However, implantation in cortical sulci and subcortical structures is essentially not possible due to the design limitation of approximately 1.5 mm for the electrode length.

To overcome this problem, silicone-based probes with long shanks have been developed that allow recording of neural signals from multiple sites along a single shank (Figure 3(b)). Such probes have a long history of success in acute experiments, but few data are available on the feasibility of this design for chronic recordings in monkeys or humans. Finally, a floating electrode array has been developed (Figure 3(d)) that combines the recording properties of metal electrodes with the advantages of a floating device. The suitability of this design has been demonstrated in a feasibility study in rabbits, but long-term results in monkeys or humans are not available yet.

Unfortunately, the signal quality of all these recording devices severely degrades within a few months after implantation, and the recorded spiking activity becomes unsuitable for operating a BCI. Apparently, the brain seems to develop an acute and, later, a chronic tissue reaction against all sorts of implanted electrodes. Although the biochemical reactions are not completely understood, histological examinations have shown that both reactive astrocytes and activated microglia are involved in this tissue response.

The acute tissue reaction seems to be triggered by the mechanical trauma during electrode insertion and is characterized by the presence of activated microglia in the first weeks after insertion. Functionally, the acute reaction alone might not be a significant problem. However, as soon as it diminishes, a chronic foreign body reaction starts and forms a sheath of activated microglia that insulates the electrodes from the nearby neurons. This reaction leads to a local neurotoxic environment that kills or significantly reduces the number of neurons immediately adjacent to the electrodes. As a result of these effects, the neural signal quality progressively degrades in the weeks and months after insertion until all spiking activity is eventually lost.

Although there may be some differences in the acute and chronic tissue reactions for different devices and implantation procedures, no systematic study exists for primates and the number of reported cases is relatively low. It has been argued that floating devices should be less traumatic in the long term and therefore should produce fewer tissue reactions than electrodes that are rigidly attached to the skull. However, tissue reactions seem to be quite similar

for the different electrode materials and insertion procedures. It remains to be seen whether advancements in the biocompatibility of the implanted materials or the use of drugs, such as neurotrophic factors or anti-inflammatory agents, can improve the long-term stability of the recorded neural signals in the future, such that these devices can be used in paralyzed patients over years and possibly decades. In a different approach, several groups have started to investigate other brain signals that are more robust, such as the local field potential, for the decoding of movement intentions.

Decoding from Local Field Potential Signals

The local field potential (LFP) is a summation signal of excitatory and inhibitory dendritic potentials from a large number of neurons in the neighborhood of the recording site. Spiking activity, in contrast, originates from a single neuron located close to the electrode tip. Because of its larger 'listening sphere,' LFP activity is much less affected by the tissue reactions following electrode implantation. Therefore, the question is interesting whether LFP signals could in principle be used to control a neural prosthetic device.

LFP activity has been investigated in cortical and subcortical areas. Several studies that related LFP activity in motor, parietal, and premotor cortex with the behavior of the animal showed that LFP signals are modulated during the task, as well as by the different behavioral conditions. For example, Scherberger, Jarvis, and Andersen investigated the LFP spectral power in the PRR during the planning and execution of a center-out reach or saccade task. The panels in Figure 4(a) show the LFP power spectrogram (in decibels relative to the baseline period) of a population of recording sites for reaches and saccades and for movements to the preferred and nonpreferred direction. Evidently, the low-frequency components (0–15 Hz) encoded the movement type (reach vs. saccade) during planning and execution independently from the movement direction. At higher frequencies (15–50 Hz), however, the LFP was also modulated by the movement direction, particularly for reaching.

Furthermore, decoding simulations based on these sequentially recorded data showed that LFP activity from PRR could predict the behavioral state of the animal, as well as the movement direction. Figure 4(b) illustrates the error rates for predicting five behavioral states (baseline fixation, reach and saccade planning, and reach and saccade execution) with a Bayesian classifier using various numbers of recording sites. For LFP activity, prediction errors were less than 10% when 20 or more sites were used for decoding. In contrast, errors were much larger when the predictions were made with spiking activity that was recorded simultaneously at the same sites.

The capabilities of the LFP to predict the movement direction are illustrated in Figure 4(c), which shows a confusion matrix for a decoding simulation of the reach and saccade directions using the LFP activity of 89 tuned sites during the planning period. Correct predictions lined up on the unity line, whereas directional errors occurred predominantly in the saccade task and to the neighboring directions. Notably, reaches and saccades were never confused, and the overall decoding accuracy was 81% for reach and 40% for saccade directions (chance, 6.25%). In comparison, 97% of the reach and 72% of the saccade predictions were correct when the decoding was made from the simultaneously recorded spiking activity at the same sites (not shown). Taken together, LFP activity in PRR can predict the behavioral state and the planned reach direction, and the somewhat diminished accuracy for using LFP instead of spiking activity might be compensated with an increased number of LFP recording sites that are relatively easy to acquire. Similar results have also been obtained in other studies that used LFP activity from motor cortex to predict reach movements and from the lateral parietal area to predict saccades.

It therefore appears that the LFP is a suitable and robust signal for decoding movement intentions and might help overcome some of the major drawbacks of current recording technology with respect to the long-term quality and stability of chronic recording.

More research is needed to determine whether spiking activity recorded from electrodes with improved biocompatibility characteristics or LFP or ECoG signals, or a combination of these, are best suited to overcome the current limitations of long-term recordings in invasive BCIs.

Finally, other recording techniques, such as the electrocorticogram (ECoG), might also play an important role in future neuroprosthetic devices. The ECoG is recorded with electrodes that are placed on the surface of the brain or between the skull and dura. It is a cortical summation signal that is more broadly localized than individual LFPs but still much finer than the EEG. Since ECoG electrodes do not penetrate the brain or dura, they are clinically safer than intracortical recordings, whereas the signal characteristics are still more closely related to the LFP than to the extracranial EEG. Tuning properties of the ECoG are not well explored. However, studies have demonstrated that the high-gamma frequency components of the ECoG can easily be modified through biofeedback and used for the online control of a curser. ECoG signals might therefore be advantageous for future neuroprosthetic devices with improved robustness and long-term signal stability.

Figure 4 Decoding of reach movements from LFP activity in the parietal reach region. (a) Population spectrogram of LFP activity during the reach and saccade task is presented for movements to the preferred and nonpreferred directions. Color code indicates LFP power relative to baseline activity. Vertical lines mark the start of the cue, planning, and movement period. (b) Decoding simulation of five behavioral states using LFP (blue) or spiking activity (red) as a function of recording sites. Behavioral states are indicated by markers: baseline (circles), reach planning (squares) and execution (diamonds), and saccade planning (upward-pointing triangles) and execution (downward-pointing triangles). (c) Decoding simulation of reach and saccade directions from LFP activity during movement planning. Color codes the distribution of the decoded directions for each direction planned by the animal (chance level, 6.25%). Reproduced from Scherberger H, Jarvis MR, and Andersen RA (2005) Cortical local field potential encodes movement intentions. *Neuron* 46(2): 347–354, with permission from Elsevier.

Conclusions

Much progress has been made to bring functional neural prostheses for reaching into clinical practice, but more research is needed to better understand the fundamental coding properties of brain areas that contribute to the planning and execution of arm movements. The question is still open regarding which brain areas and what kind of decoding algorithms are best suited to operate a neural prosthesis and how well the different neural signals, spiking activity, LFP, and EcoG can be employed to operate a BCI. Furthermore, the longevity of these signals during the long-term recordings needs to be further explored. However, the most important issue to make neural prosthetics a reality for paralyzed patients is to improve the biocompatibility of the implanted electrodes in order to ensure the long-term stability of the recorded signals following the months, years, and, it is hoped, decades after electrode implantation.

Neural Repair and Regeneration: Inflammatory Mechanisms and Cytokines

A Hartmann, INSERM UMR 679, Paris, France

Introduction

Inflammation is a specialized immune response of the organism to an invading pathogen, a traumatic event, or, in general terms, an injurious agent. The agent may be foreign or self, as in a necrotic cell, and inflammation may be acute or chronic. Inflammation in the classical sense involves innate and adaptive immune responses. Innate immune responses involve typically macrophages, natural killer cells, the complement system, and numerous cytokines, chemokines, acute phase proteins, and arachidonate metabolites. The adaptive immune response uses the same soluble mediators as well as T and B lymphocytes and specific antibodies. The inflammatory reaction that characterizes most neurodegenerative diseases is often called 'neuroinflammation' and consists mainly of elements of the innate immune response. Activated microglia – the resident macrophages of the brain – and astrocytes are the main neural populations that participate in this response.

Whereas an inflammatory response is necessary and crucial if the agent is a pathogen or dying cell, aberrant inflammatory responses are well-known causes of tissue damage and disease. Persistent inflammatory responses can lead to permanent scarring and tissue damage. Many wrongly equate the term 'inflammation' with these detrimental outcomes only. However, several observations have challenged this definition: Whereas the healthy central nervous system (CNS) is hostile to immune activity and is destroyed by it, immune activity may be an essential requirement for the protection and maintenance of the damaged CNS. The possibility that inflammation is a purposeful response in the CNS has long been ignored due to the fact that the beneficial effect of inflammation does not come free of charge (in terms of additional neuronal loss) and that there is a need for an optimal balance in terms of the time of onset, duration, phenotype, and intensity of inflammation.

In the healthy CNS, microglia and astroglia are quiescent, but in the event of injury to axons or cell bodies they exercise their neural function by buffering harmful self-compounds and clearing debris from the damaged site and their immune function by providing immune-related requirements for recovery. Proper regulation of the inflammatory response to injury will arrest degeneration and promote regrowth, whereas inappropriate regulation will lead to ongoing degeneration. Regulation is achieved by the operation of a T cell-mediated response directed to abundant self-antigens residing in the damaged site.

Cytokines

Cytokines are low-molecular-weight glycoproteins that may either function as membrane-bound complexes or are secreted into the surrounding tissues, sometimes packaged into vesicles. Cytokines are now known to be synthesized and secreted by many different types of cells, including nonlymphoid cells such as endothelial cells, epithelial cells, fibroblasts, and microglia. They comprise a large group of proteins and have a wide range of activities. Cytokines are generally classified into five families: the interleukins (ILs), interferons (IFNs), colony-stimulating factors, chemokines, and peptide growth factors. Like hormones, their names reflect the activities first recognized, but additional functions are frequently being discovered.

Cytokines act in a paracrine or autocrine fashion by interacting with specific cell surface receptors, and most cytokines can function as ligands for more than one receptor. This has led to the growing recognition that it is the property of the specific receptor that is activated which defines the functional properties of any one specific cytokine. Because these receptors are themselves regulated by cytokines, it becomes evident that the potential physiological and pathological effects of these mediators may be dramatically altered by the presence of other cytokines in the surrounding tissues.

Microglia

Microglia are commonly described as the CNS equivalent of tissue macrophages. However, resting microglia in the normal brain should rather be viewed as cells with macrophage-like potential because the resting state is characterized by ramified morphology and weak expression of molecules associated with macrophage function. Access of resting microglia to the macrophage-like repertoire of response options requires their transformation, which is triggered by appropriate stimulation. However, resting microglia are far from inactive. They are constantly on the lookout for changes in their environment and always stand ready to support endangered neurons or to fight off any threat to tissue integrity. Microglia can sense homeostatic disturbances in the form of alterations in

the biochemical composition or structural organization of their extracellular milieu. Even relatively minor deviations from normal metabolic neuronal activity seem to be sufficient to alert microglia. More generally, signals vary in origin and chemical nature, but they can be classified according to whether the phenotypes they trigger in microglia can be tolerated by the CNS and are thus beneficial or cannot be tolerated by the CNS and are thus destructive. Specifically, injured neurons may generate rescue signals that trigger microglia to produce trophic or other factors that promote neuronal recovery, and this microglial response is amenable to well-controlled boosting by T cells, whose specificity to CNS self-antigens directs them to the afflicted sites.

Upon activation, microglia release soluble effectors that can directly or indirectly cause damage to neural cells. One of the first effectors to be produced is IL-1β. In addition to producing IL-1β, microglia release IL-3, IL-6, tumor necrosis factor-α (TNF-α), vascular endothelial growth factor (VEGF), lymphotoxin (LT), macrophage inhibitory protein-1α, matrix metalloproteinases, nitric oxide (NO), and other reactive oxygen species. The cytokines IL-1, IL-6, TNF-α, and LT alter vascular adhesion molecule expression, which recruits lymphocytes and macrophages to sites of injury. In addition, LT, TNF-α, NO, and reactive oxygen species can directly kill cells. Although astrocytes also produce these potentially toxic factors, microglia produce much higher levels of these cell-damaging intermediates. Therefore, the initial response to CNS injury is mediated by microglia, which then recruit other immune cells to clear pathogens and infected or damaged cells. Feedback mechanisms are then initiated to prevent excessive tissue destruction, and there is good evidence that the astrocyte reaction is indeed an important compensatory response to bring about the resolution of the injury response and to restore homeostasis.

Astroglia

Astrocytes are ubiquitous glia whose finely branching processes envelope all cellular components throughout the CNS. In the uninjured CNS, astrocytes provide many supportive activities essential for neuronal function, including homeostatic maintenance of extracellular ionic environment and pH, clearance and release of extracellular debris, provision of metabolic substrates for neurons, coupling of cerebral blood flow to neuronal activity, and possibly the sculpting and maintenance of synapses. In addition, astrocytes become 'reactive' in response to all CNS insults. Also, astrocytes express numerous receptors that enable them to respond to virtually all known neuroactive compounds, including neurotransmitters, neuropeptides, growth factors, cytokines, small molecules, and toxins. These receptors enable astrocytes to not only participate in signal processing but also function as sentinels, as do microglia. Astrocytes also establish and maintain CNS boundaries, including the blood–brain barrier (BBB) and the glial limitans, through interactions with endothelial and leptomeningeal cells.

The characteristics that are most frequently associated with the astrocytic response to insult involve cellular hypertrophy, astrocyte proliferation, process extension and interdigitation, and increased production of the intermediate filaments glial fibrillary acidic protein (GFAP), vimentin, and nestin. This constellation of responses, called anisomorphic gliosis, is the consequence of gross tissue damaging injuries and results in the formation of a tightly compacted limiting glial margin termed the astrogliotic scar. These reactive astrocytes may also exacerbate tissue damage because they can release proinflammatory cytokines such as TNF-α, which can inhibit neurite outgrowth and kill oligodendrocytes, and they can produce and release arachidonic acid metabolites, NO, and reactive oxygen species that can adversely affect cell survival. However, as stated previously, microglia produce much higher levels of these cell-damaging intermediates than astrocytes; therefore, astrocytes may not be culpable for the bystander damage that occurs subsequent to reactive gliosis. There is another type of astrocyte response to insult that is less dramatic and frequently transient which is classified as isomorphic gliosis. This astroglial response is associated with improved recovery from tissue-damaging insults. At sites distant from traumatic injury or in regions where the tissue has been merely disturbed (e.g., following axotomy, nerve crush, or after a mild stroke), the astrocytes become larger in size and undergo nuclear hypertrophy; transform into a more pronounced stellate shape; and increase their production of many cytosolic enzymes, antioxidants, structural proteins, and organelles. Additionally, these 'activated astrocytes' produce soluble trophic and growth factors that enhance the survival of adjacent neurons and glia, as well as coordinate tissue remodeling. Thus, these isomorphic changes should be considered adaptive and beneficial to restoring homeostasis.

The Role of Adaptive Immunity in Regulating the Glial Inflammatory Response

Whether the CNS inflammatory response is beneficial or detrimental is determined by how the response is controlled. Studies indicate that inflammation is

mediated not only by the innate arm of the immune system (represented by microglia and macrophages) but also by its adaptive arm in the form of peripheral immune cells. This view recognizes that inflammation can be beneficial for traumatized CNS tissue by promoting clearance of cell debris and secretion of neurotrophic factors and cytokines. Their activation by T cells allows microglia to express dual activity: as immune cells with the function of antigen presentation and as neural cells that supplement the buffering of destructive self-compounds. Thus, an insult to the CNS signals the immune system for assistance in protecting the tissue against the local threat. Accordingly, inflammation should rather be described as a series of local immune responses that are recruited to damaged tissue, and its ultimate outcome depends on its regulation, which in turn depends on both genetic and environmental factors (timing and intensity).

Thus, in addition to resident microglia and infiltrating macrophages, peripheral lymphocytes (T and B cells) also participate in the local response to an acute or chronic CNS insult. The T cell-mediated assistance is aimed at providing the activated microglia with optimal conditions, leading to a beneficial outcome while minimizing the risk. Thus, microglia that encounter adaptive immunity can acquire a phenotype capable of presenting antigens and engaging in dialog with T cells. Depending on the nature and amount of T cell-derived cytokine that they encounter, such microglia can become activated without producing the potentially cytotoxic cytokine TNF-α themselves, and they can even downregulate its production in other cells. For example, in response to relatively small amounts of IFN-γ, T helper (Th)-1 cells, which are classically viewed as proinflammatory, can cause microglia to buffer glutamate (commonly involved in neurodegenerative diseases) and to protect neural tissue, provided that the amount of IFN-γ is tightly controlled. Likewise, Th2 cells, which are commonly viewed as anti-inflammatory, via IL-4 stimulate microglia to produce insulin-like growth factor (IGF)-1, which is associated with cell renewal. Microglia activated by IFN-γ or IL-4 protect neurons and can support both neurogenesis and oligodendrogenesis.

Excitoxicity and Adaptive Immunity

Glutamate, a key neurotransmitter, is pivotal to CNS function. Alterations in its concentration can be dangerous, as seen in acute injuries of the CNS and also in chronic neurodegenerative disorders. Its homeostasis is attributed to the efficient removal of glutamate from the extracellular milieu by reuptake via local transport mechanisms. Thus, the levels of glutamate transporters and glutamine synthetase increase when astrocytes become activated. Astrocytes possess two glutamate transporters that sequester excess glutamate, GLT-1 and GLAST, which may thus have neuroprotective functions. Moreover, studies suggest that glutamate, either directly or indirectly, elicits a purposeful systemic T cell-mediated immune response directed against immunodominant self-antigens that reside at the site of glutamate-induced damage. This harnessed autoimmunity may help the resident microglia in their dual function as antigen-presenting cells (serving the immune system) and as cells that clear the damaged site of potentially harmful material (serving the nervous system). The interplay between glutamate and an adaptive immune response illustrates the bidirectional dialog between the immune and nervous systems.

Regulation of Cytokine Release: Intensity and Timing

Because the ability of the CNS to tolerate any deviation from homeostasis is poor, even defensive activity on the part of activated microglia can exacerbate a chaotic situation rather than resolve it. This might explain why, for example, in mouse organotypic hippocampal slice cultures exposed to toxic concentrations of the glutamate-like compound AMPA, small doses of TNF-α (which is considered to be proinflammatory) can render microglia protective of neural cells, whereas large doses render them cytotoxic. Similarly, if microglia are exposed to small amounts of IFN-γ, they buffer any toxic excess of glutamate and support neuronal survival and neurogenesis from adult neural progenitor (stem) cells (NPCs). However, if they are exposed to IFN-γ in large amounts, they become cytotoxic to both neurons and oligodendrocytes generated from NPCs. Interestingly, these adverse effects can be counteracted not by total suppression of IFN-γ but by neutralization of TNF-α, a cytokine that is upregulated when microglia encounter large concentrations of IFN-γ. These results thus suggest that IFN-γ in small amounts endows microglia with a phenotype that favors neural tissue survival. This phenotype is not altered by an increase in the concentration of IFN-γ to which the microglia are exposed, but it is accompanied by undesirable activities such as TNF-α production.

Regarding the timing of the inflammatory response, examination of the processes of neuronal regrowth and neuronal protection suggests that within the same process the requirements for recovery might vary at different postinjury stages. For example, the anti-inflammatory cytokine IL-10, which has a strong positive effect on recovery when applied soon after spinal

cord injury, is not beneficial when first applied at later posttraumatic stages. Similarly, anti-inflammatory treatment was found to be neuroprotective only if applied within the first few hours after ischemia in experimental stroke models.

Astroglial Scar Formation

Reactive astrocytes form scar tissue after CNS insults, but the purpose of scar formation has been unclear. Ablation of scar-forming reactive astrocytes in transgenic mice shows that these cells are essential for the spatial and temporal regulation of inflammation after CNS injury. In the presence of reactive astrocytes, scar tissue composed of astrocytes and fibroblast lineage cells demarcates and surrounds damaged tissue. Within the walled-off area, a robust inflammatory reaction occurs with the release of potent cytotoxic agents targeted at potential invading microorganisms but that also sacrifices local neural cells. Outside of and immediately adjacent to the astrocyte scar, inflammation is minimal and cytoprotective mechanisms are active. Although the astrocyte scar may serve primarily as a migration barrier that keeps inflammatory leukocytes from invading adjacent healthy tissue, the redundancy of migratory guidance cues among neurons and leukocytes may account for the inhibition of axon regeneration by this barrier. Evolutionary pressure seems likely to have favored mechanisms able to wall off small injuries and keep them uninfected rather than mechanisms able to deal with large and disabling injuries. Thus, in transgenic mice in which reactive astrocytes are ablated after brain or spinal cord injuries, fibroblast lineage cells do not organize, no scar forms that demarcates damaged tissue from viable tissue, and inflammation spreads over a large area and continues unabated for prolonged times after injury.

Central Nervous System Pathologies Associated with a Beneficial Inflammatory Response

Inflammatory mechanisms beneficial for neuronal plasticity can take place at different sites: the BBB, the neuronal cell body, the axon, and the synapse. Also, evidence suggests that both microglia and astroglia can participate in neurogenic responses through the release of cytokines. As discussed in the following sections, a large amount of knowledge regarding the beneficial effects of inflammatory mediators has been gained through the use of mouse models with deletions of both major cytokines (IL-1β, IL-6, and TNF-α) and astroglia. A knockout model for microglia has been published (CD11b-HSVTK mice) but not characterized with regard to the potentially deleterious effects of microglial deletion on CNS plasticity.

Blood–Brain Barrier Integrity

Astrocytes not only maintain the BBB but also participate in reforming the BBB following CNS injury. When a stab wound is inflicted to the forebrain of adult mice selectively ablated for reactive astrocytes adjacent to the injury site, there is a failure of BBB repair, increased leukocyte infiltration, and increased neuronal degeneration. Also, ablation of reactive astrocytes after experimental brain injury leads to massive local tissue edema compared with control mice, suggesting that reactive astrocytes help to regulate tissue fluid levels and that toxic edema may occur when astrocytes have exhausted their capacity to do so. Interestingly, subsequent grafting of nontransgenic astrocytes restores BBB function.

Further evidence implicating cytokine-stimulated astrocytes in BBB restoration comes from experiments on IL-1β null mice: Animals lacking IL-1β show less astrocyte reactivity 2 or 3 days following cortical lesion, and increased permeability of the BBB at 7 days postlesion, compared with wild-type controls. These results link the early activation of astrocytes and their subsequent role in BBB repair following traumatic injury to the inflammatory response and, specifically, to the production of IL-1β.

In addition, after an injury with disruption of the BBB, angiogenesis and neovascularization must occur to provide nutrients and oxygen. Angiogenesis can be induced by numerous factors, including VEGF, which is a potent mitogen for endothelial cells and is rapidly produced in the brain in response to both hypoxia and cytokines. Several lines of evidence implicate activated astrocytes and subsequent cytokine release in VEGF-mediated angiogenesis following CNS injury.

Neuronal Survival

Astrocytes produce a large array of neurotrophic factors, including nerve growth factor (NGF), brain-derived neurotrophic factor, activity-dependent neurotrophic factor (ADNF), hepatocyte growth factor, ciliary neurotrophic factor (CNTF), and fibroblast growth factor-2 (FGF-2), in response to injury, disease, and activation of cytokine receptors.

Experiments demonstrating that IL-1β potently increases astrocytic expression of NGF provided the first evidence that glial activation may promote neuronal survival and perhaps regeneration. When cultured spinal cord astrocytes are activated with CNTF *in vitro*, they support the survival of a significantly greater number of ventral spinal motor neurons compared to unstimulated astrocytes. CNTF likely achieves these effects by increasing astroglial

neurotrophic factor production, particularly by inducing the expression of FGF-2.

IL-6 is a cytokine that has often been termed as anti-inflammatory. It shares the signaling receptor gp130 with several growth factors, including CNTF, leukemia inhibitory factor, oncostatin M, and IL-1β in the CNS. IL-6 has been shown to promote neuronal survival and neurite growth. Unlike IL-1β and TNF-α, which are responsible for the induction of multiple proinflammatory genes, IL-6 often fails to induce these genes and, furthermore, can downregulate the expression of TNF-α. Moreover, IL-6 is able to induce the nerve growth factor and counteract *N*-methyl-D-aspartate-mediated toxicity. Together, these features are suggestive of IL-6's role in repair and regulation of inflammation in the CNS. However, IL-6 is not completely harmless because the proinflammatory potential of IL-6 has been clearly shown in transgenic mice that display CNS inflammation and neurodegeneration. Therefore, IL-6 may affect inflammation and neuronal regeneration through a number of mechanisms, whose involvement would be expected to vary as a function of physiological state.

In experimental traumatic brain injury studies on TNF knockout mice, it was demonstrated that there may be an early neurotoxic function (1 or 2 days) and a neuroprotective TNF function later in the posttraumatic phase (2–4 weeks). Furthermore, mice lacking either or both TNF and IL-6 showed a higher mortality rate than wild-type mice after closed head injury. However, no significant changes in the neurologic outcome among the survivors in the IL-6 knockout group were observed. Also, a slower rate of recovery and a higher permeability of cerebral vessels were found in IL-6 knockout mice after trauma, whereas transgenic GFAP–IL-6 mice with a higher astrocytic IL-6 expression showed accelerated tissue revascularization and repair. Independent of brain injury, previous studies examining two different types of IL-6 transgenic expression reported a higher toxicity in GFAP–IL-6 overexpression (astrocytic) compared to neuron-specific enolase–IL-6 overexpression (neuronal) that did not reveal any neurologic abnormalities, although both exhibited astrogliosis and microglial cell activation. This finding enhances the idea of the diverse effect of cytokines, depending on their cellular origin.

In stroke models, one study demonstrated that a mild hypoxic insult increases the basal levels of glycogen within the brain. As such, mild insults 'precondition' the brain and decrease the extent of damage subsequent to more severe traumatic events. Levels of glycogen storage in astrocytes have been shown to be directly regulated by IGF-1 that is downstream of IL-1β signaling, which is induced after injury, specifically after a stroke. These data support the hypothesis that astrocytes, by responding to cytokines, comprise an important substrate of preconditioning insults. Furthermore, in line with the contention that microglia can benefit tissue repair, intracerebroventricular microinjection of exogenous microglia during occlusion of the middle cerebral artery in rats significantly inhibits the behavioral dysfunction induced by focal ischemia. The injected microglia possibly protect the neural tissue against ischemia-induced neurodegeneration, but the mechanism remains unclear.

Finally, in Alzheimer's disease transgenic mice models, inflammation has been shown to induce beneficial responses that include the activation of microglia to phagocytose dying cells or antibody assemblies. TGF-β1 and acute lipopolysaccharide (LPS) treatment seem to promote this phagocytic state. In contrast, chronic LPS treatment induces a neurotoxic state, highlighting the importance of duration of the microglial response. However, it must be stressed that in Alzheimer's disease, the inflammatory response is not directly neuroprotective but, rather, indirectly neuroprotective by targeting amyloid plaques; this is the rationale behind vaccine studies that have failed, probably because the inflammatory reaction could not be limited to plaques alone but affected surrounding neural tissue.

Remyelination

Emerging evidence implicates cytokine-activated astrocytes in the regenerative phases of demyelinating diseases. In particular, the cytokines IL-1β and CNTF play important roles. Animal experiments revealed that IL-1β is present early during the course of demyelination, whereas CNTF is present later, during the remyelination phase. These studies indicate that an abrogated astrocyte reaction due to a lack of IL-1β signaling significantly impairs remyelination. Astrocytes also become activated after injury by CNTF, and CNTF has been implicated in the production of FGF-2, which can enhance oligodendrocyte precursor proliferation.

Transgenically targeted ablation of reactive astrocytes after CNS injury markedly exacerbates tissue degeneration in both gray and white matter, increasing the death rate of both neurons and oligodendrocytes and increasing demyelination. NMDA receptor antagonists attenuate neuronal death, suggesting that astrocyte loss leads to accumulation of extracellular glutamate with subsequent excitotoxicity toward both neurons and oligodendrocytes.

TNF-α expression is induced in the CNS of cuprizone-treated mice, a model of demyelination and remyelination in which both microglia and astrocytes show evidence of cytokine production. The TNFR2 (p75

receptor), but not the TNFR1 (p55 receptor), is upregulated in the CNS of these mice. Using mice with targeted deletions of TNF-α and/or TNFR1 or TNFR2, studies showed that lack of TNF-α leads to a significant delay in remyelination. Further studies showed that this reparative function of TNF-α was dependent on expression of the TNFR2 because mice lacking this receptor fail to show regeneration of oligodendrocytes. Oligodendrocytes, as well as astrocytes and microglia, have been found to upregulate both TNFR1 and TNFR2 in response to inflammation; thus, changes in the relative levels of these receptors could alter the balance between cytotoxicity (p55 receptor) and growth and differentiation (p75 receptor). Furthermore, in the cuprizone model it was shown that IL-1β-deficient mice fail to remyelinate properly and that this failure correlates with delayed differentiation of oligodendrocyte precursors and with a lack of astrocytic and microglial production of IGF-1.

Axogenesis and Synaptogenesis

Reactive scar-forming astrocytes have long been regarded as a major obstacle to axon regeneration after CNS injury. Thus, it is important to acknowledge other data demonstrating that astrocytes support neurite outgrowth during development and that mature astrocytes may be essential for local nerve fiber sprouting and plasticity in adults. Moreover, reactive astrocytes express fibronectin and can support the regrowth of certain types of CNS axons along their cell surfaces. Also, CNTF-stimulated astrocytes promote neurite outgrowth better than untreated astrocytes. It will be important to understand the different contexts in which astrocytes might release inhibitory guidance cues or present permissive cues and to determine the signaling mechanisms that might regulate these different activities.

Few data are available regarding the role of inflammation at the synaptic level. However, it has been reported that ADNF stimulates synapse formation, and vasoactive intestinal peptide (VIP) elicits the release of ADNF from astrocytes. Therefore, the VIP-activated, astrocyte-derived factor ADNF acts directly on neurons to enhance synaptic connectivity and alter neuronal morphology.

Neurogenesis

Studies have demonstrated that astrocytes stimulate neurogenesis from adult neural stem cells (NSCs). Coculturing adult NSCs with primary hippocampal astrocytes increases the number of newly formed neurons tenfold. These results suggest that astrocyte-derived factors regulate neurogenesis during development. Also, neurogenesis in highly expanded NSCs can be rescued by coculture with microglial cells or microglia-conditioned medium, indicating that microglia provide a secreted factor(s) essential for neurogenesis but not for NSC maintenance, self-renewal, or propagation. These findings suggest an instructive role for microglial cells in contributing to postnatal neurogenesis the mammalian brain.

With regard to specific cytokines (from astrocytic origin) displaying neurogenic potential in the adult brain (e.g., in the adult dentate gyrus), TGF-β was shown to promote neurogenesis in NSC primary cultures. Furthermore, IL-1β and IL-6, and a combination of factors that included these two interleukins, were also able to promote NSC neuronal differentiation. The finding that cytokines and chemokines can promote NSC neuronal differentiation may help us to understand how injuries induce neurogenesis in adult brains.

Introduction

The pathologic lesions of many neurologic disorders in the central nervous system (CNS) are often globally dispersed throughout the brain. But other disorders are manifest by a loss of more discrete neural populations affecting a more limited area of the CNS (Table 1). Transplantation of neural stem cells (NSCs) offers promising regenerative therapies for many CNS diseases. Results of transplantation experiments suggest that NSCs appear to be able to respond to neurogenic signals, reminiscent developmental cues evoked by degenerative processes. NSCs possess other inherent biologic properties that make them attractive for treatment of metabolic, degenerative, traumatic, or other lesions in the brain, particularly those that are widely distributed. They are easy to administer (often directly into the cerebral ventricles) and are readily engraftable. Additionally, preconditioning regimes such as total body irradiation are not required prior to administration (as required for bone marrow transplantation). In the following sections, we discuss these characteristics and the therapeutic potential of NSCs in CNS diseases.

Neural Stem Cell Biology

Definition of NSCs

NScs are the most primordial and least committed cells of the nervous system. Because immunocytochemically detectable markers that are sufficiently specific and sensitive have not yet been defined, the NSC is still best defined operationally. The NSC must have the following functional properties: (1) 'self-renewal' (produces unaltered daughter cells in response to mitogens) and (2) 'multipotency' (generates all three fundamental neuroectodermal lineages – neurons, astrocytes, and oligodendrocytes – in a regional and developmental stage-appropriate manner). There is no consensus about how many intermediary steps exist between the stem cell stage and the emergence of a mature functional cell. If a cell type appears to have a more limited self-renewal capacity and a narrower range of fates, it is by convention called a 'progenitor' or 'precursor' rather than a stem cell.

Stem Cell Niche and Function of NSCs in the Developing and Adult CNS

The population of NSCs in the adult brain is harbored in special locations of the CNS called 'niches.' To sustain homeostasis of NSC populations, NSCs proliferate and differentiate following an innate genetic program and in response to the signals from this specialized microenvironment. It is not yet known to what extent NSC's commitment is preprogrammed within the cell (i.e., cell autonomous), compared to the contribution of external signals (i.e., cell nonautonomous). It is possible that the number of cell divisions – and hence the degree to which multipotency and environmental responsiveness can be maintained – changes with the age of the stem cell or the age of the organism within which the stem cell resides.

In the early stages of mammalian cerebrogenesis, NSCs are located in a primary germinal zone known as the ventricular zone (VZ). In the telencephalon of an embryonic day-10 (E10) mouse, it is estimated that stem cells account for 5–20% of the cells in the VZ. The earliest NSCs divide symmetrically to amplify identical daughter cells. A stem cell retains continuous mitotic potential while remaining multipotent. Somewhat later in cerebrogenesis, in response to specific developmental signals, the NSCs then divide asymmetrically, to generate partially differentiated neural progenitor cells. Neural precursor cells begin to express differentiation markers while remaining mitotically active. They differentiate once they exit from the cell cycle, with the final fate of a given progenitor cell depending on extrinsic morphogenic signals, growth factors, and specific patterns of transcriptional activation, generally resulting in the generation of neurons prior to the generation of glia during development.

Secondary germinal zones, believed to develop from the VZ, includes the subventricular zone (SVZ) of the forebrain, the subgranule layer (SGL) of the hippocampus, and the external germinal layer (EGL) of the cerebellum. The EGL disappears once cerebellar development is completed, by 3 weeks postnatally in rodents and by 2 years of age in humans. NSCs are believed to populate these areas as well, perhaps allocated there during early development to maintain homeostasis throughout life. In the SVZ, NSCs are tightly packed and communicate with one another via

gap junctions. The SVZ is known to serve as an endogenous source of multipotent neural precursors that give rise to neurons and glia to support cell turnover and/or compensate for cell death. In the rodent SVZ, newly generated neuronal precursors reach their final destination in the olfactory bulb after long-distance migration through a well-defined path called the rostral migratory stream (RMS).

Although a rather limited region of the adult CNS has been documented to harbor NSCs – these secondary germinal zones and perhaps a dispersed group of NSCs throughout the gray matter and white matter – the very presence of such endogenous cells has raised the possibility that they may be recruited for neural reconstruction. It remains unclear whether adult-derived NSCs can make projection neurons and necessary connections as precisely as they are naturally generated in the embryo.

Table 1 Neuronal disorders in the CNS with potential stem cell action

Disease	*Potential stem cell action*[a]
Global diseases	
Lysosomal storage diseases	1, 2, 3, 4
Leukodystrophies	1, 2, 3, 4
Hypoxic–ischemic encephalopathy	3, 4, 5
Multiple sclerosis	1, 3, 4
Focal/discrete diseases	
Amyotrophic lateral sclerosis	2, 3, 4, 5
Parkinson's disease	1, 2, 3, 4
Huntington's disease	1, 2, 3, 4

[a]Potential action: 1, enzyme supply; 2, cell replacement; 3, neurotrophic factors; 4, anti-inflammatory molecules; 5, antioxidants.
The pathologic lesions of neurologic central nervous system (CNS) disorders are either globally dispersed or are in discrete areas of the CNS. Potential actions of transplanted stem cells are indicated for each disease.

Isolation, and Propagation of Murine and Human NSCs

There has been rapid progress in stem cell biology since it was first demonstrated that a single neural cell with stemlike qualities could be isolated from a mouse brain and reimplanted into another mouse brain, wherein progeny of the reimplanted cell then differentiated into integral members of the CNS (Figure 1). Since that time, neural cells with stem cell properties have been derived from the embryonic, neonatal, and adult rodent and human CNS using several different *in vitro* expansion methods.

Both mouse and human NSCs can be isolated from the ventricular zone of the fetal telencephalon and

Figure 1 Implantation of neural stem cells into neonate brain of the mouse models of central nervous system diseases. *LacZ* β-galactosidase-labeled neural stem cells are traced by an X-gal reaction (blue) and/or anti-β-galactosidase immunocytochemistry in serial coronal sections of recipient brains. Assessment times of neural stem cell impact are shown in implanted mice in terms of survival and motor function and vary according to disease model. Electrophysiology on acute slices from engrafted brains can be performed to assess the identity and functional integration of donor neural stem cell-derived cells.

the SVZ, from the SGL, and even from the cortical parenchyma of the adult brain. NSCs are then selected and propagated using a serial growth factor selection procedure to select small numbers of cells that respond to both basic fibroblast growth factor (bFGF) and epidermal growth factor (EGF). The principal differences so far observed between mouse and human NSCs seem to be the length of the cell cycle (to 4 days in humans), the predilection of human NSCs to senesce (after ~100 cell divisions), and the relative NSC responsiveness to various types of mitogens. The ability to recognize marker proteins consistent with an immature phenotype has contributed to the characterization of such cells. Commonly used NSC markers include: nestin and vimentin, intermediate filament proteins; musashi 1, an RNA-binding protein; Sox1, a transcription factor; and CD133, a surface marker. These markers are selective rather than specific for NSCs because they are also expressed (at lower levels) in neural progenitor cells (i.e., cells with a more limited potential and self-renewal capacity) and even in nonneural cells (e.g., muscle and endothelium). Therefore, performing functional assays is better than looking for the presence of markers.

NSCs can also be derived secondarily *in vitro* from embryonic stem cells (ESCs), which are derived from the inner cell mass (ICM) of a blastocyst. ESCs can give rise to differentiated progeny from all three embryonic germ layers, including neural derivatives. Also, ESCs, by definition, never senesce, and they require a great deal of instruction to direct their differentiation fates unequivocally toward a given lineage. Using ESCs as a source of NSCs would obviate the problems of abstracting a relatively small population of 'native' NSCs from a given organ, maximize their proliferation, and avoid senescence. It is still under debate whether ESCs progress through a neural stem cell stage before they give rise to a particular neural cell type. Furthermore, being able to 'tame' an ESC is still quite challenging – undifferentiated ESCs can be tumorigenic following transplantation. For example, dopaminergic neurons were derived from human ESCs (hESCs) by co-culturing with a cell line composed of midbrain astrocytes. Transplantation of these cells into parkinsonian rats improved motor function. However, engrafted regions exhibited undifferentiated mitotic neoplastic-appearing neuroepithelial cells. There is growing evidence that tumorigenic potential may be reduced by significantly extending the neuronal differentiation time of the hESCs *in vitro* prior to transplantation.

Another approach is being pursued to create graft material for the CNS. It is somatic cell nuclear transfer (NT), whereby donor nuclei from a mature somatic cell of the intended recipient (e.g., a fibroblast) are inserted into an unfertilized oocyte, which, when stimulated, will divide to the blastocyst stage, from which ESCs can be derived. NSCs can theoretically be derived from these ESCs, but there are caveats to this approach. For example, nuclei from mature somatic cells may have developmentally imposed epigenetic changes, such as specific DNA methylation patterns that might be difficult to safely overcome. That the oocyte cytoplasm harbors molecules that can mediate a process of dedifferentiation is a fascinating concept, and this requires greater exploration and may be exploited in contexts even broader than NT (perhaps making 'adult cells' act stemlike).

The success in isolating stemlike cells from the CNS led to attempts to derive neural stemlike cells from nonneural organ systems, including bone marrow mesenchyme, muscle, skin, retina, fat, blood, and liver. Whether such nonneural stem cells can yield neural stem cells remains unresolved and exceptionally controversial.

NSCs and CNS Repair

Sources of NSCs for CNS Repair

Despite the presence of endogenous NSCs in the adult mammalian brain, it is recognized that following CNS injury, intrinsic self-repair activity of the adult CNS (at least for the most devastating of injuries) is inadequate or ineffective. This poor regenerative ability may be due to the restricted location and limited number of NSCs and/or to limitations imposed by the surrounding microenvironment, which may not be supportive or instructive for neuronal differentiation. Therefore, NSCs expanded *ex vivo* in culture and then implanted intracerebrally to regions in need of repair may overcome those limitations that are related to inadequate numbers of NSCs in proximity to the affected region.

Maintaining NSCs in a proliferative state *in vitro* by epigenetic or genetic manipulation does not appear to subvert their ability to respond to appropriate environmental cues *in vivo* following transplantation into the developing brain. Such cells have the ability to migrate throughout the brain and to differentiate appropriately and nontumorigenically into neurons, astrocytes, and oligodendrocytes. It remains to be determined, however, whether prolonged passaging of cells *in vitro* produces fundamental changes in these cells that begin to change them from their *in vivo* predecessors and counterparts.

It is important to learn what will be the best means to derive a source of NSCs: (1) isolating

NSCs directly from the neuroectoderm of fetuses or adults, (2) deriving NSCs from ESCs that have been directed toward a neuroectodermal and NSC lineage, or (3) isolating NSCs from nonneural but more accessible structures. Finding better genetic and epigenetic markers of NSC identity may be useful in mapping the precise location of adult NSCs as potential targets for new pharmaceuticals aimed at specific and selective activation, mobilization, and recruitment. Genomic methods (such as gene expression microarrays) and proteomic approaches may provide valuable tools for identifying these genes and their products. The neural differentiation genes may be useful targets for agents aimed at producing specific cell types from these NSCs. Certain genes, including those that help mediate mitogen action, can also be introduced into stem cells to extend the cells' ability to self-renew and preserve their multipotency. Such genes are *MYC*, telomerase reverse transcriptase, and SV40 large T antigen gene.

Identification and Fate of Donor NSCs in the CNS

NSCs can be labeled with the *lacZ* β-galactosidase protein, with bromodeoxyuridine (BrdU), or with fluorescent proteins such as enhanced green fluorescence protein (eGFP) for identification and tracing purposes following transplantation in mouse models of CNS diseases. *LacZ* encodes β-galactosidase (β-gal), thus allowing easy histochemical tracing of donor cells by the 5-bromo-4-chloro-3-iodolyl-β-D-galactosidase (X-gal) reaction and/or anti-β-gal immunocytochemistry in recipient brains. BrdU is incorporated into DNA during S phase and can be detected after fixation of the tissue by specific anti-BrdU antibodies. Fluorescently labeled cells can be viewed directly in live or fixed tissue sections. The presence of engrafted-human NSC-derived cells in transplanted mice can be confirmed by their immunoreactivity to antibodies against human-specific proteins.

The fate of engrafted NSCs in the recipient brain can be analyzed by using cell type-specific immunomarkers. These may include oligodendrocyte markers (2′,3′-cyclic nucleotide 3′-phosphodiesterase (CNPase), monoclonal antibodies O1 and O4, myelin basic protein (MBP)), astrocyte markers (glial fibrillary acidic protein (GFAP)), neuron markers (β-III-tubulin, neurofilament, NeuN, microtubule-associated protein-2 (MAP2), Hu-D), and immature progenitor markers (nestin, vimentin, musashi 1, NG2, A2B5). NSC fate can also be analyzed by looking at the ultrastructure for cell type identification, formation of synaptic contacts, presence of normal myelin, and condition of subcellular organelles. Retrograde tracing methods can be performed to see whether neuronal projections extend to the proper targets. Electrophysiology (often on live slices isolated from engrafted brains) can be performed to assess functional integration of the donor NSC-derived cells (Figure 1).

Properties of NSCs for CNS Therapy

Ideally, when producing engraftable cell populations, NSCs should be in an undifferentiated state and still capable of mitosis. Immediately postgrafting, NSCs replicate a limited number of times, then exit the cell cycle relatively quickly, migrate, and differentiate in response to local microenvironmental cues.

NSCs and their progeny should intermingle nondisruptively with endogenous neural progenitor/stem cells, responding to the same spatial and temporal cues in a similar manner. Because of their ability to develop into integral cytoarchitectural components of many regions throughout the host brain, as neurons, astrocytes, oligodendrocytes, and even incompletely differentiated but quiescent progenitors, NSCs may be able to replace a range of missing or dysfunctional neural cell types within the same region. NSCs, particularly in certain differentiation states, might express proteins that support regeneration (e.g., many neurotrophic factors, lysosomal enzymes, angiogenic factors, anti-inflammatory molecules, anti-oxidants).

NSCs can migrate and integrate widely throughout the brain, particularly when implanted into germinal zones, and may be attracted, even across long distances, to regions of neurodegeneration in brains of all ages.

Representative Therapeutic Uses

NSC therapy for globally affected CNS diseases Many CNS diseases are characterized by global degeneration or dysfunction. Treatment for these disorders requires widespread gene and/or cell replacement. Globally affected CNS diseases include the inherited neurodegenerative diseases of the pediatric age group (inborn errors of metabolism, including lysosomal storage diseases (LSDs) such as leukodystrophies and hypoxic–ischemic encephalopathy) and some adult CNS diseases (e.g., multiple sclerosis). The ability of NSCs to treat these diseases was first observed in a mouse model of genetically based neurodegenerative LSD known as mucopolysaccharidosis type VII (MPS VII; β-glucuronidase deficiency). Implanting wild-type, diffusely engrafting, enzyme-producing NSCs into the telencephalic ventricles of these mutant mice as newborns, to create 'chimeric forebrains,' essentially reversed the cerebral manifestations of the disease through cross-correction. This process is essentially like performing a bone marrow transplant on the brain.

NSC-mediated treatment of many LSDs may not require genetic manipulation but may rely on the

NSC's intrinsic production of the required enzyme, particularly when that enzyme is secreted and can be readily taken up by deficient cells and is required in only small quantities to restore normal metabolism. This strategy has proved promising for other enzyme deficiencies, including the gangliosidoses, in which β-hexosaminidase (Hex) requires repletion to thwart the pathological accumulation of GM_2 ganglioside in the brain.

A specific example of NSC use in this way is in the mouse model of Sandhoff disease (SD), a gangliosidosis characterized by a mutation in the Hex β subunit. SD is a uniformly fatal, rapidly progressive, autosomal recessive LSD caused by an absence of both HexA and HexB, leading to accumulation of GM_2 and GA_2 gangliosides in the CNS (**Figure 2(a)**). Transplantation of NSCs delayed disease onset and prolonged the survival of SD mice. Mouse and human NSCs (from both neuroectoderm and ESCs) migrate extensively throughout the brain following neonatal transplantation, thereby reducing widespread ganglioside storage. The small percentage of implanted NSCs generated electrophysiologically active neurons in SD mouse brain. Of note is that there is a synergistic effect from adding substrate-reducing pharmacological therapy to standard cellular transplantation treatment. In other words, the combined administration of NSCs plus drugs prolonged life span beyond what is seen from a single treatment alone (**Figure 2(b)**).

