The neocortex develops on the surface of the cerebral hemispheres as a series of waves of newly generated cells many of which migrate radially outward from the proliferative ventricular and subventricular zones lining the primitive lateral ventricles while others invade by migration from the region of the developing basal ganglia. The earliest arriving cells form a primordial cortex which is invaded by successive waves of other cells. Each successive wave pushes through its predecessors and comes to lie external to them. In this is the beginnings of one of the overt histological features of the neocortex: lamination. Cells in a particular lamina are born during the same limited time window and aggregate together in the cortex. In all but the most superficial layer of the cortex of a fully developed mammal there are two major neuronal classes (and, of course, neuroglial cells). The two neuronal types are called pyramidal and nonpyramidal. Among the latter are several subtypes. The names of the cells reflect their morphology as seen with stains such as that of Golgi which reveal the morphology of the whole cell. The lamination of the cortex is, at the routine histological level seen with the Nissl stain (which stains only cell somata), a lamination of cell bodies. Stains such as that of Golgi show that processes of the cells can extend across laminae.

In most parts of the mammalian cortex, a six-layered pattern first introduced by the anatomist Brodmann and based upon Nissl staining, has come to be accepted as the standard, though five- and seven-layered patterns have also been in vogue. Layer I is the layer immediately beneath the pia mater and contains very few cell bodies, belonging mainly to neuroglial cells and to a few nonpyramidal neurons – hence its name, 'molecular layer'. Layer II consists of small, tightly packed cell bodies, most of which are small pyramidal neurons, but nevertheless is called the 'external granular layer'. Layer III is a thick layer in which pyramidal cell somata increase progressively in size from superficial to deep. It is referred to as the pyramidal or 'external pyramidal layer'. Layer IV is thin but densely packed with the somata of small pyramidal and nonpyramidal cells. It is called the 'internal granular layer'. Layer V consists primarily of large, loosely dispersed pyramidal cell somata. It is referred to as the ganglionic or 'internal pyramidal layer'. Layer VI is composed of relatively tightly packed, small, round cell somata that belong mostly to a modified form of pyramidal cell. It is called the 'multiform' or 'polymorph layer'. In certain areas, some of these layers can be reduplicated or further subdivided.

The features of the Nissl-stained laminar pattern are superficial. Each layer defined in the terms given, apart from layer I, contains pyramidal and nonpyramidal cells of varying types. All these cells have dendrites and axons that can extend into or through other layers. The majority of the pyramidal cells-with somata in any layer send their apical dendrites through all the supervening layers to end, commonly in a tuft of branched dendrites, in layer I. When stained with the Golgi method, therefore, the lamination of the cortex is far less clear than in a Nissl-stained preparation.

The cerebral cortex is also laminated in terms of the distribution of afferent axons and of some of its intrinsic axonal systems. Traditionally, these layers have been described from myelin-stained preparations, but they can also be discerned in well-stained Golgi and reduced silver preparations which stain axons and dendrites. In these preparations, a tangential fiber plexus is revealed in layer I which is consequently called the plexiform layer. A condensation of fibers in the deepest part of layer I is called the stria of Kaes or Bechterew (Figure 1). Horizontal plexuses of fibers in layer IV and deep in layer V are called

Figure 1 Vogt's scheme of the fundamental plan of cellular (left) and fiber (right) layering in the cerebral cortex. The cellular layers (I through VI) are those given in the text and Vogt divides them into sublayers. Fiber layers 4 and 5b are the bands of Baillarger; the stria of KaesBechterew, when present, is in layer 1c. From Vogt C and Vogt O (1919) Allgemeinere Ergebnisse unserer Hirnforschung. *Journal of Psychology and Neurology* 25: 279–462.

the inner and outer bands of Baillarger. These are probably formed primarily by intrinsic axons of the cortex (i.e., axons of some nonpyramidal cells and collateral branches of axons of pyramidal cells). The outer band of Baillarger is traditionally thought to be formed by the terminal ramifications of thalamocortical axons, but this has been disputed in the visual cortex where the band is referred to as the stria of Gennari and consists mainly of axons arising from intrinsic cortical sources.

Vertical bundles of myelinated axons extend through layers III to VI of the cortex, becoming thicker as they descend and as more axons are added. The bundles are referred to as radial fasciculi and contain axons of pyramidal neurons as they proceed to exit the cortex, and the axons of certain nonpyramidal neurons. Afferent axons coming into the cortex can usually be identified in myelin preparations as thick, obliquely running fibers separate from the radial fasciculi (**Figure 1**).

The laminar patterns seen in Nissl- and myelin-stained preparations vary from mammal to mammal and across the surface of the cortex of an individual mammalian species. The art of identifying and determining the boundaries of different cortical areas is known as cytoarchitectonics or myeloarchitectonics, depending on whether Nissl or myelin stains are used as the basis for the delineations made. Cortical areas, many with known functional characteristics (visual, auditory, motor, etc.) have cyto- and myeloarchitectonic features and common differences in histochemical staining as well, that enable their borders to be defined and a distinction to be made between them and adjacent areas. The basic types of neocortex are:

'homotypical', found in the frontal, temporal, and parietal lobes; 'heterotypical', divided further into granular and agranular cortex. 'Granular' or 'koniocortex' is found in the sensory areas and in it there is a predominance of small cell bodies in layers II–IV, resulting in a blurring of the borders between the layers; in 'agranular cortex', found in the premotor and motor areas, layer IV disappears during development, and layers III and V form a continuum of increasing pyramidal cell somal size. In conjunction with the changes in the Nissl staining pattern, there are changes in the myelin staining pattern. The homotypical cortex shows all the laminated plexuses, in granular cortex the bands of Baillarger predominate, and in agranular cortex thick radial fasciculi predominate.

With one or two exceptions, mainly in the visual cortex, the pyramidal cells are the output cells of the cerebral cortex, sending their axons to subcortical targets and to other cortical areas on the same and opposite sides of the brain (Figure 2). To a large extent the pyramidal cells with somata in a particular cortical layer send their axons to a defined set of targets, and the laminar localization of cells projecting to the same target(s) does not vary greatly from area to area. The modified pyramidal cells of layer VI send their axons to the principal thalamic nucleus providing the input to the cortical area in which they lie, to the claustrum, and to cortical areas linked functionally with their own. Layer V pyramidal cells provide connections to all other subcortical structures: corticospinal, corticobulbar, corticopontine, corticorubral, corticotectal, corticostriatal, and corticothalamic fibers to nonspecific thalamic nuclei. There are conflicting reports about the extent to which axons to one site arise as branches of those directed to another and there may be species differences in the degree to which this occurs. Pyramidal cells of layers II and III provide most of the axons of the corpus callosum and most of those forming ipsilateral corticocortical connections, though some callosal and ipsilateral corticocortical axons can arise from pyramidal cells with somata in other layers as well. The precise constellation of cortical and subcortical connections emanating from a cortical area varies, with some types of connection and thus the parent cell category being absent from some areas. Corticorubral fibers, for example, arise only in the motor and premotor areas. Others, such as the corticostriatal and corticopontine, probably arise in all areas. It is probably the variation in pyramidal cell size and shape related to these differential connections that helps determine the architectonic characteristics of the individual cortical areas.

Afferent axons entering a cortical area arise from a variety of sites. Every cortical area receives specific afferent fibers from a particular thalamic relay nucleus or nuclei and from a particular set of ipsilateral and contralateral cortical areas. These three sets of fibers release the excitatory amino acid transmitter glutamate. All the inputs to the sensory areas, at least, are highly ordered, topographically organized sets of connections that form an essential element in the mapping of the external world and surface of the

Figure 2 Basic cell types in the monkey cerebral cortex. (Left) Spiny neurons which include pyramidal cells and spiny stellate cells (A), a form of nonpyramidal neuron. Spiny neurons utilize the neurotransmitter, glutamate (Glu). (Right) Nonpyramidal cells all of which use the neurotransmitter, GABA. B, cell with local axon arcades; C, double bouquet cell; D, H, basket cells; E, chandelier cells; F, bi-tufted, usually peptide-containing cell; G, neurogliaform cell. Cambridge, MA: MIT Press.

body on to the cortex. Other, more diffusely organized afferent fibers whose cortical distribution does not respect cytoarchitectonic boundaries arise in so-called nonspecific nuclei of the thalamus, in the noradrenergic cells of the locus coeruleus, serotoninergic cells of the midbrain, cholinergic cells of the basal forebrain, and, for many cortical areas, in the dopaminergic cells of the midbrain. It is customarily assumed that some or all of these nonspecific afferent systems are concerned with controlling levels of cortical excitability, arousal and the conscious state. The specific and nonspecific afferent fiber systems terminate in particular cortical layers that tend to vary from area to area and from species to species. In general, specific thalamic fibers end predominantly in the middle layers (III and IV) and corticocortical fibers in layers I–IV. Many nonspecific systems end predominantly in layers I and/or VI.

The three specific afferent fiber systems terminate on both pyramidal and nonpyramidal cells. The further, internal, elaborative circuitry of the cortex is then effected by the axons of nonpyramidal cells and by the intracortical collaterals of pyramidal cell axons. Depending on their morphological types the nonpyramidal cells' axons have rather precise targets, mainly on different levels of the soma-dendritic membranes of other cells. The collaterals of pyramidal cell axons tend to be preferentially distributed to certain layers depending on the target of the principal axon of the pyramidal cell. Most output cells, seem to be affected monosynaptically by specific afferent fibers and polysynaptically by these fibers after relays through one or more other cortical neurons.

Nonpyramidal neurons belong to several morphological categories, each of which has been given a name that usually reflects some aspect of its dendritic or axonal arborization pattern (**Figure 2**). The distributions of their axons are the best determinants of cell type and determine in turn the range of action over which these intrinsic cortical interneurons act. Those with local axons probably serve to modulate local synaptic actions between afferent fibers and efferent cells; those with vertical axons effect interlaminar connections (ascending and descending) and are probably the main determinants of the columnar organization of the cortex such as is manifested in the visual cortex. Those with horizontal axons effect intralaminar and intercolumnar actions. While the division of cortical neurons into pyramidal and nonpyramidal types reflects their division into extrinsically projecting and intrinsic neurons, a further division of equal functional importance is into those which possess substantial populations of dendritic spines and those that are essentially nonspiny. This reflects a division into neurons that produce the excitatory amino acid transmitter glutamate, and those that produce the inhibitory neurotransmitter, γ-aminobutyric acid (GABA). All pyramidal cells are spiny and glutamatergic. Long horizontal collaterals of the axons of layers III and V pyramidal cells are the main sources of horizontally spreading excitation in the cortex. Nonpyramidal cells are divided into spiny and non-spiny types. Spiny nonpyramidal cells (spiny stellate cells) dominate layer IV, are the major recipients of thalamic synapses, are glutamatergic, and their axons provide the main route for information to flow out of layer IV into other layers. The majority of nonpyramidal neurons lack significant populations of dendritic spines, are found in all layers, and use GABA. They account for up to 30% of the total population of cortical neurons. They can be further divided into subpopulations based upon their production of one or other of three calcium-binding proteins: 28KD calbindin, 29KD calretinin, or parvalbumin. The chemical profile of each type of cortical interneuron tends to be associated with the possession of a particular set of membrane conductances that confers different discharge properties upon the cells. A small subpopulation also contains one or more neuropeptides. The combination of inhibitory and excitatory effects mediated by the various types of cortical cell are thought to be critical in shaping the receptive fields of neurons recorded in different layers of the cortex, in maintaining columnar organization in the cortex, and in setting up afferent inhibition between columns.