The preceding study provided additional insight into the role NSCs may play in LSDs, which is the provision of anti-inflammatory molecules. CNS inflammation, characterized by microglial activation and macrophage infiltration, is a hallmark of Sandhoff disease, found in humans and mice. Stem cells appear to home preferentially to regions characterized by an inflammatory signature (**Figure 3(a)**). Mouse and human NSCs constitutively express molecules that help mediate their homing to the pathological source of inflammatory chemokines. Transplanted NSCs reduced CNS inflammation in the SD brain, as measured using microglia/macrophage activation markers (**Figure 3(b)**).

In addition to widespread molecular therapy, one can imagine widespread neural cell replacement therapy as well. For example, the oligodendroglia of the dysmyelinated *shiverer* (*shi*) mouse are dysfunctional because they lack myelin basic protein, which is essential for effective myelination. Therapy, therefore, requires widespread replacement with normal MBP-expressing oligodendrocytes. When undifferentiated murine and human NSCs were transplanted at birth into the ventricles of newborn *shi* mice, NSCs became integrated throughout the *shi* brain and remyelinated some of the axons. In some recipient animals, the symptomatic tremor decreased. The ability of human NSCs to remyelinate is of particular importance because dysmyelination/demyelination plays an important role in many genetic and acquired neurodegenerative processes. For example, patients suffering from Krabbe leukodystrophy, also called globoid cell leukodystrophy (GCL), are devoid of galactosylceramidase activity (also called galactocerebrosidase, or GalC). The primary substrate of GalC is a constituent of the myelin sheath. GCL is characterized by CNS demyelination, degeneration of oligodendrocytes, and infiltration of macrophages. There is a long-standing question regarding the pathophysiology of GCL: Is the observed pathology a cell autonomous defect (i.e., a sick cell that dies) or is the disease caused by a toxic environment that would kill not only host cells but also new cells entering that environment?

The absence of GalC activity in *twitcher* (*twi*) mice (as in human GCL patients) may permit the buildup of toxic glycolipid psychosine. *In vitro* experiments suggest that the absence of GalC activity in *twi* mice predisposes neural cells (especially oligodendrocytes) to be more susceptible to the toxic metabolite. Wild-type murine NSCs (i.e., expressing a normal amount of GalC) tend to be resistant to those toxic effects. When transplanted into newborn *twi* mice, NSCs can survive and differentiate into myelinating oligodendrocytes throughout the *twi* cerebral environment. This suggests that the environment in the *twi* brain is not inherently nonpermissive for NSC survival and differentiation. Murine NSCs engineered to overexpress GalC appear to be more resistant to higher levels of psychosine than are unengineered, immature NSCs, and transplant of these overexpressing cells produces modest increases in the *twi* mouse life span. These results suggest that replacing both cells and molecules (e.g., NSCs that can become oligodendrocytes and secrete GalC to antagonize psychosine toxicity) may be a promising strategy to treat the disease. Thus, NSC-mediated cell replacement is feasible not only in diseases in which the disorder is cell intrinsic, but also in disorders in which the toxic environment can be rendered more benign via genetic manipulation.

In the preceding studies, multipotent NSCs appeared to shift their fate to yield more oligodendroglia, the particular type of cell that is needed. Consequently, NSCs might be capable of sensing the deficiency of a particular cell type, or perhaps a particular niche is created by the absence of a particular cell type and can alter NSC fate to compensate. This phenomenon was observed for neurons in two other circumstances. The *meander tail* (*mea*) mouse

Figure 2 (a) Sandhoff disease pathophysiology. Lysosomal storage diseases, Tay–Sachs disease, and Sandhoff disease result in abnormal accumulation of GM_2 and GA_2 gangliosides due to genetic deletion of the enzyme β-hexosaminidase A (HexA) in Tay–Sachs disease, and of both HexA and HexB in Sandhoff disease, the latter disease thus being more severe. Besides ganglioside accumulation and toxic by-product production with concomitant neural dysfunction, these diseases are also marked by a prominent injurious inflammatory signature. (b) Multimodal therapeutic potential of neural stem cells in lysosomal storage diseases. In this model, neural stem cell transplantation (trophic effects and/or cell replacement), substrate reduction therapy (inhibition of ganglioside production and supply of Hex enzymes), and reduction of inflammation are complementary therapies.

mutant is characterized by the failure of a sufficient number of granule cell (GC) neurons to develop in certain regions of the cerebellum. NSCs implanted at birth produced GCs at the expense of other cell types, suggesting that environmental signals may encourage NSC differentiation into this inadequately developed cell type. This phenomenon is not restricted to young animals. When NSCs were implanted into an adult rodent neocortex in which a narrow region was depleted of projections, graft cells differentiated into pyramidal neurons only within the abnormal region. Outside that region, they became nonneurons in the cortex.

Figure 3 (a) Physiological processes common to many brain pathologies attract neural stem cells. Inflammation: activated microglia mediate pathology-induced central nervous system inflammation by secreting cytokines and chemokines, resulting in activation of astrocytes and endothelial cells. Reactive astrocytosis: direct pathology effects and microglial signals activate astrocytes, which secrete their own set of chemotactic factors, increasing the inflammatory reaction. Lesion-induced angiogenesis and inflammation-activated endothelial cells: secretion of more chemoattractant factors enhances neural stem cell homing to the area of brain pathology, where the stem cells are presented with an atypical, perivascular niche for their support. (b) Transplanted neural stem cells (NSCs) show tropism for areas of brain pathology. Note the phenomenon of exogenous NSCs migrating to the area of brain pathology from a distant implantation site. This homing ability may have therapeutic applications for targeting widespread metastatic central nervous system pathology.

The examples discussed here highlight the potential for an abnormal environment to direct the behavior of transplanted NSCs. However, we are beginning to learn that the response between an NSC and the injured host is one of ongoing reciprocal interactions. In response to implanted NSCs in the context of an injured CNS, the host nervous system can also contribute to its own repair. For example, hypoxia–ischemia (HI), a common cause of neurologic disability in adults and children, causes much of its damage from an extensive loss of cerebral parenchyma and loss of the cells and connections that reside there. When NSCs were implanted into animal models of this disorder, the exogenous implant and the injured host brain both participated in the reconstitution of parenchyma and anatomic connections, as well as in the reduction of parenchymal loss, secondary cell loss, inflammation, and scarring. Similar results were observed in the hemisectioned adult rodent spinal cord, in which there was evidence of an upregulated host neuronal regenerative response.

NSC therapy in locally affected CNS disorders In most neurodegenerative disorders (e.g., Parkinson's disease), neurons do not die abruptly but instead undergo a gradual, inexorable deterioration leading to death. Often the neurons that die comprise a discrete subtype. To explore the effect of NSCs on this type of pathological process, a mouse model of Parkinson's disease was generated by sequential systemic administration of high doses of the selective dopaminergic (DA) toxin 1-methyl-4-phenyl-1,2,3, 6-tetrahydropyridine (MPTP) to aged mice. The MPTP permanently impaired (but did not kill outright) the DA neurons of the mesostriatal nuclei. When such mice received implants of murine NSCs, the DA cell population was reconstituted, as demonstrated by renewed expression of such DA-specific molecules as the DA transporter (DAT) and, importantly, by behavior. Although restoring this DA function was graft dependent, it was not predominantly due to differentiation of the donor NSCs into DA neurons. The majority of the functionally restored DA neurons were host neurons. It appears that in this case, the transplanted NSCs were serving a supportive function, perhaps by secreting glial cell line-derived neurotropic factor (GDNF), a neuroprotective factor of DA neurons. A similar observation is beginning to emerge from the implantation of human NSCs into the MPTP-lesioned subhuman primate model of Parkinson's disease, as well as the implantation of murine and human NSCs into the spinal cords of the superoxide dismutase 1 (SOD1) transgenic mouse model of amyotrophic lateral sclerosis (ALS). These observations suggest that exogenous NSCs may not only replenish inadequate pools of endogenous NSCs for the purposes of compensating for missing neural cells, but may also serve to enhance endogenous regenerative capacities.

Future Needs and Directions

NSCs hold great promise for regenerative medicine through cell or enzyme replacement or as a means to enhance intrinsic regenerative processes. However, successful translation of the NSCs therapeutic potential in animal models to that in human diseases will rely on further characterization of the following aspects: (1) detailed characterization of human NSCs, including identification of their markers and mapping of the neural cell lineages involved in brain development; (2) better understanding of methods for controlling the propagation of and phenotype specification of NSCs *in vitro* and *in vivo*; (3) identification of the genetic and epigenetic processes that confer NSC identity to an immature cell and ultimately to mature neural cell-type specification; (4) examination of functional integration of engrafted NSCs, such as a neuron's ability to form synaptic connections that are electrophysiogically active and appropriate; and (5) observations of behavioral recovery following NSC engraftment.

We also require a better understanding of the pathophysiology of the diseases to be targeted – that is, knowing what aspects actually require repair and which cell types really require replacement or rescue. Finally, it is clear that complex diseases such as those affecting the nervous system will require complex and multifaceted solutions, including pharmacologic, genetic and molecular, cell replacement, tissue engineering, angiogenic, anti-inflammatory, antiapoptotic, proregenerative, and proneurite-outgrowth-promoting therapies. The NSC, as a key player in a set of fundamental developmental mechanisms, may serve as the glue that holds many of these strategies together, by participating dynamically in multiple aspects of the therapeutic intervention. However, determining how these strategies may be intelligently, effectively, and safely orchestrated in clinical practice will require a great deal more careful investigation.

Neural Stem Cells: Adult Neurogenesis

C Zhao and F H Gage, Salk Institute for Biological Studies, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Adult neural stem cells (NSCs) are cells in the adult nervous system that can self-renew and differentiate into all types of neural cells, namely neurons, astrocytes, and oligodendrocytes. Free-floating neurosphere and adherent monolayer cultures are the methods that are commonly used to expand and characterize NSCs. Both of these types of cultures contain heterogeneous populations of cells, including the putative NSCs and their progeny. The self-renewal of adult NSCs is determined by serial passage and clonal analysis. The multipotency of adult NSCs is characterized by their ability to differentiate into all types of neural cells from single neurospheres or single cell clones. The existence and characteristics of adult NSCs have been mostly analyzed *in vitro* and have yet to be corroborated *in vivo*. Therefore, the term progenitor has often been used to loosely describe all proliferating precursor cells. Progenitor is a generic term for any dividing cell with the capacity to differentiate. This includes putative stem cells in which the self-renewal and/or multipotency have not yet been demonstrated. Precursors are cells from which more mature cells can be formed.

Location of Adult NSCs in the Mammalian Brain

The phenomenon that new neurons are generated in the postnatal brain was first described by Altman and colleagues in the 1960s. It is now known that neurogenesis continues in the adult central nervous system at two locations: the subventricular zone (SVZ; also known as the subependymal layer) of the lateral ventricles and the subgranular zone (SGZ) of the dentate gyrus of the hippocampus. In rodents, new neurons generated in the SVZ migrate through the rostral migratory stream (RMS) and incorporate into the olfactory bulb, whereas new neurons generated in the SGZ migrate a short distance into the granular cell layer and become granule neurons (Figures 1(a)–1(c)).

The identification and characterization of adult NSCs began in the 1990s, when Reynolds and Weiss found that proliferating cells could be isolated from adult mouse brain and expanded in culture when supplemented with epidermal growth factor (EGF). These cells form neurospheres in culture and secondary neurospheres when dissociated. This characteristic fulfilled one criterion for a stem cell: self-renewal. Cells in the neurospheres can differentiate into astrocytes and neurons, as defined by their expression of glial fibrillary acidic protein (GFAP) and neural-specific enolase, respectively. This phenomenon fulfilled the other criterion for a stem cell: multipotency. A collaborative effort between the groups of Weiss and van der Kooy later found that the neurosphere-forming cells reside in the periventricular region of the lateral ventricles.

The periventricular region of the lateral ventricles consists of the ependymal cells lining the ventricles and the SVZ. An observation by Frisen and colleagues suggested that the ependymal cells were the stem cells that gave rise to the proliferating cells in the SVZ. However, independent studies by the groups of Alvarez-Buylla, van der Kooy, and Temple showed that ependymal cells did not form neurospheres in culture and suggested that adult NSCs resided in the SVZ. A lentiviral labeling study by Vescovi, Naldini, and colleagues provided more definitive evidence that cells in the SVZ, but not the ependymal layer, are responsible for the long-term, continuous neurogenesis in the olfactory bulb. Lentiviral vectors can integrate into the chromosomal DNA of the host cells; therefore, the progeny of labeled cells can be traced. Even 3 and 6 months after lentiviral injection into SVZ, labeled cells were found in the RMS. The long-term presence of labeled cells in the RMS was not seen when the virus was injected into the ventricles to label ependymal cells. Therefore, SVZ has been considered to be the site of adult NSCs in the periventricular zone.

Gage and colleagues were the first to characterize NSCs from the hippocampus, the other brain region in which adult neurogenesis occurs. Adult hippocampal progenitor (AHP) is a term that has often been used to describe all proliferating precursor cells in the adult hippocampus. The progenitors/NSCs isolated from hippocampus could be passaged over an extended period of time in monolayer cultures when exposed to mitogens such as basic fibroblast growth factor (bFGF; also known as FGF2). Clonally derived adult hippocampal NSCs in monolayer culture could differentiate into all three neural lineages. In addition, cultured adult rat hippocampal progenitors were capable of neuronal differentiation when grafted into the hippocampus and the RMS of the adult rat. Contrary to these findings, van der Kooy and colleagues suggested that the hippocampus does not have multipotential NSCs but only progenitors because they were not able to isolate cells

Figure 1 Neurogenesis occurs in the subventricular zone (SVZ) and the subgranular zone (SGZ). (a) Sagittal and coronal views of the mouse brain with the two main germinal zones shown in red. New neurons are generated in the SVZ of the lateral ventricles (LV) and the SGZ of the dentate gyrus (DG) of the hippocampus. Neurons generated in the SVZ migrate through the rostral migratory stream (RMS) and incorporate into the olfactory bulb (OB). Neurons generated in the SGZ migrate a short distance and become granule neurons in the dentate granule cell layer. CB, cerebellum; cc, corpus callosum; NC, neocortex. (b) An example of cell proliferation in the SVZ. Mice were given three shots of BrdU over 24 h and the sample was taken 2 h after the last BrdU administration. Note that more proliferating cells are found on the lateral side of the SVZ. (c) An example of cell proliferation in the SGZ. Images in (b) and (c) were kindly provided by Wei Deng. (d) It has been proposed that three types of cells exist in the SVZ. Type B cells are GFAP-expressing NSCs that give rise to C (immature precursor) cells and B (migrating neuroblast) cells. Reprinted from Doetsch F, Caille I, Lim DA, Garcia-Verdugo JM, and Alvarez-Buylla A (1999) Subventricular zone astrocytes are neural stem cells in the adult mammalian brain. *Cell* 97: 703–716, Copyright 1999, with permission from Elsevier. (e) Three types of proliferating cells have been proposed to exist in the subgranular layer of the DG. The identification of these cells is mainly based on their specific expression patterns of molecular markers. Adapted from Kempermann G, Jessberger S, Steiner B, and Kronenberg G (2004) Milestones of neuronal development in the adult hippocampus. *Trends in Neuroscience* 27: 447–452, Copyright 2004, with permission from Elsevier.

from the hippocampus that form neurospheres; furthermore, they only found neuronal differentiation. However, neurogenesis continues in the dentate gyrus throughout the life of mammals, although at a reduced rate upon aging. Therefore, it is unlikely that these new neurons are derived from cells with limited self-renewal capacity.

Identity of Adult NSCs

Adult NSCs in the SVZ are thought to be slow-dividing cells. Following a high dose of ^{3}H-thymidine to kill proliferating cells in the SVZ, these cells can be repopulated within a few days, suggesting that the proliferating cells are derived from some relatively quiescent cells that are not susceptible to the antimitotic treatment. A similar phenomenon was seen when another antimitotic drug, cytosine arabinoside (Ara-C), was used. The proliferating cells in the SGZ of the dentate gyrus could also recover within 2–3 weeks after the animals were treated with the DNA methylation agent methylazoxymethanol acetate (MAM); however, whether this recovery is caused by the expansion of the remaining proliferating cells or whether slow-dividing NSCs also exist in the SGZ is not known.

Three types of cells have been proposed to exist in the SVZ: type B NSCs, type C transit-amplifying cells, and type A migrating neuroblasts. Type B cells appear to express GFAP and they are the only cells in the SVZ that survived the antimitotic treatment. Type C and A cells recover sequentially soon after cessation of the treatment, leading to a lineage hypothesis from B to C to A cells (**Figure 1(d)**). The identification of B, C, and A types of cells mainly relies on the morphological analyses at the electron microscopic level. In parallel to the SVZ, three types of precursor cells appear to exist in the SGZ: type 1 stem/progenitors and type 2 and type 3 precursor cells. The identification of these different types of cells in the SGZ is mainly determined by the specific expression patterns of molecular markers (**Figure 1(e)**).

Identification of NSCs by Cell Division Markers

One of the features of NSCs is their ability to divide; therefore, the thymidine analogues ^{3}H-thymidine and 5-bromo-2-deoxyuridine (BrdU) are often used to characterize adult NSCs. Both chemicals can be administered systemically, and the labeled cells can be detected through autoradiography and immunohistochemistry. Because NSCs in the SVZ are considered to be slow dividing, and because new neurons generated in the SVZ migrate to the olfactory bulb through the RMS, cells that remain labeled in the SVZ long (1 month) after BrdU or ^{3}H-thymidine labeling are presumably mainly NSCs. In addition to nucleic acid analogues, molecular markers such as the proliferating cell nuclear antigen and Ki67 have been used to recognize mitotic cells by immunohistochemistry. Another way of identifying NSCs is to use retroviruses because retroviral vectors can integrate into the chromosomal DNA and their integration is dependent on mitosis. The ubiquitous distribution of the molecular markers allows detailed morphological analyses of labeled cells. Furthermore, when retrovirus is used to mediate the expression of fluorescent proteins, live cells can be followed in both cell culture and brain slice preparations. All of these methods label both NSCs and their progeny and are biased toward cells with an active cell cycle. Since SVZ NSCs are proposed to be relatively quiescent, the labeling efficiency of NSCs is hypothetically lower than that of rapidly dividing, transit-amplifying cells.

Identification of NSCs by Molecular Markers

Using a transgenic mouse line in which avian leucosis virus-mediated reporter gene transfer only takes place in cells with an active GFAP promoter, Doetsch, Alvarez-Buylla, and colleagues showed that C and A cells in the SVZ were indeed derived from GFAP-expressing B cells. Studies using transgenic mice expressing cre recombinase from the murine GFAP promoter provided consistent results. In addition, in transgenic animals that expressed the herpes simplex virus thymidine kinase (TK) from the murine GFAP promoter, adult neurogenesis in the olfactory bulb and the dentate gyrus was diminished when the animals were given elaidic acid ganciclovir, a drug that can be converted to a toxin by TK. These studies suggest that a subpopulation of GFAP-expressing cells is the precursor of newborn neurons. GFAP-expressing cells have two different morphologies: bipolar or unipolar GFAP cells are considered to be stem cells, and multipolar GFAP cells are astrocytes. Because GFAP-expressing astrocytes are much more abundant than GFAP-expressing NSCs, GFAP has not been considered to be an optimal marker for adult NSCs.

The intermediate filament protein nestin is specifically expressed in the neuroectoderm during development and is highly expressed in the germinal zones in the adult brain. Bartlett and colleagues used fluorescence-activated cell sorting (FACS) to separate cells based on their size (>12 μm), low binding to peanut agglutinin, and low level of the heat stable antigen (mCD24a). Approximately 80% of purified cells can form neurospheres, and all of them express nestin.

Sox2 is a member of the Sry-related HMG box transcription factors. It is expressed in totipotent

inner cell mass stem cells and in the neuroepithelium of the developing central nervous system. In the adult brain, Sox2 is expressed in both SVZ and SGZ, although its expression is not restricted to these two neurogenic areas. Most Sox2-expressing cells appear to be proliferating neuroblasts. A subpopulation of Sox2 cells also expresses GFAP with one major process spanning the granular cell layer, and these cells have been proposed to be NSCs. Although Sox2 deficiency was shown to cause impaired neurogenesis, no fate mapping studies have been documented using Sox2 as a marker.

A number of cell surface markers have been reported to be able to enrich NSCs through FACS. LeX/ssea-1 (also known as CD15), fucose-containing trisaccharide, was found on the surface of mouse embryonic stem cells and primordial germ cells. Approximately 25% of FACS-sorted LeX+ cells from the adult mouse SVZ generated neurospheres *in vitro* and approximately 18% of LeX+ cells are GFAP+. A monoclonal antibody 473HD that recognizes the chondroitin sulfate epitope was also able to enrich the population of neurosphere-forming cells.

Several other markers have also been reported based on studies in other systems or during early development, including CD133 and Musashi homologue 1. However, these markers have not been extensively characterized in adult NSCs. All of the molecular markers discussed here label heterogeneous populations of cells *in vivo*. Cells that express both GFAP and nestin (or Sox2) have been proposed to be adult NSCs. However, it is not clear whether these cells represent only a subpopulation of adult NSCs.

Identification of NSCs by Genetic Methods

The second intron of the nestin gene contains an enhancer element that is specific for its expression in the central nervous system. This regulatory element has been used either in conjunction with the nestin promoter or with hsp68 minimum promoter to label NSCs. When the nestin promoter and the enhancer from the second intron were used to drive the expression of green fluorescent protein (GFP), GFP expression was more or less restricted to neurogenic regions in the adult brain, including both SVZ and SGZ. GFP was also found in the RMS. FACS-sorted nestin:GFP cells can self-renew and are multipotent. Nestin:GFP cells in the dentate gyrus appear to have two distinct populations, GFAP-positive radial glia-like cells and polysialylated neural cell adhesion molecule (PSA-NCAM)-positive cells. The GFAP+ nestin–GFP cells have been proposed to be stem/early progenitors (type I cells) that give rise to the PSA-NCAM+ nestin–GFP cells (type II cells). Transgenic mice have also been generated using the Sox2 promoter fragment to drive the expression of the reporter β-geo or of GFP.

Regulation of Adult NSCs

Adult NSCs can be regulated at different levels, including the self-renewal and fate determination of NSCs, proliferation and differentiation of their immediate progeny, and cell survival at different stages. All of these forms of regulation may eventually be reflected in a change in adult neurogenesis. Indeed, many conditions have been reported to alter adult neurogenesis. Aging and stress appear to have a negative effect on cell proliferation in both SVZ and SGZ. Hippocampal neurogenesis is enhanced by enriched environment, voluntary exercise, antidepressant treatment, seizure, and many other conditions. It is not clear which component of the process of neurogenesis is affected by these different conditions. Determining the microenvironment in which the NSCs reside (also known as the neurogenic niche) and the intrinsic mechanisms that instruct NSCs will help us better understand the physiological and pathological conditions that are intricately associated with adult neurogenesis.

Extracellular Influences

The behavior of adult NSCs and their progeny is directly influenced by their surroundings – that is, the microenvironment (neurogenic niche) in which they reside. NSCs have been isolated from almost all areas of the adult brain and from the spinal cord. These cells display multipotency in culture; however, neuronal differentiation only occurs in the SVZ and SGZ.

A clear example of the microenvironment playing a critical role in adult neurogenesis came from a transplantation study in which cultured spinal cord NSCs were able to give rise to neurons when grafted into the hippocampus but they showed no neuronal differentiation when grafted back into the spinal cord. Gage and colleagues later found that hippocampus-derived astroglia were able to promote both the neuronal differentiation of AHPs and the maturation of differentiated neurons in culture. Astrocytes from the spinal cord did not have such effects, suggesting that the presence of hippocampal astrocytes might be one of the determinants that permit adult neurogenesis in the dentate gyrus. Wnt-3 might be one of the factors that are responsible for astroglia-induced neurogenesis. Overexpression of Wnt-3 was sufficient to promote neurogenesis, whereas expression of a dominant negative form of Wnt-3 blocked neurogenesis *in vivo*. Neurogenesin-1, a bone morphogenesis protein (BMP)-interacting molecule, has

also been proposed to be a component secreted by hippocampal astrocytes that promote neuronal differentiation.

Dividing cells in the dentate gyrus were found to be closely associated with the vasculature, and possibly coupled with angiogenesis. Endothelial co-culture can significantly increase the number of new neurons in adult SVZ NSC adherent clones. Studies using embryonic cortical NSCs have proposed that factors derived from endothelial cells promote symmetric cell division and, therefore, self-renewal of NSCs. Interestingly, adult mouse NSCs can even transdifferentiate into endothelial lineage when co-cultured with human endothelial cells. Supporting a role for the vasculature niche in adult neurogenesis, the level of vascular endothelial growth factor (VEGF) is closely linked to the level of neurogenesis in the adult hippocampus. VEGF is required for enriched environment- and running-induced neurogenesis in SGZ. VEGFR2 (also known as fetal liver kinase-1 (Flk-1) and kinase insert domain receptor (KDR)) may be expressed by Doublecortin+ cells in the neurogenic zones. Expression of a dominant negative VEGFR2 is able to antagonize VEGF-induced neurogenesis. One study has suggested that, in addition to VEGF, another factor secreted by endothelial and ependymal cells, pigment epithelium-derived factor, can promote self-renewal of adult SVZ NSCs.

Ependymal cells were also reported to express Noggin, an antagonist of BMPs. Noggin might promote SVZ neurogenesis in the adult brain. Ectopic expression of Noggin in striatum was able to promote neuronal differentiation of transplanted NSCs. BMPs promote astrocytic fate in embryonic NSCs. Similarly in the adult, BMP and the leukemia inhibitory factor have been used to induce astrocytic differentiation of cultured AHPs.

The existing neurons may influence adult NSCs through neurotransmitters. Indeed, neurotransmitters such as dopamine, γ-aminobutyric acid (GABA), serotonin, and glutamate have been shown to regulate adult NSCs and/or their progeny. It is controversial whether dopamine promotes or inhibits the proliferation of NSCs in the SVZ. The dopaminergic neurons in the substantia nigra may project to the SVZ and affect SVZ neurogenesis. In the SGZ, GABA could mediate the input to the putative transit-amplifying progenitors and promote the differentiation of these cells and the maturation of the newly generated granule neurons. Antidepressant drugs that act to inhibit serotonin reuptake can consistently upregulate neurogenesis in the SGZ. In addition, glutamate agonist and antagonist could reduce and increase proliferation in the dentate gyrus, respectively. Contrary to these observations, glutamate agonist and antagonist were shown to increase and decrease the proliferation of AHPs *in vitro*.

In addition to the effects of different types of cells within the neurogenic niche, NSCs are subjected to regulation by soluble factors including growth factors, growth hormones, and cytokines. EGF and FGF2 are potent growth factors maintaining SVZ NSCs in culture. In fact, EGF has been shown to convert transit-amplifying cells into multipotent stem cells *in vitro*. EGF also has been claimed to convert adult NSCs to radial glial cells. The morphogen sonic hedgehog (Shh) could induce the proliferation of AHPs in culture. A transgenic study showed that NSCs were responsive to Shh *in vivo*, and that Shh-responsive cells might represent the slow-dividing cells described by van der Kooy and colleagues. Although many factors have been implicated in regulating adult NSCs, it is not clear which cells in the microenvironment secrete these factors.

Intracellular Signaling

It is perhaps not surprising that genes involved in cell cycle regulation, DNA repair, and chromosomal integrity are found to regulate NSCs. SVZ NSCs from p53 knockout mice form more and larger neurospheres compared to wild-type controls. Mice deficient in the cell cycle inhibitor p21 have more NSCs in the SVZ initially, but the number of NSCs decreases after they are 8 months old. It has therefore been proposed that NSCs have a limited number of cell divisions. An intact telomere appears to be important to maintain adult neurogenesis. Reduced proliferation was seen both *in vivo* and *in vitro* in the absence of the telomerase RNA component (Terc) after the mice were bred for four or five generations and the condition worsened when the mice were also deficient in ataxia-telangiectasia mutated (Atm). More interesting, one study suggested that the retrotransposon long interspersed nuclear element-1 (LINE-1 or L1) is actively expressed in adult hippocampal NSCs, and an engineered human L1 was shown to be mobile in the mouse brain.

Adult NSCs are also regulated at the epigenetic level and by transcription factors and their cofactors. Valproic acid, an inhibitor of histone deacetylase, could induce neuronal differentiation in cultured AHPs. Adult NSCs lacking the methyl-CpG binding protein 1 exhibited increased genomic instability and reduced neuronal differentiation. TLX, an orphan nuclear receptor, is required for the maintenance of adult forebrain NSCs. As mentioned previously, sox2 deficiency causes defects in neurogenesis. NeuroD, a neuronal differentiation basic helix–loop–helix transcription factor, is required for the formation of the

dentate gyrus. In addition, the polycomb family transcriptional repressor Bmi-1 was found to be required for the maintenance of both embryonic and adult NSCs. During development, the maintenance and fate specification of embryonic NSCs are defined by a series of bHLH transcription factors. The precise mechanisms of how self-renewal and differentiation are modulated in the adult NSCs still need to be determined.

The Function of Adult NSCs

Adult NSCs have been isolated from many species, including humans. Studies have clearly demonstrated that newly generated neurons in the dentate gyrus and the olfactory bulb are functionally integrated into the preexisting circuitry. By using a retrovirus-mediated labeling approach, Gage and colleagues showed that new neurons born in the adult hippocampus became morphologically indistinguishable from mature granule neurons within 4–8 weeks. More important, the newborn neurons fired action potentials in response to perforant path stimulation. Detailed electrophysiological characterization of new neurons born in the adult SGZ showed that these neurons adopt a developmental process that is similar to that in neurons born during embryonic and postnatal stages. In the olfactory bulb, newly generated periglomerular and granule neurons are also similar to their preexisting counterparts based on their morphological and electrophysiological properties. Interestingly, new neurons in the dentate gyrus have been shown to have a lower threshold for the induction of long-term potentiation at their immature stage, suggesting that the function of adult NSCs might depend on the unique plasticity of newborn neurons before they reach maturation.

Because the hippocampus is required for certain forms of learning and memory, the putative function of adult neurogenesis in the SGZ has been studied extensively in recent years. The level of adult neurogenesis has been well correlated with certain forms of learning and memory. For example, voluntary exercise and enriched environment were both shown to significantly enhance adult neurogenesis, and rodents exposed to these conditions could perform better in a hippocampus-dependent spatial learning task. Similarly, in the olfactory bulb, the survival of new neurons is enhanced by enriched odor exposure.

In addition to the correlative observations, several studies have reported a potential causal relationship between neurogenesis and different forms of learning and memory. Systemic antimitotic treatment with the DNA methylation agent MAM could reduce the level of adult neurogenesis, and the treated animals displayed defects in a trace conditioned eye-blinking task. Low-dose irradiation has also been used to inhibit adult neurogenesis, and treated rats showed impairment in long-term spatial memory and in a nonspatial nonmatching-to-sample task. Furthermore, adult neurogenesis in the SGZ appears to be required for the behavior effects of antidepressant treatment. Localized X-ray irradiation in the hippocampal area significantly reduced cell proliferation in the SGZ, and the irradiated mice failed to respond to the fluoxetine treatment in an anxiety-related, novelty-suppressed feeding test. These studies await corroboration from more spatial- and temporal-specific ablation of adult neurogenesis. In addition, conflicting results have been reported on certain learning paradigms such as the context fear conditioning test. Nevertheless, these are the first results indicating that neurogenesis in the adult brain might be required for hippocampus-dependent learning and memory.

Computational modeling has also been used to predict the function of adult neurogenesis in learning and memory. Among other putative functions in memory formation, an interesting hypothesis is that the continuous neurogenesis in the dentate gyrus might contribute to the formation of time-associated memories.

Conclusion

The discovery of continuous neurogenesis in adult rodent brains was embraced with skepticism for many years. It has now become clear that this phenomenon is conserved in all mammals examined, including humans. The facts that neurons generated in the adult brain functionally integrate into the existing circuitry and that adult neurogenesis is regulated by physiological and pathological conditions suggest that adult neurogenesis has survived evolution to serve some specific functions. More interesting, although NSCs have been purified from both SVZ and SGZ of the human brain, neuronal differentiation has been found in the hippocampus only but not the SVZ in humans. This appears to correlate with the functional differences between the two structures. Compared to rodents, humans rely much less on olfaction for daily activities and probably rely more on the hippocampus for emotions, learning, and memory. With the current advances in the field of adult neurogenesis, it is hoped that in the near future we will understand how new neurons born in the adult brain contribute to the normal brain functions and why the specific functions of adult neurogenesis cannot be fulfilled with the preexisting neuronal population.

The discovery of adult NSCs has triggered new therapeutic studies to treat diseases related to the

central nervous system. Such approaches include grafting NSCs to the site of injury or degeneration and targeting of endogenous stem cells. Indeed, it has been reported that neurogenesis could be induced *in vivo* in some of the nonneurogenic regions. The identification of small molecules that can induce neurogenesis from endogenous NSCs in damaged areas of the adult nervous system will change how we currently view central nervous system therapies.

Introduction

Most of the neurons in the mature central nervous system (CNS) are generated during the embryonic or neonatal periods of development. In a few 'neurogenic' regions of the mature CNS, new neurons continue to be generated throughout life. The subventricular zone and hippocampal progenitor zone are the two neurogenic regions of the mammalian brain that have been best characterized, whereas in nonmammalian vertebrates, other neurogenic regions include the HVC of the songbird and, most important for this article, the ciliary margin of the retina. In all these regions, it is thought that a region-specific 'neural stem cell' maintains the progenitors that produce the new neurons and glia. Several lines of evidence indicate that a 'retinal stem cell' exists throughout life in nonmammalian vertebrates. Evidence from both rodents and primates, including humans, indicates that multipotential, mitotically competent cells exist at the retinal margin and can be activated *in vitro* to generate neuronal cells. This article discusses the literature on retinal development and the developmental origins of the retinal stem cells in nonmammalian vertebrates, describes their function in retinal growth and regeneration, and details efforts to identify and manipulate the remnants of this zone in mammals. Finally, common features among neural stem cell zones throughout the mature nervous system are discussed.

Retinal Progenitors in Normal Development

Each retina is initially derived from one of two evaginations of the ventral diencephalon of the neural tube, known as optic vesicles. Soon after they form, the optic vesicles undergo a further morphological transformation to form the optic cups. The cells of the optic cup resemble neural progenitors from other regions of the CNS in that they have a simple bipolar morphology and span the width of the neuroepithelium. Clonal analysis of the progeny of the mitotically active progenitor cells shows that they can give rise to all the different types of retinal neurons, and that the clones have mixed neuronal and glial lineages (Figure 1(a)). Birthdating studies have demonstrated that the different types of retinal neurons are generated by the progenitor cells in a sequence that is conserved among vertebrates. Ganglion cells, cone photoreceptors, amacrine cells, and horizontal cells are generated during early stages of development, and most rod photoreceptors, bipolar cells, and Müller glia are generated in the latter half of the period of retinogenesis.

Progenitor cells in the retina have gene expression profiles that are similar to those of progenitors from other regions of the CNS. They express many of the same homeodomain transcription factors. Several homeodomain transcription factors, such as Pax6, Chx10, Prox1, Sox2, and Six3, are expressed in retinal progenitors and are sometimes collectively called the eye field transcription factors (EFTFs) since their early expression defines the presumptive eye-forming region of the neural tube. However, these genes are also expressed in progenitors in other anterior regions of the CNS. The retinal progenitors also express some unique transcription homeodomain transcription factors, such as Rx and Crx. A similar pattern is observed for proneural transcription factors, such as Mash1, Neurogenin2, and Math3; these genes are expressed in progenitors from retina as well as other regions of the CNS. In addition, retinal progenitors express at least one unique member of this family of transcription factors, Math5. Presumably, it is through unique combinations of the common CNS factors and the retinal-specific factors that the unique retinal cell types, such as photoreceptors and retinal ganglion cells, are specified.

In addition to the complex intrinsic factors regulating retinal progenitors, these cells are also influenced by extrinsic signaling factors. Most of these factors have similar effects on the retinal progenitors as they would elsewhere in the CNS. For example, epidermal growth factor (EGF) was first described as a mitogen for retinal progenitor cells prior to its identification as a mitogen for brain-derived neural stem cells. Fibroblast growth factors (FGFs) and sonic hedgehog are additional mitogens for retinal progenitor cells that have also been demonstrated to have mitogenic effects in other regions of the CNS. Negative regulators of proliferation are also present in the developing retina to control the extent and duration of neurogenesis. Transforming growth factor-β2 is the most well-described inhibitor of proliferation in the retina, as it is in other regions of the CNS, and it likely functions through the regulation of the cell cyclin-dependent kinase inhibitor p27kip.

Another key regulator of progenitor cells in the retina is the Notch pathway. At least two Notch

Figure 1 (a) Diagram of the multipotent progenitor that generates neurons (pink) and Muller glia (black) during embryonic development. (b) These cells persist at the retinal margin, in the 'ciliary marginal zone' (CMZ (red)) and are then called retinal stem cells, since they can persist the lifetime of the animal. The CMZ is located between the ciliary epithelium of the ciliary body (CB). The relative contributions of the retina derived from the embryonic progenitors (dark gray) and the CMZ (light gray) in a frog is also shown in this figure.

receptors and several Notch ligands are expressed by the retinal progenitor cells. Loss-of-function and gain-of-function studies have shown that Notch activity regulates progenitor differentiation. If the Notch receptor is activated in progenitors, they remain as progenitors, whereas inactivation of the Notch receptor occurs just prior to differentiation into one of the retinal neuronal types. The downstream effectors of the Notch pathway are the Hes genes. Hes1 and Hes5 are both expressed by subsets of the mitotically active cells in the developing retina, and both respond to Notch activation. Knockout and overexpression studies of the Hes genes indicate that they are necessary for both maintenance of the undifferentiated state of the progenitors and the development of the Müller glia.

In summary, the mitotically active cells in the developing retina have many characteristics of neural/glial progenitors in many other regions of the CNS. They share many of the same transcription factors, signaling molecules, and cell biology. In the retina, these cells have been called multipotent progenitors because at early stages of retinal development, these cells are competent to generate the entire complement of retinal neurons and glia. Thus, these cells have many characteristics of neural stem cells that have been isolated from other regions of the CNS. In addition, several groups have shown that the early progenitors can be cultured as 'neurospheres' (i.e., nonadherent aggregate cultures of neural stem and progenitor cells that can be passaged in EGF and/or FGF-containing medium). As described later, the adult retina of some vertebrates continues to add new neurons and glia at the peripheral margin, and thus true retinal stem cells exist. Presumably, these cells were derived from a population of similar cells in the developing retina, but there is currently no definitive way to distinguish the stem cells from the progenitors during retinogenesis.

Retinal Stem Cells in the Ciliary Marginal Zone

In the mammalian retina, the neurons and glia are generated in a continuous period of time from fetal to neonatal stages. In the mouse, for example, retinal neurons and glia become postmitotic starting at embryonic day 12.5 and ending approximately 1 week after birth. In all vertebrates, there is a central-to-peripheral pattern to histogenesis and differentiation in the retina. The first neurons are produced in the central retina and the last are produced at the periphery.

In contrast to the mammalian retina, in the amphibian, fish, or avian retina, histogenesis continues after the embryonic or neonatal period. In these animals, the retina continues to add new neurons into adulthood and, in some, throughout life. Teleost fish, for example, have a dramatic growth of the eye during their lifetime of up to 100-fold. The growth of the retina is accomplished by the continued production of new retinal neurons from a zone of cells at the peripheral margin, adjacent to the non-neuronal ciliary body, called the ciliary marginal zone (CMZ; Figure 1(b)). This zone is similar to neural stem cell zones in other regions of the CNS, such as the hippocampal progenitor zone or the subventricular zone. However, in contrast to these other zones, which typically generate only one type of neuron, the CMZ cells generate all types of retinal neurons

and Müller glia. In fact, most of cells in the retina of the mature frog or fish are generated by the cells of the CMZ. Lineage tracing studies of CMZ cells have shown that these cells can give rise to clones that contain all types of retinal neurons. The CMZ is thought to be organized with the most primitive cells (true stem cells (?)) in the most peripheral part (possibly mixed with the cells of the ciliary epithelium) and progressively more mature progenitor cells (transit amplifying cells (?)) closer to the differentiated retina.

The CMZ is highly productive in fish and some amphibians, but in birds it is greatly reduced. In birds, most of the retina is generated during embryonic development and only a small number of retinal neurons are generated by the CMZ. It is not known whether this zone persists throughout the lifetime of the bird, but new retinal neurons are generated at the peripheral edge of the retina in chickens up to 1 month of age and in the quail eye for up to 1 year. Like those of fish and amphibians, the CMZ cells of birds resemble the early progenitor cells of the retina, in terms of both their gene expression and their response to mitogenic factors.

The CMZ is greatly reduced or absent in the eyes of mammals that have been examined to date, including rodents and nonhuman primates. However, there is evidence that a CMZ-like zone can form in rodents under certain conditions. For example, mice with a single functional allele of the patched gene, a negative regulator of Shh signaling, retain a small number of proliferating, nestin-expressing cells at the retinal margin into adulthood. Moreover, when these mice are bred onto a background in which photoreceptors degenerate, the proliferation increases, reminiscent of the response to retinal damage observed in the CMZ cells of lower vertebrates. Studies have found that the normal period of proliferation of retinal progenitors can be extended by the injection of specific growth factors, but no study has successfully 'resuscitated' cells at the retinal margin of an adult mammal *in vivo*.

The CMZ in fish, amphibians, and birds can provide a source of regeneration following damage to the retina. In fish and amphibians, destruction of retinal neurons with neurotoxins or by surgery causes an increase in the proliferation of the CMZ cells. The cells produced by the CMZ then differentiate into neurons and in some cases migrate considerable distances to replace the cells lost by the experimental injury. In birds, neurotoxin damage does not by itself stimulate the proliferation of the CMZ cells, but destruction of retinal ganglion cells, followed by insulin-like growth factor and FGF injections, causes the CMZ cells to produce new ganglion cells, replacing the lost ganglion cells in the peripheral retina.

Additional Sources of Retinal Stem and Progenitor Cells

The Pigmented Epithelium

One of the most striking examples of regeneration in vertebrates is that of the amphibian retina. Following complete removal of the neural retina in larval frogs and adult urodeles (newts and salamanders), the adjacent pigmented epithelial (RPE) cells reenter the cell cycle, lose their pigmentation, and begin to express markers of retinal progenitors. The de-differentiated RPE cells go on to generate new retinal neurons in a recapitulation of normal retinal histogenesis. During a period of just a few weeks, histogenesis is complete and new retinal ganglion cells reconnect with visual centers in the brain. This process of RPE transdifferentiation into retinal progenitors does not occur in fish, adult birds, or adult mammals. However, a similar process occurs in birds and mammals at very early stages of eye development in embryos. The molecular mechanisms underlying the transition of the pigmented epithelial cells to retinal progenitors are only beginning to be understood. The de-differentiating pigment cells begin to resemble retinal progenitors soon after the retinal injury and express many of the EFTFs. FGF is a key stimulus for retinal regeneration from the RPE cells in both amphibians and chick embryos. When FGF is added to cultures of RPE cells or implanted into the vitreous *in ovo*, the RPE cells adopt a retinal progenitor identity and new, laminated retina is generated. Additional factors, such as activin and Shh, antagonize the transdifferentiation of RPE into regenerated retina, and blocking these factors enhances the retinal regeneration from the RPE that is induced by FGF.

The Ciliary Epithelium

The ciliary body is also considered a possible source of retinal stem cells or progenitors. The ciliary body is composed of a neural tube-derived part, called the ciliary epithelium, as well as a neural crest-derived part. The ciliary epithelium has two layers (**Figure 1**) – a pigmented layer that is continuous with the RPE and a nonpigmented layer that is continuous with the neural retina. The ciliary epithelium is anatomically and developmentally analogous to the choroid plexus in the rest of the CNS. The nonpigmented layer of the ciliary epithelium can generate neurons under certain conditions *in vivo* in birds. Intraocular injection of growth factors (insulin, FGF2, and EGF) stimulates the proliferation and neuronal differentiation of a subset of ciliary epithelial cells. Like the CMZ, the cells of the nonpigmented ciliary epithelium also express at least some of the EFTFs. The neurons

generated in this region following intraocular growth factor injections resemble amacrine cells and ganglion cells but not bipolar cells or photoreceptors. Thus, these cells may not actually be true multipotent progenitors but, rather, retain only some of their characteristics.

The mammalian ciliary epithelium has also received attention as a potential source of new neurons in adult animals. Several groups have found that cells can be isolated from the rodent ciliary epithelium that display characteristics of neural stem cells isolated from the mature brain. Although the cells appear initially pigmented, suggesting they are resident in the pigmented layer of the ciliary epithelium, they give rise to spheres of both pigmented and nonpigmented cells. Some of the spheres derived from the ciliary epithelium can be passaged to form new spheres, and although they appear to have a more limited life *in vitro* than neurospheres derived from the brain, they have been labeled retinal stem cells by the authors of these studies. The spheres are also capable of differentiation into cells that express markers of retinal neurons, including the rod photoreceptor-specific protein, rhodopsin. Human eyes also contain these cells, and they can be grown *in vitro* for extended periods of time and transplanted. However, the cells derived from the spheres typically express markers of specific neuronal types without taking on the morphological characteristics of the neurons. This is particularly clear in the case of photoreceptors, which have a distinct morphology when derived from retinal progenitors during normal development but appear flat and glial-like when derived from ciliary epithelial-derived cells. Thus, it is unclear whether the situation for these cells is more like what was previously described for the bird ciliary epithelium – that is, the cells take on some, but not all, of the characteristics of retinal progenitors. The nonpigmented epithelial cells from mammalian eyes can also be maintained as dissociated cell cultures grown on adherent substrates. Under these conditions, the cells are also capable of expressing neuronal markers, but again only some of the normal markers of retinal progenitors are expressed.

Intrinsic Stem Cells, Rod Precursors, and Müller Glia

In fish, there are several sources of new retinal neurons within the differentiated retina. In teleosts, new rod photoreceptors are added throughout the retina as it grows. The addition of new rods to the circuitry allows the fish to maintain a constant rod density as the retina stretches with ocular growth. Thus, sensitivity to light is maintained with increasing size. To accomplish this feat, the fish has a specific progenitor, called the rod precursor, which is normally restricted to generating new rods. These cells are found in association with the Müller glia and divide in the outer nuclear layer. In addition to the rod precursors, fish also have a relatively quiescent stem cell in the inner nuclear layer. Like the cells of the ciliary epithelium and those of the CMZ, this cell has also been labeled the retinal stem cell. The role of this slow-cycling retinal stem cell in normal retina is not clear, but when a small patch of central retina is surgically removed, both the rod precursor and the intrinsic retinal stem cell proliferate and form a blastema. The blastemal cells also resemble retinal progenitors, and over a few weeks they fill in the excised patch of retina.

The final source of retinal progenitors that have potential to replace lost neurons from within the retina are the Müller glia. Müller glia are the only glial cells in the retina produced by the multipotent progenitor. Müller glial cells are among the last cell types produced by the retinal progenitors during the normal period of histogenesis, and gene expression profiling studies have shown a high degree of overlap in the genes expressed by Müller glial cells and retinal progenitors. Despite their similarity, Müller glial cells in mammals and birds do not normally express many of the critical transcription factors that define progenitors in the retina and elsewhere in the CNS, such as Neurogenin2, Pax6, or Mash1. However, in posthatch chickens, damage to the retina by neurotoxins causes some of the Müller glia to reenter the cell cycle and reexpress both proneural genes, such as Mash1, and EFTFs, such as Pax6 and Chx10. In addition, after neurotoxic damage to the retina, some of the proliferating Müller glia go on to generate cells that express markers and morphology of neurons. The regenerative process initiated by retinal damage in young birds is largely abortive, however, and the majority of the Müller glial progeny remain as undifferentiated cells.

A similar process of regeneration from Müller glial cells may occur in teleost fish. As noted previously, regeneration of the teleost retina is particularly robust, and both rod precursors and intrinsic retinal stem cells are thought to contribute to the process. However, lesions to the retina of mature zebra fish also lead to Müller glial proliferation, and these cells may also contribute to the process, as in the chick. Attempts to stimulate regeneration from Müller cells in mammalian retina are under way and initial findings are promising, although there are still major hurdles to overcome.

Neural Synchrony and Feature Binding

Linguistic and mathematical descriptions consist of symbols for objects, qualities, and relations. Through rule-based recombination of these symbols, a virtually infinite number of different descriptions can be generated with a relatively small set of symbols. The efficiency of this versatile strategy is further enhanced by chunking. In order to reduce the length of descriptions, frequently occurring constellations are represented by symbols of higher order that summarize sets of component features and their respective relations in a single term. This chunking strategy requires a larger number of different symbols, but it saves time because it reduces the length of descriptions. There is thus a trade-off between required storage capacity and processing speed. It appears as if the brain uses a similar strategy to represent perceptual objects and motor programs and that it possesses learning mechanisms to optimize the trade-off between storage requirement and processing speed. Perceptual objects can be represented by scripts that consist of symbols for their components and their respective qualities and symbols describing the relations between these items. The same is true for movements which can be decomposed into elementary motion components and a specific set of relations that define the respective combination and sequence of components.

Analyses of the response properties of neurons encountered at the various levels of the processing hierarchy of sensory systems suggest the following sequence of processing steps. Neurons in the sensory organs encode in their responses very elementary, local properties and qualities of the components of perceptual objects and barely any relations. An exception is the retina of the eye. Unlike most other sensory organs, it possesses a complex, multilayered network that permits, first, recombination of signals in convergent feed-forward architectures and, second, extensive lateral interactions that modulate responses in a context-dependent way. Thus, the rate modulated output of ganglion cells signals not only the presence of a local property of an object, in this case the brightness and spectral composition of a small part of its surface, but also the neighborhood relations of these particular features. However, chunking at larger scales occurs only once signals are processed at the cortical level. As one proceeds along the hierarchically arranged cortical processing areas, one encounters neurons that respond selectively to increasingly complex constellations of elementary features. It is commonly held that this chunking is achieved by iterative recombination of feed-forward connections from lower to higher order neurons. If the thresholds of the respective higher order neurons are adjusted such that they respond only if the full set of the feeding neurons is simultaneously active, they assume the function of conjunction detectors. Their responses signal not only the presence of certain sets of component features but also the way in which these features are related to each other. The latter information is implicitly encoded in the architecture of feed-forward connections that link selected sets of feeder neurons to higher order conjunction detectors.

Several theoretical arguments suggest that these chunking operations are complemented at each level of processing by additional mechanisms that permit flexible definition of relations among the responses of distributed neurons. Natural scenes, for example, usually contain a large number of different objects, the contours of which may be overlapping or partially occluded. Hence, a single border may be shared by several objects. This introduces ambiguities that need to be resolved in order to provide appropriately sorted signals to the feed-forward chunking circuits. Without such prior sorting it would be difficult to avoid accidental formation of false conjunctions. Thus, responses to contours belonging to the same object need to be grouped together for further joint processing and chunking, and they need to be segregated from responses to other objects and the embedding background. This selection of 'chunkable' responses has to occur in a context-dependent way and hence needs to be based on an evaluation of neighborhood relations. Responses evoked by coherent contours need then be tagged as related in a way that ensures their selective binding by subsequent chunking. These grouping operations must occur at early levels of the processing hierarchy because successful scene segmentation is a prerequisite for the later identification of individual objects. However, context-sensitive dynamic definition of relations is also required at the highest levels of processing where neurons are encountered that respond to very complex constellations of features, such as the various components of a face, the mouth, the eyes, or the nose. The main argument for the need to flexibly define relations also at these high levels of processing derives from the evidence that perceptual objects are represented not only by individual highly complex chunking neurons but also by distributed assemblies of cells. First, chunking neurons whose response properties are sufficiently complex and selective to encode

only a single perceptual object are rare and seem to exist only for highly overlearned objects or objects of particular behavioral relevance. Second, it is inconceivable that novel objects can be represented by preestablished chunking neurons because the required feed-forward architectures would have to be specified *a priori* to support formation of the appropriate chunks. Third, objects that are simultaneously encoded in different sensory modalities elicit responses in several different sensory systems, and these need to be related to each other in order to arrive at a comprehensive polymodal description of this object. These considerations suggest that objects not representable by individual chunking neurons are encoded by assemblies of distributed neurons, each of which represents only a particular component of the object. In assembly coding, however, a relation-defining mechanism is again required that tags responses as related that are evoked by the components of the same object. The reason is that assemblies, just as the previously mentioned scripts, consist of symbols representing particular features – here neurons tuned to particular components and qualities of perceptual objects – and relation-defining codes that indicate which symbols have actually been recruited into the description of a particular perceptual object.

Synchrony as Tag of Relatedness

Psychophysical and electrophysiological evidence indicates that attentional mechanisms play an important role in grouping operations both at the level where scene segmentation is accomplished as well as at the higher levels where object identification is thought to occur. However, the mechanisms underlying these relation-defining grouping operations are still poorly understood. One proposal is that attentional mechanisms modulate the discharge rate of neurons and enhance the amplitude of responses to attended features. In this scenario, the signature of relatedness is the concomitant enhancement of discharge frequency. Responses selected for chunking or the formation of an assembly would be distinguished from all others by their higher discharge frequency. This interpretation has been challenged by the argument that response amplitude may be an ambiguous signature of relatedness because it depends on too many other stimulus-related variables, requires long read-out times, and makes it difficult to segregate assemblies from one another that are simultaneously configurated within the same neuronal network. Therefore, it has been proposed that neurons exploit two independent coding strategies in order to convey two messages in parallel. First, they should signal that the feature or the chunk of features for which they code is present, and second, they should indicate with which of the other simultaneously active neurons their responses are related. This latter code should ensure that responses tagged as related are processed jointly at subsequent stages – that is, are routed together into the appropriate chunking channels and/or are recognizable without ambiguity as originating from cells of the same assembly. It is commonly held that the first message is encoded in the discharge rate of the neurons because at lower levels of processing discharge rate reflects reliably different physical aspects of elementary stimuli and at higher levels the presence of complex chunks. Following the discovery that neurons in the primary visual cortex can synchronize their spike discharges with a precision in the millisecond range, it has been proposed that the synchronization of responses could serve as the required tag of relatedness. One way to select subsets of responses for further joint processing, and thus for binding them together, is to selectively raise their saliency. Most models on the binding function of selective attention are based on such a mechanism, but they usually assume that saliency is enhanced by rate increases. However, precise temporal synchronization of spike discharges is an equally efficient means to raise selectively the saliency of neuronal responses. The reason is that synchronized input to target neurons has a much stronger impact than temporally uncoordinated input. Simultaneously arriving excitatory postsynaptic potentials (EPSPs) summate much more effectively than temporally dispersed EPSPs, and this coincidence sensitivity of neurons is further augmented in cortical neurons by a number of specific mechanisms: (1) active dendritic conductances that amplify fast-rising depolarizations of large amplitude; (2) the frequency adaptation of synaptic release and postsynaptic receptors which attenuates temporal summation of EPSPs; and (3) a dependence of firing threshold on the rising slope of depolarizations, favoring responses to fast-rising depolarizations. These mechanisms increase selectively the impact of synchronous inputs, and they do so with a temporal resolution in the millisecond range. Thus, relations can be defined within narrow temporal windows (<10 ms), and hence different relations can be encoded with less ambiguity and in much more rapid alternation than if relations were expressed by joint rate increases.

The proposal that precise temporal synchrony is used as a tag of relatedness in neuronal processing agrees well with the temporal sensitivity of mechanisms supporting synaptic plasticity and Hebbian learning. Known mechanisms of synaptic plasticity exploit temporal correlations among the discharges of input connections and/or the discharges of inputs

and those of the postsynaptic target cells. The temporal resolution of the mechanism that classifies discharges as synchronous (asynchronous) – that is, related (unrelated) – and causes synapses to strengthen (weaken) also operates with a precision in the millisecond range. Thus, there is a perfect match between the signatures of relatedness used in signal processing and Hebbian learning. This cannot be otherwise because both processes have to rely on the same relation-defining code to avoid learning of false conjunctions.

The Role of Oscillations and Spike Synchronization

Investigations of response synchronization in the visual system have revealed that precise synchronization of discharges is often associated with an oscillatory patterning of the neuronal responses. Because individual cells tend to skip cycles of these oscillations, they are rarely detectable in the spike trains of single cells but they are readily seen in data representing the responses of large populations of neurons (i.e., in multiunit recordings or recordings of local field potentials). *In vitro* experiments in cortical slices and simulation studies have in the meantime established causal relations between the two phenomena. The oscillatory patterning of the responses is mainly due to oscillations generated within the various pools of inhibitory interneurons that are coupled through both chemical and electrical synapses and capable of sustaining oscillatory activity patterns. These oscillatory inhibitory inputs to pyramidal cells veto their discharges during the inhibitory troughs and favor discharges at the depolarizing peaks, thus causing synchrony in firing. These locally synchronized oscillatory responses can become synchronized over large distances due to reciprocal coupling of the oscillatory networks via excitatory cortico-cortical connections. It follows from this mechanism that the precision with which spikes can be synchronized increases with oscillation frequency. A relation also exists between oscillation frequency and the distance over which synchronization is maintained. Synchronization among remote groups of neurons or among large assemblies of neurons tends to occur at lower oscillation frequencies than synchronization of local clusters of cells.

The Duration of Synchronized Events

Early studies were based mostly on conventional cross-correlation analysis of cell discharges and/or local field potentials. This method reliably detects synchronous firing if it is sustained over prolonged periods of time but it fails if synchronous events occur only a few times in a response. Therefore, more sensitive measures have been developed that allow assessment of brief events of coincident firing. One of these methods, the unitary event analysis, uses statistical methods to identify single, nonaccidental incidences of coincident firing, whereas the other evaluates consistent phase relations between the discharges of individual neurons and local field potential (LFP) oscillations (spike-field coherence). Application of these methods to data obtained from awake behaving animals has revealed that episodes of synchronized firing are often restricted to short epochs of particular behavioral sequences and may be as short as a few tens of milliseconds. This agrees with measurements of the minimal time required to segment scenes and identify objects. It was estimated that the grouping operations required for scene segmentation and object identification should not take more than 10 to 20 ms per processing stage. This implies that a substantial amount of information about the accomplished grouping must be encoded in the precise timing relations between individual discharges of distributed neurons. The reason is that not much information can be encoded in variations of discharge rates of individual cells because they can generate only few spikes within such short time windows.

Synchrony and Feature Binding

Evidence from studies in the visual system suggests that response synchronization may be used throughout all processing stages, from the retina to the highest cortical areas, in order to establish relations among distributed responses – that is, to bias grouping of responses for subsequent chunking and to tag responses of assembly members as related. In all cases, synchronization probability reflects some of the Gestalt criteria that are used for scene segmentation and perceptual grouping. In the retina, ganglion cell responses synchronize with millisecond precision if evoked by continuous contours or coherent objects, and there is evidence from studies on the escape response of frogs that synchronicity of ganglion cell firing is actually carrying behaviorally relevant information. Retinal synchronization is associated with high-frequency oscillations (up to 90 Hz) and based on horizontal interactions within the network of coupled amacrin cells.

In the primary visual cortex, synchrony is often associated, especially when it is observed over larger distances, with an oscillatory patterning of spike discharges in the gamma frequency range (30–60 Hz). At this processing stage, synchronization probability correlates well with elementary Gestalt rules. It is enhanced between responses evoked by continuous

contours, by contours moving with the same speed in the same direction, by colinearly aligned contour segments, and by contours belonging to the same surface. It is maximal among responses evoked by coherent patterns such as regular gratings, and it is minimal or absent among responses to incoherent stimuli such as random dot patterns. In the cortex, response synchronization among spatially distributed neurons is mediated by the network of tangential horizontal connections, and if it occurs across the midline of the visual field it is mediated by callosal connections. One of the reasons why synchrony is stronger among responses to continuous or colinearly aligned contours or contours moving in the same direction is the anatomical anisotropy of these tangential connections. Those spanning larger distances connect preferentially columns with similar feature preference. Thus, elementary grouping criteria are implemented in the anisotropies of the network of tangential connections and translated into synchronization probability. In the cat, such stimulus-specific synchronization phenomena have been observed both within and across different visual areas, both within and across hemispheres, and between the visual cortex and the superior colliculus. In primates, especially in the awake behaviorally trained animal, multisite recordings have been applied much less frequently and therefore less data are available on response synchronization. However, the results obtained from primary visual cortex closely resemble those obtained from cats, but oscillation frequencies tend to be higher and the distances over which synchrony is observed tend to be shorter. In the motion-sensitive area MT of the dorsal processing stream response, synchronization was found to reflect the Gestalt rule of common fate, which is one of the strongest binding cues for perceptual grouping. Presentation of two spatially overlapping bars moving in different directions led to the formation of two distinct assemblies of neurons whereby those responding to the same contour synchronized their discharges, whereas those responding to different contours did not. In the inferior temporal cortex of the ventral processing stream, synchronization probability reflected the binding of chunking neurons into assemblies representing individual objects. Neurons responding to the components of faces (eyes, nose, mouth, etc.) synchronized their responses when the arrangement of these components was such that the animals signaled having recognized a face while they did not synchronize when the components were scrambled or presented in a way that was judged by the animal as incompatible with the appearance of a normal face. In the case of neither MT nor IT was it possible to distinguish between the various arrangements of the presented stimuli if only the discharge rate of the neurons was evaluated. This is compatible with the interpretation that discharge rate signals the presence of particular features, whereas the correlations among the discharges of neurons indicate how these features are related to each other.

The Role of Attention

Grouping operations based on elementary Gestalt rules and the binding of the stereotyped feature constellations of highly familiar objects can occur preattentively. This automatic, attention-independent grouping is thought to be based on chunking in fixed feed-forward architectures. However, several arguments suggest that synchronization may also serve as a mechanism for automatic grouping. The synchronization of retinal responses cannot be influenced by attentional mechanisms because there are no efferent projections capable of conveying the required information. The fact that feature-specific response synchronization is readily observed in anesthetized preparations also suggests that binding through synchrony can occur preattentively. Interestingly, this may turn out to be a feature distinguishing automatic grouping by chunking or by synchronization. Automatic grouping by synchrony is highly context dependent, whereas chunking is not. Despite anesthesia, grouping by synchronization remains sensitive to the global configuration of stimuli. In cat areas 17 and 18, synchronization probability changes when variations in stimulus context require a change in grouping, and this reorganization of synchrony patterns occurs even if stimulus configurations are changed in a way that leaves the stimuli appearing within the aperture of the classical receptive fields of the recorded neurons unchanged.

In addition to this evidence for attention-independent grouping by synchrony, recent results clearly indicate that synchronization is also highly susceptible to top-down, attention-dependent influences and that it plays an important role in attention-dependent response selection and binding. Various measures have been used to assess the influence of selective attention on neuronal synchrony: correlations among spike discharges, spike-field coherence, correlations in phase locking between oscillatory field potentials, and, finally, the amplitude and the phase locking of oscillatory responses in magnetoencephalography (MEG) and electroencephalogram (EEG) recordings. Because the amplitude of these latter signals depends to a crucial extent on the synchronicity of large populations of neurons, not only variations in phase locking but also variations in the power of oscillations can be taken as a measure of synchrony. These data indicate that focusing

attention on a particular stimulus or to a particular modality increases the synchrony of responses in the neuronal networks that process the attended stimulus. Again, this enhanced synchronization is associated with and most likely caused by an oscillatory patterning of neuronal activity in the beta and especially in the gamma frequency range. At the same time, one observes a reduction of oscillatory activity in lower frequency bands (alpha and delta). Evidence also indicates that anticipation of a particular stimulus or a motor act is associated with the generation of oscillatory activity in the beta and gamma frequency band in cortical areas required for the processing of the stimulus or the execution of the task. For tasks involving sensory discrimination and motor responses, this anticipatory synchronization can extend across widely distributed networks of cortical areas. This anticipatory modulation of oscillatory activity is usually not associated with major changes in the discharge activity of neurons, suggesting that it consists mainly of a synchronous pacing of excitability through oscillatory activity generated in the network of inhibitory interneurons. It has been proposed that this subthreshold modulation of excitability facilitates rapid synchronization of responses once stimuli are available, thereby enhancing transmission across multiple cortical stages. Recent results from MEG studies in human subjects take this proposal one step further and suggest that the anticipatory induction of coherent oscillations across distributed cortical areas and executive structures facilitates selective routing of activity and rapid handshaking among the involved processing stages. However, it is unknown which centers coordinate this attention-dependent modulation.

In principle, synchronization could be used as an alternative mechanism to rate modulations in order to raise the saliency of responses. Experiments on binocular rivalry support this conjecture. In cat primary visual cortex, the responses to the respective perceived stimulus differed from those to the suppressed stimulus because they were more synchronized and not because they were more vigorous. A similar conclusion is suggested by experiments on perceived brightness. If a small grating is superimposed on a large grating, the perceived contrast of the former increases with increasing orientation or phase offset between the two gratings. This effect is closely related to changes of neuronal responses in primary visual cortex. Neurons responding to the small grating increase their discharge rate but not their synchrony with increasing orientation offset, whereas they increase the synchrony of their discharges but not the rate with increasing phase offset. This indicates that the saliency of responses can be enhanced by increasing either the rate or the synchronicity of discharges. The fact that the effects are perceptually indistinguishable illustrates the complementarity of rate codes and temporal codes.

Oscillations and Read-Out

Self-generated oscillatory activity and the associated synchronization of spike discharges are likely to also play a role in the read-out of information stored in the architecture of neural networks. Data from multisite recordings and optical imaging have revealed that spontaneous activity is not simply noise but exhibits a high degree of spatial and temporal organization. In the visual cortex, the spontaneous activity fluctuations are coherent among columns sharing similar orientation preferences, probably because these columns are interconnected more strongly through cortico-cortical projections than are columns with dissimilar preferences. These spontaneous fluctuations have a strong impact on the latency and amplitude of light-evoked responses. Multisite recordings of spiking activity and field potentials from primary visual cortex revealed that columns preferring contours with similar orientation and in particular colinearly aligned contours engage in highly synchronized oscillations in the gamma frequency range when the cortex is in an activated state (i.e., when the EEG exhibits high power in the beta and gamma frequency range). The effect of these self-generated coherence patterns is that columns oscillating in synchrony respond with precisely synchronized latencies when activated by light stimuli, whereas response latencies fluctuate unsystematically and over a wide range for columns that have not been oscillating in synchrony prior to light stimulation. Therefore, the output of columns coding for features that tend to be grouped perceptually (same orientation, colinearity) is more synchronized than the output of columns coding for features that are less likely to be grouped. Thus, self-generated gamma oscillations translate the anisotropies in the network of horizontal connections into spatially selective patterns of coherence which in turn bias grouping by rapid synchronization of the very first components of responses to contours. Further support for this notion comes from multisite recordings in V1 of monkeys trained to freely inspect complex visual scenes. Soon after the onset of fixation (40–100 ms) one observes a brief burst of highly synchronized high-frequency oscillations in the local field potential that are precisely phase-locked across recording sites. These fixation-related oscillations are in turn associated with excess synchronization of spike discharges in the responses to the contours of the scene. Because these oscillations also occur when the animal scans a blank screen, they are most likely due to corollary activity that is generated in anticipation of having to

process new constellations of features once a new segment of the scene is fixated. In analogy to the effect of the spontaneous oscillations, this self-generated coherent activity could serve the read-out of grouping criteria residing in the network of tangential connection and to translate these criteria into specific synchronization patterns. The saccade-related oscillations and the associated spike synchronization precede by several tens of milliseconds the peak of the neurons' rate responses, which reach a maximum only approximately 100 ms after the eyes have come to rest. Grouping cues encoded in latency adjustments and spike synchronization are thus available long before the changes in the neurons' discharge rate can be fully evaluated. Such rapid processing at early stages of the visual system appears desirable given that the animals changed gaze direction on average four or five times in a second. This implies that scene segmentation, the eventual resolution of ambiguities, the selection of signals for chunking, and the subsequent dynamic grouping of chunks into object representations must have been accomplished within approximately 200 ms.

Conclusions

The data reviewed in this article suggest that sensory systems exploit two complementary ways to evaluate and represent relations between features of perceptual objects. One strategy consists of the generation of specialized neurons in feed-forward architectures that respond selectively to particular constellations of features. The discharge rate of these chunking neurons encodes both the presence of particular features and the way in which they are related to each other. This coding strategy is fast but can encode only relations defined *a priori* by the convergence patterns of the feed-forward connections. As multisite recordings suggest, there is a second strategy that exploits the precise temporal relations between the discharges of distributed neurons to encode relations. This mechanism permits flexible and context-dependent definition of relations. It exploits the coincidence sensitivity of neurons and uses precise temporal synchronization of discharges as tag of relatedness. Interestingly, the same tag appears to be exploited by the mechanisms mediating use-dependent synaptic plasticity and associative learning. As synchronization enhances the impact of the synchronized responses, it appears to be used not only to define relations among distributed responses but also in a more general way to select responses for further processing to raise their perceptual saliency and to support selective rooting of activity under the control of attentional mechanisms. Because temporal codes can only be assessed with multisite recordings and because these have a relatively short history, we are still just beginning to understand coding strategies based on the dynamic interactions among large numbers of neurons. It may turn out that precise synchronization is only one, albeit a very important, signature of the many potentially significant dynamical states. Precisely timed phase offsets and sequences of patterns defined by specific temporal relations are likely to play an equally important role. To analyze these more complex patterns and to examine whether they contain information that can be related to behavior is one of the great challenges in future systems neurobiology.

Neurexins

M Ahmad, Georg-August University, Göttingen, Germany
M Missler, Georg-August University, Göttingen, and Westphalian Wilhelms University Munster, Munster, Germany

© 2009 Elsevier Ltd. All rights reserved.

Neurexins constitute a family of cell-surface proteins that are expressed in neurons and (neuro)endocrine cells. Their hallmark is a high degree of polymorphism with potentially thousands of isoforms. Neurexins are essential for synaptic transmission and are potent inducers of synapse formation *in vitro*.

Gene Structure

Neurexins are encoded by three genes in vertebrates (NRXN1, -2, and -3). Each gene contains two promoters: an upstream promoter that directs the transcription of the larger α-neurexins and a promoter in the middle of the gene that initiates the transcription of shorter β-neurexins. NRXN1 (Figure 1) and NRXN3 genes are among the largest of mammalian genes, with sizes of ~1.1 and 1.6 Mb, respectively. NRXN2 is smaller, with a size of 110 kb. The three neurexin genes have a similar exon–intron structure with an almost identical number of exons. The neurexin genes are conserved in vertebrates, being present in mammals, birds, and frogs. However, in contrast to vertebrates, *Caenorhabditis elegans* and *Drosophila melanogaster* have only one NRXN gene, which codes for an α-neurexin-like molecule. Thus, β-neurexins are not present within the invertebrates.

Protein Structure

α-Neurexins and β-neurexins are type I membrane proteins with a large extracellular region and a small intracellular C-terminal region (Figure 2). α-Neurexins contain much longer extracellular sequences than β-neurexins, but both share an identical transmembrane region and intracellular part. The extracellular region of α-neurexins has a multidomain structure, consisting of three overall repeats followed by a serine-threonine-rich sequence before the transmembrane domain, which is O-glycosylated. Each repeat contains a central epidermal growth factor (EGF)-like domain and two flanking laminin-neurexin-sex-hormone binding protein (LNS) domains. The extracellular region of β-neurexins has a single LNS domain preceded by a short β-specific sequence. The LNS domain was identified as a repeat in Laminin A and is named for Laminin, Neurexins, and Sex hormone-binding globulin, the three proteins in which it was initially discovered. Each LNS domain consists of 160–200 residues and forms a ligand-binding domain in many proteins. The crystal structure of the LNS domain of neurexin 1β (which is equivalent to the sixth LNS domain of neurexin 1α) revealed two 7-stranded β-sheets forming a jelly-roll fold with structural similarity to lectins. The two β-sheets are roughly parallel and curved, giving rise to a β-sandwich structure. The ligand-binding site is believed to be at one edge of the β-sandwich, designated as the hypervariable surface. The crystal structure of the second LNS domain of neurexin 1α revealed a similar overall fold, along with a Ca^{2+}-binding site at the hypervariable surface. The short intracellular region of neurexins (55 aa) is highly conserved among isoforms and contains a terminal class II postsynaptic density-ZO protein (PDZ) domain-binding motif. The invertebrate neurexin has a domain structure identical to vertebrate α-neurexins and modest sequence homology to the human α-neurexins, with *C. elegans* possessing 23–24%, and *D. melanogaster* neurexin possessing 29–30%, identity.

A characteristic feature of neurexins is the extensive alternative splicing of their transcripts, giving rise to >1000 potential isoforms. There are five sites for alternative splicing in α-neurexins, designated 1–5, with the last two being shared by β-neurexins. Alternative splicing involves the exclusion or insertion of sequences, which can range from a few amino acids at some sites to >30-amino-acids at others. Three of the sites in α-neurexins and one in β-neurexins are present within the LNS domain and splice insertions in some of these have been shown to interfere with ligand binding. Some insertions in splice site 5 of neurexin 3α/β contain stop codons that may truncate the protein before the transmembrane region, generating putatively secreted variants. The sites for alternative splicing as well as the splice insert sequences are evolutionarily conserved among mammals. Homologous splice sites (1–5) and splice-insert sequences were found for neurexin 1α in chick sympathetic ganglia. Splice variants for three α-neurexins in *Xenopus* embryos were detected at splice sites 1–2 but not at 3; however, splice sites 4–5 have not yet been analyzed. Significantly, alternative spliced sequences have not been detected in invertebrates and no evidence is as yet available to indicate alternative splicing in the invertebrate neurexin.

Sequence analysis of a putative additional *Drosophila* neurexin (*Drosophila* nrxnIV) identified it as the ortholog of vertebrate CASPR. This has now been placed, together with other proteins with similarities

Figure 1 Structure of the human/mouse neurexin 1 gene. Shown here are 24 coding exons of the gene as red boxes or lines along with their numbers. The exons which are alternatively spliced are denoted by asterisk. The promoter for neurexin 1α lies upstream of coding exon 1, whereas the promoter for β-neurexin is located between coding exons 17 and 18. Exon 18 represents the β-specific exon.

Figure 2 Domain structure of α- and β-neurexin proteins. The extracellular region of α-neurexins consists of six LNS domains and three EGF-like domains. The three LNS-EGF-LNS repeats in α-neurexins are followed by a serine-threonine-rich sequence (abbreviated S) that is O-glycosylated. The extracellular region of β-neurexins has a single LNS domain preceded by a short β-specific sequence (abbreviated β). The intracellular region of α- and β-neurexins is identical (abbreviated C). Arrows indicate the sites for alternative splicing. EGF, epidermal growth factor; LNS, laminin-neurexin-sex-hormone binding protein domain.

to neurexins, in the neurexin superfamily, which also includes CASPR/Paranodin (vertebrate) and BAM-2 (*C. elegans*). These proteins contain LNS and EGF-like domains, but the organization of their domains is distinctly different from that of the neurexins, as are their proposed roles.

Interaction Partners

Extracellular Binding Partners

The particular domain structure of the extracellular part of neurexins points toward its role as a ligand receptor. Extracellularly, α- and β-neurexins bind to the cell surface proteins neuroligins and dystroglycan, as well as to the exogenous neurotoxin α-latrotoxin. In addition, α-neurexins (but not β-neurexins) interact with neurexophilins, which constitute a family of neuropeptide-like glycoproteins (Nphl 1–4). Neurexophilin 1 and 3 bind to the second LNS domain of neurexins, and this binding is not affected by alternative splicing. Whereas neurexophilin 1 is predominantly expressed by inhibitory interneurons, neurexophilin 3 occurs in the excitatory neurons of distinct areas of the cortex and cerebellum, and has been found to play a role in sensorimotor gating and motor coordination in knockout mice, possibly in a tight complex with α-neurexins. Neuroligins are a family of postsynaptic cell-surface proteins that were discovered as endogenous ligands for β-neurexins. Neuroligins are encoded by five genes (NLGN1, -2, -3, -4, and -4Y) in humans and at least three genes in rodents. Neuroligins are alternatively spliced in their extracellular sequences at two sites, designated A and B. Neuroligins bind to the single LNS domain of β-neurexins and to the sixth LNS domain of α-neurexins in a Ca^{2+}-dependent manner that is regulated by alternative splicing on both proteins. β-Neurexins that lack an insert in splice site 4 bind to all neuroligins; however, β-neurexins which have an insert in splice site 4 and all α-neurexins may bind to neuroligins which lack an insert in their splice site B.

Intracellular Binding Partners

The intracellular region of α- and β-neurexins is identical and has been found to bind to multiple interaction partners (Table 1). A membrane-associated guanylate kinase (MAGUK) protein, calcium/calmodulin-dependent serine protein kinase (CASK) has been found to bind to the C-terminus of neurexins via its PDZ domain. The MAGUK family consists of adaptor proteins that have a catalytically inactive guanylate kinase domain. An important feature of MAGUK proteins is their multidomain structure, which can potentially help in the formation of multipartite

Table 1 Binding partners of neurexins[a]

Binding partners	*Subcellular localization*	*Binding site on neurexin*	*Binding site on partner*	*Phenotype of knockout mice*
Extracellular				
Neuroligins	Postsynaptic membrane	LNS6 of α-neurexins; single LNS of β-neurexins	Cholinesterase-like domain	Neuroligin 1 KO: no obvious phenotype Neuroligin 2–3 KOs: not known
Neurexophilins	Not known; ?Extracellular matrix bound to α-neurexins	LNS2 of α-neurexins	Not known	Nph1 KO: no obvious phenotype Nphl3 KO: impaired sensorimotor gating and motor coordination
Dystroglycan	Postsynaptic membrane	LNS2 and LNS6 of α-neurexins; single LNS of β-neurexins	Not known	KO: early embryonic lethality, defect basal lamina Conditional KO: no changes in synaptic differentiation
α-Latrotoxin	n.a.	LNS6 of α-neurexins; single LNS of β-neurexins	N-terminal cysteine-containing domain + (?) central ankyrin-repeats domain	n.a.
Intracellular				
CASK	Pre- and postsynaptic, cytosolic	PDZ domain-binding motif at the C-terminus	PDZ domain	Males show cleft palate and die on the first day of birth. Brain-specific conditional KO: not known
Mints	Pre- and postsynaptic, cytosolic	PDZ domain-binding motif	PDZ domain	Mint1 KO: No change in excitatory synaptic transmission, increased paired-pulse depression at inhibitory synapses
Syntenin	Pre- and postsynaptic, cytosolic	PDZ domain-binding motif	PDZ domain	Not known
Synaptotagmin 1	Presynaptic, vesicle membrane	PDZ domain-binding motif	Not known	Abolished fast component of Ca^{2+}-triggered exocytosis

[a]Additional intracellular binding partner such as CIPP and AF6 have been proposed, but evidence for these candidates is currently very limited. CASK, calcium/calmodulin-dependant serine protein kinase; KO, knockout; LNS, laminin-neurexin-sex-hormone binding protein domain; n.a., not applicable; PDZ, postsynaptic density-ZO protein domain.

complexes. Consequently, multiple interaction partners for CASK have been found, including Mints, Velis, α1B Ca^{2+}-channel subunit, protein 4.1, calmodulin, rabphilin 3a, and syndecan. It has been proposed that the tripartite complex of CASK, Mint, and Veli couple neurexin-mediated cell adhesion to synaptic vesicle exocytosis machinery as well as to Ca^{2+} channels at the active zone. In addition, the binding of CASK to protein 4.1 has been shown to nucleate the local assembly of actin/spectrin filaments on the intracellular tail of neurexin, linking cell adhesion to the actin cytoskeleton. In addition to CASK, the C-terminus of neurexins has been shown to interact with Mint1–2, syntenin, channel-interacting PDZ domain protein (CIPP), AF6, and synaptotagmin1. However, the number and promiscous nature of all these biochemical interactions raise doubts about their physiological significance, and further work is required to establish their specific role for neurexin function.

Expression

Neurexins are expressed throughout all brain regions and neuron types, although the different isoforms have partly overlapping and partly differential distributions. For example, CA1 pyramidal cells of hippocampus express neurexin 1α, 2α, 2β, and 3β, but lack neurexin 3α and 1β. In contrast, the interneurons in CA1 region express all three α-neurexins and neurexin 3β, whereas CA3 pyramidal neurons express all six principal neurexin isoforms. In addition to the brain, neurexins are also expressed in the spinal cord motor neurons, sympathetic neurons, and (neuro)

endocrine cells (from the pituitary, pancreas, and adrenal gland). Moreover, the alternatively spliced sequences have also been shown to differ in regional distribution. For example, neurexin 1 and 2mRNAs without an insert at splice site 4 are present at higher levels in the hippocampus and cerebral cortex than in the striatum, substantia nigra, and cerebellar nuclei. In contrast, neurexin 1 and 2 with an insert at splice site 4 show the opposite pattern. In the brain, neurexins have been shown to be enriched at synapses by biochemical fractionation methods. They are believed to be localized at presynaptic boutons on the basis of the action of their ligand α-latrotoxin, which causes massive neurotransmitter release from presynaptic terminals. However, a precise ultrastructural localization of neurexins has not yet been published, and the mechanism that targets neurexins to the synapse is still unclear.

The transcription of neurexin genes in the murine embryonic nervous system begins within 1 day of neurons becoming postmitotic. Immunoblot analysis using pan-neurexin antibodies revealed that levels of α- and β-neurexins increase dramatically after birth and reach peak expression during the second postnatal peak, which is a period of intense synaptogenesis. Expression then decreases, reaching a steady level in older animals. Another study, which used *in situ* hybridization, revealed an essentially similar picture for the neurexin 2α transcript, but found no major change in the expression of neurexin 1, 2β, and 3 transcripts during postnatal development. The expression of alternatively spliced variants of neurexins have also been shown to change during development. The expression of neurexin 1 transcript with no insert at splice site 4 increased dramatically in chick sympathetic ganglia from embryonic day 7.5 to embryonic day 18, whereas the expression of neurexin 1 with an insert at splice site 4 did not change strongly.

Function of Neurexins

Role of Neurexins in Synaptic Transmission

Neurexins were discovered as receptors for α-latrotoxin, a component of black widow spider venom, which causes massive neurotransmitter release. The action of α-latrotoxin immediately indicated a presynaptic localization of neurexins, as well as a role for neurexins in neurotransmitter release. The generation and analysis of knockout mice for all three α-neurexin genes recently confirmed the importance of α-neurexins for synaptic transmission and for Ca^{2+}-triggered release in general.

Mice lacking all three α-neurexins died on the first day of birth. Analysis of excitatory synapses in acute brain stem slices and inhibitory synapses in neocortical slice cultures revealed that evoked synaptic transmission was severely impaired in α-neurexin-knockout mice. This was accompanied by a reduction in the frequency of miniature synaptic transmission without affecting its amplitude. This indicated that α-neurexins are essential for neurotransmitter release at both the excitatory and inhibitory synapses. Further analysis revealed that the effect of deleting α-neurexins involved an impairment of Ca^{2+}-channel function. The synapses from knockout mice showed a markedly reduced sensitivity to blockers of N-type and P/Q-type Ca^{2+} channels, implying that α-neurexins might be responsible for coupling specific Ca^{2+} channels to the release machinery. In addition, it was found that whole-cell Ca^{2+} currents in brain stem neurons were reduced in knockout mice. Rescue experiments showed that transgenic neurexin 1α (but not neurexin 1β) alleviated the functional deficits of knockout mice, confirming that α-neurexins are directly involved in regulating the efficacy of neurotransmission and suggesting that the longer extracellular sequences of α-neurexins are required for this process. Other functional defects in α-neurexin knockout mice included a reduced *N*-methyl-D-aspartate (NMDA)/α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor ratio in neocortical neurons (presumably due to a compensatory reaction to the strongly reduced inhibitory transmission) and a profound inability of neuromuscular junctions to upregulate presynaptic release in response to postsynaptic receptor blockage. Significantly, a recent study revealed that deletion of α-neurexins from the pituitary gland melanotrophs also leads to an impairment of the secretory granule release, validating and extending the importance of α-neurexins as general organizer molecules of Ca^{2+}-triggered exocytosis in various systems (**Figure 3**).

Because mice lacking all β-neurexins are not yet available, a similar investigation for the function of β-neurexins in synaptic transmission has not been performed. However, the continued presence of β-neurexins in α-neurexin-knockout mice was not able to compensate for the profound deficits in neurotransmission. Therefore, it seems likely that α-neurexins have an essential function in synaptic transmission that is not shared by β-neurexins.

Role of Neurexins in Synaptogenesis

Considerable evidence has accumulated from cell culture studies to show that β-neurexins and their postsynaptic binding partners neuroligins are sufficient to induce *de novo* formation and differentiation of functional synaptic contacts. These studies concentrated on β-neurexins and not α-neurexins because the binding of

Figure 3 Impaired synaptic transmission at inhibitory and excitatory synapses in α-neurexin triple knockout (TKO) mice: (a) paired recordings of evoked $GABA_A$-receptor-mediated postsynaptic currents in pyramidal neurons of cultured neocortical slices from control (S2) and TKO mice; (b) glutamatergic-evoked responses in hypogoglossal motor neurons after field stimulation of axons from the pre-Bötzinger complex. In (a), the evoked release is reduced by 95% in α-neurexin TKO mice. In (b), the TKO mice show impaired evoked responses at different stimulation intensities. GABA, γ-aminobutyric acid; WT, wild type. From Missler M, Zhang W, Rohlmann A, et al. (2003) α-Neurexins couple $Ca2^+$ channels to synaptic vesicle exocytosis. *Nature* 423: 939–948.

α-neurexins to particular neuroligin isoforms was unknown until recently. In addition, the data from α-neurexin knockout mice showed a stronger effect on synaptic transmission than on synapse formation. Multiple groups have now detailed the role of β-neurexins and neuroligins in various aspects of synaptogenesis using cell culture assays; however, *in vivo* evidence from knockout mice is pending.

Presynaptic assembly The initial evidence for the involvement of β-neurexins in presynaptic assembly came from a chimeric culture model. The presentation of neuroligin 1 on nonneuronal HEK293 cells triggered presynaptic differentiation in contacting axons of pontine explants. There was accumulation of synaptic markers and the adaptor protein CASK at the site of induced synaptic contacts, where accumulated vesicles could also undergo depolarization-dependent turnover. Significantly, the synaptogenic effect on these *de novo*-formed contacts was lost when soluble neurexin 1β was added to the culture, implying that the interaction of neuroligins with β-neurexins is responsible for inducing presynaptic assembly. A subsequent study showed that clustering β-neurexins on the presnaptic surface is sufficient to induce presynaptic differentiation and that the synaptogenic activity of β-neurexin depends on the protein interactions of its intracellular part, although the downstream binding reactions are still unclear. One possibility is the binding of the neurexin C-terminus to modular adaptor proteins such as CASK and Mint, which can generate a scaffold of presynaptic machinery. Another possibility is the polymerization of actin on the cytoplasmic tail of neurexins through CASK and actin binding-protein 4.1, followed by F-actin stabilizing the clusters of synaptic vesicles at the induced presynaptic terminal.

Postsynaptic assembly As expected from a reciprocal interaction between neurexins and neuroligins, β-neurexins have also been shown to induce the assembly of the postsynaptic apparatus via their interaction with neuroligins. The presentation of neurexin 1β on nonneuronal COS cells triggered postsynaptic differentiation in contacting dendrites of primary hippocampal neurons, resulting in the clustering of scaffolding proteins postsynaptic density (PSD-)95 and gephyrin, as well as the neurotransmitter receptor (NR)1 subunit of NMDA receptors and γ-aminobutyric acid A ($GABA_A$) receptor subunits α2 and γ2. Interestingly, no accumulation of AMPA receptor subunits glutamate receptor (GluR)1 and GluR2 was observed, implying that the β-neurexin–neuroligin interaction might first assemble silent synapses. Later, recruitment of GluR1 subunit into the β-neurexin-induced scaffolds occurred following brief activation of NMDA receptors. This conversion of silent synapses into active synapses on NMDA receptor activation mimics the developmental maturation of synapses.

Development of synapse specificity When neurexins were discovered, the presence of multiple isoforms gave rise to the hypothesis that neurexins might act as a component of a recognition code for generating different types of synapses. This view was strengthened by the finding of a differential distribution of neurexins in different brain regions as well as in pyramidal cells and interneurons. However, the distribution was found to be overlapping, with no evidence for the selective expression of specific neurexin isoforms

in glutamatergic or GABAergic cells. However, the situation turned out to be different for neuroligins. It was shown that neuroligin 1, 3, and 4 are localized to glutamatergic (but not GABAergic) synapses, whereas neuroligin 2 is localized mainly to GABAergic synapses. The presentation of neurexin 1β on COS cells induced clustering of neuroligin 1 and 2 in contacting dendrites which subsequently recruited both gephyrin and PSD-95-containing postsynaptic scaffolds. However, more neuroligin 2 puncta were associated with gephyrin clusters than with PSD-95 clusters. Recent evidence points toward a stronger role for neurexin isoforms in determining synapse specificity. In contrast to insert-negative neurexin 1β (at splice site 4) used in the studies previously discussed, insert-positive neurexin 1β (at splice site 4) and neurexin 1α exclusively triggered the assembly of gephyrin clusters through selective recruitment of neuroligin 2. Interestingly, α-neurexin-knockout mice showed a reduction in the area density of inhibitory synapses, although the overall number of excitatory synapses also appears to be reduced due to a neurophil defect evident in older knockout animals that lack only two out of three neurexin genes. These findings suggest a role for some neurexin isoforms in determining glutamatergic versus GABAergic synapse induction (Figure 4).

Figure 4 Diagram summarizing the synaptogenic potential of the neurexin–neuroligin interaction in chimeric culture assays: (a) nonneuronal cells transfected with neuroligin cluster neurexin molecules at the presynaptic terminus of contacting axons, leading to the recruitment of synaptic vesicles and scaffolding proteins (e.g., MAGUKs such as CASK); (b) presentation of neurexin on nonneuronal cells induces the recruitment of postsynaptic scaffolding proteins (e.g., MAGUKs such as PSD-95 and gephyrin) and neurotransmitter receptors (e.g., NMDA and $GABA_A$ receptor subunits) via neuroligins. CASK, calcium/calmodulin-dependent serine protein kinase; GABA, γ-aminobutyric acid; MAGUKs, membrane-associated guanylate kinases; NMDA, *N*-methyl-D-aspartate; PSD-95, postsynaptic density 95.

Synaptic cell adhesion Some studies also point toward the role of the neurexin–neuroligin interaction in mediating mechanical cell adhesion at synapses, which could help in aligning the pre- and postsynaptic specializations. Normally nonadhesive insect cell lines expressing neurexin 1β or neuroligin 1 formed cell aggregates only when these two cell lines were mixed together in the presence of Ca^{2+} ions, indicating that neurexin–neuroligin binding is capable of mediating actual cell adhesion. Moreover, neurexins have been found to be enriched in the growth cones of isolated axons emerging from pontine explants in culture. Their concentration in growth cones localizes them appropriately to catch neuroligin-containing postsynaptic targets. However, α-neurexin-knockout mice did not reveal an increase in the width of the synaptic cleft or a misalignment of pre- or postsynaptic densities.

Clinical Aspects of the Neurexin–Neuroligin Complex

Mutations in neurexins have not yet been directly implicated in any major disorder. Nonetheless, a recent study using pooled association genome scanning has revealed a putative link of a single-nucleotide polymorphism (SNP) residing within the neurexin 3 gene with addiction vulnerability to polysubstance abuse. The involvement of the neurexin–neuroligin interaction in autistic spectrum disorders is currently under intensive investigation because some studies have reported a linkage of mutations in neuroligin 3 and 4 to cases of autism, without, however, any implication of mutations in neurexin genes.

Along this line, the expression of neurexins appears to be under dynamic control and has been found to vary under pathophysiological conditions. One study reported increased expression of neurexin 2 mRNA following kainate- and pentylenetetrazole-induced seizures in the dentate gyrus of rats. Transient global ischemia has also been shown to induce the elevation of neurexin 2α and neurexin 3α mRNA in the hippocampal CA1 and CA3 regions, respectively. In addition, there was an appearance of an insert-positive isoform of neurexin 3α (at splice site 4) in the CA3 region following ischemia. Gene expression analysis of spontaneously hypertensive rat cerebral cortex revealed altered levels of neurexin 1β following transient focal ischemia. It is unclear, however, whether these changes in neurexin expression are part of a compensatory homeostatic response, or whether they participate in the progression of the pathological insult.

Neuroanatomy Methods in Humans and Animals

P Lavenex, University of Fribourg, Fribourg, Switzerland

The study of the structural organization of the nervous system dates back many centuries, but our understanding of the detailed organization of the brain and other nervous tissue has been largely dependent on the development of technologies within the past 150 years. In particular, two pieces of equipment developed in the middle of the nineteenth century have been fundamental to the study of the nervous system: the microtome and the compound microscope. Although the first compound microscope was developed at the end of the sixteenth century by Hans and Zacharias Janssen (by placing lenses at each end of a tube), major technological improvements were made in the mid-nineteenth century, leading to the predecessors of modern-day light microscopes. The microtome, used to cut thin slices of biological preparations adequate for microscopic evaluation, similarly came into common use during the mid-nineteenth century. Eventually, detailed examination of the fine structure of axons, dendrites, and synapses required the development of additional technologies. The limited magnification and resolution of the light microscope led to the development of the electron microscope in the early 1930s. Since the advent of these technologies, numerous biological staining procedures have been developed enabling the study of the fine structure of the nervous system, thus ushering in this modern era of neuroscience. Interestingly, however, despite the great advances in modern *in vivo* imaging techniques and informatics, some neuroanatomical procedures developed more than 100 years ago are still central to current investigations of the structural organization of the nervous system of humans and other animals.