Introduction

Different brain regions have specialized neural circuits with characteristic structures that presumably facilitate appropriate information processing to influence behavior. Consistent with its participation in higher cognitive functions, the cerebral cortex is composed of extremely complicated neuronal circuits, the properties of which are still largely unknown. To understand the operation of the neocortex it is necessary to uncover both the structural composition of the circuit (neural circuit analysis) and to reveal the way information is represented and propagated through the circuit (electrical signal analysis). Therefore it is essential to identify, structurally and physiologically, the functional classes of cortical neurons. For convenience, models of the cortical circuit have tended to minimize the number of cortical cell types. However, experimental data demonstrate that cortical neurons are extremely diverse in their morphological and physiological properties.

Morphologies of cortical neurons were systematically described first by Santiago Ramón y Cajal (1852–1934) in Spain. Using newly developed Golgi staining, Cajal observed the details of dendritic and axonal elongations and revealed the morphological composition of cortical neurons. While much subsequent work examined the morphological and physiological properties of the larger pyramidal neurons, our understanding of the less numerous and smaller nonpyramidal cells lagged behind. In comparison with the analysis of information representation on the cortical surface by recording neuron spikes in correlation with the sensory stimulation or behavioral patterns, the structural analysis of local circuitry proceeded slowly. However, recent advances allowing experimental access to individual neurons in the neocortex have facilitated the characterization of nonpyramidal neurons and revealed that these local-circuit neurons are extremely diverse in structure, connectivity, and physiological properties.

Two Basic Neuron Types in Cortex

Cortical neurons are divided into two broad types, pyramidal and nonpyramidal cells. Pyramidal cells comprise ~80% of cortical neurons, and utilize glutamate as a fast excitatory neurotransmitter. They are projection neurons that send axons to extracortical targets as well as to other, sometimes distant, cortical regions. Pyramidal cells have a relatively distinct and uniform morphology, with a single apical dendrite extending toward the pia, basal dendrites extending locally around the soma, and the main axon projecting into the white matter. Most pyramidal cells have small, spinelike protrusions from their dendrites, but the spine density on individual dendrites can be variable among different pyramidal cells. The apical dendrites display variable extension patterns. Physiologically, layer V pyramidal cells can be divided into several groups.

In contrast to pyramidal cells, nonpyramidal cells are extremely heterogeneous in both their dendritic and their axonal arborizations (Figure 1), and contain both excitatory and inhibitory cells. Layer IV in primary sensory cortical regions contains spiny nonpyramidal cells (spiny stellate cells) that utilize glutamate as an excitatory neurotransmitter. They induce excitatory postsynaptic potentials (EPSPs) in other spiny stellate cells in layer IV and in pyramidal cells in layers II/III. Most other nonpyramidal neurons in the neocortex are inhibitory and utilize γ-aminobutyric acid (GABA) as their primary transmitter. Although the specifics of cell classification are still intensely debated, extensive research by many laboratories over the past decade has defined several basic cellular subtypes. These subtypes have been identified by a combination of anatomical, physiological, and chemical characteristics, as well as by the timing and location of their cellular differentiation. In the following section we introduce the organization of GABAergic nonpyramidal cells.

Morphological Diversity of Cortical GABA Cells

The morphological details of individual neurons were initially investigated by Golgi staining, but modern studies have employed intracellular dyes and genetically linked dye expression to stain specific subsets of cortical interneurons. In nonpyramidal cells, dendritic and axonal arborizations can be used for their broad classification (Figure 1), and most classification systems to date have relied on differences in local axonal arborization patterns to describe five main nonpyramidal cell types:

1. Basket cells making multiple synaptic boutons onto the somata of other neurons.

Figure 1 Examples of cortical nonpyramidal cells. Somata and dendrites are depicted in yellow, and axons in red. FSB, fast-spiking basket cell; Ch, fast-spiking chandelier cell; Ng, late-spiking neurogliaform cell; LSB, late-spiking basket cell; LB, non-fast-spiking large basket cell; DscB, non-fast-spiking descending basket cell; SB, non-fast-spiking small basket cell; DBq, double-bouquet cell; Ma, Martinotti cell. Layer V cells are indicated (V); other cells belong to layers II/III. Adapted from Karube F, Kubota Y, and Kawaguchi Y (2004) Axon branching and synaptic bouton phenotypes in GABAergic nonpyramidal cell subtypes. *Journal of Neuroscience* 24: 2853–2865, with permission.

2. Chandelier cells displaying vertical arrays of several boutons, like a chandelier.
3. Martinotti cells extending axon collaterals ascending to layer I.
4. Double-bouquet cells issuing descending axonal bundles.
5. Neurogliaform cells making dense axonal arbors resembling spider webs.

Dendritic patterns of these neurons are heterogeneous and include distinct morphologies, such as a multipolar pattern in which dendrites are projected in all directions from the soma, or a bitufted pattern in which fewer dendrites arise from the soma and tend to project orthogonally toward the pia and white matter. Although GABAergic nonpyramidal cells tend to have a much lower dendritic spine density than do pyramidal cells, the expression of spines in nonpyramidal cells is diverse, ranging from sparsely spiny to completely aspiny. Because of the diversity in these morphological properties, and the lack of correlation between specific dendritic and axonal patterns, morphological appearances alone do not suffice for the identification of individual nonpyramidal subtypes.

Expression Patterns of Specific Chemical Substances

GABA is synthesized by the enzyme glutamic acid decarboxylase (GAD), which has two isoforms identified by their molecular size, 65 and 67 kDa. Immunohistochemistry has revealed that most nonpyramidal cells, except spiny stellate cells in layer IV, express GAD and package the transmitter GABA in their synaptic terminals. Most cortical GABA cells express both isoforms of GAD. The 67 kDa GAD is expressed in both somata and axon terminals, but the 65 kDa one is found mostly in the terminals, more preferentially involved in GABAergic synaptic transmission. Further, nonpyramidal neurons tend to selectively express several peptides that are less common in pyramidal cells. These peptides include somatostatin, cholecystokinin (CCK; also expressed in some pyramidal neurons), vasoactive intestinal polypeptide (VIP), and corticotropin-releasing factor (CRF). Additionally, several types of calcium-binding proteins are also preferentially expressed in nonpyramidal cells: parvalbumin, calretinin, and calbindin. Calbindin is also expressed in some pyramidal cells. While we do not

Figure 2 (Left) Three classes of GABA cells immunohistochemically stained with different chromogens in the rat frontal cortex. Somatostatin (SOM) cells are demonstrated using a rat monoclonal antibody (brown); parvalbumin (PV) cells, using a mouse monoclonal antibody (blue); and calretinin (CR) cells, using a rabbit antiserum antibody (red). These three cell classes belong to separate populations of cortical GABA cells. (Right) Schematic showing shared chemical composition of GABA cells (CB, calbindin D28k; CCK, cholecystokinin; CR, calretinin; PV, parvalbumin; SOM, somatostatin; VIP, vasoactive intestinal polypeptide). In addition to pyramidal cells of layers II/III, calbindin D28k is expressed either weakly or strongly in GABA cells immunoreactive for somatostatin or parvalbumin. In layer V, calbindin D28k is strongly expressed mainly in somatostatin cells. The relative number of cells immunoreactive for a substance is proportional to the size of the box. Micrograph of stained cells adapted from Kawaguchi Y and Kondo S (2002) Parvalbumin, somatostatin and cholecystokinin as chemical markers for specific GABAergic interneuron types in the rat frontal cortex. *Journal of Neurocytology* 31: 277–287, with permission.

as yet understand the functional significance of these peptides and calcium-binding proteins, these expression patterns are not uniform, but rather are restricted to the subpopulations of GABA cells. The uneven distribution of these peptides and proteins in GABAergic neurons stimulated researchers to use immunohistochemistry for multiple substances to reveal classes of interneurons that co-express discrete combinations of these markers (Figure 2). The findings from these studies demonstrate that parvalbumin, somatostatin, and VIP cells are distinct, nonoverlapping groups. Further, calretinin cells are negative for parvalbumin and somatostatin, but partially overlap with VIP cells. As a result, we can identify five major interneuron groups: (1) parvalbumin-positive cells, (2) somatostatin-positive cells, (3) VIP- and calretinin-positive cells, (4) VIP-positive, calretinin-negative cells, and (5) VIP-negative, calretinin-positive cells. CCK is expressed in VIP cells, but also in cells negative for VIP, somatostatin, calretinin, or parvalbumin. CRF is differentially expressed between layers II/III and V/VI, and, in layers II/III, most CRF cells are positive for VIP. Calbindin is expressed mostly in somatostatin cells, but also weakly in layer II/III parvalbumin cells. Nitric oxide synthase (NOS), the enzyme generating NO, is also found in some GABA cells expressing somatostatin and neuropeptide Y. While the expression patterns for these markers are complex and their physiological roles still largely unknown, the distinctive expression patterns in neocortical interneurons have greatly aided the identification and classification of these neurons.

Firing Pattern Diversity

Firing characteristics of cortical neurons have been investigated in both *in vivo* and *in vitro* preparations. Response patterns to artificial current injections are heterogeneous among cortical cells. Differences in spike duration, spike afterhyperpolarization, and repetitive firing pattern responses to step depolarizations are used in the physiological classification of cortical neurons. Although pyramidal cells exhibit a range of firing properties, physiologically they are a much more homogeneous group than are neocortical interneurons. The physiological characteristics of interneurons, however, are even more heterogeneous than are their dendritic and axonal morphologies. Even so, some distinctions can be made between cell types. Here we introduce the most simplified scheme for the physiological classification of nonpyramidal cells (Figure 3):

1. *Fast-spiking (FS) cells.* These neurons have relatively hyperpolarized resting membrane potentials and have lower input resistances and shorter duration spikes than do other nonpyramidal cells.

Figure 3 (Left) Firing responses of nonpyramidal fast-spiking (FS; A_1, A_2), late-spiking (LS; B), and non-FS (C_1, C_2, C_3, C_4) cells induced by depolarizing current pulses (r.p., resting membrane potential). Membrane potential changes by direct current somatic current injection (shown in parentheses) are indicated for the traces. (Right: cells D_1 and D_2) Immunohistochemical identification of physiologically characterized and biocytin-injected cells as positive for somatostatin (SOM) or cholecystokinin (CCK). (Right: cell E) The diagram above the micrograph depicts a reconstruction of dendrites (thick lines) and axon collaterals (thin lines) of an intracellularly stained fast-spiking cell. Micrograph of the stained cell shows that soma, dendrites, and axon collaterals are stained, as are axonal boutons (inset).