Classical Histochemical Techniques

Our understanding of the detailed structural organization of the nervous system is still largely dependent on the microscopic examination of postmortem tissue. To produce these specimens, nervous tissue needs to be prepared with a fixative solution that preserves the integrity of the structures to be examined. This is generally accomplished by perfusion of aldehyde solutions through the vasculature of deeply anesthetized experimental animals or by immersion in a fixative solution for the case of postmortem human tissue. The block of tissue is then sectioned either frozen or after being embedded in media such as paraffin or celloidin, and the micrometers-thick sections are stained by different methods. The most widely used staining procedure is undoubtedly the technique published in 1894 by Franz Nissl and now commonly known as the Nissl stain (Figure 1). Basic dyes, such as thionin or cresyl violet, stain the acidic and basophilic components of the Nissl bodies (stacks of granular endoplasmic reticulum in the cytoplasm of cells), as well as the chromatin in the nuclei and nucleoli of cells. This technique has the advantage, and the disadvantage, of indiscriminately staining neuronal and glial cells. Because of its simplicity, the Nissl stain can easily be implemented in any neuroscience laboratory. It works well on tissue fixed with almost any kind of fixative and even on unfixed tissue. Nevertheless, great care is necessary to produce consistent and reliable Nissl-stained preparations in order to perform quantitative analyses of the nervous system. Although modern neuroanatomical definitions of cortical and subcortical brain areas are based on a convergence of evidence linking cytoarchitectonic, neurochemical, molecular, connectional, and developmental criteria, they always refer eventually to the cytoarchitectonic description of the distinctive types and arrangement of cells in a given area as described in Nissl-stained tissue.

Another important technique that remains of current interest is the Golgi technique, allowing the visualization of the dendritic and axonal processes of neurons (Figure 2). This technique was first published in 1873 by Camillo Golgi and employed extensively by Ramón y Cajal for his seminal work *Histologie du Système Nerveux de l'Homme et des Vertébrés*. Although adult brain material is generally considered more difficult to stain than tissue from younger organisms, variants of the technique can be adapted to produce good quality preparations from a broad variety of ages and species, and with either fresh or fixed tissue. Small pieces of tissue are immersed in solutions containing potassium dichromate for several days, followed by immersion in silver nitrate solutions kept in the dark for several more days. Serial sections of 150–250 μm are then cut, revealing neurons filled with a black precipitate of silver chromate. The strength of the approach is that, for unknown reasons, it labels only a small portion of all neurons in a nonspecific manner, enabling the reconstruction of the dendritic and umyelinated axonal plexus of individual cells. One shortcoming of the Golgi technique is that it is difficult to accurately reconstruct entire dendritic and axonal arborizations

Figure 1 (a) Photomicrograph of a Nissl-stained coronal section through the dentate gyrus of an 180-day-old Sprague–Dawley rat. (b) High-magnification photomicrograph of the pyramidal cell layer of the CA3 field of the hippocampus. Pyramidal neuron indicated by an arrow; nucleus of a glial cell indicated by an arrowhead. Scale bar = 250 μm (a) and 25 μm (b).

Figure 2 (a) Photomicrograph of a Golgi-stained section illustrating the dendritic arborization of CA1 pyramidal neurons in the macaque monkey. (b) High-magnification photomicrograph of a Golgi-stained CA1 pyramidal neuron in the macaque monkey. Scale bar = 1mm (a) and 100 μm (b). Modified from Altemus KL, Lavenex P, Ishizuka N, and Amaral DG (2005) Morphological characteristics and electrophysiological properties of CA1 pyramidal neurons in macaque monkeys. *Neuroscience* 136(3): 741–756, with permission.

due to the necessity of using thin sections in order to visualize the stained processes. Quantitative measurements of dendritic processes derived from Golgi-filled neurons therefore underestimate such parameters, compared to intracellularly labeled neurons (which can be visualized in thicker sections). Nevertheless, it remains a powerful technique to study the morphological characteristics of neurons, including the shape and size of their soma, the length of dendrites, and the number of branches and spines, in both human and experimental animal tissue.

A number of other histochemical staining procedures have been developed during the past 150 years in order to visualize various molecules, such as myelin, or study specific cell types or neuron populations. Histochemical myelin stains remain common in fundamental research because variations in myelination patterns provide additional information by which to define structurally different brain regions. Neuropathology laboratories also rely on myelin stains to evaluate the demyelination processes that occur in diseases such as multiple sclerosis. The first histochemical myelin staining method was published in 1884 by Weigert, but it has largely been replaced by simpler and more reliable methods using silver nitrate or gold chloride staining procedures. Immunohistochemical procedures using antibodies against myelin basic protein are also becoming more common.

Other stains developed to study specific cell populations are based on the detection of enzymatic activity linked to the synthesis or degradation of particular neurotransmitters. One example is acetylcholinesterase, the enzyme that breaks down acetylcholine and is present at all cholinergic synapses and therefore in many neurons that receive cholinergic innervation

Figure 3 (a) Low-magnification photomicrograph of a coronal section through the monkey hippocampal formation stained for acetylcholinesterase enzymatic activity. (b) High-magnification photomicrograph of the monkey dentate gyrus stained immunohistochemically with an antibody raised against acetylcholinesterase. Note the high level of labeling in the inner portion of the molecular layer of the dentate gyrus observed with the two different staining methods. Scale bar = 1 mm (a) and 100 μm (b).

but that are not necessarily cholinergic. Interestingly, the activity of this enzyme is very robust and does not seem to be impacted by delays between death and fixation, making it particularly suitable for the study of human postmortem tissue, as long as this material is not overfixed (Figure 3(a)). In contrast, choline acetyltransferase, the enzyme necessary for the synthesis of acetylcholine and which is present exclusively in cholinergic neurons, is detected immunohistochemically (acetylcholinesterase can also be detected immunohistochemically; Figure 3(b)). Thus, acetylcholinesterase enzymatic activity and choline acetyltransferase immunohistochemistry can be used as differential markers of the cholinergic system.

Modern Molecular Techniques

A major advance in the study of the detailed organization of the nervous system has been the development of molecular detection techniques such as immunohistochemistry and *in situ* hybridization. The great advantage of these techniques is that they enable researchers to study specific subpopulations of neuronal or glial cells. Immunohistochemical staining procedures entail incubating tissue sections in a solution containing antibodies raised against particular molecules or peptides that are constitutive elements of neurotransmitters, receptors, enzymes, or structural proteins. These primary antibodies can be tagged by a marker that can be visualized under the microscope, but most often they are visualized via the use of a secondary antibody raised against the IgG of the host animal producing the primary antibody (indirect detection system). The secondary antibody can be tagged with one of various fluorescent markers (fluorophores), which can be visualized using fluorescent light microscopy, or with biotin, which can be visualized using avidin–horseradish peroxydase (avidin–biotin complex method) as the reagent and diaminobenzidine tetrachloride as the chromogen to produce a permanent labeling for bright field or dark field light microscopy. The indirect detection of antigens, which relies on two antibodies and a separate detection system, enables the amplification of the signal and thus increased sensitivity. Literally thousands of molecules present in neuronal and glial cell populations can now be detected with such techniques (Figures 3(b) and (4)). However, the spurious staining of unrelated molecules that happen to cross-react with the antiserum is an important concern. Primary antibodies are produced by injection of a known molecule into an animal such as a mouse or a rabbit, followed by the purification of the IgG immunoglobulins directed against this molecule from the animal's serum. Primary antibodies can be either polyclonal (i.e., produced by several B cell lines and typically recognizing several epitopes) or monoclonal (i.e., derived from a single B cell line and recognizing one single epitope). Thus, the specificity of the antibody for a given molecule should always be verified, particularly when working with novel molecules or specimens in which the normal distribution of the target molecule is not known. Finally, immunohistochemical reactions are also very sensitive to the quality and the nature of the fixation. An antibody might recognize a given epitope in a protein's native state but not when the protein has been exposed to a fixative which modifies its three-dimensional configuration. The most commonly used fixative is paraformaldehyde, which ensures the preservation and detection of the greatest number of proteins, thus allowing for the use of multiple antibodies directed at multiple target molecules. However, certain molecules, particularly smaller ones such as γ-aminobutyric acid (GABA), require

Figure 4 (a) Coronal section through the monkey dentate gyrus stained immunohistochemically with a primary antiserum which recognizes somatostatin-281-12 (S320). (b) Coronal section through the monkey medial temporal lobe stained immunohistochemically with a primary antibody against nonphosphorylated high-molecular-weight neurofilaments (SMI-32). (c) Coronal section through the monkey entorhinal cortex stained immunohistochemically with a primary antibody against the calcium-binding protein, calretinin. (d) Coronal section through the monkey entorhinal cortex stained immunohistochemically with a primary antibody against the calcium-binding protein, calbindin. Note the separate neuronal populations revealed by the two antibodies raised against different calcium-binding proteins. Scale bar = 100 μm (a), 1 mm (b), and 250 μm (c, d).

the addition of glutaraldehyde to the fixative solution in order to produce reliable results. Glutaraldehyde is also often required to produce quality material for electron microscopy examination.

In situ hybridization techniques, in contrast, target the mRNA that codes for the proteins. Chemically or radioactively labeled RNA or DNA antisense probes that are complimentary to the mRNA sequence of interest are used to localize the expression of that mRNA in the tissue. The major advantage of *in situ* hybridization is its specificity because probe sequences are generated to match one single protein-coding mRNA. Sense strand probes, which contain the same nucleic acid sequence in reverse order, are used to control for nonspecific binding of a given probe. However, *in situ* hybridization techniques detect specific mRNAs rather than the proteins that ultimately contribute to the function of the nervous system. Posttranslational modifications, such as phosphorylation, may have such a fundamental impact on protein function that *in situ* hybridization is not necessarily sufficient to obtain a comprehensive description of the phenomenon under study.

In addition to immunohistochemistry and *in situ* hybridization techniques, high-throughput molecular biology techniques, such as cDNA microarrays, serial analysis of gene expression, and real-time quantitative reverse-transcriptase polymerase chain reaction, enable researchers to study the expression of a large number of genes in defined brain regions or even in individual cell types. Nervous tissue is generally frozen or treated with an RNA preservation solution. Careful microdissection or sophisticated laser capture microdissection techniques are used to obtain tissue specimens. Following extraction, mRNA is typically amplified before the sample is analyzed. Commercially available DNA microarrays, for example, can be used to evaluate gene expression over the entire genome in humans as well as in other animals. Such techniques, however, require follow-up experiments using immunohistochemistry and *in situ* hybridization techniques to provide precise information about the regional and cellular localization of target genes.

Confocal Microscopy

In order to realize their full potential, the development of the described sophisticated molecular biology techniques capable of detecting small quantities of particular molecules has required the development of equally sophisticated imaging techniques. One such development has been that of the confocal

Figure 5 Confocal microscope images demonstrating the co-localization of cell division and neuron-specific markers in the adult human dentate gyrus. (a) Immunodetection of the neuronal marker NeuN (arrowhead). (b) Immunodetection of the cell-division marker BrdU (arrowhead). (c) Immunodetection of the glial marker GFAP (arrowhead). (d) Merged images demonstrating the co-localization of NeuN and BrdU (arrowhead). The arrows in (a–d) indicate nonspecific fluorescence. The specificity of BrdU–NeuN co-expression in three dimensions is demonstrated by a series of focal planes above (e, f) and below (g, h) the focal plane shown in (d). The appearance of adult BrdU-positive neurons in the human dentate gyrus is equivalent to BrdU-labeled neurons in the adult rat dentate gyrus. Scale bar = 25 μm (a–l). Reprinted by permission from Macmillan Publishers Ltd: *Nature Medicine* 4(11): 1313–1317, Eriksson PS, Perfilieva E, Bjork-Eriksson T et al., Neurogenesis in the adult human hippocampus, copyright (1998).

microscope. Confocal microscopes use pinholes to filter the light arriving from a defined focal plane in the specimen, thus improving the *z*-resolution of the light microscope to the submicrometer range. This increased resolution enables the localization of labeled substances within defined cellular compartments of individual cells. Confocal microscopy is now routinely used in studies employing multiple biological markers or labels. First, biological specimens are incubated with several primary antibodies, raised in different species, directed against different target molecules. Secondary antibodies, marked by different fluorophores which can be activated by different lasers to emit light at specific wavelengths, are then used to detect the primary antibodies and therefore determine the precise location of the various molecules of interest. Because of the increased resolution in the vertical axis, the use of confocal microscopy can verify whether different molecules that are co-localized in the *x* and *y* axes when observed in conventional light microscopy are also co-localized in the *z* axis.

Confocal microscopy has been particularly useful for the study of neurogenesis in the developing and adult vertebrate brain. Early studies using the autoradiographic detection of the cell division marker ^{3}H-thymidine did not possess the necessary resolution to unequivocally demonstrate the neuronal or glial nature of new cells that had incorporated the marker. The advent of immunohistochemical markers of cell division such as 5-deoxy-bromo-uridine (BrdU) and cell-specific markers such as NeuN for neurons and GFAP or S100beta for glia, combined with confocal microscopy, has enabled researchers to disprove the dogma that no new neurons were generated in the adult mammalian nervous system (Figure 5).

Quantitative Studies of the Nervous System

Modern neuroanatomical studies increasingly include the quantification of various aspects of the central nervous system. Quantitative estimates of the basic morphological characteristics of the nervous system are an essential prerequisite to generating realistic models of human brain function and pathology. It is only with the development of design-based stereological techniques that researchers have finally been able to provide reliable estimates of volume and neuron number in the nervous system. Volume estimates are typically calculated with the Cavalieri

method, which is based on a mathematical principle described in 1635. The volume of a structure can be estimated from the profile areas of the structure on cut sections, given that the first section to be measured is chosen randomly and all subsequent sections are at fixed intervals (e.g., systematic random sampling). The area of the structure on each section is estimated by overlying a grid and counting the number of points present in the structure (Figure 6(A)). The volume of the structure is obtained by multiplying the total number of points contained within the structure across all sections (P_i) by the area associated with each point ($a(i)$) and the distance between sampled sections (t):

$$\text{volume} = \sum P_i \times a(i) \times t$$

Figure 6 (A) Point grid overlay used to measure the volume of the molecular layer of the rat dentate gyrus using the Cavalieri method. The number of points (cross' intersections) are counted for each coronal section in the series. (B) Diagramatic representation of the optical fractionator sampling scheme. The area sampling fraction is the area of the counting frame (inset) relative to the area associated with each stepping frame: asf = a(frame)/a(x,y step). The thickness sampling fraction is the height of the dissector relative to section thickness: h/t. Modified from West MJ (1993) New stereological methods for counting neurons. *Neurobiology of Aging* 14(4): 275–285, with permission.

Note that the Cavalieri principle does not require any sophisticated equipment and can be applied to any kind of preparation, ranging from photomicrographs of electron microscopy material to printouts of magnetic resonance images.

Another important stereological probe is the optical fractionator used to estimate the total number of neuronal or glial cells in a defined structure (Figure 6(B)). This method also depends on the systematic random sampling of the structure of interest. That is, all the cells in the target space must have an equal probability of being sampled and therefore the integrity of the entire structure of interest is necessitated. The optical fractionator provides an estimate of the number of objects in a given space, and it has the major advantage of being free from the confounds of differential shrinkage and does not require any knowledge of the volume of the structure. The total number of neurons is counted in a known fraction of the structure of interest:

$$N = \sum Q \times (1/\text{ssf}) \times (1/\text{asf}) \times (1/(h/t))$$

where ssf is the fraction of sections being sampled, asf is the fraction of the surface area of every section being sampled, and h/t is the fraction of the thickness of the section being sampled. As with the Cavalieri method, the optical fractionator can be performed with all sorts of preparations, but in contrast it requires the assistance of a computerized microscope analysis system. Other stereological probes based on systematic random sampling have been developed to measure fiber length, cell size, and other biological parameters of interest.

Intracellular Techniques and Three-Dimensional Reconstruction of Individual Cells

Modern intracellular labeling techniques, combined with thick slice preparations, have provided a unique contribution to the study of the morphology and the intracellular electrophysiology of neurons and glia. Tissue is typically blocked to produce 400-μm-thick slices that are maintained in oxygenated artificial cerebrospinal fluid. Glass recording electrodes are filled with a tracer substance, such as biocytin, horseradish peroxidase (HRP), or Lucifer Yellow, and inserted into an individual cell. Following intracellular recordings, the tracer is infused by passing hyperpolarizing current into the cell. Once the section is fixed with paraformaldehyde, the intracellular tracer can be visualized by common histological procedures. Labeled neurons can be photographed and reconstructed at high magnification with a computer-assisted analysis system (Figure 7). The strength of this

Figure 7 (a) Photomicrographs of monkey CA1 pyramidal neurons labeled intracellularly with biocytin. (b) Three-dimensional, computer-aided reconstruction of a typical monkey CA1 pyramidal neuron. l-m, stratum lacunosum moleculare; o, stratum oriens; p, stratum pyramidale; r, stratum radiatum. Scale bar = 100 μm (a, b). Reproduced from Altemus KL, Lavenex P, Ishizuka N, and Amaral DG (2005) Morphological characteristics and electrophysiological properties of CA1 pyramidal neurons in macaque monkeys. *Neuroscience* 136(3): 741–756, with permission.

approach is that it enables researchers to establish relationships between the structure and function of individual cells. Electrophysiological data about basic intrinsic electrical properties, firing patterns, and the pharmacological characterization of neurotransmitter receptors and ion channels can be gathered for individual cell types that can be fully characterized morphologically. Although intracellular injections of tracer substance can also be performed in experimental animals *in vivo*, intracellular recordings in whole brain preparations tend to be technically more challenging and typically do not permit a detailed study of the electrophysiological properties of these cells. Thick-slice techniques can be applied to nervous system preparations from experimental animals, as well as to human pathological material removed during neurosurgeries. Potential differences in electrophysiological or morphological characteristics between animals and humans are often difficult to interpret, however, because they could reflect true species differences or the pathology of the human material (obvious ethical concerns preclude the use of brain tissue from healthy human individuals). Nevertheless, parallel studies using classical histochemical techniques, such as the Golgi technique, can be used in healthy human postmortem preparations to determine the normal morphological characteristics of the cells.

Neuroanatomical Tract-Tracing Techniques

Although knowledge of the anatomical pathways of the brain cannot in itself explain how the brain works, the mapping of the central nervous system is absolutely fundamental to such understanding. Early studies of the connectivity of the nervous system were based on the physicochemical properties of circuits and utilized the Golgi technique, as well as other silver-impregnation methods, for detecting degenerating neurons following restricted lesions (Wallerian degeneration). The Golgi silver impregnation technique enables the description of the fundamental features of local connectivity (Figure 8). Major limitations of this technique, however, are that neuron impregnation is nonspecific and that it does not enable the visualization of myelinated axons and is therefore inadequate to study the long-distance connections of the brain. The development of a silver-staining method for selective labeling of degenerating axoplasm by Nauta and Gygax in the early 1950s constituted a major advance for the mapping of the brain. Although these physicochemical techniques have largely been replaced by modern tracing methods that are dependent on the active, anterograde and retrograde, transport processes of living neurons, they are still of interest for postmortem studies of the connectivity of the human brain in patients who suffered focal injury.

A number of substances dependent on active intraneuronal transport mechanisms have been used to define the connectivity of the central nervous system. These substances are injected into the brain through glass micropipettes, either by simple injection (with a syringe or a pressure injection system) or by iontophoresis (passing a low electric current through the pipette containing electrically charged tracer molecules). Following a survival period, the experimental animal is killed, its brain cut in thin sections with a microtome, and the tracer visualized in tissue sections. Most tracers are transported preferentially in one direction, either anterogradely from the cell body along the axon to the axon terminals or retrogradely

Figure 8 Diagram illustrating the structure and connections of the hippocampus drawn by Ramón y Cajal. A, retrosplenial area; B, subiculum; C, Ammon's horn; D, dentate gyrus; E, fimbria; F, cingulum; G, angular bundle or dorsal hippocampal commissure (crossed temporoammonic path); H, corpus callosum; K, recurrent collaterals from pyramidal cells to the stratum lacunosum of Ammon's horn (Schaffer collaterals); a, axon entering the cingulum; b, cingulum fibers ending in the retrosplenial area; c, fibers of the perforant or direct temporoammonic path; d, perforant fibers of the cingulum; e, plane of dorsal perforant path fibers; g, subicular cell; h, pyramidal cells in field CA1 (regio superior) of Ammon's horn; i, ascending (Schaffer) collaterals of large pyramidal cells; r, collaterals of alvear fibers. Figure 9 (a) Low-magnification, dark field photomicrograph of terminal labeling and fibers in the deep layers of the monkey entorhinal cortex following a PHA-L anterograde tracer injection in the CA1 field of the hippocampus. (b) High-magnification photomicrograph of a PHA-L-labeled fiber located in the superficial layers of area TE (following tracer injection in the amygdala). The arrows point to varicosities along the fiber. Scale bar = 250 μm (a) and 25 μm (b). Reproduced from Freese JL and Amaral DG (2006) Synaptic organization of projections from the amygdala to visual cortical areas TE and V1 in the macaque monkey. *Journal of Comparative Neurology* 496(5): 655–667, with permission.

from the terminal arborizations to the neuronal soma. The first anterograde tracer developed that was selectively taken up by neuronal cell bodies, and not by axons traveling through the injection site, was based on the uptake and transport of radioactive amino acids, typically a mix of ^{3}H-leucine and ^{3}H-proline, which are incorporated into proteins and transported toward the axon terminals. The radioactively labeled proteins are then detected by autoradiographic techniques. Many other tracers that can be detected by immunohistochemistry have been developed, enabling a very sensitive and precise visualization of the axonal arbors and synapses of the neurons that have incorporated the tracer. Among those, PHA-L, the plant lectin *Phaseolus vulgaris-leucoagglutinin*, is perhaps one of the most effective and selective anterograde tracing substance (**Figure 9**). Biotinylated dextran amine as well as other dextran amines marked with various fluorophores are also commonly used as anterograde tracers. They are taken up by cell bodies and not by fibers of passage, and they are transported toward the axon terminals; however, some retrograde transport is observed in certain conditions. Other substances are used specifically for retrograde labeling. HRP was the first retrograde label to be developed in the 1970s, and many modifications have been made throughout the years to

improve its uptake and transport by using HRP conjugated to various substances. Fluorescently labeled dyes and cholera toxin subunit B marked by different fluorophores are now commonly used as more specific retrograde tracers, especially in double-labeling studies of the divergence of fiber tracts originating from a defined brain area.

Although autoradiography and HRP tracing methods were originally developed to trace monosynaptic connections, these compounds can also cross the synaptic cleft and thus be transferred from neuron to neuron. These tracers, however, have not proven efficient enough to reliably trace multineuronal pathways because they are diluted at each synapse they cross. Alternate methods, such as attenuated live viruses, have therefore been developed for this purpose. Neurotropic viruses are particularly effective because the tracer multiplies itself in every neuron to which it is transported and can therefore label a series of neurons connected to each other, forming a defined neuronal circuitry.

Most of our understanding of the detailed connectivity of the human brain has been derived from experimental studies conducted in other animals using the methods described previously. However, lipophilic substances, such as the carbocyanins DiI or DiO, can be used to verify this information in postmortem human preparations. Dye crystals are deposited in a defined area of the brain. They are not transported actively but diffuse a few millimeters within the lipid membrane of neurons and can therefore be used to study short-distance fiber tracts in the human brain.

The full potential of neuroanatomical tracers is still being established by researchers who combine these techniques with modern molecular biology, electrophysiology, and microscopy techniques to decipher the complexity of brain connectivity.

Electron Microscopy

The study of the finest details of the structure of the nervous system, such as synapses, requires the use of an electron microscope, whose resolution of approximately 1 nm goes well beyond that of light microscopes (200 nm). This technique requires the tissue to be extremely well fixed, typically by adding glutaraldehyde to the fixative solution. The tissue is also treated with osmium tetroxyde to make it electron dense and then embedded in plastic for cutting. Semithick sections of a few micrometers are first cut and stained for examination at the light microscope level. These preparations are then cut into thin sections of approximately 10 nm on ultramicrotomes and further stained with lead and uranyl salts for examination in the transmission electron microscope. Immunohistochemical techniques using antibodies marked with electron-dense markers can be used to study specific components or circuits of the nervous system (Figure 10).

Figure 10 Electron micrograph of PHA-L-labeled varicosities forming asymmetric axospinous synapses in (a) the superficial layers of area TE, (b) the deep layers of area TE, and (c) the superficial layers of area V1 of the monkey. Arrows point to the postsynaptic density. For comparison, the arrowhead in a points to an asymmetric synapse formed by an unlabeled presynaptic bouton. Scale bar = 0.5 μm (a–c). Reproduced from Freese JL and Amaral DG (2006) Synaptic organization of projections from the amygdala to visual cortical areas TE and V1 in the macaque monkey. *Journal of Comparative Neurology* 496(5): 655–667, with permission.

Live Imaging Techniques

On the other end of the spectrum, new neuroanatomy techniques have been developed to study the organization of the nervous system in the living organism. Magnetic resonance imaging (MRI) techniques have been developed to study the connectivity of the brain. In experimental animals, MRI-detectable paramagnetic substances such as manganese (Mn^{2+}) are injected into the brain and the distribution of the tracer can then be evaluated after different delays. Transsynaptic transport of manganese in the central nervous system can be used to delineate multisynaptic networks in the living animal. Similarly, diffusion tensor imaging has also provided an invaluable tool to studying neuronal connectivity in the living human brain. This technique relies on the detection of anisotropic water diffusion across tissue (i.e., the alignment of water molecules along fiber tracts). Sophisticated algorithms can reconstruct fiber bundles originating from a particular point within the brain. Nevertheless, despite the advances of live imaging techniques, postmortem evaluation of neuroanatomical tracers injected into experimental animals remains the most precise and reliable mechanism for studying the detailed structural organization of the connectivity of the mammalian nervous system.

Neurodegeneration in Psychiatric Illness

R J Schloesser, M Lan, and H K Manji, National Institute of Mental Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Definitions and Research Limitations

In this article, the term 'neurodegeneration' is defined as chronic and progressive loss of structure or function of neurons. Classic neurodegenerative disorders such as Alzheimer's, Huntington's, and Parkinson's diseases display gross tissue or cell loss, usually including glial reactions such as scarring. For the psychiatric disorders discussed in this article (schizophrenia, bipolar disorder, and unipolar depression), there is no evidence pointing toward similar large-scale cell loss, gliosis, or severe morphologic alterations, however. Other common histopathological hallmarks of neurodegenerative disorders, such as inclusion bodies, neurofibrillary tangles, or amyloid plaques, are also not present in these disorders. Neurodegeneration in psychiatric disorders is therefore likely to be of comparatively limited scope and severity. The fact that degenerative processes are less apparent, however, does not imply that they are of low importance. Further research determines their importance in the development of the symptoms of the disorders.

Schizophrenia, bipolar disorder, and major depression are defined clinically by distinct behavioral and psychosocial symptoms, although other abnormalities, such as endocrine, cognitive, and motor dysfunction, usually accompany these symptoms. So far, no biological markers for the disorders have been identified, and the diagnoses depend on symptomatology only. It is therefore likely that several disorders with a distinct pathophysiology are subsumed under one clinical category, leading to unfortunate problems in research data interpretation.

Evidence for Neurodegeneration in Psychiatric Illness

Numerous observations from different research perspectives support the idea of neurodegenerative processes in the pathophysiology of these major psychiatric illnesses. The disorders have a characteristic progressive course. Imaging and postmortem data show structural and functional abnormalities in brains of psychiatric patients. Preclinical experiments on animal and cell culture models display neuronal death in response to stimuli that model risk factors for psychiatric disorders. In addition, in some cases drugs with proven efficacy in the treatment of these disorders exert neuroprotective and neurotrophic properties both *in vivo* and *in vitro*.

Clinical Course

In classic neurodegenerative disorders, a deteriorating illness course with increasing severity and frequency of symptoms is common. To various degrees, the clinical course of schizophrenia, bipolar disorder, and major depression also displays a progression. The following section illustrates general clinical characteristics of psychiatric disorders and highlights evidence for illness progression over a patient's lifetime.

Schizophrenia Schizophrenic disorders present with episodes of fundamental distortions of thinking and perception as well as blunted or inappropriate affect. The symptoms consist of positive ones, comprising hallucinations and delusions, and negative ones, such as flat affect, apathy, and poverty of speech. Typically, the onset of the disorder occurs in late adolescence or young adulthood, manifesting with an episode of predominantly positive symptoms. Prodromal symptoms, such as a marked social withdrawal, often occur before and lead up to a 'psychotic break.' Two-thirds of patients experience more than one episode, and in at least one-third of cases, the disorder becomes chronic, lasting throughout the patient's life.

Emil Kraepelin first noted a progressive nature to the symptoms of schizophrenia, labeling the disorder 'dementia praecox,' implying a progressive deterioration leading to severe cognitive dysfunction. Many longitudinal studies have corroborated his early observations and show an increased duration and number of periods of active positive symptoms with time. Negative symptoms also progress, often becoming more clinically prevalent than positive symptoms. The disorder also leads to severe cognitive dysfunction, thought disorganization, and motor symptoms as it progresses. Early initiation and maintenance of antipsychotic treatment, in particular with atypical antipsychotics, helps to enhance clinical outcomes and improves cognitive ability, suggesting a protective effect of drug treatment rather than mere symptom suppression.

The buildup of symptoms to a psychotic break and the worsening of symptoms with time are consistent with a neurodegenerative course to the disorder.

Bipolar disorder and major depression Episodes of debilitating depressed mood, decreased interest and pleasure, neurovegetative symptoms including changes

in diet and sleep, and thoughts of death or suicidal ideation sustained over a prolonged period of time characterize a major depressive episode. In major depressive disorder, these depressive states are often episodic and frequently recur throughout the patients' lives, with periods of relative remission between episodes. A nonrecurring major depressive episode can also occur, however.

Patients with bipolar disorder usually experience episodes of clinical depression also, but the presence of episodes of mania define the disorder. Manic symptoms are in many ways the opposite of what is experienced during depressive episodes. Patients have racing thoughts, increased self-esteem or grandiosity, distractability, and increased goal-directed and risk-taking behavior. Patients frequently experience an alternation between depression and mania over time, with each episode lasting weeks or even months. Between episodes, a resolution of many symptoms typically occurs to some extent. Similar to schizophrenia, the onset of symptoms typically occurs in late adolescence or early adulthood, and the disorder often remains chronic and lifelong.

In the past, both major depression and bipolar disorder were thought to have a *restitio ad integrum,* or complete remission of symptoms between episodes. They were also considered to have a good chance for patient recovery. Recent evidence, however, suggests that for a large percentage of patients, the outcome is poor, with a high rate of chronicity. Also, residual depressive or manic symptoms are common between episodes, and the likelihood of developing other chronic illnesses, such as cardiovascular disease or diabetes, is higher. Over the course of the disorder, episode frequency increases, with the risk of recurrence positively correlated with the number of prior episodes. Early episodes often occur when the patient experiences severe psychosocial stress, whereas later episodes arise more autonomously. With time, patients often have a progression of residual symptoms, cognitive impairment, psychosocial disability, and diminished well-being as well, illustrating progressive clinical decline. Some evidence shows that mood stabilizers, medications for bipolar disorder, can prevent or decrease the occurrence of further episodes, suggesting a neuroprotective effect of these drugs. Taken together, these characteristics demonstrate a continuous, progressive etiology.

The clinical course for bipolar and unipolar disorders is consistent with a neurodegenerative etiology. In addition, the major affective disorders increase the risk of developing several classic neurodegenerative diseases, including Parkinson's and Alzheimer's disease. A possible explanation for this is a higher susceptibility of neurons in affective disorders, likely caused by divergent or common degenerative pathophysiology. Notably, however, schizophrenia in itself does not increase the risk for neurodegenerative disorders.

Neuroimaging

Clinical studies using magnetic resonance imaging (MRI) and computer-assisted tomography (CT) have identified structural tissue alterations in people with schizophrenia, bipolar disorder, and unipolar depression when compared with matched controls. In schizophrenia, volumetric increases in the third and lateral ventricles have been robust and consistent. These increases suggest possible periventricular tissue deficits in schizophrenia. Other regions showing changes are the medial temporal lobe area, including the hippocampus and subregions of the prefrontal cortex. Less consistent changes were reported in subcortical regions. These deficits are consistent with a neurodegenerative process. Several longitudinal studies demonstrate an increase in severity of these deficits with time, also consistent with a neurodegenerative course. Structural deficits found in first-onset patients suggest the changes may occur before the onset of symptoms. The latter finding would be consistent with the initiation of neurodegeneration prior to first onset.

Affective disorders are also associated with volumetric changes. Patients with bipolar disorder have increases in third and lateral ventricle volumes, although this finding has been less consistent than in people with schizophrenia. Findings of decreased volume and blood flow in the subgenual prefrontal cortex of patients with bipolar and unipolar depression have complemented postmortem findings showing deficits in that region. The subgenual prefrontal cortex is of functional interest because of its role in executive function and modulation of emotions, important processes disrupted in acute affective episodes. The cerebellar vermis and the hippocampus and amygdala also show decreased volumes in bipolar and unipolar depression. These structural findings are consistent with a neurodegenerative process.

By means of magnetic resonance spectroscopy (MRS), certain metabolites can be quantified in particular regions of the brain tissue *in vivo*. *N*-acetyl aspartate (NAA), a major metabolite quantifiable with this technique, serves as a marker for neuronal viability. It increases in the brain with neurogenesis and decreases with neurodegeneration or damage. Neural damage causes a decrease in the metabolite even before structural loss can be noted. In people with either schizophrenia or bipolar disorder, NAA

decreases in various brain regions, including the orbital and prefrontal cortex, compared with controls, which is consistent with a neurodegenerative process in the disorders. Shigher frequency in the brains of patients with bipolar, unipolar, or schizophrenic disorders compared with matched control participants, consistent with a neurodegenerative process. These small lesions can occur after neural damage such as demyelination, astrogliosis, or microvascular infarcts. They also increase in frequency in the normal aging process.

These clinical imaging findings could all conceivably be caused by subtle neurodegeneration. None of the findings constitute definitive proof for degeneration, however, and are consistent with other hypotheses as to the etiologies of the disorders. The subtle morphological changes, for example, occur in both neurodegenerative and nonneurodegenerative neurological disorders. Structural brain deficits also occur with chronic stress and high glucocorticoid levels in animals (see the section titled "Unipolar depression and bipolar disorder"), calling into question the role stress plays in their development. It is unknown whether the structural and MRS changes are state dependent (occurring with symptoms only) or trait specific (occurring at all times with the disorders), a question imperative to identify possible irreversible neurodegeneration. Except for ventricular enlargement in schizophrenia, most imaging findings warrant further confirmation, and there is a need for further longitudinal studies. More sensitive and accurate imaging modalities may provide better data concerning these early findings of neural pathology.

Postmortem Neuropathological Findings

Postmortem brain tissue of psychiatric patients shows several distinct morphological alterations. Such changes in cell numbers, densities, and cytomorphological characteristics appear mostly in areas of the brain important for emotion perception and control: the limbic system, anterior cingulate gyrus, and the prefrontal and orbitofrontal cortex.

Schizophrenia Early postmortem studies of schizophrenic patients suggested decreases in brain weight and smaller cortical volumes. Although some studies examining cortical volumes did not reveal significant differences, several more-recent studies, using advanced stereological analysis, report decreased gray matter volume. Neuronal abnormalities have been reported in various brain regions with schizophrenia. Some reports show fewer neurons in the thalamic nuclei, notably in the mediodorsal nucleus and pulvinar. Other reasonably well-replicated findings include smaller cell bodies of pyramidal neurons in the hippocampus and neocortex, with fewer dendritic spines and reductions of dendritic arborizations. These findings could be due to less extensive or less active axodendritic trees and correlate with reported decreases in molecular markers for neuronal plasticity such as microtubule-associated protein 2 and spinophilin. Decreased densities of neurons, especially nonpyramidal cells or interneurons in the anterior cingulate cortex and hippocampus, have also been reported. Decreased expression of genes associated with synaptic plasticity, such as synaptophysin, SNAP-25, and complexin-II, support these data. Molecular changes that indicate a general cellular pathology have also been reported in postmortem tissue. Several studies have identified changes in mitochondrial molecules related to oxidative stress and energy metabolism altered in the postmortem brain tissue of patients with schizophrenia. Abnormalities in myelination have also been reported, consistent with oligodendrocyte dysfunction. Although postmortem studies cannot completely control for differences in the agonal effects of death or the postmortem interval, these findings are consistent with a degenerative neuropathology of the disorder.

Unipolar depression and bipolar disorders Gross morphological examination of the postmortem brain from major depressive or bipolar patients does not expose dramatic changes such as gross tissue loss or the presence of focal lesions. However, specific brain regions, including the orbitofrontal cortex, dorsolateral prefrontal cortex, anterior cingulate cortex, and hippocampus, show changes in cell number and density and in cell body size. Pyramidal neurons were found to have reductions in cell body size in specific layers of the cortex in areas associated with emotion perception and control. This reduction indicates a general atrophic process likely involving the dendritic tree. It is possible that these neurons are less resilient toward degenerative stimuli and thus show more atrophy than the other cells in the tissue. Decreased pyramidal neuron densities have been reported in older patients with a lifelong history of depression, corroborating the idea of increased susceptibility in these cells that ends in neuronal death. It is interesting that the density of γ-aminobutyricacidergic interneurons, which are particularly vulnerable to apoptotic stimuli, is lower in cortical and hippocampal areas of patients with major affective disorders. Postmortem brain tissue from bipolar patients also displays myelination changes consistent with oligodendrocyte dysfunction and mitochondrial changes consistent with apoptosis and cell death. These molecular findings are also consistent with a neurodegenerative process.

Classic neurodegeneration and depression As discussed above, unipolar depression is associated with a higher risk for other recognized neurodegenerative disorders. Histopathological features characteristic of these disorders, such as gliosis, neurofibrillary tangles, plaques, or inclusion bodies, are absent in psychiatric disorders. However, there is evidence for higher levels of both plaques and tangle formation in the hippocampus of patients with Alzheimer's disease and a lifelong history of depression compared with patients with Alzheimer's disease but without a history of depression.

Preclinical Data

Preclinical studies into the mechanism of psychiatric disorders and their treatments are hampered by a lack of accurate models. These limitations are due to the still modest insights into genetic and biological underpinnings of the disorders, as well as a lack of the complexity of associated psychosocial function in other species that is characteristic of the disorders in humans. Certain aspects of etiological importance in these disorders, such as chronic stress or hyperdopaminergic states, can be modeled and studied in both animal models and cell cultures, however. In addition, *in vivo* and *in vitro* experiments can provide data on cellular and intracellular effects of drugs with known efficacy in the treatment of psychiatric disorders. Such experiments provide data showing neuroprotective effects of several psychiatric medications as well as their ability to increase neurotrophic signaling and neurotrophic function on the molecular and cellular level.

Animal Models for Psychiatric Disorders

Psychosis and mania Several psychotropic drugs elicit symptoms similar to those seen in psychiatric disorders. Psychostimulants such as amphetamine and its derivates can induce mania and schizophrenia-like symptoms in humans. These compounds are indirect agonists of monoamine neurotransmitters; they cause the increased release of the transmitters and block their reuptake from the synapse. In animals, amphetamine also induces behavior resembling mania and psychosis, such as hyperactivity, stereotypic behavior, and deficits in prepulse inhibition. It is interesting that these drugs have been found to be neurotoxic and induce degeneration of monoamine nerve terminals, especially when given chronically. In addition, they are capable of eliciting apoptosis and mitochondrial dysfunction in neurons. Thus, pharmacologic manipulations that model the symptoms of both bipolar disorder and schizophrenia also have a neurotoxic effect, consistent with a neurodegenerative component to the disorders' etiologies.

Depression In humans, the likelihood of developing a depressive disorder increases with the experience of negative life events. Stress, and the accompanying activation of the hypothalamic–pituitary–adrenal axis, is thus considered to be a factor contributing to the course and severity of the disorder. This element of the disorder can be effectively modeled in animals such as rodents and primates. In fact, acute and chronic stressors can induce depressive-like behavior such as learned helplessness and anhedonia in animal models. For example, chronically restraining rodents by limiting their movement can both induce the physiologic stress response and elicit depressive-like behaviors. What is more, antidepressant treatment prevents these behavioral changes. In these stress-induced depression models, animals have subtle brain atrophy in certain areas in a manner similar to that found in mood-disordered and schizophrenic patients. This finding implies that the patients' cell loss and atrophy, indicative of a neurodegenerative process, could potentially be involved in the pathophysiology of the disorders. High levels of glucocorticoids that accompany stress can also lead to neurodegeneration and can weaken the capacity of neurons to survive coincident neurotoxic insults. This effect has been found especially in the hippocampus. In this way, stress has been shown to cause a neurotoxicity, implying that stress may either cause or exacerbate a neurodegenerative process in the disorders.

High glucocorticoid levels can also lead to a decline in proliferation of neural progenitor cells in the dentate gyrus of the adult hippocampus, whereas antidepressants and the mood stabilizer lithium, as well as atypical antipsychotics, increase proliferation of adult hippocampal progenitor cells. Antidepressants block the decrease in adult neurogenesis induced by stress and high glucocorticoid levels. A decrease in neuroproliferation with stress and an enhancement with psychiatric medications implies that neurotrophic processes that can cause these changes may be involved in the pathophysiology of the disorder and the mechanism of its treatment. This finding is consistent with a neurodegenerative etiology of the disorder.

Neuroprotective Effects

In vivo and *in vitro* experiments show neuroprotective properties of the mood stabilizers, lithium, and valproate. In cell culture models, they show protective capacity against several damaging environments, such as glutamate toxicity and low potassium. Furthermore, mood stabilizers are neuroprotective against many damaging insults in animal models. Both medications limit the damage from ischemia in the brain, for example. These two medications have distinct molecular structures, and this common function thus might underlie their shared mood-stabilizing ability.

Several different types of antipsychotics are efficient in the treatment of psychotic symptoms of schizophrenia and mood disorders. One class of compounds, the phenothiazine derivatives, including clozapine, olanzapine, and quetiapine, has shown neuroprotective properties against several insults both *in vitro* (including oxidative stress) and *in vivo* (including A beta toxicity). Risperidone, a member of the benzisoxazole derivative family, also has neuroprotective properties. These two classes of compounds are 'atypical' antipsychotics with complicated pharmacological profiles. 'Typical' antipsychotics such as haloperidol are thought to act primarily by inhibiting dopamine receptors and do not show neuroprotective properties, however.

Neurotrophic Effects

The mood stabilizers lithium and valproate, and atypical antipsychotics and antidepressants, induce biochemical changes consistent with neurotrophic effects. Lithium and valproate both increase the mRNA and protein levels of bcl-2, for example, a protective compound that stabilizes the cell's mitochondrial membrane and protects against apoptosis. Both lithium and valproate also increase the levels of bcl-2's chaperone protein BAG-1. Lithium and valproate have also been shown to stimulate the extracellular signal-regulated kinase (ERK) and mitogen-activated protein kinase (MAPK) pathways, cell survival, and growth signaling, consistent with a neurotrophic effect. Similarly, atypical antipsychotics induce the ERK and MAPK pathways as well as the phosphoinositide-3 kinase (PI3K)/protein kinase B (Akt) pathway, also consistent with a neurotrophic effect. A number of antidepressant therapies, including the selective serotonin reuptake inhibitors, the norepinephrine selective reuptake inhibitors, the monoamine oxidase inhibitors, atypical antidepressants, and electroconvulsive seizures, also increase neurotrophic cascades, indicated by increased levels of brain-derived neurotrophic factor (BDNF) in the animal brain after chronic treatment. BDNF in turn increases intracellular neurotrophic cascades and thereby modulates cell survival and neuronal outgrowth in the brain.

The protective capability and the neurotrophic effects of these compounds indicate that processes associated with cellular survival are stimulated with the medications. This effect is consistent with a neurodegenerative etiology to the disorders that is reversed or corrected with the drugs. The 'typical' antipsychotics are the exception to this paradigm, although they could potentially exert their effects through an independent mechanism.

Summary

Evidence from the clinical course of the disorders, molecular and cellular postmortem studies, *in vivo* imaging of patients, and preclinical studies modeling the disorders and their treatments suggests that a neurodegenerative component exists in the pathophysiology of the psychiatric disorders. These data are neither exhaustive nor definitive, but this perspective may be useful in understanding the etiology of these disorders and in the quest for novel treatments.

Neuroeconomics: History

Overview

Within the neurobiological community this rapprochement had its origins in the early 1990s. At that time, significant progress was being made toward understanding the neurobiological basis of simple sensory–motor decision making in nonhuman primates. The catalyst for that progress was Newsome and colleagues' work on the relationship between activity in the middle temporal area of visual cortex (area MT) and perceptual decisions. The goal of this work was to relate the activity of single neurons in area MT to the perceptual decisions of monkeys. They accomplished this using a formal mathematical model that defined an optimal perceptual decision-making process, a normative psychophysical theory, which was rooted in the theory of signal detection that had dominated behavioral studies of perception for several decades. As other research groups began to extend this work, studying more complicated and less perceptual forms of decision making, it became clear that the normative models of psychophysics that define optimal performance in perception could not be extended to situations in which choices relied on complex functions of nonsensory variables: a point made decades earlier, but often overlooked, by the mathematical psychologists Duncan Luce and Patrick Suppes.

At the same time, cognitive psychologists employing functional magnetic resonance imaging (fMRI) also became interested in understanding the neural basis of decision making. In the late 1980s and early 1990s, a number of early studies were conducted that also demonstrated the need for a unified theory of choice in the neurobiological setting.

This gap between theory and experiment led a number of physiologists and psychologists to begin to explore alternative models for understanding what constitutes efficient decision making. What quickly became clear was that the academic discipline of economics, although far behind neuroscience experimentally, possessed an extremely well-developed corpus of elegant normative models that could serve the same role for neuroscientific studies of decision making that signal detection theory had served for neuroscientific studies of perception.

At the same time that this gradual realignment was taking place in theoretical neuroscientific circles, economics was also experiencing the beginnings of an important sea change. Until the early 1970s, economics had developed as a theoretical and analytic discipline that lacked an experimental tradition. The goal of economics, since the neoclassical revolution of the first half of the twentieth century, had been to relate external-world variables to the choices made by individuals, or groups of individuals, using purely theoretical approaches. Within neoclassical economics, only preexisting data about choices in real-world situations served as acceptable dependent variables for tests of theories, and unsurprisingly many dominant theories were only weakly tested by these existing data sets. In the 1960s, a number of empirical demonstrations raised serious challenges to this approach, suggesting that the existing corpus of normative theory was not as predictive of choice as had been hoped. Partly in response to these challenges and in response to others, in the 1970s a number of economic scholars began to develop a homegrown experimental methodology to empirically explore how theories could explain behavior in laboratory, or artificial, markets and games, and how the trading behavior of human subjects was influenced by changes in the rules governing the operations of those markets.

Together, these two groups of scholars laid the foundations for what was essentially a new economic approach, one in which hypotheses could be posed and addressed experimentally. Like those that had come before them, however, they also believed strongly that the goal of economics was to predict and explain choice. As a result, they argued that while studies of hidden psychological or neurobiological processes might be of interest to scholars studying the algorithms by which choice was accomplished, these biological studies would add little in the way of predictive power to models of choice itself, the object of economic study.