These characteristics suggest that these neurons need stronger excitatory input for action potential initiation. As their name suggests, sustained depolarization can induce nonadapting, repetitive firing at frequencies higher than 40 Hz.

2. *Late-spiking (LS) cells.* Given just-suprathreshold current injections, these neurons display ramp depolarizations before spike discharge. Above the threshold, nonadapting firing is observed in response to current pulses.

3. *Non-FS cells.* These neurons are neither FS nor LS cells, and are diverse in firing patterns. Some cells show a low-threshold spike (LTS) following depolarization from hyperpolarized potentials, and some occasionally generate multiple spikes following depolarization (i.e., burst-spiking nonpyramidal (BSNP) cells). Other cells, known as regular-spiking nonpyramidal (RSNP) cells, do not show LTSs, and fire continuously with variable adaptation patterns in response to current pulses. Some RSNP cells also have rebound depolarization after release from hyperpolarizing current steps that can sometimes generate a single spike, perhaps due to hyperpolarization-activated cation currents activated during hyperpolarization. Some BSNP or RSNP neurons have irregular interspike intervals; these irregular-spiking (IS) cells sometimes exhibit an initial burst of spikes. Some neurons of this group, phasic firing cells, fire several spikes or a burst discharge only during the initial depolarization in response to current pulses, displaying strong spike adaptation.

Nonpyramidal Cell Subtypes Identified by a Combination of Anatomical, Physiological, and Chemical Characteristics

Cortical nonpyramidal cells seem highly heterogeneous in their individual characteristics, anatomically, physiologically, and chemically. However, comparison of all three types of characteristics reveals

several basic cellular subtypes that can be defined as shown in Table 1 although the specifics of cell classification are still intensely debated.

FS/Parvalbumin Cell Group

FS cells are mostly positive for parvalbumin and negative for somatostatin, VIP, CCK, and calretinin. FS cells have very few spiny dendrites. This group is generally composed of basket and chandelier cells. The axon collaterals of both of these cell types do not extend into layer I. A few dendritic branches of FS basket cells arborize with in layer I, whereas FS chandelier cells extend dendrites into layer I freely. FS chandelier cells are found mostly in layers II/III (Figure 4). However, there are also non-FS chandelier cells without dendritic extensions into layer I, supposed to be negative for parvalbumin.

FS basket cells in layer V are larger in their dendritic field than are those in layers II/III. Layer V FS basket cells include large basket cells. In addition to basket and chandelier cells, there are a few FS cells issuing axon collaterals without basket terminals, some having wider and sparser axonal fields relative to other FS cells.

Table 1 Major groups of cortical GABAergic cells

Fast-spiking parvalbumin cells
Basket cells, including large basket cells
Wide arbor cells, including cells without basket terminals
Chandelier cells
Late-spiking neurogliaform cells
Non-fast-spiking cells
Somatostatin cells
Martinotti cells
Wide arbor cells
VIP/CCK/calretinin cells[a]
Double-bouquet cells
Horizontal/descending arbor cells
Small basket cells
Descending basket cells
Arcade cells
CCK large basket cells

[a]VIP, Vasoactive intestinal polypeptide; CCK, cholecystokinin.

LS Neurogliaform Cell Group

LS cells are found in layers II/III and I, and include a few neurons in layer V. LS cells in layers II/III are mostly neurogliaform. They are also called spiderweb cells based on their axonal morphologies. In neurogliaform cells, the LS characteristic is observed from both resting potential and hyperpolarized potentials. LS neurogliaform cells have a dendritic field spanning 100–200 μm, and axonal arbors about twice as wide. Their axon collaterals run horizontally, but turning at the horizontal edge of the axon territory, seemingly to observe the restricted axonal field. GABAergic nonpyramidal cells are generally divided

Figure 4 Reconstructions of five chandelier cells, demonstrating characteristic vertical arrays of terminal boutons. Four cells (b–e) were FS cells. Two cells (c, d) were also immunohistochemically identified as parvalbumin positive. Layers I, II/III, and V are indicated. Adapted from Kawaguchi Y and Kondo S (2002) Parvalbumin, somatostatin and cholecystokinin as chemical markers for specific GABAergic interneuron types in the rat frontal cortex. *Journal of Neurocytology* 31: 277–287.

into basket and non-basket cells based on their innervation preference for somatic domains, but innervation patterns of LS nuerogliaform cells are more variable in thier tendency to choose somatic targets. The peptides and calcium-binding proteins previously described have not been detected in LS neurogliaform cells, but alpha-actinin-2, an action-binding protein is expressed in them.

A few LS cells with dendritic and axonal morphologies different from the neuroglia form cells have basket terminals, and these may belong to the non-FS basket cell group described in the following section.

Somatostatin Cell Group

Somatostatin is expressed only in non-FS cells. Somatostatin cells in layers II/III are mostly RSNP cells, but layer V somatostatin cells include both RSNP and BSNP cells. In contrast to FS cells, these neurons have sparsely spiny dendrites, although the spine density is much lower than that found in pyramidal cells. This group contains two morphological classes: Martinotti and wide arbor cells. Martinotti cells were originally defined as deep layer cells with ascending axonal arbors. We now classify layer II/III somatostatin cells with axonal arbors ascending into layer I as Martinotti cells. Wide arbor somatostatin cells typically have axon collaterals that are ascending, but that also project in descending and horizontal directions. The dendritic fields of Martinotti cells tend to be larger in layer V cells than in cells in layers II/III. Additionally, layer I innervation is more robust in layer II/III Martinotti cells than in cells located in layer V.

VIP/CCK/Calretinin Cell Group

The cells of the VIP/CCK/calretinin cell group are more diverse in their morphological, physiological and chemical characteristics than are the aforementioned groups. Physiologically they are non-FS cells and include both BSNP and RSNP cells, as well as IS cells and phasic firing cells. They can be subdivided into six cell groups: double-bouquet, horizontal/descending arbor, small basket, descending basket, arcade, and CCK large basket cells.

Double-bouquet cells In primates, double-bouquet cells are bitufted and multipolar cells with descending axon collaterals restricted in their horizontal span. In this group we include non-FS cells with mainly descending axon collaterals, even if they do not descend together in a seemingly 'horsetail-like' fascicle. Axons of double-bouquet cells rarely make basketlike terminals. These neurons express VIP or calretinin, with some expressing both CRF and VIP. Although they are expressed in some overlapping population of GABA cells, VIP- and calretinin-expressing double bouquet cells may have different connection patterns.

Horizontal/descending arbor cells VIP- or calretinin-positive cells typically have axonal arbors that extend horizontally in layers II/III, with a few axon collaterals that descend into layer V.

Small basket cells These are non-FS cells with small somata that make basketlike terminals onto the somata of nearby neurons. They express VIP or calretinin, and some express VIP and CRF, or VIP, CRF, and CCK. They are found in layers II/III, and have axons that are generally restricted to those layers.

Descending basket cells Like the double-bouquet cells, these neurons have descending axonal arbors that innervate deeper layers. However, their axons tend to make basketlike terminals on their target neurons. The expression pattern of chemical markers in these neurons is similar to that of the small basket cells.

Arcade cells VIP cells in layer V have short ascending main axons that branch into local collaterals that send additional branches descending into the dendritic field. This axon arborization pattern looks like arched roofs (thus the name 'arcade cell'). The terminals of some VIP arcade cells make multiple boutons onto postsynaptic somata, and therefore may be classified as a type of basket cell.

CCK large basket cells Large CCK-positive cells in layers II/III, negative for VIP and CRF, are basket cells producing multiple boutons onto the somata of other cortical neurons. Thus, CCK cells include large basket cells negative for VIP, and small basket cells positive for VIP. The neocortex has both FS and non-FS basket cells, the latter being composed of small and large neurons, descending basket cells, and arcade cells.

Comparison of FS Basket Cells with Other Classes

To better understand the functional relevance of the different kinds of cortical interneurons, it is useful to compare several subtypes with FS basket cells, because they are the most abundant GABAergic neurons and have been most frequently investigated in their details, compared with the other subtypes. Despite their name, only about 20% of the axonal terminals of FS basket cells innervate somata. Most FS basket cell boutons form synapses onto dendritic shafts and spines. Therefore, basket cells innervate both somatic and dendritic domains of postsynaptic

pyramidal cells. FS basket cells generally inhibit postsynaptic cells via activation of $GABA_A$-type receptors.

Chandelier cells make multiple synaptic contacts almost exclusively onto the axonal initial segments of pyramidal cells. Given that the axonal initial segment is the primary site of action potential generation in pyramidal neurons, it has been widely suggested that chandelier cells provide a powerful inhibitory input to block the spike initiation in pyramidal cells. However, new data suggest that these GABAergic synapses may actually promote spike generation in pyramidal neurons by generating depolarizing responses in the axonal initial segment. Because single chandelier cells synapse onto up to 1000 axonal initial segments, these neurons likely control the output of large groups of cortical pyramidal neurons.

LS neurogliaform and FS basket cells both show nonadapting spike discharges compared to other nonpyramidal cell classes, but have different spike frequencies in response to depolarizing current pulses. Both cell types have multipolar aspiny dendrites. Layer II/III basket cells mostly do not extend dendritic or axonal collaterals into layer I, whereas neurogliaform cells often do. Axonal arborizations extend more horizontally in FS basket cells, but are more restricted in neurogliaform cells. Neurogliaform cells induce both $GABA_A$- and $GABA_B$-receptor mediated inhibitory postsynaptic potentials (IPSPs) in target neurons. FS basket cells are connected with each other through electrical coupling via gap junctions in their dendrites, while neurogliaform cells are electrically coupled not only with each other but also with other nonpyramidal cell types.

Somatostatin Martinotti cells make symmetrical synaptic contacts onto thin dendritic branches and spines, rather than onto somata. FS basket cells have mostly aspiny dendrites, whereas sparely spiny Martinotti cells have the highest dendritic spine density among the nonpyramidal cell subtypes. In addition to their density, the spines of FS basket and Martinotti cells also differ in their shape. Individual spines are longer in Martinotti cells than in FS basket cells. Mushroom spines, spines with a larger head compared with the neck, and multihead spines are commonly found in Martinotti cell dendrites but are very rarely observed in FS basket cells. Like FS basket cells, somatostatin cells are electrically coupled with each other. However, these two cell types process excitatory input differentially. Successive excitatory synaptic transmissions between pyramidal cells and FS cells show short-term depression in response amplitude, while responses in Martinotti cells show facilitation. Additionally, thalamic fibers from the somatosensory relay nuclei preferentially innervate FS cells rather than somatostatin cells in layer IV of somatosensory cortex, suggesting that FS cells participate in feed-forward inhibition to a greater extent than do somatostatin cells.

Basket cells innervating somata are heterogeneous and contain several subtypes of nonpyramidal cells. Non-FS basket cells include small, large, and descending cells. It remains to be investigated why multiple types of basket cells exist in the cortex, but FS and non-FS (often VIP- or CCK-positive) basket cells are distinct in their chemical modulation. FS cell terminals express muscarinic receptors, whereas CCK basket cells have cannabinoid receptors. The activation of these receptors suppresses the release of GABA in both neuronal subtypes, suggesting that GABA release is differentially regulated in these two basket cell subtypes.

Comparison with Hippocampal GABAergic Cells

Compared with inhibitory interneurons in the neocortex, those in the hippocampus, especially the CA1 region, have been investigated in more detail; comparison of GABA interneuron organization will be helpful for understanding the fundamental principles. Basically, the chemical and morphological characteristics are correlated in hippocampal interneurons, but one chemical marker is usually found in more than one class, as in neocortex. As found in neocortical basket cells, basket cells in the CA1 region of the hippocampus are heterogeneous and express (1) parvalbumin alone, (2) CCK alone, or (3) both CCK and VIP. Hippocampal interneurons that innervate dendrites express somatostatin, but also some of them express parvalbumin in addition to somatostatin. The calbindin expression pattern is also different from that in the neocortex. This suggests that the expression patterns of the various peptides and calcium-binding proteins are dependent on the local cortical area in which the neurons reside.

There are also neurogliaform cells in the hippocampus. Among calretinin- or VIP-expressing GABA cells, there are interneurons that selectively innervate other GABAergic cells; these are called 'interneuron-selective interneurons.' It is possible that a similar type of nonpyramidal cell also exists in the neocortex.

Hippocampal interneurons are profoundly involved within the hippocampus in generating network oscillations, such as theta rhythm (4–10 Hz) and high-frequency 'ripples' (120–200 Hz). Interneurons belonging to different connectivity classes are suggested to fire preferentially at distinct time points during a given oscillation. In contrast, the neocortex displays different types of oscillations, such as slow oscillation (about 1 Hz) and gamma oscillation (30–80 Hz).

The differences in interneuron organization between hippocampus and neocortex may be related to differences in these oscillation patterns.

Developmental Differentiation of GABAergic Cells

Pyramidal and GABAergic nonpyramidal cells are derived from distinct precursor cells. Pyramidal cells derive from precursor cells the dorsal telencephalon, but most cortical GABAergic neurons originate from stem cells in the ventral telencephalon (the ganglionic eminence) and migrate into the cortex tangentially. Furthermore, the subtype of GABAergic neuron originating in the ganglionic eminence depends not only on the subregion of the ganglionic eminence from which it derives, but also on the developmental stage at which it starts to migrate into the cortex. The medial ganglionic eminence generates FS cells and somatostatin cells, whereas the caudal ganglionic eminence produces calretinin cells. Therefore, the physiological, chemical, and morphological characteristics in individual subtypes are to a large extent genetically predetermined before interneurons finish their migration into the cortex, suggesting that various transcriptional factors control the fates of cortical interneurons. Indeed, some transcriptional factors involved in cortical GABA cell differentiation have already been identified.

Neuron Types and Circuit Organization in the Cortex

Recent research has revealed that there are several archetypes of cortical interneurons. Here we have classified them according to their morphological, chemical, and physiological properties. However, there are additional characteristics that may further differentiate this already heterogeneous collection of neurons. For example, the firing patterns of interneurons may differ depending on the state of ongoing cortical activity (often correlated with the behavioral state of the animal). Other differences include the expression of ion channels (ligand-gated receptors and voltage-gated channels). For instance, voltage-gated potassium channels are selectively expressed in some interneuron subtypes. Potassium channel Kv3.1 proteins are found in parvalbumin cells, while nicotinic or 5-hydroxytryptamine ($5\text{-}HT_3$) receptors are selectively expressed in CCK- and VIP-expressing neurons.

Modern molecular genetic technologies have produced several lines of transgenic mice in which a subpopulation of GABA cells is selectively labeled with fluorescent material. The ability to selectively study these genetically distinct interneurons will allow for more detailed characterization of different subclasses of interneuron. The expression patterns of multiple genes have been recently examined in identified subpopulations of interneurons, including parvalbumin- and somatostatin-expressing cells. The results indicate that while cortical interneurons are highly heterogeneous, each subtype has a specific expression pattern of genes, including transcriptional factors. It is hoped that this method of molecular taxonomy will generate a consensus regarding neuronal organization of the cortex, facilitating our understanding of how the various subclasses of neurons interact together to form functional cortical circuits.

Cerebral Cortex: Symmetric vs. Asymmetric Cell Division

G Fishell and C Hanashima, New York University Medical Center, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The human cerebral cortex contains approximately 10^{10} cells that exhibit a wide array of physiological properties; these cells are wired together by synaptic connections that show remarkable specificity. This highly ordered structure is organized along two axes. Vertically, the cerebral cortex can be divided into six discrete laminae, each of which displays distinct afferent and efferent connections. Horizontally, cortical columns within each region of the cortex subserve specific aspects of cortical function, such as processing somatosensory or visual information or coordinating motor outputs. Despite this impressive architecture, cortical neurons can be grossly subdivided into two major classes, the excitatory pyramidal or principal neurons (80%) that are glutamatergic and provide the major structural inputs and outputs of the cortex, and the inhibitory GABAergic interneurons (~20%) that regulate cortical function through local connections. Pyramidal neurons with characteristic axonal connections, dendritic morphologies, and physiological properties are segregated in each of the different cortical layers. For instance, morphologically, deep-layer (V/VI) neurons have a bigger soma compared to the superficial-layer (II/III) neurons, which typically contain smaller cell bodies. Moreover, a majority of layer V/VI pyramidal neurons project to subcortical structures, including the thalamus, basal ganglia, and spinal cord, whereas layer II/III neurons project intracortically to other cortical areas. Similarly, cortical interneurons at least in some cases are enriched within specific cortical laminae. While the cell bodies of the Martinotti interneurons are found predominantly in the deep layers of the cortex, the neuroglioform interneurons are preferentially found in the superficial cortex. A similar subdivision of both of these populations occurs within the horizontal plane, as best shown by the expansion of input cortical layers (layers I and IV) in sensory regions such as visual cortex and enlargement of output layers of the cortex (layers V and VI) in motor regions. Understanding how such exquisite organization is established during development is one of the major challenges in developmental neurobiology.

Efforts to understand how cortical cellular diversity arises dates back to the late ninteenth century. The first systematic attempts to explore the organization of the developing brain came from the study of early neurogenesis, a time when epithelial cells span their fibers across the entire cortical wall. These epithelial cells, which appear to be equivalent to what we today call 'radial glial cells,' were referred to by His as 'spongioblasts' based on their elongated spongelike appearance and were thought to give rise solely to glial cells. The other 'cell type' observed by His was the rounded 'germinal cells' that reside at the apical surface of the neural tube, which he proposed were the mitotically active neuronal progenitors. This view was challenged by Magini, who observed dramatic morphological variations within the spongioblasts, and suggested that the spongioblasts and germs cells were simply the same population at different points in the cell cycle, an idea that was later confirmed by Sauer. Sauer reached this conclusion through the observation that cell nuclei at the basal side of the neural tube contain an increased complement of DNA (i.e., S phase), while those adjacent to the ventricle were tetraploid (i.e., M phase). This suggested that neural progenitors undergo 'interkinetic nuclear migration' as they progress through the cell cycle and concurrently undergo dynamic changes in their cellular morphology and nuclear position. That this occurred was definitively shown in 1959 where the movements of dividing cells were followed using *post hoc* analysis of cells previously labeled with [^{3}H]thymidine. This autoradiographic method revealed that cortical progenitor cells indeed undergo DNA replication at a distance from the ventricular surface, and then subsequently translocate to the apical surface, where the cells round up and undergo mitosis. From these divisions arise daughter cells that either terminally differentiate into neurons and migrate to the pia or undergo a second cycle of proliferation. Although nuclei prior to neurogenesis translocate across the entire width of the neural tube, subsequent to the onset of neurogenesis, interkinetic migration is confined to a region adjacent to the lateral ventricle. The geographical restriction of cells undergoing interkinetic nuclear migration led to this region being designated as the 'ventricular zone.'

Within the cortex, postmitotic cells exit the ventricular zone and migrate along radial glia toward the pial surface. Surprisingly, the structural role of radial glial cells in guiding migration in the cortex was established long before it was appreciated that the radial glia were themselves the progenitor population that gave rise to newborn neurons. Indeed, for the three decades after radial glial cells were known to support neuronal migration, the radial glia and cortical neuronal progenitors were considered to be two distinct cell lineages, with the former solely

Figure 1 Asymmetric and symmetric cell division in the cerebral cortex. Top panel: Radial glial progenitors undergo interkinetic nuclear migration during the cell cycle. One asymmetric cell division results in the production of two daughter cells, one of which remains in the VZ and inherits the radial fiber and the other of which translocates outward toward the pia along the radial fiber to become a postmitotic neuron. Bottom panel: Alternatively, SVZ progenitors arise from the VZ and subsequently undergo symmetric divisions to produce two postmitotic neurons. Adapted from Noctor SC, Martinez-Cerdeno V, Ivic L, et al. (2004) Cortical neurons arise in symmetric and asymmetric division zones and migrate through specific phases. *Nature Neuroscience* 7: 136–144.

producing astrocytes. However, the seminal paper by Noctor and Kriegstein used time-lapse imaging of retrovirally infected cortical progenitors to demonstrate that radial glial cells, in addition to supporting the migration of nascent neurons, gave rise to them. These studies revealed that neurons assembled in close radial units are not only clonally related, but also that radial glial cells can simultaneously give rise to both differentiated neurons and progenitor cells (Figure 1). This once and for all established that radial glial cells are the major and perhaps sole progenitor for cortical pyramidal neurons. Moreover, although previous analysis suggested that asymmetric cell divisions occurred in the cerebral cortex, this analysis provided the first definitive evidence establishing the existence of this phenomenon.

Cell-Type Specification in the Neocortex

Temporal Determinants: Birthdate and Laminar Fate

How is the diversity of distinct layer neuronal subtypes created from a restricted progenitor pool within the VZ? The VZ appears to utilize temporal cues to sequentially produce different subclasses of neurons, rather than simultaneously generating multiple progenitor pools, each of which gives rise to particular cell type. Studies examining the origin of distinct neuronal subtypes indicate specific neuronal populations arise at precise times during development, presumably in response to changing temporal determinants. The first evidence that birthdate was a strong predictor of neuronal fate in the cerebral cortex came from [^{3}H] thymidine studies in rodents; it was revealed that the administration of a tritiated thymidine injection at distinct times during neurogenesis resulted in the labeling of neurons within particular cortical laminae. Moreover, this occurred in an inside-out fashion, where early-born neurons occupy the deepest position within the cerebral cortex, while later-born cells migrate past their ascendants, to take up more superficial positions. Hence, in the mature cortex, layer VI neurons are born first and layer II neurons are born last. The only exception to this rule is the earliest-born neurons, the Cajal–Retzius (RC) cells that transiently reside in layer I. The inside-out relation of laminar position to birthdate, although evident in other mammals, is more precise in higher species, such as primates. This has been interpreted as suggesting that the progenitors within the ventricular zone undergo multiple cell cycle divisions, resulting in the production of neurons destined for sequentially more superficial positions.