The rise of fMRI in the 1990s, however, changed that assumption for some economists. During that period, brain scanners became relatively cheap to use and widely distributed in the academic community. The popular press also showed a tremendous interest in brain scanning, and a constant flood of articles describing 'how the brain worked' appeared in the general press. The result was an interest, particularly among younger economists, in the possibility that measurements of neural state could be used to test or refine economic models.

The two communities, neuroscience and economics, thus came toward a union from two very different directions. Neurobiologists largely turned toward economics as a source of normative theory while economists turned toward neurobiology for new measurements that could be used to test or constrain existing theory. Both of these approaches were, and remain, controversial in many circles. Neurobiologists opposed to the use of economic theory argued that the complex normative models of economics would be of little value for understanding the behavior of real humans and real animals. In a similar vein, many economists argued that algorithmic-level studies of decision making were unlikely to improve the predictive power of normative models in any meaningful way.

Critical First Steps

Despite the vocal criticism of mainstream elements in both communities, these social and technological trends led to a convergence of interest among a group of economists, neuroscientists, and cognitive psychologists in the late 1990s. This community of scholars, who began to call themselves neuroeconomists around 2002 or 2003, aggregated around a small set of meetings and papers during this period. Although the first explicitly neuroeconomic papers preceded the first interdisciplinary workshops by several years, these meetings were probably the critical step that allowed these social and natural scientists to develop a common language.

Probably the first of these interdisciplinary interactions was held in 1997 at Carnegie-Mellon University, organized by the economists Colin Camerer and George Loewenstein. After a hiatus of several years this was followed by two meetings in 2001, one held by the Gruter Foundation for Law at their annual meeting in Squaw Valley. At that meeting the Gruter Foundation chose to focus its workshop on the intersection of neuroscience and economics and invited several speakers active at the interface of these converging disciplines. The second meeting was focused more directly on what would later become neuroeconomics and was held at Princeton University. The meeting was organized by the neuroscientist Jonathan Cohen and the economist Christina Paxson. This meeting is often seen as the inception point for the present-day Society for Neuroeconomics. At that meeting, economists and neuroscientists met to explicitly discuss the growing convergence of these fields and to debate the value of such a convergence. There was, however, no consensus among the scholars present at that meeting that such a convergence would be desirable. In fact, when asked specifically at the end of the meeting what he thought of such a convergence, the internationally acclaimed economist Ariel Rubenstien (then at Princeton) concluded, essentially, that there was nothing in neuroscience that would change how he thought about economics.

Nonetheless, the Princeton meeting generated significant momentum and 2 years later (2003) a small invitation-only meeting that included nearly all of the active researchers in the emerging area was held on Martha's Vineyard and organized by Greg Berns of Emory University. This 3-day meeting marked a clear turning point in which a group of economists, psychologists, and neurobiologists began to identify themselves as neuroeconomists and began to explicitly shape the convergence between the fields. This led, the subsequent year, to an open registration meeting at Kiawah Island, South Carolina that was attended by 83 people in which the Nobel Laureate in economics Vernon Smith delivered the keynote address. At that meeting a decision was made to incorporate the existing group as an academic society that would sponsor an annual meeting that would serve as a focal point for neuroeconomics internationally. At that meeting Paul Glimcher was elected President of the Society for Neuroeconomics which held its first formal meeting the following year (2005) at Kiawah Island with a group of 114 people.

At the same time a group of European scholars undertook the establishment of a similar meeting in 2002. The first meeting of the European conference on neuroeconomics (ConNEcs) was held at the Westfalian Wilhelms University of Muenster in northern Germany. This was followed by a second meeting in 2004, establishing neuroeconomics as an international discipline.

Landmark Papers

Against this backdrop of meetings, a series of critical papers and books were emerging that shaped the interactions between these scholars and also served to communicate the goals of the emerging neuroeconomic community to the larger neurobiological and economic communities. Probably the first neurobiological paper to explicitly rest on a normative economic theory was Peter Shizgal and Kent Conover's 1996 review in *Current Directions in Psychological Science* entitled: 'On the neural computation of utility.' This was followed the next year by a related paper published in *Current Opinion in Neurobiology* entitled 'Neural basis of utility estimation' authored by Shizgal. The reason that these papers can be viewed as the first neuroeconomic papers is that they attempt to describe the neurobiological substrate for a behavioral choice using a normative theory rooted in neoclassical

economics. In these papers, Shizgal analyzed the results of studies of intracranial self-stimulation in rats using a type of utility theory related loosely to the standard expected utility theories of Savage and VonNeuman and Morgenstern. The papers argue that the choices an animal makes about whether or not to work for direct electrical activation of the medial forebrain bundle can be construed as an effort to maximize the animal's instant-to-instant utility. In their analysis, changes in the desirability of brain stimulation reward, for example, as a function of stimulation frequency, can be formally interpreted as changes in the utility of the electrical stimulation. Unlike standard theories of utility, however, Shizgal proposed that the expected utility of an action is perceived by the animal as the expected utility of that action divided by the sum of the expected utilities of all available actions. This particular formulation had its origin in the work of the psychologist Richard Herrnstein who proposed that many choices reflect this 'normalization' with regard to the value of other alternatives, a phenomenon he referred to as the matching law (1997).

This equation was introduced to self-stimulation studies about 5 years earlier by Shizgal's mentor C Randy Gallistel. In the early 1990s, Gallistel used Herrnstein's work to inspire quantitative choice-based experiments intended to cardinally scale the desirability of any given set of self-stimulation parameters. Shizgal's extension of this work is critical for the history of neuroeconomics because he retained Gallistel's goal of quantitatively measuring, or more precisely cardinally scaling, the desirability of a neurobiological manipulation while focusing on the idea that such a scale implies an underlying utility theory. What Shizgal's work did not do, however, was to fully incorporate the standard economic model, but rather a more normative version of Herrnstein's approach.

In 1999, this work was followed by a paper published by Michael Platt and Paul Glimcher (another student of Gallistel's) in *Nature* that argued quite explicitly for a normative utility-based analysis of choice behavior in monkeys. As they put it in that paper: "Neurobiologists have begun to focus increasingly on the study of sensory–motor processing, but many of the models used to describe these processes remain rooted in the classic reflex. ... Here we describe a formal economic–mathematical approach for the physiological study of the sensory–motor process, or decision-making." The paper goes on to argue for an approach to the study of decision making rooted in standard expected utility theory. At an experimental level, the paper demonstrates that the activity of single neurons in the posterior parietal cortex is a lawful function of both the probability and magnitude of expected rewards. This was significant because standard expected utility theory predicates choice on lawful functions of these same two variables. The paper, however, makes a misstep in its final examination of choice behavior. The authors examine a matching-law type behavior, which they interpret in terms of normative expected utility theory. This is problematic because there is no normative standard for the analysis of the classical matching-law. The result is a mixing of normative and nonnormative approaches that characterized many of the early neuroeconomic papers from neurobiologists.

At the same time that this paper appeared in print, the economists Colin Camerer, George Lowenstein, and Drazen Prelec began circulating in economic circles a manuscript by the name of 'Grey matters.' In this manuscript the authors also argued for a neuroeconomic approach, but this time from an economic perspective. Over the course of the preceding decade behavioral economists, a group of scholars interested in deviations of actual choice behavior from normative theory, had argued that the choices of humans often did not reflect optimal calculations that perfectly maximized utility. Instead, these behavioral economists had noted that, particularly under conditions in which choosers experience strong emotions, decisions typically deviate systematically from the predictions of standard normative models. What these three scholars argued was that these systematic deviations may reflect neurobiological constraints on decision making and that future neurobiological studies might serve to reveal and define these constraints that cause deviations of behavior from normative theory. What was striking about this argument, in economic circles, was that it proposed an algorithmic analysis of the physical mechanism of choice, a possibility that has been explicitly taboo in economic circles. Prior to the 1990s it was a completely ubiquitous view in economic circles that models of behavior, like utility theory, were 'as if' models: the model was to be interpreted as if utility was represented internally by the chooser. But critically it was irrelevant whether this was actually the case because the models sought to link options to choices not to make assertions about the mechanisms by which that process was accomplished. Camerer and colleagues argued against this view suggesting that deviations from normative theory should be embraced as clues to the underlying neurobiological basis of choice. In a real sense then, the economists turned to neurobiology for exactly the opposite reason that the neurobiologists had turned to economics. They embraced neuroscience as a principled complement to the axiomatic reasoning that characterized the core features of standard economic practice.

In sum then, some members of the neurobiological community had turned toward economics in an effort to embrace a normative theory that they were just beginning to understand, but a normative theory that had only limited predictive power. Members of the economic community had turned toward neuroscience in an effort to find an alternative to normative theory that could account for the choices of real individuals. Of course, these conflicting goals were well aligned; both groups were becoming poised to meet in the intersection of their disciplines.

At this point there was a rush by several research groups to perform an explicitly economic experiment that would mate these two disciplines in human choosers. Two groups succeeded in this quest in 2001. The first of these papers appeared in the journal *Neuron* and reflected a collaboration between the fMRI pioneer Hans Breiter, Shizgal, and the Princeton psychologist/economist Daniel Kahneman (who would win the Nobel prize for his contribution to behavioral economics the following year). That paper was loosely based on prospect theory, a nonnormative form of expected utility theory that guided much research in judgment and decision-making laboratories throughout the world. In that paper Breiter and colleagues manipulated the perceived desirability of a particular lottery outcome (in this case, winning zero dollars in a 'wheel of fortune' game) by changing the values of the two other possible lottery outcomes it was competed with. When winning zero dollars is the worst of three possible outcomes, Kahneman and Tversky's prospect theory predicts, as do several related theories, that subjects should view it negatively, but when it is the best of the three outcomes then subjects should view it more positively. The scanning experiment revealed that brain activation in the ventral striatum matched these predicted subjective valuations.

The other paper published that year reflected a collaboration between the economist Kevin McCabe, his colleague Vernon Smith (who would share the Nobel prize with Kahneman the following year for his contributions to experimental economics), and a team that included economists, a psychologist, and a biomedical engineer. Their paper, which appeared in the pages of the *Proceedings of the National Academy of Sciences* in the United States, examined behavior and neural activation while subjects engaged in a strategic game. This also represented the first use of game theory, an economic tool for the study of social decision making, in a neurobiological experiment. In that paper, subjects played a trust game either against an anonymous human opponent or against a computer. In their game, two players interact regarding an investment. The game begins when the first player is given 45 monetary units and given a choice between keeping that money or investing it with an unseen partner, the trustee. Any money given to the trustee is then multiplied by nine, and the partner must decide whether or not to share 180 units of this windfall to the original investor. What is interesting about the game is that standard normative theory (which assumes a self-interested chooser) assumes that the trustee wishes to maximize her gain. This predicts that in a consequence-free laboratory environment the trustee should refuse to share the windfall. Her partner, the investor, is presumed to know this about her opponent and thus is expected, in the first round, to keep all of the money for herself. What is striking about the game, however, is that humans do not behave in accord with these normative predictions when playing against another, even anonymous, human. Some players, however, do approximate this approach when facing a computer opponent. What McCabe and colleagues therefore did was to scan subjects while they played against both humans and computers and to take the difference between activation in the two states. These neurobiological data revealed that in some subjects the medial prefrontal cortex is differentially active under these two conditions, becoming more active when subjects play this cooperative strategy that deviates from the normative prediction. From these data the authors hypothesized that this nonnormative pattern of cooperation has its origin in circuits of the prefrontal cortex.

The following year, many of these emerging trends were reviewed in an important special Society for Neuroscience conference issue of the journal *Neuron*, edited by Jonathan Cohen and Kenneth Blum, entitled 'Reward and decision.' As these editors wrote in the introduction to that issue: "Within neuroscience, for example, we are awash with data that in many cases lack a coherent theoretical understanding (a quick trip to the poster floor of the Society for Neurosciences meeting can be convincing on this point). Conversely, in economics, it has become abundantly evident that the pristine assumptions of the 'standard economic model' – that individuals operate as optimal decision-makers in maximizing utility – are in direct violation of even the most basic facts about human behavior." In that issue, although all of the articles are written by neurobiologists, particular attention is drawn to normative theories of decision. Of particular interest are articles by Montague and Berns, Schultz, Dayan and Balleine, Gold and Shadlen, and Glimcher, which all point toward the interaction of normative models and neurobiology. In particular, the issue draws attention to the ongoing debate about the role of the neurotransmitter dopamine in reward processing and draws upon previous work that had identified normative or near-normative models of

learning that posit a role for dopamine. What followed was a literal flood of decision-making studies in the neuroscientific literature, many of which relied on normative economic theory.

At the end of this initial period a set of summary reviews began to emerge that served as manifestos for the emerging neuroeconomic discipline. In 2003, Glimcher published a book, directed primarily at neuroscientists, that reviewed the history of neuroscience and argued that this history was striking in its lack of normative models for higher cognitive function. Glimcher proposed explicitly in that book that economics could serve as the source for this much needed normative theory for cognitive neuroscience. Shortly thereafter, the Camerer, Loewenstein, and Prelec paper was published (2005), which also served as a manifesto for neuroeconomics, but this time from the economic side. More recently, an invited review detailing many of these advances appeared in the journal *Science*, marking the advancing visibility of neuroeconomics in the scientific community at large.

The next major step in neuroeconomics was probably the incorporation of game theoretic normative models into a broader neurobiological spectrum. In 2004, two key papers appeared that employed normative game theory for the study of single neurons in awake-behaving primates. A paper by Daeyeol Lee and colleagues studied animals trained to play a very simple classic game called matching pennies. In that game the monkeys had to choose between one of two responses, A and B. The monkeys' computer opponent made a similar choice. If they both chose the same response, the monkey earned a drop of juice, and if they made opposite choices, the monkey earned nothing. Lee varied across long blocks of trials the game theoretic sophistication of the monkey's computer opponent while recording from single neurons in the frontal cortex. What he and his colleagues found was that the behavior of the monkeys was responsive to the sophistication of the opponent and that neurons of the frontal cortex encoded properties related to both the monkeys' strategies and the recent history of the game.

In a similar vein, Dorris and Glimcher trained monkeys to play a slightly more complex game called work or shirk. Game theory, in this case Nash equilibrium theory (REF), predicts both a particular outcome for any set of payoffs in that game and that at behavioral equilibrium the monkeys should mix their responses, sometimes working and sometimes shirking. Regardless of the ratio of shirking to working, the normative theory (somewhat counterintuitively) predicts that the subjective value of working and shirking should be nearly identical at this equilibrium. They found that the behavior of the monkeys was fairly well predicted by the normative theory, and neurons in the posterior parietal cortex seemed to fire at a rate that was also predicted for elements encoding expected utility. Together, these two papers probably represented the first use of normative game theory for single-unit studies.

Within the economic community a role similar to that of the *Neuron* special issue was played by a special issue on Neuroeconomics presented by the journal *Games and Economic Behavior* and edited by the economist Aldo Rustichini, which appeared shortly after this in 2005. Within the economic community this issue was hugely influential and served to define neuroeconomics to a large degree. That issue included articles by several economists and neuroscientists, including scholars ranging from Gallistel to Smith.

Another major advance was presented in 2005 by Michael Kosfeld and his colleagues in Ernst Fehr's research group at the University of Zurich. This paper was important because it was the first demonstration of a neuropharmacological manipulation that alters behavior in a manner that can be interpreted with regard to normative theory. Subjects were asked to play a trust game much like the one examined by McCabe and colleagues. Fehr's critical manipulation was to increase brain levels of the neurotransmitter oxytocin (by an intranasal application of the compound) before some of the players made their decision. What Kosfeld and colleagues found was that trustees in the game (those players who had received money from the investors) returned more to the investors (in contravention of normative theory) if they had received oxytocin than if they had been treated with a control substance. What was most interesting about this study from a neuroeconomic point of view was the demonstration that administration of this endogenously produced hormone altered the choice behavior of subjects in a way that went against an existing and well-described normative economic theory.

Summary

The future of neuroeconomics, however, remains unclear. There is still significant opposition to neurobiological approaches within much of mainstream economics, and, in fairness, neuroeconomics has yet to revolutionize either economic theory or the culture of neuroscience. The next decade should prove a critical period for this discipline. During this second decade neuroeconomics, if it is to succeed, will have to make major contributions to both of its parent disciplines.

In 1998 the evolutionary biologist EO Wilson wrote that "The full understanding of utility will come from biology and psychology by reduction to the elements of human behavior followed by a

bottom-up synthesis, not from the social sciences by top-down inference and guesswork based on intuitive knowledge. It is in biology and psychology that economists and social scientists will find the premises needed to fashion more predictive models, just as it was in physics and chemistry that researchers found the premises that upgraded biology." It remains to be seen whether neuroeconomic studies will provide major insights in either neuroscience, economics, or both over the next few years. Only time will determine whether this emerging discipline actually can revolutionize its parent disciplines.

Neuroendocrine Aging: Hypothalamic–Pituitary–Gonadal Axis in Women

N E Rance, University of Arizona College of Medicine, Tucson, AZ, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The loss of female reproductive function in midlife constitutes the most dramatic and consistent change during aging in humans. Because menopause occurs early, at a mean age of 51 years, the average woman will spend approximately one-third of her life span in the postmenopausal phase. The hallmark of menopause is ovarian failure, which leads to a reduction in circulating blood levels of estrogen and progesterone to castrate levels. In turn, the loss of ovarian hormones leads to hypersecretion of pituitary gonadotropins and the clinical symptoms experienced by postmenopausal women, including hot flushes, vaginal dryness, and mood changes. Postmenopausal women also have an increased risk for osteoporosis and cardiovascular disease, which may reflect the effects of estrogen withdrawal on age-related diseases. Thus, the repercussions of menopause can impact a women's health for a significant portion of her life span.

Overview of the Hypothalamic–Pituitary–Ovarian Axis in Young Women

Reproduction is controlled via reciprocal interactions among the hypothalamus, anterior pituitary gland, and ovaries. Neurons in the medial basal hypothalamus that synthesize gonadotropin-releasing hormone (GnRH) project to fenestrated capillaries in the median eminence. In the median eminence, GnRH is secreted from axon terminals into hypophyseal portal vessels, a capillary system that carries blood to the pituitary gland. At the level of the anterior pituitary gland, GnRH stimulates the production and release of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), into the systemic circulation. LH and FSH target the ovaries via the systemic circulation to regulate folliculogenesis, ovulation, and the secretion of steroid and glycoprotein hormones. In turn, the ovarian steroids, estrogen and progesterone, exert complicated feedback actions on both the hypothalamus and the pituitary. The ovary also secretes glycoprotein hormones (such as inhibin and activin) that modulate FSH secretion at the level of the anterior pituitary gland. The timing of the menstrual cycle is dependent upon the pattern of ovarian hormone secretion. In addition, multiple neural inputs to hypothalamic GnRH neurons convey information on the status of physiologic systems to optimize the timing for reproduction.

GnRH is secreted in a pulsatile manner, leading to short-duration peaks of LH in peripheral plasma. Studies in the rhesus monkeys have delineated the medial basal hypothalamus as the control center for pulsatile LH secretion. The medial basal hypothalamus is the site of multiunit electrical activity (the GnRH pulse generator) that is synchronized with pulses of LH in the peripheral circulation. Neurons with high levels of GnRH gene expression are scattered within the primate medial basal hypothalamus, further evidence of its importance in the control of the reproductive axis. The frequency and amplitude of GnRH pulses vary over the menstrual cycle, and the pattern of GnRH pulsatility plays an important role in pituitary responsiveness. For example, continuous (rather than pulsatile) administration of GnRH (or one of its analogs) actually suppresses LH secretion. Moreover, the pattern of LH and FSH pulses in the systemic circulation influences ovarian follicle development.

Ovarian Aging and the Menopausal Transition

Ovarian aging is a critical determinant of menopause. At the time of birth, there are approximately 1 million primordial follicles. The absolute number of ovarian follicles declines exponentially until approximately 37 years of age, at which time follicular loss accelerates (Figure 1). At the time of the perimenopausal period, the follicle population has been reduced to less than 1000, and after menopause the ovary is virtually depleted of follicles. Fertility begins to decline in the third and fourth decades of life and this process accelerates after 35 years of age.

A staging system for the phases of reproductive life in women is shown in Figure 2. The staging system uses the final menstrual period as a reference point. In the reproductive phase, menstrual cycles are regular, except for a variable time immediately following puberty. The reproductive phase is followed by the menopausal transition, heralded by the onset of cycles of variable lengths. It is important to note, however, that alterations in hormone secretion occur quite early, even before the onset of irregular cycles.

The first endocrine marker of reproductive aging consists of an elevation of serum FSH early in the follicular phase. The rise in serum FSH has been termed monotropic because it is unaccompanied by

an elevation in serum LH. The monotropic increase in FSH secretion in the late reproductive stage is inversely correlated with declining serum levels of inhibin B (Figure 3). Inhibin B is secreted by granulosa cells in developing antral follicles. Lower levels of inhibin B may reflect a diminished number of primordial follicles recruited into the developing pool or decreased numbers of granulosa cells for each follicle. Loss of the restraining effect of inhibin B on the anterior pituitary gland results in the reciprocal increase in serum FSH. Early development of the dominant follicle, secondary to increased FSH, may lead to shortening of the follicular phase and marked increases in estrogen secretion.

Figure 1 Biexponential model of declining follicle numbers in pairs of human ovaries, from neonatal age to 51 years old. Each symbol represents one person. The different symbols represent data obtained from several studies. Reprinted from Faddy MJ, Gosden RG, Gougeon A, et al. (1992) Accelerated disappearance of ovarian follicles in mid-life: Implications for forecasting menopause. *Human Reproduction* 7: 1342–1346, with permission.

The menopause transition is a prolonged period of time characterized by irregular cycle lengths and periods of amenorrhea (Figure 2). During the early menopausal transition, there may be elevated levels of FSH throughout the cycle and lower levels of inhibin A, inhibin B, and progesterone. Serum estrogen levels of the early menopausal transition are either preserved or increased. In the late menopausal transition, frequent anovulatory cycles occur, with substantial variability in hormone levels. The multiinstitutional Study of Women's Health across the Nation (SWAN) has classified the anovulatory cycles into three types based on daily urine hormone levels: (1) cycles in which estrogen fails to induce an LH surge, (2) cycles with an LH surge but disrupted or dysfunctional corpus luteum formation, and (3) cycles with tonically elevated LH and FSH but with no evidence of a rise in estrogen. The variable cycles in the late menopausal transition lead to markedly fluctuating levels of ovarian hormones. The fluctuating levels of estrogen in particular may account for many of the symptoms experienced at this stage, including breast tenderness, menorrhagia, hot flushes, sleep disturbances, and mood changes.

The monotropic rise in FSH secretion has been postulated to produce the accelerated phase of follicular

Final menstrual period (FMP) 0

Stages:	−5	−4	ϖ3	−2	−1	+1	+2
Terminology:	Reproductive			Menopausal transition		Postmenopause	
	Early	Peak	Late	Early	Late*	Early*	Late
				Perimenopause			
Duration of stage:	Variable			Variable		(a) 1 yr	(b) 4 yrs / Until demise
Menstrual cycles:	Variable to regular	Regular		Variable cycle length (>7 days different from normal)	≥2 skipped cycles and an interval of amenorrhea (≥60 days)	Amen × 12 mos	None
Endocrine:	Normal FSH		↑ FSH	↑ FSH		↑ FSH	

*Stages most likely to be characterized by vasomotor symptoms ↑ = Elevated

Figure 2 The Stages of Reproductive Aging Workshop staging system, showing endocrine levels of follicle-stimulating hormone (FSH) at different stages. Reprinted from Soules MR, Sherman S, Parrott E, et al. (2001) Executive summary: Stages of Reproductive Aging Workshop (STRAW). *Fertility and Sterility* 76: 874–878, with permission.

Figure 3 As ovarian reserve declines throughout reproductive life, inhibin B (INH-B), a product of small, growing follicles, decreases. Concomitant with this relative loss of INH-B, follicular-phase follicle-stimulating hormone (FSH) increases in a reciprocal fashion. Reprinted from Santoro N (2005) The menopausal transition. *American Journal of Medicine* 118(supplement 12B): 8–13, with permission.

decline that occurs after the age of 37 years. Higher levels of FSH (secondary to decreased inhibin B) could recruit increased numbers of follicles into the growing pool. Once this happens, follicles must either ovulate or become atretic. An abnormal FSH signal could also be detrimental to ovarian function independent from its effects on follicular recruitment. The steady loss of ovarian follicles in late reproductive life could reach a critical threshold and initiate a cascade of events leading ultimately to complete ovarian failure.

A hypothalamic contribution to the acceleration of follicular loss has also been proposed. For example, in experimental animals, altered patterns of LH pulsatility (secondary to GnRH pulses) are detrimental to ovarian function. Moreover, reducing the frequency of GnRH pulses can produce isolated FSH secretion in experimental animals, providing a potential mechanism whereby an altered hypothalamic signal could contribute to the monotropic rise in FSH and the subsequent acceleration of follicular decline. The slowing of LH pulses in older, regularly cycling women, however, has only been demonstrated in one study, and this finding has not yet been replicated. Therefore, the proposal that hypothalamic factors trigger the ovarian failure of menopause is controversial.

Effects of Ovarian Failure on the Hypothalamic–Pituitary Axis

The hormonal milieu of the postmenopausal phase of life is characterized by profound ovarian hormone deficiency. There is a marked increase in serum gonadotropins in postmenopausal women, similar to the hormone profile seen in young, oophorectomized women. The postmenopausal increase in serum gonadotropins is secondary to both loss of steroid negative feedback and removal of the restraining action of inhibin on FSH secretion from the pituitary gland. In addition, the loss of ovarian hormones shifts the composition of the gonodotropins to more acidic isoforms. The shift of gonadotropin isoforms contributes to elevated levels of LH and FSH in the peripheral circulation by retarding their clearance. Administration of gonadal steroids still suppresses the high levels of serum gonadotropins in elderly women, indicating that the postmenopausal hypothalamus remains sensitive to negative feedback effects. Overall, many aspects of hypothalamic and pituitary function remain intact in postmenopausal women, in contrast to the complete failure of the ovaries.

Based on the central role of GnRH in the reproductive axis, research has focused on the status of GnRH neurons in postmenopausal women. Because direct measurements of GnRH secretion require invasive procedures, information on the function of these neurons has been obtained through indirect methods. For example, assessment of GnRH pulses can be inferred by examination of pulses of the free α subunit (FAS) of the pituitary glycoprotein hormones in peripheral plasma. This method was developed because measurements of LH pulses are complicated by the prolonged half-life of LH and the rapid frequency of pulses in postmenopausal women. The quantity of GnRH secretion can also be estimated by pharmacological methods such as competitive receptor blockage. Another approach to studying GnRH neurons is to quantify relative levels of gene expression in postmortem tissues using *in situ* hybridization histochemistry. This method is well suited for the investigation of human autopsy material due to the relative stability of mRNA species with prolonged postmortem intervals. A further level of anatomical resolution is provided by the localization of mRNA species at the cellular level within tissue sections.

The function of GnRH neurons in postmenopausal women appears to be dominated by the removal of steroid negative feedback. Studies have shown that negative feedback effects of estrogen and progesterone on LH secretion are maintained in postmenopausal women. The hypothalamic content of the GnRH peptide decreases in postmenopausal women, similar to response in young women who have had their ovaries removed. Therefore, it has been hypothesized that the decreased GnRH content in postmenopausal women is secondary to increased

Figure 4 Studies in younger (age 45–55 years) and older (age 70–80 years) postmenopausal women (PMW) indicate that follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels increase after menopause, but decrease with aging. Gonadotropin-releasing hormone (GnRH) pulse frequency, assessed by pulsatile secretion of the free α subunit, is also increased in relation to the early follicular phase, but is not different from the frequency in the late follicular phase of midcycle surge in healthy women. After menopause, pulse frequency decreases with aging. The quantity of GnRH (100% inhibition of LH in response to submaximal GnRH receptor blockade) increases with aging. The number of individuals contributing to each bar is indicated in parentheses. Reprinted from Hall JE (2004) Neuroendocrine physiology of the early and late menopause. *Endocrinology and Metabolism Clinics of North America* 33: 637–659, with permission.

secretion into the portal vessels. As would be expected with the removal of steroid negative feedback, GnRH pulse frequency (assessed by peripheral FAS pulses) is increased in young postmenopausal women compared with premenopausal women in the early follicular phase (Figure 4). Moreover, the quantity of GnRH secreted (estimated by competitive receptor blockage) is increased in young postmenopausal women and continues to increase with age. These findings agree with the demonstration of increased GnRH gene expression in the medial basal hypothalamus of postmenopausal women. Taken together, these studies provide evidence that GnRH neurons in postmenopausal women, instead of age-related signs of degeneration, exhibit compensatory responses due to removal of ovarian hormones.

Effects of Menopause on Neuronal Morphology and Neuropeptide Gene Expression in the Human Hypothalamus

More than four decades ago, Sheehan and Kovacs described differences in hypothalamic neuronal morphology in premenopausal and postmenopausal women. In postmenopausal women, pronounced enlargement of neurons was observed in the infundibular nucleus of the medial basal hypothalamus. The cellular hypertrophy was characterized by increased Nissl substance (indicative of increased protein synthesis) and enlarged nuclei and nucleoli (Figure 5). Based on similar findings in other hypogonadal conditions, the authors proposed that neuronal hypertrophy in the infundibular nucleus was secondary to loss of ovarian function.

Subsequent studies using *in situ* hybridization have characterized the phenotype of the hypertrophied neurons and have shown numerous alterations in hypothalamic neuropeptide gene expression in comparing tissues of premenopausal and postmenopausal women. The most dramatic change in gene expression occurs in the subpopulation of infundibular neurons that undergoes neuronal hypertrophy. These neurons co-express estrogen receptor-α and two tachykinin neuropeptides, neurokinin B (NKB) and substance P (SP). In addition to the marked increase in cell size, the number of neurons expressing NKB and SP gene transcripts in the infundibular nucleus increases by more than sixfold, indicating a marked increase in tachykinin gene expression. GnRH gene expression is also elevated in postmenopausal women, but in a separate subpopulation of neurons within the medial basal hypothalamus. The elevation in GnRH mRNA provides evidence of increased hypothalamic GnRH secretion contributing to the rise in plasma gonadotropins in postmenopausal women.

In contrast to elevated NKB and GnRH gene expression, the number of neurons expressing proopiomelanocortin (POMC) gene transcripts in the infundibular nucleus is significantly reduced in older women. Moreover, the number of neurons expressing POMC mRNA is inversely correlated with age and the expression of neuropeptide Y mRNA. Numerous studies in experimental animals have revealed that POMC and neuropeptide Y neurons in the arcuate nucleus (the rodent homolog of the infundibular nucleus) are essential components of hypothalamic

Figure 5 Representative photomicrographs of cresyl violet-stained sections of the infundibular nucleus of young, premenopausal (a) woman and an older, postmenopausal (b) woman. In the section from the older woman, note the considerably enlarged neurons, with both increased nuclear size and increased Nissl substance. Scale bar = 25 μm (a, b). Reprinted from Abel TW and Rance NE (2000) Stereologic study of the hypothalamic infundibular nucleus in young and older women. *Journal of Comparative Neurology* 424: 679–688, with permission.

regulatory circuits controlling body weight and reproduction. Arcuate POMC and neuropeptide Y neurons express leptin receptors and exert opposing actions on feeding behavior and energy balance. Experimental paradigms in laboratory animals in which nutritional status or serum leptin is altered produce reciprocal changes in POMC and neuropeptide Y gene transcripts. Thus, the finding of a reciprocal relationship between POMC and neuropeptide Y gene expression in the human arcuate (infundibular) nucleus suggests that this relationship is conserved among species.

A major limitation in interpreting changes in gene expression in premenopausal and postmenopausal women is the confounding influence of two variables, age and ovarian status. To control for the effects of aging, young cynomolgus monkeys have been used as a model to determine the effects of ovariectomy and steroid hormone replacement on hypothalamic neuropeptide gene expression (Table 1). Importantly, ovariectomy of young monkeys induces both hypertrophy and increased NKB gene expression in the infundibular nucleus. Similarly, GnRH gene expression in the medial basal hypothalamus is increased by ovariectomy of young cynomolgus monkeys. Conversely, estrogen replacement of young ovariectomized monkeys decreases NKB and GnRH gene transcripts. These data provide strong support for the hypothesis that increased NKB and GnRH gene expression observed in the hypothalamus of postmenopausal women is secondary to ovarian failure and not due to age *per se*. In contrast to the marked effect of ovarian hormones on NKB gene expression, ovariectomy or steroid replacement had no effect on POMC or neuropeptide Y gene expression in the primate model. These data suggest that factors other than ovarian failure may be more important in influencing this peptide system in postmenopausal women.

The association of increased NKB gene expression with estrogen withdrawal and gonadotropin hypersecretion suggests that these neurons participate in the hypothalamic circuitry regulating steroid negative feedback. This hypothesis is supported by the demonstration of estrogen receptor-α within the hypertrophied neurons and the location of these neurons within the primate control center for reproduction. Studies in experimental animals have also provided strong support for this hypothesis. Expression of NKB gene transcripts is increased by ovariectomy and reduced by estrogen replacement in a variety of species. NKB gene expression in the arcuate nucleus varies with the estrous cycle, and these neurons are sexually dimorphic. Moreover, anatomic studies have also revealed a close relationship between NKB and GnRH neurons. In the rat median eminence, there is close apposition of NKB and GnRH fibers at a site where GnRH fibers express the receptor for NKB, the neurokinin-3 receptor. Finally, LH secretion is modulated by central injections of a neurokinin-3 receptor agonist. Thus, multiple lines of evidence support the hypothesis that the hypertrophied neurons in the infundibular nucleus of postmenopausal women play a role in the regulation of steroid negative feedback on gonadotropin secretion.

Table 1 Effects of ovariectomy and estrogen replacement on neuropeptide gene expression in the medial basal hypothalamus of young cynomolgus monkeys

Neuron phenotype	*Changes in postmenopausal women*	*Effects of ovariectomy of cynomolgus monkeys*	*Effects of estrogen replacement in ovariectomized monkeys*
NKB	Hypertrophy, ↑ mRNA	Hypertrophy, ↑ mRNA	↓ mRNA below levels of detection
GnRH	↑ mRNA	↑ mRNA	↓ mRNA
POMC	↓ mRNA	No change	No change
NPY	↑ mRNA	No change	Not tested

NKB, neurokinin B; GnRH, gonadotropin-releasing hormone; POMC, proopiomelanocortin; NPY, neuropeptide Y.

Aging of the Reproductive Neuroendocrine Axis, Independent of the Effects of Gonadal Status

As chronological age advances, hypothalamic aging and secondary effects from the aging of other neuroendocrine systems become increasingly important. Age-associated changes occur in the reproductive neuroendocrine axis independently from those caused by ovarian failure. For example, plasma LH is lower in postmenopausal women (between 51 and 70 years old), compared to women (between 25 and 40 years old) with premature ovarian failure. A consistent decline in serum LH has also been observed in association with aging after the menopause. Moreover, some studies have reported an age-associated decline in the frequency of LH pulses, although these studies are confounded by the prolonged half-life of LH after the menopause.

Recent studies by Hall and colleagues have provided a detailed picture of the aging of the hypothalamic–pituitary axis by comparing hormone levels in postmenopausal women who are 45–55 years of age and 70–80 years of age. Using a sampling interval of 5 min and measurements of the gonadotropin free α subunit, a reduction in GnRH pulse frequency was observed in the older postmenopausal women. Because the GnRH pulse generator resides within the hypothalamus, these studies provide evidence of hypothalamic neuroendocrine aging that is independent of the changes in gonadal function.

Despite slower GnRH pulses and reduced serum LH, older postmenopausal women retain the capacity to decrease GnRH secretion in response to steroid feedback. Interestingly, indirect pharmacological measurements provide evidence that GnRH secretion increases with age in postmenopausal women. The age-related rise in GnRH secretion is consistent with the demonstration of increased GnRH secretion documented by push–pull perfusion in older rhesus monkeys. Moreover, the reciprocal changes in POMC and neuropeptide Y (NPY) gene expression that occur in the medial basal hypothalamus of older women also appear to be independent of gonadal status. It is hypothesized that loss of an inhibitory effect of POMC, combined with stimulation by NPY, could explain why GnRH secretion could continue to rise, even after the menopausal transition.

Summary

The hallmark of reproductive aging in women is degeneration of ovarian follicles, which accelerates around the age of 37 years. An early sign of reproductive aging is a rise in serum FSH, which is inversely correlated with decreased inhibin B secretion from developing antral follicles. After a transition phase characterized by irregular cycles and fluctuating hormone levels, the final menstrual period marks the cessation of cycles. In the postmenopausal period, the reproductive neuroendocrine axis is dominated by the withdrawal of ovarian hormones. Age-associated changes in the hypothalamic pituitary axis also occur and are independent of gonadal status.

Overview

A substantial volume of empirical and scientific evidence has accumulated that demonstrates that biological aging is associated with functional deficits at the cellular, tissue, organ, and system levels. Several theories have been proposed to explain these changes as well as the increased risk of disease with age. However, to date, no single explanation satisfactorily accounts for the physiological and pathological events related to biological aging, and it is apparent that several factors interact, resulting in the decline in tissue function that creates diversity in the aging phenotype. Current concepts of aging encompass genetic, free radical, somatic mutation, DNA repair, and cellular theories, all of which are not mutually exclusive. Although there is evidence to support a relationship between these theories of aging and end-of-life pathologies and/or life span, there is no overwhelming evidence that the progressive development of the aging phenotype can be adequately explained by these classical theories.

The neuroendocrine theory of aging evolved from observations that animals exhibit predictable and progressive impairments in a number of physiological processes over time, including, but not limited to, decreases in reproductive and immune function, decreases in muscle mass and function, increased adipose tissue mass, and decreases in glucose utilization and cognitive function. The role of the neuroendocrine system in these processes is related to the observation that many of the hormones regulated by the neuroendocrine system have an important trophic and integrative role in maintaining tissue function, withdrawal of hormonal support mimics some of the phenotypes observed in aging animals and humans, and hormone replacement therapy in many cases improves function in older individuals and, in some unique cases, life span.

The neuroendocrine system includes the hypothalamus and associated brain structures as well as the pituitary gland. This system includes neurotransmitters and neuropeptides within the brain that regulate hypothalamic-releasing and -inhibiting hormones secreted into hypophyseal portal blood that reaches the pituitary gland. These hormones influence the secretion of anterior pituitary hormones into the bloodstream and subsequently regulate tissue function. The posterior pituitary also is an important part of the neuroendocrine system but, in contrast to the anterior pituitary gland, is composed of long axons from specific hypothalamic nuclei. The hypothalamus and pituitary gland have the capacity to detect neural activity and/or humoral secretions from target tissues and adjust activity to maintain an optimal internal environment or 'milieu' for tissue function. It is well established that the neuroendocrine system has a critical role in regulating tissue growth and metabolism through the release of growth hormone (GH) and thyroid stimulating hormone (TSH); reproductive function through the release of luteinizing hormone, follicle stimulating hormone, prolactin, and oxytocin; and plasma electrolytes and responses to stress through secretion of vasopressin and adrenocorticotropin, respectively. In addition, the hypothalamus has an important role in the integration of parasympathetic and sympathetic nervous system activity and can thereby influence a wide variety of functions, including heart rate, blood pressure, vascular responses, and glucose metabolism, among others. Specific nuclei within the hypothalamus also regulate biological rhythms. More recently, the regulation of food intake, fat metabolism, and body composition has been shown to be regulated through the hypothalamus by its response to leptin, cholecystokinin, and ghrelin via the synthesis of neuropeptide Y and other orexigenic peptides. Unfortunately, the categorization of hormones and their primary functions noted above is an overly simplistic and only partial view of the neuroendocrine system, and it is now known that critical interactions occur between hormones that contribute to the regulation of cellular function. Because many of the early events of aging include alteration in systems regulated by the neuroendocrine axis, it was proposed (and subsequent studies supported the conclusion) that age-dependent alterations in the neuroendocrine system result in a progressive series of events that are manifest as biological aging.

Although the etiology of the age-related changes in the neuroendocrine system is unknown, it has been proposed that cellular and molecular events in specific subpopulations of neurons within the hypothalamus and brain and/or supporting structures are a contributing factor in the dysregulation of this system. The cause of the specific perturbations may be related to genetic errors or increased free radicals that lead to progressive aberrations in tissue function. As a result, the contribution of neuroendocrine

theories to aging is unique compared with other theories of aging in that alterations in this system are not considered the primary causative factor in biological aging but rather are important mediators of aging initiated by cellular changes in specific subpopulations of neurons or systems that closely interact with hypothalamic neurons. In this article, the major alterations within the neuroendocrine axis are discussed, with special emphasis on the regulation of GH, insulin-like growth factor 1 (IGF-1), TSH, and prolactin since these hormones mediate or have the potential to mediate some of more important physiological changes that occur with age. Insulin has been included in this review because of its importance for biological aging, homology to IGF-1, and potential interactions with several neuroendocrine systems.

GH and IGF-1

Invertebrate Studies

Results from studies conducted over the past several years have revealed that life span in invertebrates can be substantially increased by disrupting the insulin/IGF-1 pathway. In *Caenorhabditis elegans*, insulin and IGF-1 share a common signaling pathway, and the protein receptor encoded by the daf-2 gene binds to a circulating insulin-like substrate initiating a cascade of events, including activation of age-1, a homolog of mammalian phosphoinositide-3-OH kinase. This kinase, in turn, activates the Akt-encoded protein kinase B (PKB). PKB is a serine/threonine kinase that blocks the function of a forkhead/winged helix transcription factor (daf-16), at least in part, by preventing its translocation to the nucleus.

Disruption of the daf-2 pathway (including mutations in daf-2, age-1, or Akt genes) in *C. elegans* extends life span from 30% to 100%. This appears to be the result of the release of the Akt/PKB 'brake' on daf-16, which is the primary target of the daf-2 pathway. Although the specific mechanisms of the increased life span are not well understood, it is known that daf-16 regulates gene expression that is essential to environmental stress resistance, development, and dauer formation.

In addition to the studies in *C. elegans*, results indicate that disruption of the insulin/IGF-1 signaling pathway in flies and yeast also increases life span. These effects on life span in multiple species raise the possibility that these signaling molecules regulate a conserved pathway that influences longevity in mammals. Although there are promising data in this regard, these issues are more complex in mammals because IGF-1 and insulin regulate two independent but interacting signaling pathways and appropriate models to address these questions are not readily available.

Mammalian Studies: Background

Our understanding of GH and IGF-1 regulation and actions in mammals began in the early part of this century. It was known that a substance present in blood promotes body growth, but it was only after the isolation of bovine GH from the pituitary gland in 1945 that the biological effects of the hormone became evident. It was subsequently shown that this protein hormone stimulated cellular amino acid uptake, DNA, RNA, and protein synthesis and has a role in cellular division and hypertrophy.

Plasma levels of GH reveal a pattern of discrete pulses that increase after the onset of sleep. Although the precise function of this ultradian pattern remains unknown, the pulsatile release of GH has been confirmed in every species examined to date and is closely related to the biological actions of the hormone. GH in adolescents and young adults is characterized by relatively low-amplitude pulses throughout the day and a large pulse after the onset of sleep. In male rats, GH is characterized by an ultradian rhythm with high amplitude secretory pulses every 3–3.5 h; between pulses, GH decreases to almost undetectable levels. This secretory pattern is regulated by two different hormones released from the hypothalamus: GH-releasing hormone (GHRH) increases GH release, and somatostatin inhibits GH release. Both hormones are secreted in a phasic manner, with GHRH contributing to high-amplitude GH pulses and somatostatin to trough levels. The dynamic interrelationship between these hypothalamic hormones is necessary for pulsatile secretion. A number of other factors either within the hypothalamus or in plasma contribute to the regulation of GH release, either by acting directly on the pituitary gland or by regulating hypothalamic somatostatin and GHRH secretion. Both GH and IGF-1 inhibit GH secretion in a typical feedback relationship: They increase somatostatin and decrease GH RH release from the hypothalamus, resulting in a suppression of GH release.

More recently, there has been increased interest in small peptides that stimulate the release of GH. One of these peptides, ghrelin, is produced in the stomach and gastrointestinal tract. Although it does not interact with the GHRH receptor, it has been shown to act synergistically with GHRH to regulate both GH release and food intake. This peptide is particularly important from a clinical standpoint since oral administration of peptide and nonpeptide analogs of ghrelin increase GH secretion.

Although GH is one of the most potent anabolic factors in the body, most of the anabolic actions of the hormone are regulated through the secretion of IGF-1. IGF-1 binds with high affinity to the type 1

IGF receptor found in tissues throughout the body. The IGF-1 receptor shares 50% amino sequence homology with the insulin receptor, and competitive binding and affinity cross-linking studies have demonstrated that IGF-1 binds to the insulin receptor with 100 times lower affinity than to the IGF-1 receptor. IGF-1 is synthesized mainly in the liver under the regulation of GH but is also synthesized in smaller quantities in almost all tissues. Although regulation of local or 'paracrine' IGF-1 activity is poorly understood, it represents an important source of the hormone that also appears to be regulated by GH.

IGF-1 secreted from the liver circulates in the blood, either free or bound to specific binding proteins that prolong the half-life of the peptide. At present, at least six binding proteins have been identified and constitute an intricate transport system for the IGFs that regulate their availability to specific tissues. It is now clear that IGF binding proteins are critical regulators of IGF-1 activity yet may have actions independent of IGF-1.

The actions of GH are not entirely mediated through IGF-1, and in muscle and adipose tissue, GH can have direct effects. Specifically, GH decreases insulin sensitivity (see the section titled 'Insulin and glucose regulation') by direct effects on skeletal muscle and increases release of free fatty acids (and decreases fat mass) by increasing the activity of hormone-sensitive lipase in adipose tissue. These findings have led to the concept that the major anabolic actions of GH are mediated through IGF-1 (through either endocrine or paracrine regulation), whereas the effects of GH on free fatty acid levels are mediated by direct actions on muscle and adipocytes (Figure 1).

Effects of Age on the GH/IGF-1 Axis

Alterations in the regulation of GH have an important role in the physiological and biochemical changes normally associated with aging. Early studies in humans indicated that the amplitude of GH pulses and the rise in the concentrations of GH after insulin-induced hypoglycemia were blunted in older individuals. Subsequent studies demonstrated a prominent decrease in the amplitude of GH pulses in older animals although there were no changes in either the basal concentrations or the ultradian rhythm of GH. The age-related decline in GH results in a progressive reduction in plasma concentrations of IGF-1 in both animals and humans. Subsequent studies in various strains of rats and mice, nonhuman primates, and humans consistently confirmed the decline in GH and IGF-1 concentrations with age and suggested that changes in these hormones are a robust marker of biological aging in mammalian species.

Figure 1 Growth hormone (GH), produced in the anterior pituitary, is modulated by two hypothalamic hormones: growth hormone-releasing hormone (GHRH), which stimulates both the synthesis and secretion of GH, and somatostatin (SS), which inhibits GH release in response to GHRH. GH also feeds back to inhibit GHRH secretion and probably has a direct inhibitory effect on secretion from the somatotroph (GH-producing cells). In mammals, GH is secreted in pulsatile bursts from the anterior pituitary gland, a pattern that is necessary to achieve full biological activity. GH binds with high affinity to its receptor (GH-R), found in tissues throughout the body, and activation of this receptor stimulates the synthesis and secretion of insulin-like growth factor 1 (IGF-1). Although 90% of circulating IGF-1 is synthesized and secreted by the liver, many types of cells, including some found in the brain and vasculature, are capable of IGF-1 production. Binding of the hormone to the IGF-1 receptor (IGF-1R) causes potent mitogenic effects, including increases in DNA, RNA, and protein synthesis. Although heterogeneity exists in the processing of IGF-1 messenger RNA, these transcripts appear to produce a single peptide that is homologous to the structure of proinsulin. Blood and tissue levels as well as activity of the peptide are regulated by IGF-1 binding proteins (IGFBPs). Although it was initially proposed that all the actions of GH were mediated through IGF-1, data from several studies support direct roles for GH in the regulation of lipolysis and insulin sensitivity that are independent of IGF-1. Reproduced from Carter CS, Ramsey MM, and Sonntag WE (2002) A critical analysis of the role of growth hormone and IGF-1 in aging and lifespan. *Trends in Genetics* 18: 295–301, with permission from Elsevier.

Restoration of GH and IGF-1 levels with purified GH preparations reverses the age-related decline in cellular protein synthetic capacity in both skeletal and cardiac muscle. Although these studies did not address the question of whether tissue response to GH diminished with age, they clearly indicated that (1) cellular protein synthesis decreases in an environment of reduced GH and IGF-1 levels and (2) GH and/or IGF-1 replacement has the capacity to attenuate a classical symptom of aging, that is, the decrease in cellular protein synthesis in older people. Furthermore, these studies were supported by clinical observations that GH replacement to humans for 6 months reversed the decline in bone mass, the negative nitrogen balance (an indicator of decreased whole-body protein synthesis), and the increase in fat mass characteristic of aging in humans. Subsequent reports demonstrated that GH or IGF-1 administration could partially reverse the decline in immune function; increase the expression of aortic elastin, lean body mass, skin thickness, and vertebral bone density; and improve cognitive function in older animals and humans. Although the beneficial effects of GH administration have been confirmed repeatedly, deleterious side effects of GH replacement severely limit its usefulness as a treatment to modulate physiological changes with age. For example, GH increases cartilage growth, contributes to carpal tunnel syndrome, impairs insulin sensitivity, increases blood glucose, and in several cases has been found to increase neoplastic disease. In fact, elevated IGF-1 levels are a risk factor for breast, gastrointestinal, prostate, and lung cancer. These studies provide compelling data suggesting that the development of the aging phenotype results, at least in part, from dysfunction within the neuroendocrine axis and, more specifically, deficiencies in the secretion of GH and IGF-1. Therefore, it is evident that decreases in GH and IGF-1 have clinical significance and are a contributing factor in the genesis of tissue dysfunction in older animals and humans.

Actions of GH and IGF-1 in Older Animals

Although GH and IGF-1 are well known for their ability to increase cellular protein synthesis, muscle and bone mass, and immune function and to decrease fat mass, recent data suggest that the age-related decrease in these hormones has an important role in the genesis of brain aging. Studies indicate that IGF-1 reverses the age-related decline in cerebral microvascular density and blood flow and that IGF-1 crosses the blood–brain barrier and enhances learning and memory, long-term potentiation, glucose metabolism, synaptic density, neurogenesis, and neuronal survival and reduces oxidative stress in older animals. These results and recently published reports have led to the hypothesis that age-related deficiency in circulating GH and IGF-1 leads to vascular insufficiency and deficits in synaptic function and cell replacement in the central nervous system and are a contributing factor in the genesis of brain aging (Figure 2).

Animal Models of GH/IGF-1 Excess and Deficiency

Our understanding of the effects of GH/IGF-1 deficiency and replacement in aging humans and animal models is complicated by results of studies with transgenic and mutant animals. Transgenic mice with varying levels of GH overexpression demonstrate an inverse relationship between GH expression and life span. The reduction in life span observed with

Figure 2 Age-related changes in the growth hormone/IGF-1 axis. Left, growth hormone secretory pulses in young (6-month-old; solid circles; Y) and old (20-month-old; open circles; O) Sprague–Dawley male rats. Serial samples of blood were removed at 20-min intervals from conscious, freely moving animals and analyzed by radioimmunoassay. Hatched area represents the dark phase of the light/dark cycle. Right, age-related changes in plasma IGF-1. Data represent mean ± SE. Reproduced from Carter CS, Ramsey MM, and Sonntag WE (2002) A critical analysis of the role of growth hormone and IGF-1 in aging and lifespan. *Trends in Genetics* 18: 295–301, with permission from Elsevier.

overexpression of GH is generally attributed to increased pathologies, primarily renal lesions and a very high frequency of hepatocellular tumors, including adenoma and carcinoma. While the reduced life span observed in models of GH overexpression appears to support the hypothesis that GH reduces life span, it is important to note that GH levels in these overexpression models are 1000–10 000-fold greater than those found under physiological conditions. Therefore, the distinction between the potential of pharmacological doses of GH to increase pathology and reduce life span has to be considered separately from the physiological changes in growth that occur during the normal life span of most mammalian models. Therefore, it remains unclear whether transgenic models of GH overexpression provide relevant information on the role of GH and IGF-1 in normal life span regulation (Figure 3).

Perhaps the most commonly used animal models to investigate the effects of GH and IGF-1 are those that show deficiency in GH expression or have mutations in the GH/IGF-1 axis. Some of these models include those with deficiencies in transcription factors necessary for the generation of GH, TSH, and prolactin-producing cells in the pituitary gland (e.g., Snell and Ames dwarf mice), and others have selective impairments in the GH/IGF-1 axis (e.g., $GHRHR^{-}/GHRHR^{-}$, GHRKO, and $IGFR^{+/-}$ mice). Despite the limitations of the models with multiple hormonal deficiencies, even models with specific deficiencies in GH and IGF-1 during early development result in impaired development of related endocrine systems, and alterations in corticosterone, insulin, glucose, and thyroid hormones are routinely observed. As a result, data from these models must be interpreted cautiously since they demonstrate the potential of alterations in GH/IGF-1 early during development to affect developmental processes that regulate life span but cannot address whether these effects are mediated directly by the GH/IGF-1 actions on target tissues or are mediated indirectly via the developmental other endocrine systems dependent on GH and IGF-1. The distinction is important to resolve for the direction of future scientific studies.

The marked contrasts noted in the studies described above related to the beneficial effects of GH replacement on function in humans and animal models and the contrasting studies demonstrating that deficiencies in GH and IGF-1 increase life span represent the crux of the current issue in the GH/IGF-1 field. Recent studies have attempted to circumvent the developmental effects of GH/IGF-1 deficiency by developing a model of adult-onset GH/IGF-1 deficiency. In this model, a mutant animal that exhibits reduced levels of GH around puberty is administered GH replacement to increase circulating IGF-1 and ensure the development of other endocrine systems until adulthood. The GH injections are then terminated and the animal allowed to age normally, creating the model of adult-onset GH deficiency (AO-GHD), and these animals are compared to dwarf (GH-deficient) or wild-type (normal) animals. In these studies, no differences in life span were evident between normal and GH-deficient animals, but it is interesting that AO-GHD animals lived 15% longer than either group. End-of-life pathology indicated that both AO-GHD and GH-deficient animals had less kidney pathology and neoplastic disease compared with wild-type animals but died primarily from cardiac thrombus and intracerebral hemorrhage. The increased life span in the AO-GHD animals resulted from a corresponding delay in the appearance of cardiac thrombus and intracerebral hemorrhage. This study provided compelling data that GH and IGF-1 levels around puberty have an important role in determining life span, that life span and the factors that determine life span may be a separate entity from age-related pathology, and finally that functional changes with age are separate from life span.

The effects of GH and IGF-1 on aging and life span highlight several unresolved issues in the field

Figure 3 Probe trial in the Morris water maze assessed spatial reference memory. Performance in both Annulus-40 time (left) and platform crossings (right) that are measures of memory declined with age ($p < 0.001$ comparing young and old control (old) animals). IGF-1 treatment for 28 days reversed this decline in both measures (*$p < 0.05$ comparing young to old and old IGF–1; **$p < 0.01$ in both measures comparing old control (old) and old IGF-1 treated animals). Data are shown as mean ± SE (unpublished data).

of gerontology. Deletion or mutation of a single gene, as occurs in transgenic or mutant animals, can result in developmental anomalies, but consequences for data interpretation remain uncertain. Most investigators recognize the importance of the age-related decline in tissue function, pathology, and life span; however, few studies of life span include either functional or pathological analyses. Until gerontologists agree on standards for the conduct of aging studies designed to assess the effects of these interventions on aging, such issues will remain unresolved (Table 1).

Insulin and Glucose Regulation

Since the initial studies demonstrating that suppression of signaling in the insulin/IGF-1 pathway in *C. elegans* increases life span, there has been much interest in insulin signaling in mammalian models and its potential contribution to life span. In contrast to the common insulin/IGF-1 pathway in invertebrates, separate insulin and IGF-1 signaling pathways have evolved in mammals.

In humans, the regulation of blood glucose and insulin secretion is perhaps one of the most important areas of endocrinology because pertubations in this pathways are closely associated with cardiovascular disease and many other pathological conditions that increase with age. The postprandial rise in insulin secretion in mammals results from an increase in blood glucose that affects the pancreatic β cell. Also, glucagon-like peptide-1 release from the intestine sensitizes the β cells, resulting in optimal insulin output into the circulation. Although insulin action is a more complicated process than described here, its primary action is to stimulate glycogen synthesis in liver and, after binding to its receptor on muscle and adipose tissue, to activate glucose transporter-4 proteins in the membrane of the cell through a complicated signal transduction mechanism. The result is glucose uptake in these tissues and a reduction in blood glucose levels. In nonobese older study participants, there are minor, albeit significant, changes in both insulin secretion and glucose tolerance tests with age. These changes alone are not sufficient to result in pathology. However, in obese study participants regardless of age, basal glucose levels rise, resulting in increased pathology. The interaction of body composition (adipose tissue mass) and glucose levels has been widely recognized and results in insulin receptor insensitivity, potentially from a rise in cytokines (e.g., tumor necrosis factor-α and interleukin-6) and other hormones (e.g., leptin) secreted by adipose tissue, that interferes with insulin signaling mechanisms designed to lower blood glucose. In addition, recent studies indicate that adipose-like tissue accumulates within skeletal muscle and is an important factor in the increased incidence of disability with age. Whether these changes in adipose tissue are important corollary events or actually cause the increase in disability remains to be determined.

Unfortunately, it is unclear whether alterations in insulin levels or insulin signaling directly contribute to the development of the aging phenotype. Certainly, one might expect that obesity and the pathologies associated with obesity synergize with the pathologies of aging to shorten life span. But the interactions between these pathways are complex and remain underinvestigated. In this regard, there are data to

Table 1 End-of-life pathology in a model of adult-onset growth hormone deficiency[a]

Pathology	*Heterozygous*	*GHD*	*AO-GHD*
Tumor bearing (%)	88	73 ($p = 0.34$)	63 ($p = 0.04$)
Tumor burden (mean)	1.3 ± 0.2	0.92 ± 0.2 ($p =$ ns)	1.0 ± 0.2 ($p =$ ns)
Fatal tumor (%)	57	36 ($p = 0.21$)	31 ($p = 0.11$)
Fatal pituitary adenoma (%)	39	21 ($p = 0.30$)	13 ($p = 0.08$)
Grade of pituitary adenoma	1.57 ± 0.3	1.69 ± 0.4 ($p =$ ns)	1.19 ± 0.3 ($p =$ ns)
Fatal chronic nephropathy (%)	74	0 ($p < 0.0001$)	0 ($p < 0.0001$)
Severity of nephropathy	4.0 ± 0.3	0.8 ± 0.2 ($p < 0.001$)	1.0 ± 0.2 ($p < 0.001$)
Intracranial hemorrhage/thrombus (%)	17	50 ($p = 0.06$)	44 ($p = 0.14$)
Age of occurrence of hemorrhage/thrombus (months)	31.9	30.7	34.1
Disease burden (total)	6.6 ± 0.5	5.0 ± 0.5 ($p = 0.009$)	5.5 ± 0.4 ($p = 0.067$)

[a]End-of-life pathology was determined in the following experimental groups: (1) heterozygous (normal) male Lewis rats injected with saline from 4 to 14 weeks of age (normal size, normal GH/IGF-1 levels); (2) GH-deficient (GHD) dwarf Lewis males administered saline from 4 to 14 weeks of age (dwarf, GHD); and (3) GHD dwarf Lewis males administered porcine growth hormone from 4 to 14 weeks of age (Adult-onset GHD (AO-GHD)). AO-GHD animals exhibited a 12–15% increase in life span compared with either heterozygous or GHD animals ($p < 0.05$). ns, not significant.

Reproduced from Sonntag WE, Carter CS, Ikeno Y, et al. (2005) Adult-onset growth hormone and insulin-like growth factor I deficiency reduces neoplastic disease, modifies age-related pathology, and increases life span. *Endocrinology* 146: 2920–2932, copyright 2005, The Endocrine Society.

suggest that a knockout of the insulin receptor specifically in adipose tissue increases life span in mice, but no age-related pathological analyses or performance measures were done, and therefore this remains an important area for future research.

Endocrine Effects of Moderate Caloric Restriction: Interactions with Insulin and IGF-1

Despite the absence of changes in insulin and glucose levels in nonobese humans with age, there is important information to suggest that the insulin and IGF-1 pathways may have important roles in determination of life span in invertebrate and vertebrate subjects. Consistently, moderate caloric restriction (60% of *ad libitum* feeding) has been shown to increase life span in rodent models. Although there are data to suggest that the decrease in nutrients alters several cellular metabolic pathways (e.g., SirT1, PGC1α) that may contribute to regulation of life span, alterations in caloric intake have important effects on several hormonal systems that may affect pathology and life span. For example, reduction in calories increases GH, cortisol, and catecholamine secretion and reduces circulating insulin and IGF-1 levels. These changes are a normal physiological response designed to access nutrients that have been stored during periods of nutrient excess. The result of these changes is an increase in gluconeogenesis, glycogenolysis, ketogenesis, and fatty acid metabolism and a decrease in insulin sensitivity and cellular protein synthesis, all of which are designed to maintain blood glucose and other nutrients in the bloodstream. The endocrine changes that result from a reduction in caloric intake appear to have a direct effect on life span and age-related pathology in small animals. For example, chemical-induced bladder cancer is markedly reduced in caloric restricted compared with *ad libitum* animals, and replacement of IGF-1 to calorie restricted animals increases the incidence of this pathology. These data suggest that the decrease in IGF-1 that occurs during caloric restriction is an important part of the protective mechanism against chemical-induced cancer and provides indirect evidence that chronically lower levels of IGF-1 may protect animals from other types of neoplastic diseases that increase with age. This conclusion is supported by data from many transgenic and mutant animal strains and studies using the model of AO-GHD that show protection against dimethylbenz[a]anthracene-induced mammary cancer. In the studies using the AO-GHD model, GH replacement resulted in a dose-related rise in mammary cancer. Since many mouse strains are highly susceptible to neoplastic disease, any intervention that delays or prevents this pathology will naturally increase life span. Although it is unlikely that the increased life span from moderate caloric restriction results from reduced levels of IGF-1 and/or insulin alone, the relationship between IGF-1 and neoplastic disease is compelling, and further research to understand the specific hormones that may mediate the actions of moderate caloric restriction is required (Figure 4).

Prolactin

Basic Regulation and Actions

Prolactin secretion from the pituitary lactotroph in humans and animal models is regulated by hypothalamic dopamine secretion into the hypothalamic-pituitary portal vessels. The dopaminergic neurons of the rat hypothalamus are grouped into two main areas, A_{12} and A_{14}. The dopaminergic perikarya of the A_{12} area are located in the arcuate nucleus, with their axons projecting into the external zone of the median eminence. There, dopamine is released from the axon terminals into the portal vessels of the median eminence and travels to the anterior pituitary lobe. The A_{14} dopamine neurons are primarily located within the paraventricular and periventricular

Figure 4 Cumulative tumor incidence after dimethylbenz[a] anthracene (DMBA) injection in growth hormone-deficient dwarf animals and heterozygous (normal) control female rats. At 27 weeks after DMBA injection, 80% of heterozygous animals exhibited mammary tumors, while dwarf animals administered saline, 50 µg, or 400 µg porcine growth hormone per day demonstrated 0%, 83%, and 100% tumor incidence, respectively. Reproduced from Ramsey MM, Ingram RL, Cashion AB, et al. (2002) Growth harmone-deficient dwarf animals are resistant to dimethylbenzanthracine (DMBA)-induced mammary carcinogenesis. *Endocrinology* 143: 4139–4142, copyright 2002, The Endocrine Society.

hypothalamic nuclei and project their axons through the internal portion of the median eminence to terminate on both the neural and intermediate pituitary lobes. The A_{12} area and its corresponding axon terminals constitute the tuberoinfundibular dopaminergic (TIDA) system, whereas the A_{14} area and its fibers are known as the periventricular dopaminergic system. Both systems regulate lactotrophs exerting a tonic inhibitory control on prolactin secretion and lactotroph proliferation.

Plasma concentrations of prolactin are lowest during waking hours in humans and highest during sleep. The variable patterns of secretion are dependent on gender, environmental conditions including stress, reproductive status (including lactation), estrous and menstrual cycles, pregnancy, and other factors. Prolactin participates in multiple roles throughout the body although its primary actions are related to reproduction and maternal behavior. In some mammals, prolactin is important for the secretory activity of the corpus luteum. Within the mammary gland, prolactin induces growth and synthesis of milk (e.g., uptake of some amino acids; synthesis of the milk proteins casein and α-lactalbumin; uptake of glucose, lactose, and fats) and maintains milk secretion. Also, prolactin has a role in the immune system, stimulating mitogenesis in normal lymphocytes. Prolactin also appears to have a role in the regulation of solute and water transport across mammalian cell membranes. In keeping with its lactogenic properties, it affects water transport across amniotic membranes and acts as an osmoregulatory hormone.

Prolactin Secretion and Aging

The dopaminergic neurons of the central nervous system are among the cells most susceptible to damage produced by the aging process. For example, Parkinson's disease is a human condition characterized by a degeneration of nigrostriatal dopamine neurons. This disease affects 0.1–0.3% of the population and is the most conspicuous reflection of the vulnerability of dopamine neurons to age. In female rodents, degeneration and loss of TIDA neurons during normal aging is associated with progressive hyperprolactinemia and the development of pituitary prolactinomas. It is interesting that patients with Parkinson's disease usually reveal functional alterations within the hypothalamoprolactin axis.

Female rats ranging in age from 6 to 32 months have been studied to ascertain the impact of aging on the number and morphology of dopamine neurons of the A_{12} and A_{14} areas as well as on serum prolactin levels. In these studies, a progressive loss of both TIDA and periventricular dopaminergic neurons was evident, and these changes became more conspicuous at extreme ages. It is interesting that in old female rats, restoration of hypothalamic IGF-1 using recombinant adenoviral vectors that express rat IGF-1 was highly effective in restoring hypothalamic dopamine function, suggesting important interactions between the age-related decrease in IGF-1, the deterioration of dopamine activity, and the age-related rise in prolactin levels.

In addition to IGF-1, hypothalamic lactotrophs are controlled by a number of factors. For example, estrogen has been demonstrated to have an important effect on lactotrophs and to stimulate the development of tumorigenesis within the pituitary. Although there are data demonstrating that estrogen acts on dopaminergic cells within the hypothalamus, several investigators have proposed a lactotroph, folliculostellate cell interaction as a potential mechanism for the role of estrogen in the genesis of pituitary prolactinomas. Under basal conditions, prolactin cells are under a tonic inhibitory autofeedback of transforming growth factor-β (TGFβ)-1 acting on the TGFβII receptor. When estrogen levels rise, lactotroph cells are stimulated to release high levels of TGFβ3, which then acts on TGFβII receptors on folliculostellate cells, inducing the production and release of basic fibroblast growth factor, which in turn acts on the lactotroph to stimulate both cell proliferation and prolactin secretion. These novel interactions of estrogen on the pituitary gland may interact synergistically with the reduced levels of dopamine to produce the pronounced rise in pituitary microadenomas and frank tumors that occurs with age.

TSH: Tri-iodothyronine, Thyroxine, and Thyroid Function

Cellular metabolism is regulated by the secretion of TSH release from the anterior pituitary gland. This hormone enters the circulation and stimulates the thyroid gland to produce both tri-iodothyronine (T_3) and thyroxine (T_4). These hormones circulate bound to thyroid binding globulin and after transport are taken up by the cell. T_3 is the more potent thyroid hormone, but T_4 can be converted to T_3 with the enzyme deiodinase. Levels of these hormones regulate basal metabolic activity throughout the body. T_3 and T_4 are controlled by negative feedback regulation, primarily at the level of the anterior pituitary gland, by suppression of TSH release although the hypothalamus also produces thyroid-releasing hormone (TRH) that can stimulate TSH release. TRH has only a minor role in the regulation of TSH release under normal conditions, but in response to cold stress or other challenges, TRH exerts an important influence. In addition to prominent effects on cellular metabolism and temperature regulation, thyroid hormones have a permissive role in the regulation of

many organs and tissues, including reproductive function, bone metabolism, and glucose metabolism. Therefore, changes in the secretion or response to thyroid hormones would be expected to have broad-ranging effects on the health of the organism.

Apart from the appearance of specific thyroid diseases that increase with age, only subtle changes in the levels of thyroid hormones seem to occur in otherwise healthy older animals or humans. Investigators have reported a reduction in deiodinase activity that leads to reduced levels of T_3 within target organs, but the significance of these changes for the development of physiological changes in tissue function have not been well defined. Similarly, it is of interest that numerous animal models that exhibit increased life span also exhibit a decrease in thyroid hormone levels, but the significance of these changes remains to be determined.

Conclusions

There are now convincing data that alterations within the neuroendocrine system contribute to both the physiological and pathological manifestations of aging. Decreases in GH and IGF-1, for example, are important factors in the accumulation of body fat mass, the reduction in cellular protein synthesis, and impairments in some aspects of immune function with age. The effects of moderate caloric restriction are mediated, at least in part, through physiological changes affected by the neuroendocrine system. These studies, together with results from transgenic and mutant animals, provide compelling data of an important link between the neuroendocrine axis and the development of the aging phenotype. Nevertheless, controversies remain that can be resolved only by the development of transgenic animal models permitting close regulation of both GH and IGF-1 and assessing function, pathology, and life span.

Although the specific etiology of the age-related neuroendocrine dysfunctions is unknown, increases in oxidative damage in specific hypothalamic nuclei, impairments in neurotransmitter levels and turnover, and diminished plasticity within hypothalamic nuclei are potential mechanisms. An alternative explanation for the alterations within the neuroendocrine system is that an active regulation of hypothalamic function exists throughout the life span. Decreases in GH and IGF-1, for example, are initiated immediately after puberty and progress with age. In fact, age-related changes in the regulation of this system may be consistent with a model of antagonistic pleiotropy, a theory on the evolution of aging that suggests that the expression of particular genes is beneficial early in life but becomes detrimental as the organism ages. Certainly, the beneficial actions of GH and IGF-1 on muscle mass and organ development early in life would be expected to increase general fitness as well as reproductive fitness, whereas continued high levels may increase pathology and limit life span. Thus, the age-related decrease in GH and IGF-1 as well as other hormones regulated by the neuroendocrine axis may be a physiologically regulated, adaptive process rather than the result of damage to specific hypothalamic nuclei. The potential significance of such changes for this and other systems regulated by the neuroendocrine axis awaits further investigation.

Neuroendocrine Aging: Pituitary-Adrenal Axis

E R de Kloet, LACDR, Leiden University Medical Center, Leiden, The Netherlands

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Aging is characterized by decreased ability to maintain homeostasis and consequent less efficient adaptation to change. The impact of this age-related breakdown of adaptation is far more disruptive when integrative homeostatic communication systems are also affected. These systems include the sympathetic and parasympathetic branches of the autonomic nervous system and the neuroendocrine hypothalamic–pituitary–adrenal (HPA) axis (Figure 1). The amine, neuropeptide, and steroid components of these systems signal specific information to ensure coordination of brain and body functions during adaptation. Such coordination involves the control of emotions and cognitive performance as well as energy metabolism, cardiovascular, inflammatory, and immune regulation. The question addressed here is whether aberrant HPA activity is the cause or the consequence of signs of aging and age-related pathology. The focus is on the glucocorticoids, which operate in a bimodal fashion crucial for defense and recovery of homeostasis.

HPA Axis and Glucocorticoids

Glucocorticoid Cascade Hypothesis

The HPA axis promotes an organisms' ability to cope with environmental stressors and facilitates behavioral adaptation. At senescence, coping and adaptation usually become less efficient and as a consequence HPA reactions may become inadequate, excessive, or prolonged. In particular, the excessive and prolonged secretion of glucocorticoids has received attention. Elevated glucocorticoid levels imply that the cost to defend homeostasis has become too high. The outcome is enhanced wear and tear, a process termed 'allostatic load' by Bruce McEwen. This notion materialized in Robert Sapolsky's glucocorticoid cascade hypothesis, which focused on the damaging outcome of chronic glucocorticoid overexposure during the aging process.

While acute rises in glucocorticoid levels are essential for recovery, adaptation, and survival, prolonged elevated glucocorticoid levels may indeed become damaging to brain and body. It is thought that such elevated hormone levels are primarily caused by slowing down of cognitive operations and less efficient homeostatic control mechanisms. In the brain, the damage particularly affects the hippocampus, which is an important glucocorticoid target and is crucial for learning and memory processes. Because of ensuing feedback resistance, glucocorticoid levels further rise. Hence a feed-forward cascade develops, leading ultimately to degeneration and death. This appealing hypothesis clearly has supporting evidence: for instance, rainbow trout swimming upriver for reproductive purposes eventually die of cushingoid symptoms.

HPA Axis in Aging Rodents

In support of the glucocorticoid cascade hypothesis, excessive HPA axis activation in aging has been reported. Sprague–Dawley, Long–Evans, Fisher, and Wistar rats generally show prolonged stress-induced corticosterone levels during aging. Several scenarios have linked rises in corticosterone level to aging. First, stress and hypercorticism have been proposed to promote cognitive aging. Second, aging may cause initial hypercorticism, which then, in a feed-forward cascade of increasing feedback resistance, would further promote the aging process. Third, stress, together with hypercorticism, would amplify the individual variation in cognitive aging. However, hypercorticism during aging appears not at all to be a common phenomenon.

In aged Brown Norway rats, exposure to a novel environment or a conditioned emotional stressor produces excessive adrenocorticotropic hormone (ACTH) peak values, while corticosterone responses are not different from those of young controls, indicating an efficient feedback operation. The relatively low corticosterone concentration is partly compensated by reduced corticosteroid-binding globulin (CBG) capacity, yielding an increased free fraction of nonbound corticosterone. Hence, Brown Norway rats show adrenocortical deficiency during aging, suggesting that healthy aging and low corticosterone levels coincide. This demonstrates, however, that hypercorticism is not an inevitable consequence of aging.

The profound differences in 50% survival age between different rat strains raise the question of the appropriate rodent model for aging research. The criteria for the 'ideal' model include an almost rectangular survival curve and thus a high estimated 50% survival age. Included also is the occurrence of age-related, multiple pathologies rather than inbred-strain specific diseases (e.g., the high prevalence of testis- or pituitary-tumors in F344 or Wistar rats). The animals used in many aging studies in fact either fail to meet these criteria or should be considered middle-aged rather than old. The Brown Norway strain does

Figure 1 Bimodal organization of neuroendocrine stress response. Stressful stimuli, through afferent pathways, stimulate corticotropin-releasing hormone (CRH) and vasopressin neurons in the paraventricular nucleus (PVN), thus orchestrating behavioral, autonomous, and neuroendocrine response patterns. Physical stressors (e.g., pain, blood loss, heat, and cold) directly stimulate the PVN via ascending aminergic pathways. Psychological stressors require processing in limbic–cortical brain structures (e.g., hippocampus, amygdala, and prefrontal cortex) that communicate transsynaptically with the PVN. The neuroendocrine response pattern enhances the secretory bursts of cortisol (primates) or corticosterone (rodents) from the adrenal cortex. The corticosteroids feed back on the brain circuits that have produced their own secretion and prevent them from overexcitation. These actions exerted by the steroids are mediated by (a) mineralocorticoid receptors (MR) and (b) glucocorticoid receptors (GR). Under psychosocial stress conditions, MRs regulate the onset of the stress response, which – through CRH receptor 1 (CRH-R1) – determines the extent of CRH action on hypothalamic–adrenal–pituitary activation, sympathetic nervous system responses, and flight–flight behavior. After stress progressively activates GRs, the rise in corticosterone levels facilitates adaptation, promotes memory storage, and hence prepares for coping with future events. CRH-R2 activation by urocortins and parasympathetic nervous activity is thought to synergize with GRs to promote recovery. MRs and GRs operate in complementary fashion through a (non)genomic mechanism to facilitate defense and recovery of homeostasis; imbalance is thought to promote signs of aging and age-related pathology. From de Kloet ER, de Rijk RH, and Meijer OC (2007) Is there an imbalanced response of mineralocorticoid and glucocorticoid receptors in depression? *Nature Clinical Practice Endocrinology & Metabolism* 3: 168–179.

meet these criteria and is, as such, generally accepted as a good rodent model to study aging.

Another important consideration in these types of studies is the individual variation within a genetically homogeneous cohort of animals – variation that becomes much more pronounced at old age. With respect to many behavioral and neurobiological parameters, such as memory performance, individual animals can often be classified in impaired, intermediate, and nonimpaired subgroups. In aged Long–Evans or Brown Norway rats, approximately 30% will show excellent memory performance, whereas the rest will be partially or severely impaired; in Long–Evans rats, the extent of impairment appears related to the persistence in corticosterone secretion after stress.

HPA Axis Pulsatility

Glucocorticoids are secreted in a circadian pattern, with peak levels before the active period, which, for the nocturnal rat, is in early evening. However, hormones are secreted in distinct pulses, as is well documented for the gonadotropin-releasing hormone and growth hormone systems. Also, the HPA axis displays an ultradian rhythm and produces a complex pattern of approximately 1-h-long glucocorticoid secretory pulses. The variation in amplitude of the glucocorticoid pulses produces the circadian profile.

A stressor initiates an HPA pulse. The pulse frequency and amplitude increase, but it makes a difference at what phase of the ultradian rhythm the

stressor is experienced. As shown in Stafford Lightman's laboratory, a stressor at the ascending phase of the pulse results in a profound glucocorticoid response, while at the descending phase a refractory period exists, leading to strongly attenuated glucocorticoid secretion. This raises the possibility that modulation of glucocorticoid pulsatility serves as means of communication. Frequency encoding by glucocorticoid hormones implies that the pattern of hormone secretion matters, rather than absolute hormone concentration. It implies also that glucocorticoid pulses throughout the circadian cycle likely are required for synchronization and coordination of daily and sleep-related events.

Glucocorticoid pulsatility has an immediate consequences for HPA aging studies. This is one may wonder about the relationship between cortisol changes observed after a stressor if disparate pulsatility patterns among individuals are grouped. In some rat strains, aging is characterized by a prolonged response to stress. Taking the ultradian rhythm into account, this apparent persistence may be due to desynchronization of the pulsatile corticosterone pattern among individuals: the pulse may be delayed in some and advanced in others. Such disordered pulsatile patterns may appear seemingly prolonged after grouping the data of each individual. Hence the pulsatile pattern of corticosterone needs to be examined during the aging process.

Glucocorticoid Feedback

The recognition of pulsatile patterns of hormone secretion casts an entirely new light on the classical view of regulation and function of the HPA axis. The pulse generator is not known, but probably resides proximal to or within the hypothalamic corticotropin-releasing hormone (CRH) neurons. Furthermore, hormone pulses can be amplified and dampened at each level of the HPA axis. Central modulation occurs via afferent inputs that are involved in processing of stressful information. In this respect, excitatory afferents from the hippocampus and prefrontal cortex that process contextual information innervate a γ-aminobutyric acid (GABA)ergic inhibitory neuronal network controlling the CRH neurons. Emotional arousal through nervous input from the amygdala excites the paraventricular nucleus (PVN), as do the monosynaptic ascending aminergic pathways from the brain stem. How these inputs are integrated and translated in a CRH pulse is not known; current evidence suggests that a stressor advances the onset of the pulse and can enhance pulse frequency and amplitude.

Glucocorticoids feed back precisely in those cells and circuits that initially activated the HPA pulse generator, but in what modes does the feedback action operate? The answer to this question has been guided by the discovery of the receptors for the glucocorticoids. Two types of receptors have been identified: mineralocorticoid receptors (MRs) and the glucocorticoid receptors (GRs), which together control a spectrum of actions over time domains ranging from seconds to hours. The GRs prevail in the PVN and pituitary primary feedback sites, where they exert negative control over the stress-induced HPA pulse. The limbic–midbrain afferents express both MRs and GRs that modulate the input secondarily in either feed-forward or feedback mode, depending on time and context, and thus are capable of modulating the HPA pulse either way. The MR is promiscuous and binds aldosterone as well as corticosterone and cortisol, but is exposed to much larger amounts of the latter steroid. This is because the limbic brain lacks the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11-HSD-2), which confers aldosterone selectivity to MRs in kidney cells. Instead, limbic neurons express 11-HSD-1, a reductase that regenerates bioactive glucocorticoids.

Glucocorticoid action mediated by limbic MRs and GRs modulates higher brain functions involved in behavioral and physiological adaptations to the stressor. GRs become substantially occupied at glucocorticoid peaks during ultradian pulses and after stress, while MRs are substantially occupied already at the troughs. The MR- and GR-mediated glucocorticoid actions act in concert with the other stress signaling systems. Figure 1 depicts the bimodal nature of the stress system, with CRH/CRH receptor 1 (CRH-R1) and corticosterone/cortisol through MRs controlling the onset of the pulse, and possibly urocortin/CRH-R2, with GRs facilitating the termination of the pulse. This dualism in the stress system presents a new working model to examine the HPA axis during the aging process.

Brain Corticosteroid Receptors

Corticosteroid Receptor Balance and Aging

Crucial for stress and aging are two fundamental observations. First, MRs and GRs act as transcription factors and they are co-localized in limbic neurons, but have distinctly different properties. MRs have a tenfold higher affinity than GRs do for cortisol/corticosterone, and both act through transactivation at overlapping but distinct hormone response elements (HREs). Additionally, GRs are capable of interacting with common transcription factors such as activator protein-1 (AP-1) and nuclear factor-kappa B (NF-κB), with rapid effects on gene transcription by transrepression. Thus,

in response to a brief corticosterone pulse, waves of primary and secondary gene responses occur and initially act through predominant transrepression, probably dampening the initial stress reactions. Then transactivation prevails to exert recovery of homeostasis and adaptation.

Second, it was recently discovered by Henk Karst and Marian Joëls that the very same nuclear MRs also mediate nongenomic actions in the same neurons. Glucocorticoid pulses were found to rapidly enhance excitatory glutamate transmission in the hippocampus through nongenomic MRs; CRH release from the PVN was found to be suppressed through membrane GR-like receptors. Thus, it is very likely that these nongenomic effects have an important control function in activation and termination of the HPA pulse.

Previously, the slower genomic MR actions in the hippocampus appeared important for maintaining stability and integrity of limbic neuronal circuits. Situations with mostly nuclear MRs, but few GRs, activated are associated with small calcium currents, reduced spike frequency accommodation, stable responses to repeated stimulation of glutamatergic pathways, and relatively small responses to biogenic amines. Nuclear MR activation thus seems to guarantee a stable background of neuronal firing. Activation of co-localized nuclear GRs (and MRs) with higher glucocorticoid concentrations was found to result in enhanced calcium influx, stronger spike frequency accommodation, changes in ion channel conductances, and marked responses to biogenic amines such as serotonin. Thus, nuclear MRs also control, on another time scale, the onset of the stress reactions, and GRs control recovery and adaptation.

How this complementary function of membrane and nuclear MRs and GRs accommodates glucocorticoid pulsatility needs to be investigated. One testable prediction is that membrane MRs control the ascending, and membrane GRs control the descending, arm of the pulse. The genomic MRs promote long-term stability and defense of homeostasis, while genomic GRs facilitate recovery after a stressful challenge and help to prepare for the future. These functions are indicated for MRs as being proactive, determining the future state versus the reactive mode mediated by GRs, referring to the consequence of a stress-induced glucocorticoid pulse.

The MR/GR balance hypothesis predicts that, upon imbalance, threats to homeostasis are less well communicated. At a certain threshold, such hampered communication may lead to a condition of neuroendocrine dysregulation and impaired behavioral adaptation, which potentially can aggravate age-related deterioration and promote susceptibility to age-related disease to which an individual is predisposed. Aging, therefore, is characterized by a changing MR/GR balance and enhanced HPA lability.

Modulation of Brain Corticosteroid Receptors and HPA Axis: Implications for Aging

Interestingly, individual differences in cognitive impairment that appear at old age are subject to manipulation by early life events, such as handling of newborns and depriving newborns of maternal contact. In rats, maternal deprivation or postnatal handling during the first 2 weeks of life can alter stress responsiveness permanently. Aged Long–Evans animals handled postnatally showed an attenuated stress-induced rise in corticosterone levels and are cognitively less impaired than are animals not handled as infants. Handled Long–Evans animals show a higher expression of hippocampal GRs, an effect that is established during the handling procedure by an epigenetic mechanism acting in GR promoter regions.

The outcome of maternal deprivation depends on the age at which separation occurred and duration, and strain and gender are also important variables. Deprivation of maternal contact in Brown Norway rats for 24 h at postnatal day 3 was recently shown to cause a profound midlife surge in stress-induced corticosterone output, but senescent animals and their control, mother-reared littermates displayed comparable attenuated corticosterone responses. It was expected that the early adverse experience would cause cognitive decline in all of the aged rats. This was, however, not observed: rather, maternal deprivation amplified individual differences in old age, and gave rise to a complete shift in the percentages of animals classified as impaired, partially impaired, or nonimpaired, on the basis of their performance in the Morris water maze. Most senescent rats that were mother-reared as pups showed average partially impaired performance, but senescent rats subjected to maternal deprivation were either fully impaired or nonimpaired, at the expense of the average (Figure 2).

Whether such a previous 'midlife' surge in HPA activity is of relevance for the subsequent aging trajectory has been tested in various ways. In the classical Phil Landfield experiments, Fisher rats adrenalectomized at midlife and provided with low amounts of corticosterone, sufficient to occupy MRs, showed at senescence less age-related decline in various behavioral and neuroanatomical markers than did their untreated controls. Likewise, in Jonathan Seckl's laboratory, mutant mice in which the 11-HSD-1 gene was deleted, preventing local reactivation of corticosterone, age-related learning impairments were ameliorated. Alternatively, rats receiving high doses of corticosterone during midlife deteriorated cognitively toward old age. However, Carmen Sandi showed that such

Figure 2 Adverse early life experience amplifies individual differences in cognitive performance. At senescence, the distribution of the quality of spatial performance differs between (a) control ($n = 34$) and (b) maternally deprived ($n = 47$) animals, yielding a bell-shaped vs. a U-shaped distribution, respectively. Spatial learning of maternally deprived rats is impaired, at the expense of average performance (i.e., partially impaired). From de Kloet ER and Oitzl MS (2003) Who cares for a stressed brain? The mother, the kid or both. *Neurobiology of Aging* 24: S61–S65.

corticosterone-induced decline depends on the context in which corticosterone operates. In these experiments, Wistar rats were distinguished at midlife by high or low reaction to novelty exposure and were subsequently exposed for 28 days to stressors. Interestingly, both high and low responders showed enhanced corticosterone reactivity at senescence, but only the high novelty responders deteriorated in cognitive performance at senescence. Which factor determines this context-dependent action of corticosterone is not known.

A consistent finding has been the downregulation of hippocampal MRs in aged animals, irrespective of whether these were rodents, dogs, or primates. Strategies to enhance MR expression indeed were able to enhance cognitive performance. One example is conferred by nature: the successfully aging Brown Norway rat strain has a gain-of-function mutation in the MR. Another example is provided by tricyclic antidepressants, which in the senescent animal had no effect on cognitive performance. If, however, treatment started at midlife and was maintained until senescence, the antidepressant ameliorated cognitive impairment in the aged rats, while the drug induced MRs and downregulated corticosterone secretion. Collectively, these data suggest that the outcome of midlife corticosterone for the aging process depends on genetic and environmental contexts, in a fashion involving the corticosteroid receptors.

Glucocorticoids and Aging: Mechanisms

Age-Related Changes during Hypercorticism: The Relevance of Context

The relevance of context in corticosteroid action is provided by studies using a certified strategy for longevity: caloric restriction (CR). It has been known for a long time that reduction of caloric intake by at least 20% slows down the aging process and extends the life span of rats and other organisms. The aged CR rats have improved cognitive performance in a maze test, long-term potentiation (LTP) is facilitated, and neurogenesis is enhanced. However, this condition of energy deprivation also results in high circulating glucocorticoid levels. How is it possible that in some conditions chronically elevated glucocorticoids cause damage, but in others, such as in CR, elevated glucocorticoid levels exert protection? According to Caleb Finch, this paradox may be explained by the following processes: CR promotes (1) maintenance of microvasculature integrity, (2) attenuation of oxidative damage, (3) enhanced synthesis of growth factors, and (4) attenuation of glial cell proliferation. It is thought that these effects exerted by CR override the negative effects of elevated glucocorticoids. It might be that CR imposes a different context for corticosterone, resulting in suppression of oxidative damage and glial cell activation; the factors determining this context are not known.

Possible Mechanisms Underlying Glucocorticoid-Related Damage

Excessive glucocorticoid exposure is associated with age-related impairment in memory performance, but what is the underlying mechanism? One factor is the overall increase in calcium currents, which has a number of consequences, including suppressed synaptic efficacy, as seen from impaired LTP. Glial cell proliferation and function are affected and dendritic branching in the CA3 pyramidal cell field is suppressed. Other factors related to energy metabolism, cell birth, viability, recovery, and growth also could be implicated in corticosteroid-dependent degenerative changes accompanying the aging process.

Cortisol can suppress hippocampal glucose metabolism, which is known to reflect learning and memory capacity. Positron emission tomography (PET) measurements of cerebral glucose metabolism in elderly persons indeed show in cortical and hippocampal areas a generalized hypometabolism that precedes subsequent hippocampal volume reductions and reduced performance in long-term memory tasks. The beneficial effects of glucose, and also of insulin administration, on aspects of rat and human cognitive performance are of interest, although variable results have been reported.

Brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF), and their receptors, may be implicated, since age-associated spatial learning impairments in rats can be reversed by administration of some but not all growth factors. Most attention is on the age-related atrophy of cholinergic neurons innervating hippocampus and neocortex. Recently, in rhesus monkeys, learning impairment as well as the associated atrophy of subcortical cholinergic neurons could even be reversed using neurotrophin gene therapy. This suggests that growth factors hold some potential for treating age-related changes.

Another possibility is hippocampal dentate gyrus neurogenesis, which persists from early life but slows down at old age. It is thought that neurogenesis allows the dentate gyrus to continuously rejuvenate its neuronal population in order to adapt to change. Newborn cells become functional after 2–3 weeks as judged from increases in synaptic plasticity and LTP. Stress and elevated corticosterone concentrations suppress the rate of neuronal birth in young, adult, and aged rats. Alternatively, high corticosterone levels – as a result of calorie restriction or increased physical activity through voluntary running, and also estrogen treatment, enriched environmental housing, or training in a hippocampal learning task – increase neurogenesis into old age. Further studies are needed to explore the significance of neurogenesis for aging in these various contexts.

HPA Axis, Aging, and Age-Related Pathology in Humans

Similar to that in rodents, increased HPA activity is not a universal feature of human aging. A flattened circadian rhythm in circulating cortisol is the most consistent finding. In support of enhanced HPA activity, increased numbers of CRH/vasopressin-expressing neurons were found in the PVN of aging males. Stress responsiveness is affected by aging, as a (stressful) public speech task revealed that the subgroup with an early (anticipatory) increase in cortisol in response to the stimulus was impaired in declarative memory, whereas elderly subjects without this early rise in cortisol showed no memory deficits. These data suggest that some of the results from rat studies can be extrapolated to the human situation. However, the design of the experiments and the nature of the stressors are for obvious reasons quite different.

New information also suggests that corticosteroid receptor polymorphisms are associated with aging. In one study from Steven Lamberts' group, the ER22/23EK polymorphism, conferring a relative resistance to the GRs, was found associated with a healthy metabolic profile. The GR variant (frequency 8.9% in adults) had a significantly higher frequency in the older population. The MR Il80V polymorphism discovered by Roel de Rijk shows loss of function, and, as a result, carriers of this gene variant (frequency, 14%) display strongly enhanced neuroendocrine and autonomic responses in the Trier social stress test. Aged individuals carrying this gene variant showed a higher prevalence of depressive symptoms accumulating in the aging population.

In a prospective study, cortisol appeared related to cognitive function. Sonia Lupien observed that only aged individuals with rising cortisol levels over the 4-year period were correlated with reductions in explicit memory and attention tasks. In parallel, a reduction of 14% in hippocampal volume occurred. These volume reductions are already apparent in elderly individuals who display only mild cognitive impairment preceded by glucose hypometabolism. Similar changes in cognitive performance and hippocampal volume have been observed after exogenous glucocorticoids and in Cushing's disease. Significant correlations have, furthermore, been found between hippocampal size and delayed, but not primary or immediate, memory performance, independent of gender, generalized cerebral atrophy, or age. The extent of these early atrophic changes of the hippocampus was found to be a risk factor for accelerated memory dysfunction in normal aging.

Enhanced HPA activity, cognitive decline, and hippocampal volume reduction strongly depend on the genotype of a patient. These measures are reduced in carriers of the apolipoprotein E4 allele, which is a risk factor for age-related cognitive deficits and Alzheimer's disease. In general, basal and stress-induced HPA activation are further enhanced by Alzheimer's disease pathology. This raises the question whether Alzheimer's disease hippocampal damage is the cause or the consequence of excessive glucocorticoids. Since Alzheimer's disease pathology is absent in patients treated with corticosteroids or in severely depressed patients suffering from hypercortisim, it has been argued by Dick Swaab that these hormones are obviously not the trigger. Rather, aberrant HPA activity is considered of relevance in the variable onset and progression of Alzheimer's disease.

Future Directions

A fundamental question in neuroendocrine aging is to what extent the HPA axis contributes to physical and behavioral signs of aging and age-related pathology. This question has received renewed interest because HPA hormones, particularly the glucocorticoids, have been found to be released in pulsatile fashion, to coordinate cell and organ function. Moreover, at the tissue level, the glucocorticoids operate through complementary MR- and GR-mediated actions in the limbic brain. While MRs are involved in stability and the onset of the stress response, recovery and adaptation after stress are mediated by GRs. In balance, MRs and GRs are crucial for homeostasis and health; imbalance and consequent HPA lability are characteristic features of aging.

A major issue is how glucocorticoids should be positioned in the current theories of aging. The thrifty genotype (James Neel) and phenotype (David Barker) hypotheses of aging hinge on nutrition and metabolism. The underlying genes and physiology do not act by themselves, but need to be regulated. Glucocorticoids are essential for this purpose, but how glucocorticoid action can change from protective to damaging is not known. Also, Caleb Finch's 'gero-inflammatory manifold,' favoring systemic and local inflammations as common denominators in age-related degenerations, has an obvious link to glucocorticoids, but glucocorticoid's place in the sequence of events is virtually unknown. Whether susceptibility genes and adverse life experiences aggravate age-related processes unidirectionally in every individual, or act on a common unknown substrate, amplifying individual differences *per se*, is an unresolved issue as well.