Direct evidence for the sequential production of cortical neurons came from both static and live-imaging clonal analysis of ventricular progenitors using retroviruses. These studies revealed that individual cortical progenitors produced multiple subtypes over a prolonged period during cortical development. These clonal and birthdating studies raised the question as to how neural progenitors in the ventricular zone change their distinct laminar fate according to temporal cues. One possibility is that extrinsic cues surrounding the ventricular zone change over time to influence the fate of the progenitor cells. Alternatively, it was proposed that progenitors cells might be intrinsically programmed to sequentially produce distinct neuron types at particular developmental timepoints. To test the relative contribution of extrinsic and intrinsic factors to temporal cortical cell-fate determination, classical transplantation experiments in ferrets were carried out to heterochronically challenge ventricular zone progenitors by transplanting them reciprocally to earlier or later developmental timepoints. Specifically, in these experiments early-born progenitors fated for deep layers of cortex (layer VI) were transplanted to periods of development when late-born neurons within layers II/III were being generated. Conversely, cortical progenitors that would normally produce layers II/III were transplanted into host cortical ventricular zone at a time when layer V was being generated. The results revealed a forward ratcheting in the potential of progenitors as development progressed. While early progenitors were found to be competent to adopt later fates when transplanted to older hosts (i.e., progenitors normally fated to produce layer V neurons upon transplantation to later stages of development could produce layer II/III neurons), the converse was not true (i.e., progenitors from later timepoints in development did not produce earlier-born populations of neurons even when transplanted to host animals where earlier populations of neurons are being produced). These results highlight that the cell fate in the cerebral cortex is largely established by intrinsic determinants and that progenitor potential becomes progressively restricted as development progresses. Interestingly, while the molecular mechanism governing these fate restrictions is not well understood, timed transplants of early-born cells to late donors revealed that the fate of neurons is set within 6 h of their final S phase.

Asymmetric and Symmetric Division of Cortical Progenitors Function in the Generation of Cortical Cell Diversity

What is the mechanism by which a common pool of cortical progenitors within the germinal zone gives rise to a broad diversity of neurons over a prolonged period of time? It has been postulated that the mode of cellular division utilized by the progenitor is central to this process. During early periods of neurogenesis, a majority of cortical progenitors undergo symmetric divisions that produce two progenitor cells, in order to expand the cortical progenitor pool. However, that a common progenitor produces distinct types of neurons over multiple cell divisions also implies that later there is a second process by which two daughter cells can assume distinct cell fates. Given that postmitotic daughter cells are produced sequentially, it suggests the existence of asymmetric divisions where one daughter cell reenters the cell cycle, while the other exits to differentiate into a mature neuron. That this can occur hints that during an asymmetric division the two daughter cells adopt fundamentally distinct intrinsic cell-fate programs, where asymmetric divisions unequally bestow cell-fate determinants into only one of the two daughter cells. Considerable efforts have been made to identify these 'determinants.' *Drosophila* neurogenesis has provided a perfect context to study this question, as neuroblasts in the central nervous system (CNS) as well as sensory organ precursor cells in the PNS undergo asymmetric divisions, depending on the precise orientation of their cleavage plane. Notably, the protein Numb, together with Prospero and the adaptor proteins Miranda and Pon, are asymmetrically localized to the basal surface of neuroblasts during metaphase. Therefore, when the orientation of the cleavage plane is horizontal to the apical surface, the daughter cell on the basal side inherits the majority of determinants, such as Numb protein. Thus, asymmetrical cell division requires two events, establishing the cell polarity by regulating the orientation of the mitotic spindle along the apical–basal axis, and targeting Numb and associated proteins to the basal side. Identification of asymmetric cell-fate determinants has come from analysis of the aberrations in the neural lineages of mutant flies, where one of the critical determinants, such as Numb or Prospero, is lost. The loss of these results in a randomized spindle orientation and a corresponding perturbed cell fate. Although the precise function of asymmetric localization of Numb is not clear, it is likely that Numb functions as an inhibitor of Notch signaling, which is required for maintaining neuroblasts in a progenitor state.

In the cerebral cortex, it has been suggested that the plane of cell cleavage may also determine the fate of the resulting daughter cells. Examination of the ferret cortex has shown that around 15% of the mitosis in the ventricular zone has a horizontally oriented cleavage plane, where, following division, one daughter cell retains the apical contact and remains in the ventricular zone, while the basal daughter cell migrates away from the ventricular

zone and becomes a postmitotic neuron. Interestingly, the mouse homolog of *Drosophila* Numb, m-Numb, is asymmetrically localized to the apical membrane of the dividing progenitors in the ventricular zone, suggesting a conserved function of Numb in determining progenitor outcome in mammals. However, a majority of the cell divisions exhibit a vertical or randomly oriented cleavage plane. Thus, the cleavage orientation is not clearly bifurcated into distinct division modes as is the case in flies. Hence, as the 15% of the horizontal cleavage cannot account for all neuronal production during peak neurogenesis period, the relationship between the cleavage plane and asymmetric division, and its contribution to developmental fate in the cerebral cortex, need to be clarified.

What, then, is the function of Numb and Notch proteins in the cerebral cortex? In mammals, the interpretation of loss-of-function of either of the genes is not straightforward, as there are multiple homologs of both genes that appear to functionally compensate for each other. In mouse two *numb* homologs exist, mouse *numb* (*m-numb*) and *numblike* (*nbl*). Mice that lack *m-numb* have highly perturbed development and die prior to E11.5. Although the $nbl^{-/-}$ mutant alone does not exhibit an apparent neural developmental phenotype, this is likely a result of functional compensation between these two genes, as double mutants demonstrate a more severe phenotype and die around E8.5. To circumvent this early lethality, a conditional allele of *m-numb* was generated to test the requirement of this gene during the neurogenic period. The outcome of these experiments suggested that Numb has pleiotropic roles during the corticogenesis period, as distinct phenotypes were observed, depending on when the gene was removed. Conditionally ablating *m-numb* and *nbl* with Cre-recombinase driven under the Nestin promoter, which specifically removes genes starting around E8.5, resulted in an early depletion of the cortical progenitor pool. Similarly, compound removal of *m-numb* and *nbl* during later corticogenesis using a late Cre driver, D6-Cre (which becomes active only after E10.5), also suggested that both genes are required to maintain the progenitor cells in an undifferentiated state. However, removal of *m-numb/nbl* gene function using an Emx1-Cre (which becomes active at E9.5 and results in complete recombination within the cerebral cortex by E12.5) resulted in hyperproliferation of the cortical progenitors as well as inhibition of neuronal differentiation, suggesting that in this context Numb acts to direct progenitors to a neuronal fate. Taken together it is apparent that further work is needed to assess why the function of Numb is diametrically opposite, depending on the context of its removal.

More clear-cut is the function of Notch signaling during neurogenesis. Loss of Notch signaling results in the precocious differentiation of neural progenitors, while overexpressing a constitutively active form of Notch (caNotch) results in inhibition of neurogenesis and promotion of a radial glia cell fate. It is notable that the transient ectopic activation of Notch signaling early in neurogenesis during the period when deep-layer neurons are produced does not disrupt the normal temporal progression of neurogenesis. Upon removal of the ectopic Notch activation, upper-layer corticogenesis resumes normally. Hence even though the transient activation of Notch prevents progenitors from differentiating, on removal of Notch signaling the normal temporal progression of neurogenesis resumes. This implies that the primary function of Notch in cortical development is to maintain the progenitors in an undifferentiated state, but it does so without disrupting the developmental clock that controls the competence of progenitors. In the future, better understanding of the precise roles of Numb and Notch in cortical development, as well as their genetic and biochemical interactions, should prove informative. In addition, whether asymmetrical cell division determines cell fate or merely controls the length of corticogenesis as a means of expanding the number of neural progenitors needs to be clarified.

Does the Segregation of Progenitors to the Ventricular Zone and Subventricular Zone Represent a Bifurcation of Cell Fates?

The types of neurons produced in the cerebral cortex are clearly restricted by temporal cues within the ventricular zone; however, the mechanisms that determine layer neuron specification may not solely depend on temporal changes in progenitor competence. Recent studies have suggested that the restriction in neuronal class production can occur by a spatial segregation of cortical progenitors. In this regard, the emergence of the secondary germinal zone in the neocortex, the subventricular zone (SVZ), may play an important role in determining the identity of upper-layer neurons in the cerebral cortex. The SVZ is a transient zone that is juxtapositioned between the ventricular zone and the intermediate zone. It was traditionally defined by those progenitors that do not undergo interkinetic nuclear migration as they transit through the cell cycle. The SVZ is also distinguishable from the ventricular zone by its lack of pseudostratified epithelial morphology.

It has been postulated that since SVZ develops later than the VZ, SVZ progenitors predominantly give rise to the glial cells at the end of corticogenesis. However, since the peak neurogenesis period of upper-layer (layer II–IV) neurons overlaps with the

expansion of SVZ progenitors, the alternative view is that the spatial segregation between SVZ and VZ may directly restrict the fate of distinct layer neurons. This hypothesis is further supported by the strong correlation in genes expressed in both SVZ and upper-layer neurons. Two genes, *Svet1* and *Cux2*, specifically label mitotic cells in the SVZ. Notably, the level of expression in the SVZ population declines as the progenitors in this pool are depleted. In turn, *Svet1* and *Cux2* are expressed in postmitotic neurons that comprise neurons in layers II–IV. Beyond this simple correlation in gene expression, mutants that have abnormal development in SVZ also show abnormalities in the differentiation of upper layers of cortex. In *Pax6* mutants, the expression of *Svet1* and *Cux2* is downregulated in SVZ progenitors, and the upper-layer neurons fail to be properly established. Furthermore, expression of both *Svet1* and *Cux2* is inverted in *reeler* mutants, suggesting that these genes define the intrinsic properties of upper-layer neurons rather than their laminar position or migratory patterns. It is notable that progenitors change their mode of cell division as they transit from the VZ to the SVZ. During corticogenesis, a majority of VZ progenitors undergo asymmetric divisions, in which the two daughter cells adopt distinct fates to remain a progenitor or become a postmitotic neuron (**Figure 1**, top panel). However, SVZ progenitors are more likely to follow a symmetric pattern of division, where two daughter cells either become a pair of postmitotic neurons or together remain as progenitors (**Figure 1**, bottom panel). It is worth mentioning that not all the progenitors undergo mitosis in the SVZ, even during the peak neurogenesis of upper-layer neurons, and it remains possible that within the VZ and the SVZ there exists greater heterogeneity of progenitors than has yet to be appreciated. In this regard it is notable that in the primate neocortex studies of neurogenesis have subdivided the SVZ into inner and outer zones, the latter of which has been described to be another major source of cortical neurons. The emergence of SVZ during evolution may be the consequence of an evolutional strategy of expanding the diversity or numbers of cortical neurons that can be produced at a given time. Hence during evolution, in addition to the size and complexity of the architecture of the cerebral cortex, the cellular diversity may also have increased.