Thus, the issue on aberrant HPA axis and glucocorticoids, as either the cause or the consequence of aging processes, is unresolved. Yet, the significance of HPA pulsatility and MR/GR responsiveness provides ample opportunity for aging research. The current evidence suggests that MR/GR imbalance compromises the ability of organisms to defend and to restore homeostasis. Such imbalance may result in HPA dysregulation enhancing vulnerability through the very same genes that are otherwise essential for maintaining homeostasis, resilence, and health. The identity of these genes is not known.

Overview

The human hypothalamic–pituitary–testicular axis maintains testosterone production and spermatogenesis through an intricate feedforward and feedback system involving the intermittent exchange of neurohormonal signals. The chief components of this ensemble are hypothalamic gonadotropin-releasing hormone (GnRH), pituitary luteinizing hormone (LH), and testicular sex steroids (testosterone and estradiol). Epidemiological data and clinical experiments jointly indicate that healthy older men have lower bioavailable and free testosterone concentrations, higher sex hormone-binding globulin (SHBG) concentrations, and decreased daily testosterone secretion rates, compared with young individuals. Mechanistic analyses predict each of impaired GnRH outflow, blunted LH-stimulated testosterone secretion, and reduced negative feedback by testosterone in the older male. Aging also disrupts quantifiable synchrony among sleep stage, the secretion of LH, testosterone, prolactin, and follicle-stimulating hormone (FSH), and the oscillations in nocturnal penile tumescence, denoting erosion of coordinate central neurohormonal outflow. Prolactin, estradiol, and inhibin B concentrations fall and FSH concentrations rise with age. How age affects spermatogenesis in healthy populations is not known. In summary, aging in men is marked by multisite regulatory failure within the gonadal axis. Further studies are required to define the tempo, variability, reversibility, and import of such interlinked deficits, and to delineate safe and effective interventional strategies to obviate aging-related frailty.

The human hypothalamic–pituitary–testicular axis maintains a eugonadal state via reciprocal feedforward and feedback connections. Multiple changes in this network occur with age, resulting in a gradual (1–2% yr^{-1}) decline in testosterone availability. Whether aging also decreases spermatogenesis is not established due to the inherent difficulty in obtaining semen from representative populations. Less testosterone production may contribute to aging-associated increases in visceral fat, insulin resistance, falls, and fractures, and decreases in bone mineral density, muscle mass and strength, physical performance, perceived quality of life, libido, and potentia. Mechanistic inquiries dissecting the bases for testosterone depletion with age should facilitate the development and optimization of preventive and therapeutic strategies. Such strategies must carefully balance potential risks of androgen-induced prostatic disease, cardiovascular disease, erythrocytosis, and/or obstructive sleep apnea against psychological and physical benefits.

Rate of Evolution and Extent of Relative Hypoandrogenemia in Older Men

Testosterone depletion in aging is an increasingly pertinent clinical issue, given epidemiological data linking hypoandrogenemia with sarcopenia, osteopenia, visceral adiposity, insulin resistance, reduced physical stamina, sexual dysfunction, impaired quality of life, and (possibly) depressive mood and waning cognitive function. Impoverished testosterone availability in older men has been affirmed by (1) longitudinal investigations in healthy cohorts, (2) meta-analysis of cross-sectional data, and (3) direct sampling of the spermatic vein. In general, bioavailable (non-SHBG-bound) and free testosterone concentrations fall more markedly than do total values, as illustrated for cross-sectional data in Figure 1. Total testosterone concentrations are partially maintained by a concomitant increase in SHBG concentrations in aging men. A 15-year prospective analysis in the United States (New Mexico) reported that total testosterone concentrations fall by approximately 0.39 nmol l^{-1} yr^{-1} in men after the age of 60 years; the Massachusetts Male Aging Cohort studies estimated a 0.8–1.3% annual decrement in bioavailable testosterone concentrations and the Baltimore Longitudinal Study of Aging predicted an annual decline of 4.9 pmol testosterone per nanomole SHBG. In the last study, the age-related prevalence of hypogonadal testosterone:SHBG ratios, judged by young-adult normative criteria, exceeded 20%, 30%, and 50% at ages 60, 70, and 80 years, respectively. Thus, reduced systemic testosterone availability is especially significant in societies with high longevity.

Comorbidity in aged individuals can markedly exacerbate androgen deficiency. Comorbid risk factors include chronic systemic disease, acute illness, stress, weight loss, hospitalization, institutionalization, and the use of certain drugs. The degree to which illness-induced androgen decrements are reversible in various settings is not yet well articulated. Whether certain comorbidities represent indications for testosterone replacement also requires further investigation.

Figure 1 Plots of total, bioavailable, and free (unbound) testosterone concentrations regressed on age in healthy volunteers from Olmsted County, Minnesota, USA. The R^2 values denote the fraction of variability accounted for by age.

Mechanistic Bases of Testosterone Depletion

The fundamental mechanisms that cause hypoandrogenemia in the aging male remain unknown. However, recent clinical investigations have disclosed multiple alterations in the gonadal axis in older men: (1) lower amplitude LH pulses, suggesting reduced drive by GnRH; (2) more frequent LH pulses and less orderly patterns of LH release, consistent with diminished negative feedback; (3) preserved LH and heightened FSH responses to exogenous GnRH pulses, indicating lack of primary pituitary failure; (4) reduced pulsatile and thereby total daily testosterone secretion; and (5) impaired testosterone responses to elevated endogenous LH concentrations (stimulated by flutamide, tamoxifen, GnRH, or anastrozole) and to infused pulses of recombinant human LH. The collective findings indicate that relative androgen deficiency in the older male reflects multisite failure of the GnRH–LH–testosterone axis.

An investigative challenge arises in verifying specific mechanisms that mediate gradual aging-related adaptations in the human gonadal axis. A recent strategy is to exploit an ensemble regulatory concept of reciprocal interactions among GnRH, LH, and testosterone (Figure 2). An integrative biomathematical approach allows one to formalize and quantify underlying feedback and feedforward interactions objectively. The analytical rationale is to reconstruct aging-related adaptations among all three primary signals – GnRH, LH and testosterone – rather than evaluate any one signal in isolation. According to ensemble analyses, a parsimonious explication of collective clinical data is that aging (1) attenuates hypothalamic GnRH outflow, (2) impairs testicular responsiveness to LH pulses, and (3) decreases androgenic negative feedback. Longitudinal studies will be required to establish the relative importance of individual regulatory deficits in healthy aging (Figure 3).

Putative Pathophysiological Mechanisms in the Aging Male

Hypothalamic GnRH Deficiency in Older Men

Indirect clinical observations support the hypothesis that hypothalamic GnRH outflow is reduced in older men (Table 1). In particular, aging individuals maintain lower LH pulse amplitudes (due to a reduced mass of LH secreted per burst) and more irregular LH secretory patterns (increased approximate entropy), yet respond normally to exogenous GnRH pulses. Although such observations are congruent with decreased endogenous GnRH drive, hypothalamic GnRH secretion cannot be monitored directly

Figure 2 Simplified structure of the male gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), and testosterone (Te) (i.e., hypothalamic–pituitary–Leydig cell) axis with key feedback (–, inhibitory) and feedforward (+, stimulatory) interactions. Smooth curves denote *in vivo* dose–response interfaces mediating GnRH-induced LH secretion (top middle), LH-stimulated testosterone secretion (Te Sec; bottom left; SHBG, sex hormone-binding globulin), and testosterone-enforced negative feedback on the pituitary gland (right middle) and hypothalamus (rightmost top). Possible adaptations in LH → Te feedforward sensitivity (slope), potency (one-half-maximal stimulus concentration, or ED_{50}), and efficacy (maximal responsiveness) are illustrated (left middle).

Figure 3 Schema of inferred anatomic sites (axis; left) and adaptive mechanisms (contrast; right) that subserve relative testosterone (Te) deficiency in healthy older men (age >60 years), compared with young (age <35 years) men (GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; SBHG, sex hormone-binding globulin). Arrows define stimulation (+) and inhibition (–). The two encircled insets (dose–response; center) depict age-related contrasts in GnRH → LH drive (top center) and LH → Te feedforward (bottom center).

Table 1 Indirect evidence for impaired gonadotropin-releasing hormone drive in aging men

Low-amplitude spontaneous luteinizing hormone pulses
Increased or normal potency of exogenous gonadotropin-releasing hormone pulses
Blunted unleashing of pulsatile luteinizing hormone secretion after blockade of sex hormone feedback or opiate receptors
Normal luteinizing hormone bioactivity
Quantifiably more disorderly patterns of luteinizing hormone release
Asynchrony of central neurohormone outflow: luteinizing hormone, follicle-stimulating hormone, prolactin, sleep stage, and nocturnal penile tumescence
Mathematical predictions based on an ensemble concept

in the human. One means to estimate central GnRH outflow noninvasively entails graded competitive inhibition of both endogenously driven and exogenous GnRH-induced LH secretion. Inhibition can be enforced by escalating doses of a potent and selective GnRH-receptor antagonist (such as ganirelix). In this paradigm, age does not affect LH responses to an exogenous GnRH stimulus, whether or not ganirelix is administered. In contrast, increasing age potentiates suppression of endogenously driven LH pulses by any given blood concentration of the receptor antagonist. Given that GnRH and ganirelix compete for the same pituitary receptor, greater inhibition of LH pulses by the receptor antagonist in older men points to less hypothalamic GnRH outflow to drive gonadotrope cells. This important inference is confirmed analytically using a model in which one assumes that (1) unobserved hypothalamic GnRH concentrations stimulate LH secretion via a positive logistic function and (2) testosterone inhibits GnRH outflow (release and action) via a negative exponential function.

Laboratory experiments have also delineated significant (but not exclusive) central hypogonadotropism associated with hypoandrogenemia in the aged male rodent. Relevant evidence includes (1) reduced *in vivo* LH pulse amplitude, (2) diminished *in vitro* GnRH secretion by hypothalamic tissue, (3) attenuated castration-induced LH release, (4) normal LH responses to injected GnRH, (5) altered GnRH neuronal synaptology, and (6) restoration of sexual activity in the aged rat following hypothalamic neuronal transplantation. Nonetheless, potential species differences limit facile extrapolation of these data to humans.

Enhanced Gonadotrope Secretory Responsiveness to Small Amounts of GnRH

In principle, smaller LH pulses in older men could reflect diminished hypothalamic GnRH secretion and/or decreased pituitary sensitivity to available GnRH. In the latter context, initial studies using a single supramaximal dose of GnRH were contradictory. Recent investigations incorporating physiological doses of GnRH disclosed that aging potentiates submaximal stimulation (Figure 3). One dose–response study that injected single intravenous pulses of GnRH in random order on a single morning estimated 1.6-fold higher GnRH-stimulated LH, FSH, and free α-subunit secretion in aging men. Another dose–response analysis administered individual intravenous doses of GnRH spanning a 1000-fold range on separate, randomly ordered mornings. This stratagem disclosed that older men maintain nearly twofold greater gonadotrope sensitivity to GnRH (steeper slope of the dose–response) and twofold greater GnRH potency (50% lower dose of GnRH required to stimulate LH secretion one half-maximally) than do young counterparts, but have comparable maximal LH secretion (denoting age-equivalent GnRH efficacy). Heightened acute gonadotrope responsiveness to submaximal amounts of GnRH (2.5, 10, and 25 ng kg^{-1}) in older men could reflect upregulation of GnRH receptors, augmentation of pituitary LH stores, and/or feedback withdrawal due to lower concentrations of total, bioavailable, or free testosterone. The last consideration has been affirmed analytically. A third investigation infused pulses of GnRH (100 ng kg^{-1}) or saline intravenously every 90 min for 14 days by portable infusion pump in young and older men. The GnRH clamp increased pulsatile LH secretion equivalently in the two age groups, indicating comparable gonadotrope responsivity. However, bioavailable and free testosterone concentrations remained 50% lower in elderly men, suggesting reduced bioactivity of secreted LH or impaired testicular steroidogenesis.

Impaired Leydig Cell Steroidogenesis in Older Men

Administration of the LH surrogate, human chorionic gonadotropin (hCG), fails to stimulate maximal young-adult testosterone concentrations in many, but not all, aging men. Impaired testis responsivity in this setting is difficult to interpret definitively, because the hCG stimulus is not physiological. Three concerns exist: (1) the half-life of hCG is 20–30 h (compared with 1 h for LH), thus enforcing nonpulsatile drive, (2) hCG rapidly downregulates Leydig cell steroidogenesis *in vivo* and *in vitro*, and (3) conventional hCG doses exceed the lutropic activity of an LH pulse by >300-fold, thus testing only maximal testis responses. The last issue is relevant, because low testosterone production occurs in older men when LH concentrations are normal or only minimally elevated.

A near-physiological protocol to examine Leydig cell responsiveness involves intravenous infusion of pulses of recombinant human LH during acute suppression of

Figure 4 Pulses of recombinant human luteinizing hormone (LH) after gonadotropin-releasing hormone (GnRH) receptor blockade fail to normalize bioavailable (left) and free (right) testosterone (Te) concentrations in older men. Adapted from Liu PY, Takahashi PY, Roebuck PD, et al. (2005) Aging in healthy men impairs recombinant human luteinizing hormone (LH)-stimulated testosterone secretion monitored under a two-day intravenous pulsatile LH clamp. *Journal of Clinical Endocrinology & Metabolism* 90(10): 5544–5550. Copyright 2005, The Endocrine Society.

LH secretion with a GnRH-receptor antagonist. Application of this paradigm for 48 h unmasked 50% lower exogenous LH-stimulated bioavailable and free testosterone concentrations in older, as compared to young, men (Figure 4). Whether more extended delivery of normal-amplitude LH pulses would restore young-adultlike testosterone secretion in older individuals is not known. Although experiments in the aged Brown Norway rat suggest a fixed steroidogenic defect in Leydig cells, the exact relevance of the animal model to the human is not certain.

Aging Restricts Feedback by Endogenous Testosterone on GnRH and LH Secretion

Clinical studies have reported both greater and less reduction of LH concentrations following supplementation with testosterone or 5α-dihydrotestosterone in older men, as compared to young men. Discrepancies could relate to nonphysiological routes, amounts, preparations and patterns of androgen administration, confounding effects of endogenous testosterone, dissimilar study populations, and/or single measurements of LH concentrations. On the other hand, aging appears to mute negative feedback by endogenous testosterone consistently. The latter inference applies to comparisons made by cross-correlation, approximate entropy, and ensemble-model analyses of frequently sampled LH and testosterone concentrations. Feedback attenuation is not due solely to systemic androgen depletion in older individuals, because feedback strength decreases per unit testosterone concentration (Figure 5). The molecular mechanisms that mediate impaired feedback are not known. However, histochemical analyses have quantitated reduced androgen-receptor expression in the brain and pituitary gland of the aged rat and in genital fibroblasts of the older human.

Reduced negative feedback by androgens could contribute to the higher frequency, lower amplitude, and more irregular LH secretion patterns that typify aging individuals. In fact, blocking testosterone or estradiol synthesis with steroidogenic enzyme inhibitors elicits rapid and irregular LH pulses even in healthy young men. The sex steroid-depleting regimens fail to increase LH secretory burst size equally in older and young men. Therefore, smaller LH secretory bursts in aging individuals are not attributable to hypoandrogenemia or hypoestrogenemia *per se*. On the other hand, more frequent LH secretory bursts and less orderly LH secretion patterns may reflect both reduced feedback efficacy and reduced testosterone availability for feedback. Verification of relative age- and androgen-dependent altered LH secretion would require experimentally clamping systemic testosterone availability in different age groups.

FSH and Inhibin B

Hypothalamic–pituitary–gonadal control of FSH secretion is less well understood because (1) feedforward relationships among FSH, testosterone, estradiol, and the 90-day spermatogenic cycle in the human are complex; (2) sperm production and

Figure 5 Analytically reconstructed surfaces depicting virtual (calculated) gonadotropin-releasing hormone (GnRH) feedforward and free testosterone (Te) feedback onto luteinizing hormone (LH) secretion in men in the indicated age cohorts. Each surface interlinks pulsatile LH secretion (vertical axis) with estimated GnRH drive (oblique axis) and Te feedback (horizontal axis). Te feedback is calculated for each of free (left), bioavailable (middle), and total (right) Te concentrations. Aging is marked in three ways: by decreased maximal LH secretion, defined at maximal virtual GnRH outflow at zero (extrapolated) Te concentrations (vertical axis intercept of the surface); by less Te feedback on LH secretion at any given GnRH signal strength (right-to-left downslope at top of surface due to increasing free Te concentrations); and by greater potency of virtual GnRH (leftward shift in GnRH → LH dose–response function at any given Te concentration). Adapted from Keenan DM, Takahashi PY, Liu PY, et al. (2006) An ensemble model of the male gonadal axis: Illustrative application in aging men. *Endocrinology* 147(6): 2817–2828, with permission. Copyright 2006, The Endocrine Society.

quality are difficult to monitor serially; (3) FSH secretion is restrained by all three of testosterone, estradiol, and inhibin B; (4) both GnRH and activin appear to maintain FSH secretion in animals; (5) recombinant human activin and inhibin B are not available for clinical studies; and (6) the prolonged half-life of FSH makes reliable pulsatility analysis more difficult (Figure 6). Available clinical studies show that greater age is associated with higher serum FSH concentrations but lower inhibin B (especially before age 35 years) and bioavailable sex-steroid concentrations, and loss of coordinate LH–FSH secretion. Although estradiol, testosterone, and nonaromatizable androgens inhibit FSH secretion in older men, how age influences sex-steroid feedback potency and efficacy remains unknown.

Prolactin

Disorders associated with hyperprolactinemia are associated with suppressed LH pulsatility and reduced sex-steroid production. How hyperprolactinemia represses GnRH secretion is not established in humans. Data derived from animal models are species dependent. For example, prolactin administration suppresses LH

Figure 6 Overall gonadal axis, including the gonadotropin-releasing hormone (GnRH)–luteinizing hormone (LH)–testosterone (Te) component (left) and the seminiferous tubular compartment with GnRH, follicle-stimulating hormone (FSH), estradiol, and inhibin B (right).

pulse frequency and amplitude in sheep and castrated rats. On the other hand, a prolactin receptor-knockout mouse strain had normal concentrations of LH, FSH, and testosterone, with preserved fertility and testis morphology. Lactotrope cell number does not change, but pulsatile prolactin secretion declines with age in humans. Prolactin is not known to regulate testis function directly in men, unlike in the rodent.

Neurohormonal Network Regulation in Aging Men

Available analyses indicate that aging in men impairs hypothalamic GnRH outflow, LH-stimulated Leydig cell steroidogenesis, and testosterone-dependent negative feedback (Figure 3). How this tripartite conclusion is reached requires explanation. Strong interdependencies among GnRH, LH, and testosterone secretion signify the operation of networklike (ensemble) control of the gonadal axis. In ensemble systems, no one signal acts alone or can be viewed alone. Thus, to ensure valid mechanistic interpretation, all three signals must be analyzed together without perturbing their feedback or feedforward connections. The approximate entropy (ApEn) measure provides one means to do this. ApEn is a model-free statistic that quantifies the overall impact of regulatory inputs within an interlinked system. The endpoint is the relative regularity, orderliness, or consistency of recurring subpatterns in serial measurements. Thus, ApEn does not replace, but instead complements, the analysis of pulses or circadian rhythms. ApEn analyses unveil more irregular (less orderly) patterns of both LH and testosterone secretion with increasing age. In contrast, FSH release is quite irregular at all ages.

As an extension of the ApEn metric, the cross-ApEn statistic quantifies the joint pattern synchrony of two coupled processes, specifically paired signals. Unlike the linear cross-correlation coefficient, cross-ApEn provides a probabilistic measure of pattern similarities (reproducibility) independently of time lag. Cross-ApEn analyses unmask prominent age-related deterioration of LH's coupling with each of testosterone, FSH, and prolactin secretion, sleep-stage transitions, and nocturnal penile tumescence (NPT) oscillations. Directional cross-ApEn comparisons indicate that older individuals have symmetric erosion of LH → testosterone feedforward and testosterone → LH feedback linkages (Figure 7). Thus, aging alters ensemble control among LH, FSH, prolactin and testosterone secretion as well as sleep and autonomic nervous system outflow, which govern NPT.

Investigation of the male gonadal axis is enhanced by biomathematical formalism, which encapsulates nonlinear, dose-responsive, and time-delayed feedforward and feedback coupling among GnRH, LH, and testosterone. One analytical construct allows one to estimate endogenous dose–response properties noninvasively

Figure 7 Disruption of central neurohormone outflow in the aging male quantified by the cross-approximate entropy (ApEn) statistic, which quantifies loss of orderliness. Cross-ApEn values for each pair of neurohormone outflow measures are elevated in older men, compared with those in young men, signifying deterioration of joint synchrony (LH, luteinizing hormone; Testo, testosterone; NPT, nocturnal penile tumescence; FSH, follicle-stimulating hormone; PRL, prolactin). Greater asynchrony of paired signals in turn denotes disruption of the physiological pathways connecting the signals. Adapted from Veldhuis JD, Iranmanesh A, Godschalk M, et al. (2000) Older men manifest multifold synchrony disruption of reproductive neurohormone outflow. *Journal of Clinical Endocrinology & Metabolism* 85(4): 1477–1486, with permission. Copyright 2000, The Endocrine Society.

without the injection of GnRH, LH, or testosterone or disruption of feedback linkages. Experimental validation required repetitive direct sampling of cavernous sinus and internal jugular venous concentrations of GnRH, LH, and testosterone in the awake stallion and ram, and peripheral LH and spermatic vein testosterone concentrations in the human. Figure 8 illustrates the results of noninvasive analytical reconstruction of feedforward dose–response functions linking LH concentrations and testosterone secretion rates, using only paired systemic measurements of the two hormones in 15 older and 15 young men. The methodology is illustrated schematically in Figure 9. This approach predicts that aging selectively impairs

Figure 8 Analytically estimated luteinizing hormone (LH) → testosterone (Te) feedforward dose–response functions in young ($N = 15$) and older ($N = 15$) men. LH efficacy is defined as asymptotically maximal Te secretion; potency is defined as [ED_{50}], the half-maximally effective stimulatory concentration (dose) of LH, and sensitivity is defined as the maximal positive slope. Only LH efficacy differed by age in these analyses. Adapted from Keenan DM and Veldhuis JD (2004) Divergent gonadotropin–gonadal dose–responsive coupling in healthy young and aging men. *American Journal of Physiology* 286(2): R381–R389.

Figure 9 Model of feedforward mechanism by brain gonadotropin-releasing hormone onto pituitary gonadotrope cells to induce a burst of luteinizing hormone (LH) secretion (top left). LH concentrations drive gonadal testosterone secretion (Te Sec) via a monotonic dose–response function (top middle). Burstlike Te secretion over time (top right) is the output of the simultaneously calculated LH → Te feedforward function. Testosterone entering the blood has the five possible fates, denoted as k_1–k_5, representing random diffusion, linear advection in blood, binding to albumin or sex hormone-binding globulin (SHBG), and irreversible removal or chemical metabolism.

Table 2 Model-simulated implications of selected regulatory deficits in (aging) male gonadal axis

Deficit examined[a]	*Predicted responses*			*Orderliness or regularity*
	Available testosterone	*Luteinizing hormone pulses*

endogenous LH efficacy; that is, aging reduces maximally stimulated testosterone secretion without altering LH potency or testis sensitivity to LH. Randomly ordered dose-varying intravenous infusions of recombinant LH during GnRH-receptor blockade will be needed to establish such inferences empirically.

Computer-assisted simulations confer predictive insights. Recent model-based simulations of gonadal axis adaptations in the older male illustrate that (1) isolated attenuation of central GnRH drive forecasts lower LH pulse amplitude and attendant hypoandrogenemia, but not higher LH pulse frequency or greater irregularity; (2) exclusive impairment of Leydig cell steroidogenesis presages lower testosterone concentrations, higher LH pulse frequency, and greater disorderliness of LH secretion patterns, but not smaller LH pulses; (3) pure restriction of negative feedback projects normal or elevated testosterone concentrations with elevated LH pulse frequency, amplitude, and irregularity; and (4) combined reductions in GnRH outflow, LH-stimulated testosterone secretion, and negative feedback by testosterone predict all four of hypoandrogenemia, attenuated LH pulse amplitude, accelerated LH pulse frequency, and disorderly LH release. This tetrad is characteristic of older men. Table 2 summarizes these concepts.Accordingly, from an objective modeling perspective, no single regulatory defect can explicate the neuroendocrine phenotype observed in healthy older men.

Summary

Androgen deprivation adversely impacts libido and sexual potency, psychological well being, mood and (possibly) cognition, exercise tolerance, muscle mass, bone mineral density, intraabdominal adiposity, and lipid and carbohydrate metabolism. Clinical investigations in older men support triple impairment of hypothalamic GnRH secretion, pulsatile LH-stimulated testosterone synthesis, and testosterone-mediated negative feedback. Understanding the primary mechanistic bases of testosterone depletion in aging men should foster novel therapeutic strategies to maintain anabolism, enhance quality of life, and minimize physical frailty.

Neuroendocrine Control of Energy Balance (Central Circuits/Mechanisms)

R Coppari and J K Elmquist, University of Texas Southwestern Medical Center, Dallas, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Energy balance is maintained when energy intake equals energy expenditure over an extended period of time. This simple statement suggests that regulating body weight is straightforward. Unfortunately, the incidence of obesity is rising at an alarming rate. Fortunately, however, in approximately the past decade, there has been a dramatic increase in the understanding of the mechanisms that the brain uses to coordinate food intake and energy expenditure. Energy intake takes the form of feeding. Energy expenditure takes the form of physical activity, basal metabolism, and adaptive thermogenesis (i.e., energy dissipated as heat in response to changes in environmental temperature and diet). The brain, especially the hypothalamus and regions of the brain stem, serves as an integrator of sensory information and integrates these signals into coordinated responses to regulate energy balance.

Early studies (based on anatomically restricted brain lesions) performed in the 1940s and 1950s demonstrated that the hypothalamus is required for coordinated regulation of energy homeostasis. These studies revealed that bilateral destruction of the hypothalamus in a region centered on the medial and basal hypothalamus (including the ventromedial hypothalamic and arcuate nuclei) results in obesity, whereas bilateral destruction of the lateral hypothalamic area (LHA) causes loss of appetite and weight in rats. This early result has been largely validated by modern neuroanatomic, molecular, and genetic data, and today we have a rough map of the key brain regions required for coordinated control of energy balance. As outlined later, a key component of coordinated control of food intake and body weight is the ability of the hypothalamus to integrate a growing list of metabolic cues, including hormones, nutrients, and feedback from sensory neurons. The hypothalamus integrates all of this information and, in turn, provides neuronal outputs to key effector sites, including the anterior pituitary gland, the posterior pituitary gland, the cerebral cortex, premotor and motor neurons in the brain stem and spinal cord, and autonomic (parasympathetic and sympathetic) preganglionic neurons. The hypothalamic outputs to these effector sites ultimately result in coordinated endocrine, behavioral, and autonomic responses that maintain energy homeostasis.

Within the hypothalamus, several hypothalamic sites are thought to be key in regulating body weight. The first group is composed of neurons located in the medial hypothalamus, including the arcuate nucleus, ventral medial nucleus, dorsal medial nucleus, and paraventricular nucleus. In addition, the lateral hypothalamus (LHA and perifornical hypothalamus) is key in regulating food intake and body weight. The arcuate nucleus is a key hypothalamic nucleus involved in the control of energy balance. For example, the arcuate nucleus contributes to the actions of metabolic signals such as leptin, insulin, and ghrelin. Specifically, proopiomelanocortin (POMC) neurons within the arcuate nucleus are required for regulating body weight, food intake, and glucose homeostasis. POMC is a multifunctional pro-peptide that is differentially processed into key peptides in different tissues. In the brain, α-melanocyte-stimulating hormone (α-MSH) is an important product that regulates food intake and body weight. α-MSH is the agonist for the melanocortin-4 receptor (MC4-R), which is a key regulator of food intake and body weight. An endogenous MC4-R antagonist exists, agouti-related protein (AgRP), that is coexpressed with the orexigenic neuropeptide Y (NPY) in neurons in the arcuate nucleus of the hypothalamus.

Hypothalamic neurons also orchestrate the major neuroendocrine responses occurring upon starvation. The thyroid gland-secreted hormone thyroxine positively acts on basal metabolism. Reduced energy content leads to decreased secretion of thyrotrophin-releasing hormone (TRH) by neurons located in the paraventricular hypothalamic nucleus (PVH). These neurons release TRH into the pituitary portal circulation to stimulate thyroid-stimulating hormone (TSH) secretion by the pituitary gland. Since TSH is essential for normal production of thyroid hormones, its decrease causes reduced blood thyroxine levels and therefore low basal metabolism. The hypothalamic–pituitary–adrenal (HPA) axis is also positively influenced by starvation. The HPA axis consists of PVH neurons secreting corticotrophin-releasing hormone (CRH) directly into the pituitary portal circulation. CRH stimulates the secretion of ACTH by the pituitary.

Key Hormonal Signals

Leptin

Leptin (Greek root *leptos*, 'thin') is one of the most important peripheral signals for energy balance.

Leptin is secreted from adipocytes proportionally to the body fat content. Leptin was discovered in 1994 by Zhang and colleagues, who used a positional cloning approach to identify the mutation causing massive obesity and neuroendocrine abnormalities in *ob/ob* mice. Its receptor was cloned a year later by Tartaglia and colleagues, and five different splice variants have been identified. The mRNA for the signaling form of the leptin receptor (*Lepr-b*) is expressed by selected nuclear groups in the brain. Within the hypothalamus, abundant expression is observed in the arcuate (ARH), dorsomedial (DMH), ventromedial (VMH), and ventral premamillary nuclei. Also, moderate expression is found in PVH and LHA. Outside the hypothalamus, *Lepr-b* mRNA is found in thalamus, midbrain (e.g., in dopamine neurons), caudal brain stem, and cortex. A key concept regarding leptin physiology is that starvation leads to a rapid decrease in leptin levels, which has profound effects on several neuroendocrine systems including activation of the HPA axis, inhibition of the growth hormone and thyroid axes, and inhibition of reproductive function. Therefore, many physiological responses that occur when there is a lack of leptin are also found in a state of starvation. Notably, many of these starvation-induced endocrine and autonomic changes are blocked or blunted by pretreatment with systemic leptin. These observations support the model that leptin is a signal to the brain that energy stores are sufficient.

Soon after the discovery of leptin, it became clear that most of the varied effects of leptin are mediated by the brain. During the past few years, studies have begun to unravel some of the complex circuitry involved in leptin signaling. For example, electrophysiological and neuroanatomical studies have established the identity of some of the neurons that are directly activated (or inhibited) by leptin (i.e., first-order, leptin-sensitive neurons). In the ARH, two classes of neurons respond oppositely to leptin: The orexigenic (i.e., feeding-stimulating) neurons expressing *Agrp* (agouti-related peptide) and *Npy* (neuropeptide Y) are inhibited, whereas the anorexigenic (i.e., feeding-suppressing) neurons expressing *Pomc* (proopiomelanocortin) and *Cart* (cocaine and amphetamine-related transcript) are activated by leptin. In the VMH, neurons expressing steroidogenic factor-1 (SF1) are also activated by leptin. NPY/AGRP and CAR/POMC neurons belong to the melanocortin systems since both secrete neuropeptides that bind to the melanocortin receptors 3 and 4 (MC3Rs and MC4Rs), which are required for normal energy balance. AGRP is the antagonist, whereas the POMC-derived α-MSH is the agonist at these melanocortin receptors.

Studies have selectively deleted leptin receptors in specific neurons. This work has directly tested the physiological relevance of leptin signaling in selected first-order, leptin-sensitive neurons. These studies have demonstrated that mice lacking leptin signaling only in POMC in the arcuate nucleus and SF1 neurons in the VMH develop increased body fat mass. These results have established that ARH and VMH neurons are critical mediators of leptin's body weight-reducing effects. Nevertheless, the degree of obesity in these mice was much less than in mice completely lacking leptin signaling. Therefore, other neuronal populations are also involved in mediating leptin's effects on energy balance. These neurons are likely located in other hypothalamic sites and in neurons in the midbrain and the caudal brain stem. For example, midbrain dopamine neurons within the ventral tegmental area (VTA) are inhibited by leptin, and by perturbing leptin signaling in these VTA neurons, feeding is altered in rats. In addition, delivery of leptin to the dorsal vagal complex (located in the caudal brain stem) reduces food intake and body weight in rats (Table 1). In summary, it is likely that the body weight-reducing effects of leptin are distributed

Table 1 Peripheral signals and central neurotransmitters governing energy balance

Producing tissues	*Hormones*	*Receptors*	*Brain sites*
Hormonal systems with partially identified sites of action in the brain			
Fat	Leptin	LEPR-b	ARH, VMH, VTA, DVC

Intestine	PYY	NPY-Y2R	ARH
Hormonal systems with unidentified sites of action in the brain			
Intestine	GLP-1	GLP-1R	?
Intestine	Oxyntomodulin	GLP-1R	?
Stomach and intestine	Obestatin	GPR39	?
Neurotransmitter systems with partially identified sites of action in the brain			
Brain	Serotonin	5-HT2CR and 5-HT1BR	ARH, LPBN
Brain	Dopamine	D1-R and D2-R	CPu

ARH, arcuate nucleus; CPu, caudate putamen; DVC, dorsal vagal complex; LPBN, lateral parabrachial nucleus; VMH, ventromedial nucleus; VTA, ventral tegmental area.

across the brain and involve neurons within the mediobasal hypothalamus, midbrain, and caudal brain stem.

Insulin

Insulin (Latin root *insula*, 'island') was discovered in 1922 by Banting and Best when they first demonstrated its glucose-lowering effects. Insulin is secreted from β cells located in the pancreatic islets of Langerhans, and since its discovery, its role in glucose homeostasis has been established. In the 1970s, insulin's effects on energy balance by acting in the brain were first explored. In 1979, Woods and Porte suggested a role for insulin in the central regulation of energy balance. First, they found that insulin levels circulate in proportion to adipose tissue mass in most mammals. Second, they showed that intracereventricular (ICV) administration of insulin results in a dose-dependent reduction in food intake and body weight in baboons. Other studies have provided evidence for the presence of insulin receptors in the hypothalamus, including POMC neurons. In 2000, Brüning and colleagues assessed the physiological role of insulin signaling in central neurons by generating mice lacking insulin receptors only in the central nervous system (CNS). Their findings established that central insulin receptors are required for normal energy balance since mice with CNS-specific deletion of insulin receptors developed increased adiposity. In 2002, Rossetti's group obtained data supporting the idea that the mediobasal hypothalamus is a key brain area mediating insulin's antifeeding effects. By selective reduction of insulin receptors in the ARH, they caused hyperphagia and increased fat mass in rats. The intracellular molecular players that relay insulin signal into coordinated energy balance and the neuronal populations involved are still to be clarified. To identify these pathways, several experimental approaches designed to perturb insulin signaling in a neuron-specific manner in mice are under way.

Ghrelin

Ghrelin (Proto-Indo-European root of the word 'grow') is secreted by gastrointestinal endocrine cells, which are mainly located in the fundus of the stomach. Ghrelin was discovered in 1999 while searching for ligands of the growth hormone secretagogue receptors (GHSRs). This gut hormone is a ligand at ghrelin receptors and a potent stimulus for pituitary somatotrophs to release growth hormone. In addition to pituitary, ghrelin receptors are expressed in several brain areas, including ARH NPY/AGRP neurons, midbrain neurons within the VTA and substantia nigra nuclei, and in all three components of the dorsal vagal complex (area postrema, nucleus of the solitary tract, and the dorsal motor nucleus of the vagus). Ghrelin levels spike before meals and decrease within 1 h of food intake. This pattern led scientists to investigate the role of ghrelin in feeding behavior and to the finding that exogenous ghrelin administrations (either ICV or peripheral) stimulate feeding. The importance of ghrelin signaling in energy balance has been tested by means of gene deletion. Both the *ghrelin* gene and its receptor (*Ghsr)* gene have been studied in mice null for both genes. These studies support that ghrelin-related pathways are required for normal energy balance, especially when food is high in fat content. In accordance with ghrelin's feeding-stimulating effects, mice lacking either one of these genes eat less and are slimmer than wild-type controls. The sites in the brain that mediate the effects of ghrelin are still to be determined. Studies using gene knockout mouse models have provided evidence that ghrelin's feeding-stimulating effects are mediated by ARH NPY/AGRP neurons in the arcuate nucleus of the hypothalamus. Studies have also proposed a role for VTA neurons as important mediators of ghrelin's feeding effects. It is worth noting that, as for leptin, neurons within the mediobasal hypothalamus and the midbrain VTA are likely important mediators of ghrelin's actions on feeding.

Peptide YY

Peptide YY (PYY) is an anorectic hormone peptide secreted by endocrine L cells in the gut. Its release depends on caloric intake because PYY serum levels increase postprandially. When exogenously delivered, PYY(3-36) reduces food intake in mammals (from rodents to humans). The importance of PYY(3-36) as a negative regulator of energy balance has been established by the finding that *Pyy* null mice have increased food intake and body weight. Pharmacological and gene knockout studies have demonstrated that PYY(3-36) effects on food intake are mediated by NPY Y2 receptors (NPY2Rs). These receptors are expressed in several brain areas, including the presynaptic terminals of NPY/AGRP neurons in the arcuate nucleus. Electrophysiological studies have shown that PYY(3-36) inhibits the electrical activity of NPY/AGRP neurons. It is worth noting that some of these neurons have GABAergic terminals projecting to nearby POMC neurons. Therefore, PYY(3-36)'s inhibitory effects on NPY/AGRP neurons lead indirectly to the activation of adjacent POMC neurons and supposedly to reduced feeding.

Glucagon-like Peptide 1

Glucagon-like peptide 1 (GLP-1) is also secreted by endocrine L cells in the endocrine gut in response to nutrients (mainly free fatty acids (FFAs) and carbohydrates). GLP-1 is one of the peptide products of the prohormone proglucagon peptide that is

cleaved via tissue-specific posttranslational processing. The biologically active form of GLP-1 is the amino-terminally truncated GLP-1(7-36) amide. GLP-1(7-36) amide exerts an array of different physiological effects: It stimulates the release of insulin and inhibits the secretion of glucagon from the endocrine pancreas, and it inhibits gastric emptying and glucose disposal. The effects of GLP-1(7-36) amide on energy intake have been identified by studies from Bloom et al.'s laboratory. They showed that ICV administrations of GLP-1(7-36) amide markedly inhibit food intake in rats. Also in humans, peripheral administration of this peptide induces satiety. Nevertheless, the physiological importance of GLP-1(7-36) amide's effects on feeding have been questioned due to data indicating that GLP-1(7-36) amide causes conditional taste aversion in rats. It is interesting to note that GLP-1Rs are found in key hypothalamic nuclei controlling energy balance (e.g., the VMH, ARH, LHA, and DMH). Moreover, GLP-1Rs are also found in caudal brain stem centers (area postrema and nucleus tractus solitarius) important for the autonomic control of energy balance. Whether GLP-1(7-36) amide activates these centers to suppress feeding has yet to be established. Oxyntomodulin (OXM) is also a satiety peptide originated by the posttranslational cleavage of proglucagon in L cells of the gut. OXM has potent anorectic effects in both rodents and humans. These effects are thought to be mediated by activation of GLP-1R on ARH neurons. However, studies are needed to clarify the physiological effects of these two hormones and also to understand whether their action on energy balance is solely mediated by central neurons.

Given the rising rates of obesity and diabetes, there is intense interest in the development of new therapies that safely and effectively lower body weight and blood glucose in diabetic subjects. A new class of drugs called incretin mimetics have been approved for treatment of type II diabetes. One of these drugs mimics the effects of GLP-1, enhancing glucose-dependent insulin secretion, slowing gastric emptying, inhibiting gastric acid secretion, and reducing food intake. Possibly, this drug acts by modulating GLP-1-sensitive neurons in the CNS involved in the control of energy homeostasis.

Metabolic Signals

During the past few years, it has become established that in addition to key hormones, the hypothalamus also directly responds to the levels of several circulating metabolites (including FFAs and glucose) to serve as a reflection of the status of the body energy supplies. For example, the food intake-reducing effects of long-chain fatty acids are mediated by neurons in the mediobasal hypothalamus. In the cytoplasm of neurons (and perhaps glial cells), FFAs are rapidly esterified to fatty acyl-coenzyme A (fatty acyl-CoA) and then may undergo β-oxidation in the mitochondria. The entering of long-chain fatty acyl-CoAs into the mitochondria requires two mitochondrial proteins – carnitine-dependent long-chain acyltransferases 1 and 2 (CPT1 and CPT2). The observation that inhibition of hypothalamic CPT1 activity causes increased accumulation of long-chain fatty acyl-CoAs in the cytoplasm and marked inhibition of food intake has provided new insights into the molecular mechanisms of brain lipid sensing. The key neurons mediating this effect remain to be determined.

Blood glucose levels are also sensed by neurons within the CNS. More than 40 years ago, it was shown for the first time that changes in blood glucose levels affect the frequency of action potentials recorded from single hypothalamic neurons in living cats and dogs. It was found that the majority of neurons within the VMH are activated by an increase in extracellular glucose levels, whereas LHA neurons are mainly inhibited by it. The identification of single populations of glucose-activated and glucose-inhibited neurons has became more expedite only recently by means of electrophysiological studies on hypothalamic slice preparations obtained from transgenic mice expressing green fluorescent protein in a neuron-specific manner. Such studies revealed that POMC neurons in the arcuate nucleus are glucose activated. In contrast, LHA neurons expressing the feeding-stimulating peptide orexin are glucose inhibited neurons. The glucose-induced modulation of the activity of these neurons is in agreement with their physiological role in energy balance. It is also important to note that brain stem neurons are also critical in sensing changing levels of glucose, especially hypoglycemia.

Neurotransmitters

Serotonin

Serotonin (5-hydroxytryptamine (5-HT)) is a biogenic amine synthesized from the essential amino acid tryptophan and produced in cells present in peripheral tissues as well as in neurons in the brain. Central neurons producing this neurotransmitter (serotoninergic neurons) are located in the raphe nuclei of the brain stem and project to virtually all parts of the CNS (from cortex to spinal cord). Serotonin binds to several receptors, all of which are G-protein-coupled receptors except for the subtypes 3, which are ligand-gated ion channels receptors. The serotonin systems are essential for several brain functions, such

as attention, cognition, mood, perception, and sleep. Its involvement in appetite was first discovered in 1976 by Breisch and colleagues. They used a pharmacological approach to deplete the brain of serotonin and observed increased feeding and obesity in rats.

In the 1990s, gene targeting approaches aimed at disrupting the gene encoding for either the serotonin 2C receptors (5-HT_{2C}Rs) or serotonin 1B receptors (5-HT_{1B}Rs) revealed that these receptors are required for normal energy balance because mice lacking either one of these genes were found to have increased body weight. Thus, the serotonin systems, with their feeding-reducing effects, are crucial components of the central circuitries that coordinate feeding behavior. Which neurons are involved in mediating serotonin's hypophagic effects? There is evidence that neurons located in the brain stem and in the hypothalamus are important. In the hypothalamus, among many neuronal groups, POMC and NPY/AgRP neurons express serotonin receptors. Specifically, the anorexigenic POMC neurons express 5-HT_{2C}Rs, and NPY/AgRP neurons express the G_i-coupled 5-HT_{1B}Rs. Thus, serotonin can directly activate POMC neurons and directly inhibit NPY/AgRP neurons. In addition to direct action, serotonin exerts indirect stimulating effects on CART/POMC neurons. This is achieved by inhibition of NPY/AGRP neurons that have GABAergic terminals projecting to nearby POMC neurons. As noted previously, these two hypothalamic neuronal populations are known to have opposite effects on melanocortin receptor-expressing neurons. Thus, serotoninergic neurons control feeding behavior in part by engaging central circuitries with upstream hypothalamic melanocortin (NPY/AGRP and CART/POMC) neurons and downstream MC4Rs-expressing neurons. Since the serotonin systems are thought to be altered in some psychiatric disorders, such as depression and anorexia nervosa, it is plausible that the serotonin–melanocortin pathways may be the link between these pathological conditions and some of their associated complications (e.g., alteration of feeding and weight loss).

Dopamine

Dopamine (DA) is a neurotransmitter synthesized from the amino acid tyrosine. DA-secreting (dopaminergic) neurons reside in many brain areas, but the majority of them lie in midbrain nuclei such as the ventral tegmental area (VTA) and the substantia nigra pars compacta (SNc). DA binds to five different receptors (D1–D5R), some of which, when activated, elicit an increase in intracellular cyclic AMP (D1R and D5R). The dopamine system is essential for several mammalian behaviors, including coordinated movement, reward responses, and learning. Although pharmacological experiments provided support for a role of dopamine in feeding behavior, the critical studies were performed using the generation of mice deficient in dopamine. These mice developed locomotor deficits (bradykinesia) and severe hypophagia. The fact that mice lacking dopamine starve if not otherwise treated with exogenous L-DOPA supports the hypothesis that dopaminergic neurons are critical components of the central circuitries controlling energy balance. In agreement with dopamine's effects on energy balance, mice lacking D1R or D2R have reduced body weights. VTA and SNc dopaminergic neurons send inputs to many brain sites, including the caudate nucleus and the putamen in the telencephalon. Although the physiological relevance of these dopaminergic networks has been established for normal and coordinated ambulatory movements, studies performed by Palmiter's group indicate an additional role for the VTA + SNc innervations in the caudate putamen (CPu). They showed that restoration of dopamine signaling to the CPu (mainly from SNc neurons) is sufficient to restore normal feeding (as well as motor behavior) in mice otherwise deficient in DA. The identity of the key neurons within the dopamine systems involved in energy balance is unknown. However, as previously described, studies have brought to light a potentially important role for VTA DA neurons in responding to leptin and ghrelin to coordinate feeding behavior.

In summary, dopamine circuitries appear to be critical for controlling feeding behavior, and dysregulation of these circuitries may contribute to obesity and may also underlie the wasting syndrome characteristic of patients with Parkinson's disease.

Introduction

Maternal behavior emerges and wanes over the course of development in female mammals. In recent years, our understanding of the biochemical regulation of maternal care and the neural substrates involved in regulating the expression of maternal behavior has significantly increased. This article focuses primarily, but not exclusively, on research conducted in rodents, species that have provided a foundation for our understanding a complexity of processes associated with raising and nurturing young. The initial objective is to identify or define maternal behavior. The underlying physiological events that transpire during pregnancy and lactation are then presented in light of their roles in affecting maternal care. Next, the actions of the hormones of pregnancy on the neural substrates that regulate maternal responsiveness are discussed as well as the role of genetic and epigenetic factors and their interactions over the course of development. Finally, the effects of experience on the modification of parental care are explored. This article is not fully comprehensive; rather, it is designed to present a broad overview of the neuroendocrine and endocrine–neural regulation of maternal behavior.

Measurement of Maternal Behavior

The neurobiological capacity to respond in a maternal or parental-like manner is present throughout most of prepubertal and adult development in female mammals. The capacity to display enhanced maternal care, however, is most pronounced coincident with the birth of young and during lactation. Specifically, the onset of maternal behavior is associated with increased interest in the sensory modalities of the amniotic fluid and pup-related olfactory cues and an enhanced motivation to respond to the young.

What behaviors emerge at approximately the time of parturition that help promote maternal care and reproductive success? In the rat and other rodents, the new mother ingests amniotic fluid as well as engages in placentophagia. These behaviors are thought to both reduce the likelihood of predators finding the nest site by removing olfactory cues and provide possible hormonal sources from the amniotic fluid and placentas that appear to help promote lactogenesis and provide energy and fluid sources for the new mother (Table 1). During the postpartum period, mothers display a range of young-oriented as well as non-young-oriented responses that are unique to the lactational phase of care. Among these behaviors are retrieval to place the young into the nest site, pup licking to stimulate urination and to enhance sensory stimuli from the mother, and crouching over the young to permit suckling and modulate thermal loss and needs.

In addition to these young-oriented responses, the dam exhibits increased levels of nest building to provide a centralized location for the young; a heightened level of aggression toward intruders, a response that first emerges during late pregnancy and is maintained at high levels throughout much of lactation; increased feeding to generate food resources for the young (i.e., milk); and reductions in anxiety.

Developmental Aspects of Maternal Behavior

Maternal behavior is separated into an onset phase and a maintenance phase. The onset phase focuses on the initial expression of maternal care at parturition. In contrast, the maintenance phase consists of maternal care during lactation and care beyond the end of lactation. As noted previously, the neurobiological ability to display parental care is present independent of the reproductive states of pregnancy, parturition, and lactation. In female rats, maternal care is typically measured by the animal's latencies to display the more active components of pup-oriented care toward young (i.e., pup retrieval, grouping of the young, and crouching over the young). Interestingly, when exposed to 3- to 8-day-old foster pups, prepubertal females display a very rapid onset of maternal behavior as early as 20–24 days of age. As shown in Figure 1, this response latency increases from approximately 1 or 2 days at 24 days of age to approximately 5 or 6 days by 30 days of age. The latencies to respond maternally remain at this level unless a female becomes pregnant. The gravid female's response latency toward foster young decreases prior to parturition, indicating that the expectant mother is ready to exhibit spontaneous maternal care. Once maternal care is initiated, postpartum maternal behavior persists until weaning.

The ability of the parous female to display a rapid onset of maternal behavior, once established, persists well into adulthood. It has been shown that as little as 1 or 2 h of postpartum maternal experience is sufficient to establish a 'maternal memory.' That is, parturient mothers will remember or retain how to be a mother for more than 1 month following a brief

maternal postpartum experience. The maternal response latencies remain at approximately 1 day compared with a latency score of 5 or 6 days for a female that is cesarean delivered 1 day prior to expected parturition but not given any immediate pup contact and maternal experience following surgery.

In addition to pup-directed behaviors, most lactating mammals exhibit heightened levels of maternal aggression. Maternal aggression is a specialized form of aggression exhibited by females just prior to parturition and during lactation. This type of aggression is remarkable in that females are often able to display high levels of both maternal aggression and parental care in the same period. In mice and voles, maternal aggression is actually inversely correlated with attacks on their own young. Maternal aggression may increase the fitness of the female by increasing the probability of offspring survival. The vast majority of studies investigating various aspects of maternal aggression have used rodent models, in which aggression is most robust during the first postpartum week, followed by a decline in intensity as lactation progresses. The behavior consists of frontal attacks, lateral attacks, jump attacks, rearing, biting, arching of the back, piloerection, and upright boxing. Olfaction is an important component in the expression of maternal behavior in rats, mice, and hamsters. Whereas intruder vocalizations and sensory stimulation of the nipples are important stimuli in mice, maternal aggression in rats is more dependent on olfaction and hormonal priming by estrogen and progesterone. Nevertheless, although slight differences exist in the expression of maternal behavior across rodent species, the general behavioral ethogram is similar for most species.

Table 1 Maternal Behaviors

Parturitional responses
Consumption of amniotic fluid
Placentophagia
Young-directed responses
Retrieval
Licking and grooming
Crouching/nursing
Nest building
Young-related responses
Protection of the young – maternal aggression
Increased food consumption
Reduced anxiety

The responses displayed by mothers include a set of parturitional behaviors together with responses directed toward the young. An additional set of related responses are present during lactation that further support the development and protection of the offspring.

Hormonal Regulation of Maternal Behavior

The endocrine events accompanying pregnancy, in addition to maintaining a healthy environment for fetal growth and development and preparing the mother to meet the nutritional needs of her offspring, also play an important role in altering the affective state of the female during pregnancy and postpartum. In studies of rats, critical roles for both steroid and protein hormones have been demonstrated, especially during the initial pregnancy. These hormones appear to act synergistically to prepare the newly parturient dam to be fully maternal at the time of birth.

Steroid Hormones

Estradiol Estradiol (E_2) which is synthesized by the ovaries and conceptus during pregnancy has an

Figure 1 A developmental profile of maternal responsiveness in female rats. Points represent the median latencies in days for a female to respond maternally to pups – that is, retrieve, group, and crouch over the young during a 1 h daily test session. Reproduced from Bridges RS (1990) Endocrine regulation of parental behavior in rodents. In: Krasnegor NA and Bridges RS (eds.) *Mammalian Parenting: Biochemical, Neurobiological, and Behavioral Determinants*, pp. 93–117. New York: Oxford University Press, with permission.

important role in stimulating the onset of maternal behavior in rodents as well as sheep. The pattern of increasing blood levels of E_2 during pregnancy is shown in Figure 2. In addition to its own action as a behavioral inducer, E_2 acts permissively to allow other hormones and neurotransmitters to exert stimulatory actions on maternal care. That is, progesterone (P), prolactin (PRL), as well as oxytocin (OT) all require the presence of E_2 for their actions. Studies using a rat model have further established that E_2 acts centrally at the level of the medial preoptic area (MPOA) to stimulate a rapid onset of maternal behavior. Other studies have found that E_2's actions are mediated through the alpha subtype of the estrogen receptor (ER), since mice with deletions of this receptor display deficits in maternal care.

Progesterone – 'Priming and timing' P, the progestational hormone, is synthesized in large amounts during the course of pregnancy in most mammals (Figure 2). In the pregnant rat, the corpora lutea in the ovaries are the primary source of P, whereas in primates the placenta is the major site of P production. P has two distinct roles in the induction of maternal behavior. First, the prolonged exposure to P over the course of pregnancy primes the maternal brain to respond intensively to a host of stimulatory signals at approximately the time of parturition. In addition to this 'priming action,' P exerts an inhibitory action on the expression of the rapid onset of maternal behavior. The prepartum decline in P prior to parturition serves as a 'timing signal' that coordinates the stimulation of a range of physiological and neurobiological processes. These processes include stimulation of uterine contractions, enhanced sensitivity to the actions of OT on parturition, stimulation of lactogenesis, and stimulation of maternal care. The behavioral and physiological actions of P apparently

Figure 2 Hormone profiles of estradiol, progesterone, prolactin, and rat placental lactogens during pregnancy in the rat. Adapted from Bridges RS (1990) Endocrine regulation of parental behavior in rodents. In: Krasnegor NA and Bridges RS (eds.) *Mammalian Parenting: Biochemical, Neurobiological, and Behavioral Determinants*, pp. 93–117. New York: Oxford University Press, with permission.

are mediated through the progesterone receptor (PR) since treatment of rats with the PR antagonist RU-486 stimulates a more rapid onset of maternal behavior after pregnancy termination. It has been reported that aggression toward pups is reduced and caregiving behaviors are increased in male mice in which the PR is knocked out. Thus, deactivation or inactivation of the P system helps to facilitate parental care. It is of interest that in humans P levels do not decline until after delivery of the placenta. However, expression of the PR in the uterus declines prepartum, suggesting that in women a functional P withdrawal occurs in the uterus and perhaps in the brain at this time.

Protein Hormones

Prolactin/placental lactogens The lactogenic hormones, PRL and placental lactogens (PLs), are secreted in copious amounts during the course of pregnancy and lactation (Figure 2). Both PRL and PLs bind to PRL receptors (PRL-Rs) located within the choroid plexus and brain. Treatment of inexperienced, virgin rats with a combination of PRL, E_2, and P can stimulate a rapid onset of maternal behavior, reducing latencies from 5 or 6 days to 1 or 2 days. Blocking secretion of PRL in hormonally primed virgin rats prevents the rapid onset of maternal care, an effect that is reversed by concurrent treatment with PRL. The actions of PRL as well as PLs in priming the brain to respond maternally at parturition appear to occur during the course of pregnancy and not just at parturition. Within a physiological setting, therefore, prolonged exposure to the hormonal milieu of gestation alters the neural processes that account for the subsequent rapid onset of maternal care. It is of interest that in both pregnant rats and women, PLs gain access to the cerebrospinal fluid and bathe the gestating brain in hormonal signals that communicate that the female is pregnant. Evidence in support of a role for the PRL-R in mediating the behavioral actions of PRL is provided by studies of steroid-primed virgin rats in which infusions of the PRL-R antagonist, S179-D PRL, into the brain delay the rapid onset of maternal behavior. Likewise, mice with null mutations of the PRL-R respond slower to foster pups than do wild-type subjects.

Neural Basis of Maternal Behavior

Neural Network of Maternal Behavior

The research of neuroscientists Michael Numan and Alison Fleming has provided a solid foundation on which our understanding of the neural regulation of maternal behavior is based. Numan's early finding that the integrity of the MPOA was crucial for the expression of ongoing maternal care in rats provided an important foundation on which to establish a maternal neural network. Overall, the MPOA appears to be a convergence point that processes information from sensory and motivational systems and translates this information into downstream motor output. Fleming's work, which first established a key role for olfactory input, has gone on to identify neural sites, such as the nucleus accumbens (NAcc), which can affect motivation, as well as cortical inputs from the prefrontal cortex that influence maternal affect. A schematic representation of a neural network involved in the regulation of young-oriented maternal behavior is depicted in Figure 3.

Although a complete characterization of the neural connections and actions is beyond the scope of this article, it is important to recognize that the olfactory system plays a valued role in regulating maternal care in

Figure 3 Schematic of key neural regions and connections that constitute the maternal neural network in the rat. Blue arrows represent stimulatory inputs, whereas red connections represent inhibitory inputs AH, anterior hypothalamus; AOB, accessory olfactory bulb; BNST, bed nucleus of the stria terminalis; MeA, medial amygdala; MPOA, medial preoptic area; NA, nucleus accumbens; OB, olfactory bulb; PAG, periaqueductal gray; VMH, ventromedial hypothalamus; VP, ventral pallidum; VTA, ventral tegmental area.. Adapted from Numan M (2006) Hypothalamic neural circuits regulating maternal responsiveness toward infants. *Behavioral and Cognitive Neuroscience Reviews* 5: 163–190, with permission.

numerous species. During adult development in the inexperienced rat, this system exerts a primary inhibitory role on the expression of maternal care. Lesions of the olfactory bulb and tract as well as its principal projection site (i.e., amygdala) actually stimulate maternal care. The projections from the amygdala terminate in various hypothalamic nuclei, including the MPOA and anterior hypothalamus, with the latter region also being inhibitory to maternal behavior. It has been proposed that naive females find the smell of young aversive and must overcome this aversion in order to exhibit maternal care. In support of this concept are the findings that rats find the smell of young more attractive during late pregnancy and ewes are attracted to the odors of amniotic fluid soon before birth.

Whereas the amygdala may influence MPOA function, the output from the MPOA to lower brain centers involves downstream projections to the ventral tegmental area (VTA). The VTA in turn projects to the NAcc, a structure that reflects the motivation state of the female to engage in maternal care during the postpartum period and lactation. Lesions of the shell region of the NAcc prior to parturition disrupt the establishment of maternal care and maternal memory. Other research in prairie voles suggests that this region mediates OT-related pair bonding. Finally, the NAcc inhibits activity of the ventral pallidum, resulting in enhanced behavioral reactivity to pups.

Neural Underpinnings of Maternal Aggression

Compared to the wealth of knowledge on the neuroanatomy of parental behavior, the neuroanatomy of maternal aggression is less well understood. Studies indicate that there are numerous areas of overlap in the neural regulation of parental care and aggression. Brain regions that increase in activity in response to maternal aggression include the bed nucleus of the stria terminalis (BNST), MPOA, paraventricular nucleus (PVN), amygdala, septum, peripedunacular nucleus (PPN), and periaqueductal gray (PAG).

Ventral sensory inputs associated with suckling appear critical for the display of maternal aggression. One key neural region involved in the transmission and processing of this sensory information is the PPN, which transmits sensory information to the midbrain, hypothalamus, and several limbic structures. Lesions of the PPN decrease maternal aggression.

The PVN is another key neural component in the control of maternal aggression. PVN lesions may increase or decrease aggression in lactating dams, depending on the stage of lactation in which lesioning is performed. PVN lesions early postpartum increase maternal aggression, whereas late postpartum lesions decrease aggression. The effects of early lesions may be due to a decrease in OT neurons since the disruption of OT signaling in the PVN can increase some components of maternal aggression. In the PAG, both pre- and postpartum lesions reduce attack latency and increase the number of attacks, indicating a substantial inhibition of maternal aggression by this nucleus in intact animals.

Finally, increases in cell activity are seen in the MPOA in response to maternal aggression, and inhibition of nitric oxide (NO) synthase suppresses aggression and reduces MPOA c-Fos expression in this region, suggesting that the MPOA is part of the neural circuitry controlling both pup-related maternal behavior and maternal aggression.

Hormone–Brain Interactions

Studies have localized neural sites of action for estrogen, PRL, and OT in the regulation of maternal behavior. The central site(s) of P action in regulating the priming and timing actions on maternal care has not been demonstrated, although hypothalamic areas are likely involved. One common key central site of E_2 and PRL action is the MPOA. Using a pregnancy termination model, it was first demonstrated that local application of estrogen to the MPOA stimulated a more rapid onset of maternal care in first-time pregnant rats than in control animals. A more detailed study of PRL's action showed that central infusions of PRL into either the lateral ventricle or bilaterally into the MPOA stimulate a rapid onset of maternal care in steroid-primed, virgin rats (Figure 4). PRL

Figure 4 Stimulation of maternal behavior after bilateral infusions of ovine (o) PRL (40 ng/side) into the MPOA region of steroid-primed nulliparous rats. $^*p < 0.01$ versus vehicle controls. Reproduced from Bridges RS, Numan M, Ronsheim PM, Mann PE, and Lupini CE (1990) Central prolactin infusions stimulate maternal behavior in steroid-treated, nulliparous female rats. *Proceedings of the National Academy of Sciences of the United States of America* 87(20): 8003–8007, with permission.

infusions were ineffective in the absence of steroid priming. Infusions of PRL into the ventromedial hypothalamus (VMH) were also suggestive of a similar stimulatory role for PRL in this region. It is noteworthy that MPOA has numerous PRL and E_2 receptors which can bind their respective ligands. A related study in mice examined the role of STAT5B in maternal behavior. STAT5B is a component of a key transduction pathway that mediates PRL's actions after PRL binds to its receptor. In STAT5B knockout animals, maternal behavior was unaffected. Thus, the STAT5B pathway's integrity appears not to be essential for normal maternal care. Further studies are needed to investigate the pathways through which PRL and E_2 stimulate maternal care.

In addition to PRL's ability to stimulate maternal behavior in inexperienced rats, related research has demonstrated that rat PL-I and rat PL-II gain access to the cerebrospinal fluid during pregnancy and thus may play an important physiological role in priming the maternal brain to respond maternally. Central infusions of these PLs into the MPOA, like PRL, stimulate the onset of maternal care, presumably through their action on PRL receptors.

One intriguing possibility that merits study is whether the increase in neurogenesis during gestation in rodents that is reported under PRL and perhaps PL regulation may alter the mother's responsiveness to her young. New neurons produced within the subventricular zone migrate along the rostral migratory stream and become integrated into the olfactory bulb. Certainly, given the key role for olfaction in maternal care in numerous mammals, an involvement of these new neurons in olfactory recognition of young is possible.

In addition to pituitary PRL's role in stimulating maternal behavior, a role for centrally derived PRL in maternal care is also possible. The expression of neural PRL in the hypothalamus of lactating rats increases in response to both stress and suckling in the hypothalamus of lactating rats (Figure 5), in which neural PRL may act locally to reduce anxiety and affect other behaviors. The possible role of brain-derived PRL in maternal care merits further study. It is conceivable that once maternal care is induced via an endocrine mechanism at parturition, the central sensitivity to neural-derived PRL is sufficient to maintain maternal care.

An important role for the neuropeptide OT in maternal behavior in rodents and sheep and in affiliative behavior in voles has been well documented. Specifically, when OT is infused into either the ventricular system or the MPOA of E_2-primed, inexperienced rats, a rapid onset of maternal behavior occurs. In sheep, during the periparturitional period vaginal distension and stimulation induces a central release of OT which contributes to the ewe's acceptance of her newborn lamb. OT can also act within the NAcc to promote maternal-like behavior in juvenile rats and to stimulate pair bond formation in prairie voles. Thus, OT can be conceived of as a more general promoter of affiliative responses. The neurobehavioral relationships between PRL and OT have not been firmly established. It is of interest, however, that PRL receptors are located on OT neurons in the PVN. Therefore, it seems tenable that these two crucial lactational hormones may also act in concert to stimulate given aspects of maternal behavior.

Neurotransmitter Systems

Pup-Directed Maternal Behavior

Roles for the more classic brain dopaminergic, noradrenergic, and opioidergic systems have been

Figure 5 Effects of a 30 min immobilization stress and suckling on prolactin mRNA in the rat hypothalamus. Determination of fold induction of PRL mRNA is expressed as a ratio with mean ± SEM. $^*p < 0.05$ and $^{**}p < 0.01$ versus the control group. Reproduced from Torner L, Maloumby R, Nava G, Aranda J, Clapp C, and Nuemann ID (2004) *In vivo* release and gene upregulation of brain prolactin response to physiological stimuli. *European Journal of Neuroscience* 19: 1601–1608, with permission.

identified in the expression of maternal care in mammals. The dopaminergic system's involvement includes both motoric and motivational elements. Activation of the nigrostriatal dopaminergic system produces increases in pup retrieval and activity levels. The striatal dopaminergic system, through the actions of dopamine on the D2 receptors, also modulates maternal motivation and the establishment of maternal memory. The involvement of the noradrenergic system is somewhat less defined and equivocal. Perhaps the most convincing support for a role for norepinephrine (NE) is its role in olfactory-mediated maternal care in ewes. Stimulation of the birth canal during parturition results in the release of NE within the olfactory bulbs, and pharmacological blockade of NE at this time interferes with the establishment of maternal behavior in ewes. Whereas surgically induced depletions of hypothalamic NE only modestly affect the onset of maternal care at birth in rats, some studies have indicated a role for the ascending noradrenergic systems in the onset of maternal behavior. It is possible that increased activity of the noradrenergic system at the time of parturition facilitates a more general increase in attention and arousal which enables the new mother to respond to the sensory stimuli provided by the offspring.

Research also indicates that the endogenous opioid system may modulate maternal responsiveness. In rats, infusions of opiates that bind to the mu opiate receptor block ongoing maternal behavior when infused into the MPOA but not the VMH. Since suckling is a strong stimulus for inducing opiate release within the brain, it has been suggested that endogenous opiates, such as beta endorphin, may function physiologically to modulate nursing bouts in lactating rats by quieting the female once suckling has begun. Termination of the suckling bout may be produced by the increase in body temperature that accompanies endogenous opiate release and activity. Opioid peptides may also affect maternal behavior through their ability to alter brain dopamine activity. For example, beta endorphin can suppress dopamine function and perhaps in that manner reduce either maternal motivation or motor function.

Another neurotransmitter, NO, likewise has been implicated in regulating ongoing maternal care in rodents. Intracerebroventricular infusions of an NO synthase inhibitor (L-NAME) into rats eliminated pup retrieval during early lactation as well as decreased milk ejections. Possible sites of NO action include the MPOA and amygdala. Further studies are warranted to investigate the relationships between the endocrine events of pregnancy and lactation and NO activity in light of these behavioral findings.

Maternal Aggression

Neurotransmitters implicated in the expression of maternal aggression include serotonin, GABA, dopamine, OT, arginine vasopressin (AVP), corticotrophin-releasing hormone (CRH), NO, and opioids. In a correlational study of humans, central serotonin was inversely correlated with male aggression but not maternal aggression. A similar result is seen in biparental prairie voles, in which selective serotonin reuptake inhibitors decrease male aggression but have no effect on maternal aggression. However, work in pigs has recorded decreased serotonin activity in the medial amygdala and lateral septum in aggressive female pigs.

GABA receptor antagonists injected into the VMH or medial amygdala decrease the number of female attacks, and benzodiazepine agonists increase maternal aggression at low doses. In mice, benzodiazepine agonists increase aggression toward males but decrease maternal aggression toward females in aggressive dams. Evidence of the role of dopamine in maternal aggression is inconclusive. Whereas decreasing catecholaminergic activity by global or directed lesioning increases rat maternal aggression, treatment with haloperidol, a D1/D2 receptor antagonist, actually decreases mouse maternal aggression. It is possible that the actions of haloperidol in mice may be due to nonspecific effects on locomotion.

Maternal aggression increases in rats after infusion of OT into the central nucleus of the amygdala. Lesion studies, on the other hand, have not found effects of neural lesions of OT nuclei on this behavior. It has been proposed that OT may mediate a dam's ability to identify intruders through its established role in social recognition. OT cells in the PVN and supraoptic nucleus are activated during maternal aggression, and OT concentrations increase in the central amygdala of 'high-anxiety' rats during resident intruder challenges. When OT activity is blocked in these high-anxiety dams with antagonist injections into the PVN or central amygdala, maternal aggression decreases. Conversely, exogenous OT infusions into the PVN increase maternal aggression.

Studies suggest that AVP may also modulate maternal aggression. Cellular activity in the PVN and SON of lactating rats increases in association with maternal aggression, as reflected by increased double-labeling for c-Fos and AVP. Likewise, AVP receptor expressing cells in the central amygdala and BNST have increased c-Fos activity. Moreover, in lactating rats bred for high levels of anxiety, both OT and AVP release increases in the central amygdala during resident–intruder challenge, and exogenous AVP injected into the central amygdala increases aggression.

NO also appears to modulate the display of maternal aggression. Treatment with the NO synthase antagonist L-NAME suppresses maternal aggression. Neuroanatomical studies have found that female mice and prairie voles increase citralline levels, a by-product of NO synthesis, in several brain nuclei in response to the display of aggressive behavior. Additional work in prairie voles indicates that the blockade of NO synthesis depresses maternal aggression. It is possible that the effects of NO on maternal aggression are related to its ability to modulate CRH release. Studies using central CRH injections show a decrease in maternal aggression in response to the peptide, and since NO and CRH may be negatively correlated, this mechanism is feasible. When NO increases, there may be a corresponding decrease in CRH that potentiates increased expression of aggression.

Genes and Motherhood

Null Mutations

With the development of techniques in genetics and molecular biology, a number of studies have identified roles for specific genes in maternal responsiveness. One of the earlier studies reported that knocking out the immediate early oncogene, Fos-B, resulted in severe parenting deficits in mice. Similar deficits in maternal care in mice were reported after null mutations of the long form of the PRL-R but not after deletion of the PRL gene. A careful reexamination of these findings is warranted. Likewise, mice in which the OT gene was deleted, while failing to lactate, did not display deficits in maternal care. In contrast, in a related study, deletion of the CD38 gene, which is a transmembrane glycoprotein that regulates OT release within the brain, resulted in notable deficits in both maternal and social behaviors. A similar deficit in pup retrieval was present in mice when the gene dopamine β-hydroxylase, the rate-limiting enzyme controlling NE and epinephrine synthesis, was deleted.

Overall, it is worth noting that interpretation of the behavioral consequences of gene deletions should be made with caution since prolonged developmental absence of a ligand or receptor may result in physiological compensation or emphasis on redundant systems. Moreover, the behavioral specificity of such deletions needs to be established to ensure that the deletions do not result in more global biochemical modifications that can indirectly affect behavior.

Parent of Origin Effects

The genetic materials inherited from a mother and father can be differentially expressed in the offspring. In some instances, select genes inherited from the father, but not the mother, are expressed. This can result in differences in maternal responsiveness. One example of this is provided by studies of Peg 1, Peg 3, and Mest knockout mice that display deficits in maternal care. The behavioral responses of the female offspring can differ based solely on the paternal gene that they receive since genes inherited from the father are expressed by the daughter offspring, whereas the maternal alleles are methylated and thus inactive. This phenomenon, referred to as imprinting, can account for variation in parental care based on the paternal allele. Other studies have shown that maternal behavior can be affected by the maternal genotype. When mice are reciprocally crossbred, the maternal care of the offspring is often similar to the genetic background of the maternal phenotype, supporting the idea that the maternal genotype can itself impact the maternal care of its offspring.

Epigenetic Transmission of Maternal Behavior

In addition to the genetic transmission of behavior, the behavioral experience of the subject can be transferred partially through modifications of genetic material passed on to her offspring. Provocative studies by Meaney and colleagues have demonstrated that higher levels of crouching and pup licking–grooming (LG) behaviors in lactating rats are associated with increased expression of ER-α in the MPOA. Furthermore, these behavioral traits are transmitted across generations (Figure 6). The differences in LG behaviors of the females appear to be associated with differences in the methylation of the ER-α1b promoter within the MPOA, such that in low LG mothers the available ER-α in the MPOA is reduced (due to increased DNA methylation of the promoter) and hence lower levels of maternal responsiveness result. What perhaps is most intriguing is that environmentally induced changes in methylation patterns appear to be passed on from one generation to the next in almost a Lamarckian fashion.

Experimental Modifications of Maternal Behavior

Maternal Memory

At the time of parturition, the female rat forms a behavioral memory that is reflected by shortened latencies to respond to foster young weeks following delivery and a brief period of parenting. This memory formation is thought to be associated with increased gene expression and new protein synthesis since treatment with protein synthesis inhibitors such as actinomycin D can interfere with the formation of this

Figure 6 Effects of maternal care of young on their subsequent expression of ERα mRNA in the MPOA as adults. Females cross fostered from a high or low licking–grooming (LG) mother to a low LG mother had equivalent levels of ERα mRNA and had less ER expression in the MPOA than females cross-fostered from a high or low LG to a high LG mother. The original mother is designated on the left and the cross-fostered mother on the right of hyphenated terms (i.e., low-low). Adapted from Champagne FA, Weaver ICG, Diorio J, Dymov S, Szyf M, and Meaney MJ (2006) Maternal care associated with methylation of the estrogen receptor-α1b promoter and estrogen-receptor-α expression in the medial preoptic area of female offspring. *Endocrinology* 147: 2909–2915, with permission.

memory. Maternal memory is also promoted by treatment of a pregnancy hormone regimen consisting of E_2 and P, suggesting that the endocrine changes associated with pregnancy prime the maternal brain to enhance maternal memory at parturition. One key neural region that has been implicated in regulating the formation of maternal memory is the shell region of the NAcc. Lesions of this region prior to parturition prevent the normal formation of maternal memory. Moreover, increased dopaminergic activity within this region appears to participate in this process. Dopamine acts through D2 receptors to mediate this process since treatment with the D2-like antagonist clebopride, but not a D1 antagonist, delayed the reestablishment of maternal behavior 1 week postpartum. The possible involvement of other neurotransmitters, neuropeptides, and hormones in this process remains to be determined. However, it appears that central sensitivities may shift on a long-term basis as a function of behavioral and reproductive experiences, which likely impacts the female's subsequent maternal care and memory.

Reproductive Experience and Maternal Behavior

Studies have established that giving birth and raising young can produce profound long-term changes in neuroendocrine function, hormone secretion, and behavior. Specifically, prior parity in rats as well as women results in reductions in PRL secretion and an increase in central dopaminergic tone. It has further been shown that parity results in a long-term increase in expression of the long form of the PRL receptor within both the MPOA and the arcuate nucleus and

Figure 7 Schematic representation of the effects of reproductive experience on the relative control of maternal behavior by the neural–endocrine and endocrine systems. With increasing reproductive experience, the reliance of the female on endocrine signals declines, whereas the involvement of the neural–endocrine system (i.e., neural prolactin) increases.

an increase in the ability of PRL to activate the PRL-R transduction pathway as measured by increased SOCS-1 and SOCS-3 expression in the MPOA. It thus appears that the neural–endocrine axis within the MPOA undergoes an extended, if not permanent, shift as a function of reproductive experience, shifting from an endocrine to a neural–endocrine basis of control (Figure 7). What does this mean in terms of the neuroendocrine regulation of maternal behavior? It may mean that key hormone-sensitive behavioral centers, such as the MPOA, become more responsive to PRL stimulation of maternal behavior in experienced mothers. If this is true, then the rapid reactivation of maternal behavior in animals displaying

maternal memory may reflect this altered and enhanced central sensitivity to biochemical signals that trigger maternal care.

Finally, the fact that experienced animals display a shift from an endocrine trigger to a neural endocrine trigger, perhaps of neural origin, may shed light on the regulation of maternal care in species that do not rely as heavily on endocrine triggers to stimulate maternal care. For example, women may in fact rely on similar neural–endocrine signals which may mediate aspects of their affective responses, and perhaps when they go amiss, postpartum mood disorders emerge.

Introduction

The human and mouse genome are predicted to encode approximately 30 000 gene products. The estimated number of primary protein products, however, is 10–30 times higher, mainly due to alternative splicing and posttranslational modifications. The latter can lead to both reversible (e.g., phosphorylation and sulfation) and irreversible (e.g., N-glycosylation, proteolytic cleavage, C-terminal amidation, and N-terminal acetylation) modifications of proteins (Figure 1). Some of the major irreversible posttranslational modifications are afforded by proteases, which either cleave within proteins and peptides, resulting in two or more products, or trim them from the N-terminus (aminopeptidases) or C-terminus (carboxypeptidases), leading to the generation or loss of functional activity. Proteases comprise approximately 1.7% of the predicted proteins of the human genome. Thus, it is estimated that the approximately 500–600 mammalian proteases expressed as active enzymes belong to one of the five classes of eukaryotic proteases, which are classified based on the required nucleophile and on the identity of the catalytic subunit between each family members (Figure 2). Proteases are either of a digestive nature, resulting in protein degradation via multiple cleavages of the protein substrate, or they participate in the limited proteolysis of precursor proteins (proproteins) to generate diversity within the proteome by increasing the number of polypeptide products that can be generated from a single proprotein. The cleavage process can take place either intracellularly at the cell surface or in the extracellular milieu. Within the cell, processing can occur in various subcellular locations and organelles, including the cytosol, nucleus, mitochodria, endoplasmic reticulum (ER), various lamellae of the Golgi apparatus, and within secretory granules, endosomes, and lysosomes. This article focuses on the cleavage of proteins within the so-called secretory pathway. This includes the processing of proteins that enter the ER (via a signal peptide or stop transfer hydrophobic sequences) and that either remain there or are transported to the Golgi apparatus and beyond, including the cell surface, dense core secretory granules, recycling endosomes, and lysosomes. Within the secretory pathway, there exists at least two routes for cell surface secretion – a rapid (minutes) default constitutive secretion from small vesicles fusing with the plasma membrane and a slower (minutes to hours) regulated one allowing the stimulated secretion of dense core secretory granule contents. This article focuses on the role of specific proteolytic enzymes within both pathways.

The Proprotein Convertase Gene Family

The mammalian proprotein convertases (PCs) represent a family of secretory serine proteinases distinct from the trypsin/chymotrypsin subfamily and much more closely related to bacterial subtilisin. Across the phylae, six different subtilase clans can be distinguished, but the nine members of the secretory mammalian PC family belong to only three of these (Figure 2). The seven mammalian convertases related to yeast kexin (Figures 2 and 3) cleave after basic amino acids (basic aa-specific PCs) and are known as PC1/3, PC2, Furin, PC4, PC5/6, PACE4, and PC7. These enzymes cleave after single or paired basic residues predominantly within the motif (Arg/Lys)-X_n-Arg↓, where $n = 0$, 2, 4, or 6, which are variable amino acids separating the two canonical basic residues required for cleavage recognition (Figure 2). The other two convertases (SKI-1/S1P and PCSK9) (Figures 2 and 3) cleave at nonbasic residues within the motifs R-X-(hydrophobic)-Z↓ and (V/I/L) FAQ↓, respectively (Figure 2). All these convertases are initially synthesized as inactive zymogens (proPCs) in the ER. Upon folding, most of these (except for PC2) undergo an initial autocatalytic processing in the ER at an N-terminal site in their prosegment, resulting in a tight binding complex of the inhibitory N-terminal prosegment noncovalently associated with the main protease (Figure 4). Usually, a second autocatalytic zymogen activation event is needed to liberate the protease from its prosegment, thus specifying the location within the cell where the protease can then cut substrates in *trans*. This zymogen activation step can occur in at least five different subcellular organelles: in the *cis*/medial-Golgi (SKI-1); in the early *trans*-Golgi network (TGN), as is the case for PC5/6B; in the last lamella of the TGN that is insensitive to brefeldin A (BFA), as is the case for Furin and PC7; at the cell surface, as seems to be the case for PC5/6A and PACE4; or in dense core secretory granules (PC1/3 and PC2) (Figures 4 and 5).

Analysis of the subcellular distribution of the convertases allowed their classification into at least five distinct groups (Figure 5): First, the membrane-bound convertase SKI-1 is mostly localized in the *cis*/medial-Golgi and is autocatalytically shed, resulting in the secretion of a soluble form of the proteinase.

Figure 1 Posttranslational modifications of secretory proteins. On the left is shown part of a hypothetical secretory protein posttranslationally modified by phosphorylation at either a Ser (S) or a Thr, sulfation at Tyr (Y), and N-acetylated at an Asp acid (D) residue. Cleavage of this protein at the Arg–Arg (RR) pair of basic amino acids by one of the basic aa convertases (represented schematically by a pair of scissors) exposes a C-terminal Arg residue, which is then trimmed by a basic aa-specific carboxypeptidase such as CPE (others include CPD and CPX). This exposes a C-terminal Gly (G) residue that is a substrate for the amidation enzyme PAM, which then amidates the penultimate Glu (E) residue.

Figure 2 Classification of proteases with emphasis on the secretory PCs. The five classes of proteases are represented on the left, with the nucleophile used with each enzyme class. The emphasis is on serine proteases of the subtilisin type, of which six subfamilies within the clan SB can be identified. The basic amino acid PCs are related to yeast kexin, whereas the convertases SKI-1/S1P and PCSK9 are related to pyrolysin and proteinase K, respectively. The three different motifs generally recognized by the seven basic aa-specific convertases, SKI-1/S1P and PCSK9, are also shown, with the downward arrow indicating the cleavage site. X, any amino acid; Z, any amino acid except Glu. Asp, Val, Pro, and Cys.

The second group includes the membrane-bound convertases Furin, the isoform PC5/6-B, and PC7, which cycle from the cell surface to the TGN through the endosomal pathway. Their subcellular trafficking is regulated by signals in their cytosolic tail. These membrane-bound convertases process most precursors in the Golgi (including the TGN), cell surface, or endosomes. The membrane-bound convertases Furin and PC5/6B (but not PC7) are shed into soluble secreted enzymes. Shedding/cleavage of Furin and PC5/6B is performed by membrane-bound metalloproteases, including ADAMs. Third, the secretory convertases PC5/6A and PACE4 contain a specific Cys-rich domain (Figure 3) that binds to the C-terminal segment of tissue inhibitors of metalloproteases (TIMPs). This complex is retained at the cell surface by heparin sulfate proteoglycans (HSPGs), possibly a site where processing of specific HSPG-bound precursors takes place. Fourth, the regulated convertases PC1/3 and PC2, and sometimes PC5/6A, are sorted to dense core secretory granules and process most polypeptide hormones, which are then secreted following specific

Figure 3 Schematic representation of the primary structure and domains of the PCs. The primary structures and domains of the nine mammalian PCs (h, human; r, rat; and m, mouse) are compared to the original subtilisin and yeast (y) kexin. The basic aa-specific PCs together with yeast kexin, SKI-1, and PCSK9 are individually boxed to emphasize their distinct subclasses. Only PC5 exhibits two validated alternative spliced forms, namely PC5A and PC5B. The membrane-bound PCs include Furin, PC5B, PC7, and SKI-1. The presence of a signal peptide, a prosegment, and catalytic domain is common to all convertases that exhibit the typical catalytic triad residues Asp, His, and Ser and the oxyanion hole Asn. Except for SKI-1 and PCSK9, all the basic aa-specific convertases exhibit a β barrel P domain that apparently stabilizes the catalytic pocket. The C-terminal domain of each convertase contains unique sequences regulating their cellular localization and trafficking. PC5 and PACE4 contain a specific Cys-rich domain, which in combination with TIMPs binds to HSPG at the cell surface. In contrast, PCSK9 exhibits a Cys–His-rich domain that is required for cell surface binding in an LDLR-dependent manner.

stimuli. Finally, the last member of the family, PCSK9, is secreted and then reinternalized into clathrin-coated endosomes, where it exerts its action on LDL-R as an inactive enzyme.

The processing of protein precursors by Furin, PC5/6, PACE4, PC7, and SKI-1 can be inhibited by overexpression of their prosegments, by specific chloromethylketone (CMK) containing membrane-permeable decanoylated (dec-) peptides such as dec-RVKR-CMK or dec-RRLL-CMK, or by variants of the serpin α_1-PDX (Figure 5). These inhibitors have been shown to block metastasis and tumor growth, suggesting that the basic aa-specific Furin-like PCs, and possibly other PCs, should be considered as major targets for the control of tumor progression and cancer metastasis.

Neural and Endocrine Functions of the Proprotein Convertases

Because a number of excellent reviews have been written on the general functions of the proprotein convertases and their targets, we consider here only the implications of the PCs in neuronal functions.

Neuroendocrine Convertases PC1/3 and PC2

PC1/3 and PC2 are the principal activators of prohormones and proneuropeptides within the regulated secretory pathway of neural and endocrine cells. PC1 and PC2 process many precursors into their functional hormones: proopiomelanocortin (POMC; precursor of adrenocorticotropic hormone (ACTH) and β-endorphin), proinsulin (Figure 6), pro-melanin concentrating hormone (MCH), secretogranin II, proenkephalin, prodynorphin, prosomatostatin, chromogranins A and B and PACAP, proenkephalin, and the neurotrophic factor pro-BDNF. The functional activation of the convertase PC2 is regulated by an approximately 30-kDa neuroendocrine PC2-binding protein 7B2 that is coregulated with it. Both proteases are calcium-dependent enzymes that function within the confines of dense core secretory granules (Figure 5), where they exert their maximal activity.

The physiological importance of PC1/3 and PC2 was deduced from studies of the phenotypes of their gene knockout in mice and the discovery of some human patients with defects in PC1/3. In all cases, mice were viable, suggesting that individually the genes

Figure 4 Zymogen activation of the PCs. A PC usually undergoes a first autocatalytic zymogen cleavage in the endoplasmic reticulum (ER) generating an N-terminal inhibitory prosegment that remains noncovalently tightly bound to the enzyme. This bimolecular complex then exits the ER and is directed toward the Golgi apparatus. For SKI-1, a second autocatalytic processing event in the prosegment activates the enzyme in the *cis*/medial-Golgi. Zymogen activation of Furin, PC7, and PC5B occurs in the *trans*-Golgi network (TGN), where the acidic (pH 6.2) and high calcium concentrations (~5–10 mM) favor a second autocatalytic cleavage of the prosegment, thereby liberating the enzyme from its inhibitory prosegment. These enzymes can then cleave *in trans* other substrates. In the case of PC5 and possibly PACE4, the second autocatalytic cleavage may occur either in the TGN or at the cell surface, where these proteinases may then cleave and sometimes inactivate specific proteins. The zymogen activation steps of the regulated endocrine and neural convertases PC1/3 and PC2 occur in the highly acidic (pH ~5.2) immature secretory granules, which explains why they are maximally active only in dense core secretory granules. Finally, the secreted PCSK9 is complexed with its prosegment even after prosegment in recycling endosomes upon reinternalization of the secreted bimolecular complex.

of these convertases are not essential for life. Nevertheless, although PC2 null mice appear normal at birth, they exhibit retarded growth. Analysis of these mice reveals chronic fasting, hypoglycemia, and a deficiency in circulating glucagon. PC2 is known to process various neuroendocrine precursors, and many of these were not fully processed in PC2 null mice, including prosomatostatin, neuronal proCCK, neurotensin, neuromedin N, prodynorphin, proorphanin FQ/nociceptin, and POMC-derived peptides.

Contrary to PC2, PC1/3 gene disruption results in developmental abnormalities. PC1/3 null mice exhibit growth retardation. Adult mutant mice are approximately 60% of the normal size and phenotypically resemble mice that have mutant growth hormone-releasing hormone (GHRH) receptor. Interestingly, insulin growth factor-1 (IGF-1) and GHRH levels are significantly reduced along with pituitary GH mRNA levels, suggesting that this reduction contributes to the growth retardation observed in these mice. Similarly, analysis of several protein precursors known to be processed by PC1/3 revealed that these mice, like PC2 mutant mice, exhibit multiple defects in various hormone precursor processing events. These include the hypothalamic GHRH, pituitary POMC, pancreatic proinsulin, and intestinal proglucagon. In contrast to PC2 null mice, PC1/3 null mice process normally pituitary POMC to adrenocorticotropic hormone (ACTH) (Figure 6) and have normal levels of blood corticosterone. Like PC2 null mice, they also develop hyperproinsulinemia.

Figure 5 Subcellular localization and sorting of the PCs. The subcellular localization of the color-coded convertases in the Golgi, TGN, endosomes (Endo), cell surface, and dense core secretory granules (SG) is shown. The scheme also shows that the drug brefeldin A (BFA) can cause the reversible retrieval of both SKI-1 and the isoform PC5B into the endoplasmic reticulum (ER). Some of the known inhibitors (⊥) of the basic aa PCs are also shown. Finally, each enzyme exhibits the active site Ser (S) residue within the catalytic subunit (crescent shape).

Figure 6 Stepwise processing of POMC and proinsulin by PC1 and PC2. PC1 and PC2 cleave POMC and proinsulin in immature secretory granules at different dibasic sites, represented in this figure. This results in the major production of β endorphin and β-MSH by PC2, ACTH and β-LPH by PC1, and α-MSH and insulin by PC1 + PC2.

Since PC2 is the major convertase that cleaves POMC and proenkephalin to generate the morphinomimetic peptides β-endorphin (Figure 6) and Met- and Leu-enkephalins, respectively, it was important to investigate the role of PC2 in pain perception. Unexpectedly, after a short forced swim in warm water, PC2 null mice were significantly less (rather than more) responsive to the stimuli than wild-type mice, an indication of increased opioid-mediated stress-induced analgesia. The enhanced analgesia in PC2 null mice may be caused by an accumulation of opioid precursor processing intermediates with potent analgesic effects or by loss of antiopioid peptides. Thus, the presence of abnormal cocktails of pain neuropeptides in the brain of PC2 knockout mice is likely to disturb pain perception mechanisms in ways that remain to be fully elucidated.

PC1/3 deficiency in a female patient compound heterozygote for both splicing and nonsynonymous mutations resulted in very low expression of the protein. This subject exhibited neonatal obesity and abnormal glucose homeostasis as well as the presence of other endocrine defects, including very high circulating levels of proinsulin and multiple forms of partially processed POMC (intermediate ACTH precursors), low-serum estradiol, follicle-stimulating hormone, and luteinizing hormone. Another PC1/3 deficiency female subject presented with severe diarrhea, which started on the third postnatal day. Clinical investigations revealed a defect in the absorption of monosaccharides and fat, revealing the role of PC1/3 in the absorptive function of the small intestine. Although the phenotypes of the PC1/3 null mice differ from those observed in these patients (PC1/3 null mice are not obese), the findings confirmed the importance of PC1/3 as a key neuroendocrine convertase. Interestingly, obesity, hyperphagia, and increased metabolic efficiency have been identified in PC1/3 mutant mice exhibiting a homozygote mutation N222D/N222D that results in an approximately 60% decrease in PC1/3 activity, suggesting that it is the dose of PC1/3 and possibly reduced hypothalamic α-MSH (Figure 6) that may define the obesity phenotype.

Ubiquitous Convertases Furin, PC7, and SKI-1/S1P

Furin, a ubiquitous membrane protein, is initially produced as an approximately 104-kDa precursor and is rapidly converted into an active, approximately 98-kDa form. This autocatalytic cleavage, occurring in the ER, is a prerequisite for the exit of mature Furin molecules from the ER to the TGN and cell surface. Furin and PC5 seem to exhibit partial redundancy of their *in vitro* cleavage selectivity of a number of substrates and sensitivity to certain modified serpin inhibitors, such as α_1-PDX or their prosegments (Figure 6). The varied types of constitutively secreted proteins processed by the Furin-like convertases are exemplified in Table 1. In the central nervous system, Furin is responsible for the processing of a number of growth factors, including the neurotrophins pro-nerve growth factor (NGF) and neural cell adhesion and cueing proteins such as L1-CAM and semaphorins.

Inactivation of the *fur* gene (*Pcsk3*) causes embryonic death on approximately embryonic day 11 (E11)

Table 1 Major Furin and Furin-like substrates[a]

Growth factors: TGF-β, IGF-1 and -2, PDGF-A and -B, VEGF-C
Neurotrophins: NGF, BDNF, NT3 and-4
Prohormones: PTH, endothelin, somatostatin, NPY, 7B2, MCH, POMC
Blood coagulation factors: Von Willebrand factor, factor VII, factor IX, factor X
Integrins α chains: α_3, α_4, α_5, α_6, α_8, α_v
Neural molecules: L1, semaphorins, CLAC, BRI3, SorLA, BACE1, N-CAM
Receptors: Insulin-R, IFG1-R, R-PTPμ, Notch, LRP1
Metalloendopeptidases: ADAMs, MMPs, MT-MMPs
Viral envelope glycoproteins: HIV-gp160, RSV-Pr95^{env}, NDV-F, influenza hemagglutinin-HA, CMV-gB, SFV-p62
Bacterial surface proteins: Anthrax and diphtheria toxins

[a]Furin and Furin-like PCs (PC5, PACE4, and PC7) can process a wide variety of secretory precursor proteins as exemplified here. This also includes cell surface proteins originating from opportunistic viral and bacterial pathogens.
BDNF, brain-derived neurotropic factor; IGF, insulin-like growth factor; MCH, melanin concentrating hormone; NGF, nerve growth factor; NPY, neuropeptide Y; NT, neurotrophin; PDGF, platelet-derived growth factor; POMC, proopiomelanocortin; PTH, parathyroid hormone; TGF-β, transforming growth factor β_1; VEGF-C, vascular endothelial growth factor-C.

due to hemodynamic insufficiency and cardiac ventral closure defects. Mutant embryos failed to develop large vessels despite the presence of endothelial cell precursors. Transforming growth factor β_1 has been shown to be efficiently processed by Furin, and inactivation of its gene produces a phenotype similar to that of Furin null embryos. A conditional knockout in liver, with deletion of exon 2 dependent on the Cre expression from the Mx1-cre transgene, resulted in viable Pcsk3flox/flox Tg(Mx1-cre) mice with almost no phenotype. This showed some redundancy with other PCs since some typical Furin substrates were cleaved to a lesser extent.