Intrinsic Factors of Cortical Cell-Fate Specification

Fundamental to cortical neurogenesis is the prolonged production of different siblings from a common pool of progenitors within the VZ and SVZ. This almost certainly depends on intrinsic cues to direct distinct neuronal fates. This process allows the progenitor pool to expand and simultaneously produce different cell types at precise times during neural development. What, then, is the identity of temporal determinants that alter the fate of the neuron types produced? As previously mentioned, cortical progenitors appear to utilize a ratcheting mechanism by which the neuronal types produced over time become progressively restricted. Moreover, later-born progenitors retain a limited ability to differentiate into neuron types prior to their own birthdate. In rodents, the molecular identity of this progressive restriction is best understood in the switch from generating the earliest-born CR cells to deep-layer projection neurons. This process is regulated by the transcriptional repressor *Foxg1*. In the cerebral cortex, *Foxg1* is expressed in the majority of the cortical projection neurons, with the exception of layer I CR neurons. Moreover, in the absence of *Foxg1*, cortical progenitors fail to generate later-born neurons and instead continue to produce the earliest-born CR neurons. In order to determine the cell-autonomous function of *Foxg1* in cell-fate specification, *Foxg1* was conditionally inactivated in deep-layer progenitors. Interestingly, removal of *Foxg1* at E13 (the birthdate of deep-layer neurons) results in the resumption of CR cell production in the cerebral cortex. By labeling the progenitors that were born subsequent to the removal of *Foxg1* with BrdU, it was confirmed that the cells that were normally destined to become deep-layer neurons instead adopted an earliest-cell fate. This work has recently been replicated *in vitro*, where the fate of individual neuroblasts can be directly followed. These studies suggest the early cell-fate specification in the mammalian cerebral cortex is determined by an active mechanism whereby a transcriptional repressor prevents the later-born neurons from adopting an earlier fate.

How is the cortical cell fate established during the subsequent corticogenesis period? It has been reported that a zinc-finger-containing transcription factor, *Fezl*, which is specifically expressed in corticospinal motor neurons in layer V, directs both the specification and identity of these cell types. Loss of *Fezl* results in both the loss of corticospinal neurons and the failure of subcortical projections. Furthermore, overexpression of *Fezl* near the end of layer V genesis can partially override the transition of cortical progenitors to produce neurons that migrate to layer IV, which instead send a projection through the internal capsule. It remains to be explored whether the competence window of cortical progenitors responding to either *Foxg1* or *Fezl* is limited. Beyond this, it seems clear that a great deal

more remains to be learned concerning the intrinsic mechanisms by which temporal competence is controlled within the cerebral cortex.

A Cascade of Intrinsic Determinants Controls the Production of Neurons in *Drosophila*

The progressive restriction of progenitors appears to be central for the specification of distinct cell types in a variety of tissues, such as in the retina and hematopoietic systems. This mechanism appears to be evolutionarily conserved, as similar rules appear to underlie the specification of cells in the nerve cord of invertebrates. In particular, work in *Drosophila* has begun to elucidate the molecular determinants controlling the precisely orchestrated production of different neuronal subtypes during development. In flies, the cell-lineage relationships of distinct neuron types have been well characterized and transcription factors that are specifically expressed in neuroblasts at distinct times have been shown to be required for the acquisition of specific neuronal identities. For instance, the well-characterized NB7–1 lineage consists of 30+ neurons, including 5 Eve+ neurons (U1–U5) and their siblings, and subsequently 20+ interneurons. Analogous to the mammalian cortical neurons, the earliest-born U1 neurons reside in the deepest position and project a longest distance to their target muscle, whereas the latest-born U5 neurons reside superficially and send their processes only proximally. The neuroblasts that produce the 5 Eve+ distinct types express Hunchback (Hb), Hb/Kruppel (Kr), Kr, Pdm, and Pdm/Castor (Cas). It has been demonstrated by removing the function or overexpressing these genes that both Hb and Kr are necessary and sufficient to determine the first-born and second-born cell fates, respectively. Furthermore, overexpression of Hb induces Kr, and similarly expression of Kr induces Pdm, showing that sequential expression of these transcription cascades is tightly regulated to produce these distinct neuron types in an invariant order. It has also been demonstrated that the sequential expression of fate-determining genes is largely cell intrinsic, as the expression occurs in isolated neuroblasts in culture and even can partially progress in the absence of cell cycle progression (Kr-Pdm-Cas). Although corresponding mammalian homologs of Hb (Ikaros family genes), Pdm (SCIP/Oct-6), and Cas (Casz1) exist, the contribution of these factors to temporal lineage progression is not equivalent (SCIP) or has not been addressed (Ikaros, Casz1). It is also noteworthy that in *Drosophila*, the temporal progression in neuroblast identity is dependent on transcriptional factors that positively promote neuroblast identity. This is in contrast with the model in the mammalian cerebral cortex, where at least during the earliest corticogenesis, cell fate is regulated by a repressive mechanism by which a transcriptional repressor, *Foxg1*, prevents deep-layer neurons from adopting an earliest-born CR cell fate. The extent to which future analysis will reveal further similarities between mammalian cortical neurogenesis and that seen in the *Drosophila* nerve cord is presently unclear. Regardless of the precise details, it seems likely that the study of *Drosophila* neuroblasts will prove informative in helping us understand how cortical progenitors generate the diversity seen in the mature cortex. Furthermore, it seems inevitable that considerable progress will be forthcoming concerning the specific transcription cascades involved in generating cerebral cortex neuron diversity, as well as with regard to the mechanisms that ensure symmetric and asymmetric cell divisions that allow the production of the appropriate numbers of neurons at the appropriate times.

Cerebral Fissure Patterns

Introduction

The cerebral hemispheres of all mammals are smooth in early development, but as they enlarge, they become folded in many species. The folding of neocortex tends to increase with the size of the brain during development within a species and with the size of the mature brain across taxa. The folds are called fissures or sulci, whereas the crests of folds on the surface of cortex are called gyri. Each species with fissured cortex has a characteristic pattern of fissures, although there is some variability, and elements of this pattern are apparent across groups of related species. These observations can be made without modern equipment or methods of investigation, so they have intrigued neuroanatomists for some time. The explanations for the folding, and the folding patterns, have been of two types: mechanical and functional. Mechanical explanations focus on the growth of the cortical sheet relative to its subcortical core, which seems to require folding as brains enlarge, and other factors that could influence the positions of sulci, such as the overall shape of the brain and the constraints on directions of growth imposed by parts of the brain and by the shape of the intracranial cavity. The functional explanations are not truly functional since brain functions depend on neurons and their interconnections, and not on the folds of the cortical sheet. Such explanations relate to the fact that the cortical sheet is not uniform in function but is divided into a variable number (across taxa) of cortical areas that interrelate in different ways. The functional differences from one cortical area or region to another depend on structural differences in neuron types, numbers, and connections. These differences affect the differential growth of areas in surface area and thickness. All such structural distinctions that stem from functional specializations potentially impact on the way the cortex folds to form sulci and gyri. Even small perturbations of the growing cortical sheet, in principle, can have large effects on the locations of convolutions. Functional theories of folding focus on the process of regionalization of cortex and how this process relates to the folding pattern.

Both mechanical and functional theories appear to explain some of the fissure patterns observed in brains. Fissure patterns explained by mechanical theories tell us little about the functional organization of the brain, whereas fissure patterns that are a consequence of the regionalization of the brain have the potential to tell us something about how the cortex is organized. In both instances, the major fissure patterns have a relatively fixed relationship to the locations of functional areas in the brain of any particular species and can be used as a guide to where functional areas are located. Thus, the positions of sulci are useful guides in physiological and anatomical studies of cortex and also in neurosurgery and other clinical applications. However, only sulci related to brain regionalization can tell us something about the functional organization of brains where no experimental or clinical study is possible, as is the case with the brains of extinct species viewed as skull endocasts. In particular, those of us curious about our own evolutionary history need to consider that ours is the only surviving species of the radiation that followed the divergence of our hominin ancestors from those leading to modern-day chimpanzees and bonobos approximately 5–6 Ma. We know from the endocasts of the skulls of extinct hominin species that brains increased tremendously in size over that time. Yet, we know almost nothing about the course of the functional changes that occurred in the evolution of the human brain during those 5–6 My. However, it seems likely that we can and will learn something of functional significance from the positions of fissures in the brains of our long extinct ancestors since these fissures are sometimes apparent in the endocasts of fossil skulls.

Changing Patterns of Fissures with Cortical Development and Evolution

The cerebral hemispheres are initially smooth as they emerge in development, and they gradually develop those fissures that characterize the mature brain. The human brain starts to develop fissures approximately 4 months after conception and a nearly adult pattern is present at birth (Figure 1). After birth, the brain more than doubles in size, fissures increase in depth, and small additional fissures may appear. However, the proportion of cortex hidden in fissures is highest at birth, as a small, gradual decrease occurs during the next 20 years. No further decrease occurs with subsequent aging. In contrast, the newborn ferret, which is extremely immature at birth, has none of the fissures of the adult. Fissures appear largely between postnatal days 6 and 14. Other examples of the development of fissures in various species of mammals are illustrated by Welker.

Figure 1 The development of fissures in the human brain from 6 months of gestation until birth (9 months), when all the major fissures are present.

Some folding appears to occur before the arrival of thalamocortical connections, and certainly before the development of cortico-cortical connections. The progressive emergence of fissures continues during the time when these connections are made and mature.

The brains of members of the same species have very similar patterns of fissures, although there is some variation. This variation is greater with minor, shallow fissures and in large brains with many fissures. Furthermore, variation in the depth of a fissure may be offset by countervariations in the depths of adjacent fissures – a counterbalancing that has been termed compensation. Because of the different specializations of the two hemispheres of the human brain for language and other functions, the patterns of fissures are not identical. Most notably, the lateral fissure, near and including cortex subserving audition and language, has a different course and extent in the two hemispheres. Additionally, fissure patterns in either the right or the left cerebral hemisphere of humans are somewhat variable from individual to individual, although less so in monozygotic (identical) twins than unrelated individuals. In macaque monkeys, there is evidence that both brain size and sulcus length are significantly heritable.

Fissure Patterns and Brain Size

Related species of mammals of different brain sizes may have some fissures in common, but the species with larger brains have more fissures. For example, the small-brained weasel or ferret has only a few fissures; the larger domestic cat has more, whereas the large-brained lion has the most (Figure 2). Thus, all these carnivore brains are characterized by an inverted U of a suprasylvian sulcus, enclosing cortex that is divided by a pseudosylvian sulcus (called pseudosylvian because it is the comparable position of the Sylvian or lateral sulcus of primates, but it is not the same (homologous) sulcus). Primates vary from the almost smooth brain of the small-brained marmosets to the extremely fissured brains of humans, but all primates have a lateral fissure and a calcarine fissure. The main conclusions from such observations are that within taxa of related mammals with fissures, a basic pattern of fissures is often evident, but species with larger brains have more fissures. However, given this general relationship between numbers of fissures and size of the brain, it is important to note that there is considerable variation within this relationship. Thus, the rather large cerebral hemispheres (brains are approximately 400 g) of the Florida manatees have only a lateral fissure, a splenial sulcus, and a few shallow clefts. Overall, the brain is largely smooth (lissencephalic). Beavers provide another example since they are rather large rodents with a large (for a rodent) smooth brain, whereas other rodents with the same size brains have fissures. Likewise, the brains of Prosimian primates have fewer and less deep fissures than the brains of comparable size of Anthropoid primates. On the other hand, the extremely small carnivore brain of the least weasel has all of the fissures of the brains of larger species of weasels (Figure 2(a)), although these fissures are very shallow. These differences indicate that there are other factors, in addition to brain size, that influence the formation of fissures.

In general, brains acquired more fissures as mammals with larger brains evolved in various lines of descent. We are able to identify the positions of brain fissures in the endocasts of the skulls of extinct mammals because the skull cavity conforms closely to the shape of the brain. Small mammals with small brains were generally the first representatives of the major orders of the mammalian radiation, and larger members of the orders with larger brains came later. For example, as horses evolved from rather small

Figure 2 Dorsolateral views of the left cerebral hemispheres of three species of carnivores with brains of different sizes. All three brains contain some fissures that are characteristic of carnivore brains, including the suprasylvian and pseudosylvian sulci identified here, but the larger brains have more fissures. (a) The small-brained weasel has a cerebral cortex with only a few fissures. (b) The larger brain of the domestic cat has a few more fissures. (c) The much larger brain of the lion has even more fissures, and these fissures often have side branches.

ancestors, the course of evolution of these ungulates to present-day horses was characterized by the transformation of an almost smooth small brain to a large one with a complex pattern of many fissures. Similar increases in number of fissures occurred with the evolution of large brains in carnivores and primates.

Names of Fissures and Possible Homologies

The naming of sulci and gyri by various investigators has been generally based on physical features, such as location, orientation, and shape. A few have been named after investigators, such as Sylvian or lateral sulcus, and the Rolandic or central fissure. Fissures of the same relative locations in groups of related species are usually given the same name, implying that they are homologous (i.e., that they were present in the common ancestor of all species with those fissures, and that the fissures were retained in subsequent generations). Some investigators have attempted to homologize fissures that are similar in location across members of major taxonomic groups, such as between dogs and Old World macaque monkeys. However, such proclamations are not valid because the fossil record clearly indicates that the rather distant common ancestor of carnivores and primates was smooth brained (lissencephalic). Thus, the later emergence of fissures in both taxa cannot be homologous in the usual sense of the term (i.e., retained from a common ancestor). In a similar manner, New World cebus monkeys have large brains with a pattern of fissures that closely matches the pattern found in Old World macaque monkeys. Yet, the common ancestor of New

and Old World monkeys presumably had few fissures in cortex, probably only the lateral and calcarine fissures. However, there could be retained features of brain organization that led to the evolution of similarly located fissures as separate lines of evolution led to bigger brains. In this hypothetical case (functional theories of fissure formation are discussed later), the separate emergence of fissures in comparable locations would not be completely independent and could reflect shared patterns of gene expression in the brain or a 'deep' homology.

Experimental Manipulation of Fissure Formation

Attempts to experimentally alter the formation of sulci in developing brains have involved placing lesions in cortex or subcortical structures at various stages of fetal development or, recently, bilateral enucleation in fetal stages, which alters the development of visual cortex. In an early attempt to experimentally evaluate theories of fissure formation, Barron lesioned cortical and subcortical structures in the developing brains of fetal sheep before fissure formation and examined the brains at birth. Because a reduction in the volume of brain substance did not reduce the amount and general appearance of fissures in the remaining cortex, Barron concluded that the validity of one theory, that the skull restrains the brain and initiates the cortical folding, is unlikely. Because fissures also formed after the thalamus, corpus callosum, and basal ganglia were substantially damaged, Barron further concluded that cortical folding was not primarily dependent on a disproportionate growth between subcortical and cortical structures nor on the connections between subcortical and cortical structures. Thus, factors within the cortical sheet were the only remaining primary source of fissure formation. Later, Welker reported the results of placing cortical and subcortical lesions in the brains of neonatal cats and raccoons at approximately the time when fissures were starting to form and found that subcortical damage had a more limited effect. Although cortical lesions did not prevent the formation of fissures, they did alter their form. The remaining cortex grew and shifted toward the lesion site, and the fissure pattern became altered so that sulci tended to reorient toward the defect. These results were similar to the effects of cortical lesions in fetal macaque monkeys, again before fissures and cortical connections emerged. After such lesions, fissures did develop. However, there were abnormal sulci, especially near the lesion sites but also in more distant cortex and to a small extent in the other hemisphere. Thus, cortical lesions appear to have more effect on the development of cortical fissures than suggested by Barron. There may be both mechanical effects that distort the fissure pattern as cortex grows into the region of the lesion and other more distant effects that may relate to the altered connections in cortex as the result of the loss of some cortical tissue.

Another way to alter the course of cortical development and effect the formation of fissures has been to damage the developing visual system by removing the eyes in fetal macaque monkeys. The lack of retinal inputs to the lateral geniculate nucleus and the superior colliculus reduces their growth, and the lack of a relay of activation from the retina to the cortex via the lateral geniculate nucleus reduces the growth of primary visual cortex. Thus, the primary visual cortex at birth was smaller than normal, and the connection pattern of this reduced cortex with other areas of visual cortex undoubtedly was altered as well. The alterations in the visual system produced a deepening of minor dimples in the cortex of the occipital lobe, the formation of supplementary sulci, and an overall increase in the amount of convolution. Thus, changes in the sizes of cortical areas and their connection patterns can alter cortical fissure patterns.

These experimental findings are, to some extent, supported by the effects of abnormal brain development of fissure patterns in humans and other mammals. Although the causes of most of the cases of abnormal development, such as failure of the corpus callosum to form or the failure of the brain to grow to normal size, are unknown, such defects likely involve alterations in the genesis, migration, and connections of neurons. In human cases of microgyria, in which large numbers of shallow fissures form, cells fail to migrate to the deeper cortical layers, whereas in lissencephaly, in which only primary fissures form, cells in the more superficial layers are missing and cortical growth is reduced. In cases of abnormal brain development, whatever the cause, fissure patterns are typically abnormal.

Mechanical Theories of Fissure Formation

Many investigators agree that the fundamental reason fissures often form as brains grow is that the cortex remains relatively thin and grows as a sheet, increasing more in surface area while the underlying subcortical core of nuclei, ventricles, and white matter grows as a volume. In addition, the cortex is generated later and it grows disproportionately more with brain size than subcortical structures. As a result, the surface of the cortex expands faster than the surface of the core so that the cortex ends up 'shrink-wrapped' and folded over the core. Cortical

surface area varies by a factor of approximately 1000 across mammalian species, but the thickness of cortex varies by only a factor of approximately 5. The constraints on cortical thickness may be functional, stemming from the design of the local microcircuitry of the six-layered cortex, or related to metabolic requirements and a surface-based blood supply. Constraints may also be mechanical, such as the radial tensions resulting along the apical dendrites of cortical pyramidal cells as proposed by Van Essen. Other radial tensions in cortex result from radial glial and axonal fibers. Assuming cortical elasticity and plasticity along with radial tensions, the formation of cortical fissures can be modeled in a way that results in a fairly fixed number of convolutions of similar depth, with cortex being thicker in gyri than sulci. For sulci to vary in depth and placement in the model, additional factors need to be added, such as geometric asymmetries associated with the initial shape of cortex, local differences in cortical structure, and asymmetries in growth. For example, small asymmetries in the shape of the rapidly growing cortex would induce the development of convolutions at the point of distortion and trigger a wave of even more distant convolutions. There is some support from comparative studies for this prediction of the model. In many species in which the initial shape of cortex is more like a rostrocaudally elongated tube, fissures develop with a rostrocaudal orientation, whereas brains that are short and wide tend to develop transverse fissures. Thus, differences in the initial shape of the cerebral hemispheres influence the orientations of the fissures that develop. Another prediction of the model is that structural asymmetries, introduced by steps or gradients in the elasticity of cortex, tend to introduce fissures at or near the borders of change. As noted previously, cortex is not uniform in function or structure, and these local steps or gradients in cortical structure could trigger the formation of sulci. Because this mechanical effect is related to function, this possibility is discussed further in the next section on functional theories of fissure formation. Growth asymmetries introduced in the model also affect the formation of fissures in that convolutions emerge in the region of greater growth. This factor also is related to the functional regionalization of cortex and is discussed further later.

Several specific mechanical factors have been discussed as possibly contributing to the formation of fissures. Although cortical thickness does not vary much, a thicker cortex could be more resistant to bending so that fewer but deeper fissures form. Brains with thicker cortex would also require less cortical surface area for the same volume of cortex, and thereby fewer fissures. Perhaps the best support for these suppositions is that manatees have a thick cortex of approximately 4 mm, far more than most mammals, while having a highly lissencephalic brain. Also claustrocortex, a region of cortex where the deepest layer is closely approximated by the claustrum, is effectively thicker than other cortex as the claustrum acts as a seventh layer. Across species, deep folding in claustrocortex is absent. As another factor, Le Gros Clark and others have postulated that the constraining shape of the skull influences the formation of fissures. This conjecture has been widely dismissed because it appears that the growth of bones of the cranial vault is responsive to the underlying brain growth, and partial removal of the skull during development does not have a dramatic effect on the fissure pattern. Yet, some constraints, such as those on the relative width and length of the brain or the bending of the brain, likely exist and have some influence. Le Gros Clark also proposed that pressure from subcortical parts of the brain induces the formation of fissures. For example, Le Gros Clark suggested that the calcarine fissure in visual cortex of primates is induced by pressure from the underlying tectum of the midbrain causing a depression. Although it is difficult to find support for this view, it may be a factor. Le Gros Clark also argued that the joining of the two hemispheres by the formation of the corpus callosum provided a mechanical stress during cortical growth that would induce longitudinal folds to emerge in parallel to the corpus callosum and perpendicular to the lines of compression, especially near the corpus callosum. Several observations support this conclusion. Most notably, a corpus callosum does not develop in marsupials, and longitudinal fissures, especially on the medial wall of the cerebral hemisphere, are uncommon. In addition, in such rare cases in which the corpus callosum fails to develop in the human brain, sulci on the medial surface of the hemisphere tend to be vertical rather than longitudinal.

In summary, the sulci of the cortex are the result of mechanical factors that perturb the developing, ballooning cerebral hemisphere. Such factors as the constraints of the skull, subcortical structures, and the corpus callosum are considered here as mechanical causes that are largely or completely unrelated to the functional organization of the cortex. Mechanical causes that reflect the functional organization of cortex are considered next.

Functional–Mechanical Theories of Fissure Formation

Three features of the developing functional organization of the neocortex appear to have mechanical consequences that influence the formation of fissures.

First, the large functional units of cortex, the cortical areas, differ from each other in how they connect to other areas and to subcortical structures. As Van Essen forcefully argued, the axonal connections between areas generate mechanical tension, a force for inducing cortical folds. Since cortical areas differ in connections, and the cortical sheet is not uniform in connections, the regional specialization of this sheet impacts on the location and form of cortical fissures. Second, because of the regionalization of cortex, growth is uneven. Some cortical areas become thicker or more extensive than others do as they disproportionately grow in development, whereas other areas develop laminar specializations that may have mechanical consequences. These regional factors all have the potential to influence fissure formation. Third, cortical areas sometimes vary internally in structural organization. For example, primary visual cortex, area 17, is thinner in the portion that represents monocular vision than it is in the part that represents binocular vision, and greater cortical thickness resists fissure formation. In addition, many cortical areas are modularly organized, and this provides a potential influence as types of modules differ in cellular structure and in connections. Finally, cortical areas with an orderly representation of a sensory surface may have sharp disjunctions where nonadjacent parts of the receptor sheet are represented next to each other. In such instances, a segregating septum often emerges between the two parts of the representation that has different mechanical properties and thereby initiates the formation of a sulcus. The locations of such fissures that have mechanical causes, while reflecting the functional organization of cortex, can tell us something about cortical organization in those species for which experimental evidence is missing, and they can guide experimental studies where the relationship of fissures to functional areas has been established.

In general, regional differences in cortical structure have not been considered as important in the formation of fissures because cortex has been assumed to not vary much in thickness, cell density, and cell type. However, motor cortex is often thicker than visual cortex, visual cortex sometimes has a broad layer 4 with clear subdivisions, and motor cortex typically lacks an identifiable layer 4. Junctions between areas of different thicknesses are considered to be a favorable place for bends in the cortex. Bends are also likely in the middle of thinner areas that are anchored by thicker areas. Also, the lateral growth of superficial cortical layers relative to deep cortical layers has been postulated as a factor in the production of bulges and bends. Developmental and evolutionary changes in the sizes of some cortical areas relative to others would also likely alter fissure patterns. As previously noted, primary visual cortex (area 17) does not grow to a normal size after early prenatal loss of eyes in monkeys, resulting in an altered pattern of fissures in occipital cortex. Because the size of area 17 in humans and chimpanzees is approximately the same, although the size of the cortical sheet in humans is much bigger, this proportional difference likely accounts for some of the differences in occipital fissures in the two taxa. The expansion of prefrontal cortex relative to other parts of the frontal lobe in the evolution of the human brain also likely had consequences.

The argument that the connection patterns that form between cortical areas during development have a major effect on the locations of fissures has been most effectively made by Van Essen. His 'tension-based' hypothesis of cortical folding holds that especially the long-distance connections (as opposed to intrinsic connections) that emerge in developing cortex generate mechanical tension that resists the expansion of the cortical sheet and causes buckling that results in gyri. Thus, if two adjoining areas become strongly interconnected, the connections will resist spatial separation of the areas as cortex grows, and a buckle will form near the border between the areas, forming a gyrus so that the areas become closely approximated along opposite banks of the gyrus. A fortuitous consequence of this arrangement is that the connections between the two areas end up much shorter than in flat or otherwise folded cortex, and the conduction times for axons and the axon lengths (hence, axon volume) become less. Thus, computations are faster and less brain tissue is needed – both clear advantages. Possibly such advantages have influenced the evolution of brain factors that initiate fissures that reduce important connection pathways, but there is no evidence of this, and the tension theory does not require it. As a key example of a fold that is consistent with the tension theory, the lunate sulcus that forms in many of the anthropoid primates folds the second visual area, V2, under the primary visual area, V1 or area 17. These two areas are densely interconnected, and the folding shortens the lengths of these connections. In contrast, the tension theory predicts that fissures develop between areas with few interconnections. Because there would be little resistance to folding between two areas with few interconnections, depressions and then fissures tend to develop and separate such areas. The key example for this in the larger brained anthropoid primates is the central sulcus, which separates primary motor cortex, M1, from primary somatosensory cortex, S1 or area 3b. These two areas have very few interconnections because most somatosensory inputs to M1 are from higher order somatosensory fields. Thus, there are few connections to create binding tensions between M1 and S1, and a fold stretches those few connections even

further. Even though the consequences of such tensions from axons on the development of fissures have not been explored to the point of allowing a careful evaluation of the theory, the implications are clear. Many, and perhaps most, of the cortical fissures reflect the functional organization of the cortex and can be used as guides to determining the functional organization.

Finally, a specific type of cortical fissure develops within primary somatosensory cortex of some mammals and perhaps in other sensory areas as well. The skin, the receptor sheet for the cutaneous receptors of the somatosensory system, differs from the receptor sheets for vision (retina) and audition (cochlea) in that there are obvious splits, tears, and protrusions in the sheet. Thus, the upper lip is separated by the mouth from the lower lip, as are the digits from each other. In addition, the protruding limbs separate the receptors in the hand and foot from those on the body. Yet, the central representations of the cutaneous receptors have a compact form, especially in the cortex of primates, in which the representation of the contralateral skin receptors is in the form of a long mediolateral strip. This brings representations of digits next to each other and the representation of the thumb (D1) next to that of the lower face. In general, the intrinsic connections within a cortical area are short, but they are most dense along representations of uninterrupted receptor populations, and they are sparse between adjoining representations of separate receptor populations. Thus, there are few connections between the adjoining representations of the hand and lower face in primates and denser connections along representations of the phalanges of the same digit. Moreover, narrow zones of cortex between adjoining representations of separated populations of receptors receive few thalamic inputs and have smaller and perhaps fewer neurons. These septal zones are visible histologically and appear to emerge because of the segregation of thalamocortical afferents according to their source of activation as they compete for cortical space. We call these zones segregating septa because they separate parts of representations that have little interaction. Because these septa are structural perturbations in the cortical sheet, one would expect segregating septa to sometimes initiate the formation of sulci, and they do. Those segregating sulci have been called limiting sulci by Welker, and they are illustrated and described extensively in his monograph. In raccoons, which have a large representation of the hand in S1, small sulci separate the representations of the digits from each other, whereas deeper sulci separate the representation of the hand from the face and the hand from the adjoining representation of the foot. In other carnivores, fissures separating representations of the forepaw from the face, and the forepaw from the foot, are common. Similar segregating sulci occur in S1 of some marsupials, primates, ungulates, and rodents. If we knew more about the organization of S1 in other taxa, undoubtedly there would be more examples. However, these examples firmly establish the principle. Segregating septa within cortical representations are structurally different from adjoining cortex within the area, and this structural difference can induce a fold. Consistent with the tension-based theory of Van Essen, segregating fissures are between regions of cortex with poor interconnectivity.

It is unknown if cortical areas other than S1 have segregating septa that lead to fissures. The star-nosed mole, with its 22 appendages of its nose, has 11 septa for the 11 rays on the contralateral face in S1 and the second area, S2, of somatosensory cortex, but its small brain is smooth. However, the obvious segregating septa in S2 indicate that segregating sulci may be identified in cortical areas other than S1. In the visual system, the lack of photoreceptors in the location of the nerve head (optic disk) of the retina results in a structural modification of a central part of primary visual cortex in which nearby neurons represent receptors on opposite sites of the optic disk. This structural change in cortex is similar to a segregating septum, but a role in the formation of fissures has not been established. Yet, primary visual cortex in primates does fold down the middle, through the structurally modified zone reflecting the optic disk, and the structural difference together with a reduced local pattern of horizontal intrinsic connections could be initiating factors for the fissure.

Fissure Patterns in the Cortex of Extinct Mammals

There are a number of inferences that can be made about the functional organization of the brains of extinct mammals from the position of sulci on skull endocasts. One possibility is to use the positions of sulci to estimate the sizes of lobes of the brain. For example, the central sulcus is well developed in most anthropoid primates, and this sulcus consistently separates somatosensory from motor cortex, thereby separating frontal from parietal cortex (the frontal lobe from the parietal lobe). Since the frontal lobe contains motor and premotor areas, as well as the prefrontal cortex (important for foresight and planning in social primates) and orbital frontal and cingulate limbic cortex (important for evaluating stimuli and situations), the relative sizes of the frontal lobe in our hominin ancestors provide an important clue about the level of social cognition as well as other abilities. However, the frontal lobe is not proportionally larger overall in humans

than in apes, possibly because more of the human frontal lobe is devoted to prefrontal cortex than motor areas. Nevertheless, the relative proportions of the frontal lobe in extinct taxa of hominins remain a potential source of comparative information on frontal lobe functions. In a similar manner, the position of the lunate sulcus, which is located near the junction of primary and secondary visual cortex in some extant anthropoid primates, has been used (with some disagreement) to locate the rostral border of primary visual cortex as similar to that of modern humans in the brains of the earliest hominins.

Another possibility is to search for asymmetries in the patterns of sulci in the two hemispheres to evaluate when certain brain specializations may have emerged. As mentioned previously, in humans, the lateral sulcus is typically higher in the right cerebral hemisphere than in the left, and this difference has been attributed to the disproportionate expansion of auditory and cognitive areas in the left hemisphere that are associated with language. There are a few suggestions of this asymmetry in fossil hominins, possibly for language but more likely for the cognitive skills that eventually made language possible. Convolutions and protrusions have also been used to estimate the size of Broca's area, a portion of the frontal lobe that is critical in the production of speech. Because the region is larger in the left than the right hemisphere of modern humans, it is interesting that a Broca's region asymmetry with the larger size on the left has been noted in fossil hominin endocasts. Again, the asymmetry does not indicate that language was present but, rather, that neural systems compatible with language possibly existed. Overall, these hints about the functional organization of the brains of early hominins suggest an organization that was already more humanlike than the brains of modern-day chimpanzees.

There is also something to be learned from the positions of the sulci that are likely to have been segregating fissures in fossil brains. These are the fissures in somatosensory cortex that separate adjoining representations of skin surfaces that are partially or largely separate on the body. Evidence of segregating fissures in endocasts of fossil brains may be difficult to obtain because these fissures in extant mammals are often shallow. However, early efforts by Radinsky provided evidence that some extinct carnivores had enlarged representations of the face (whiskers) or the forepaws, suggesting different specializations of the somatosensory system. Further efforts to identify limiting sulci in extant and extinct mammals would be useful.

Occlusive Diseases and Stroke

Of patients who present to the emergency room with an acute onset of a focal neurologic deficit, typically 95% have problems caused by a vascular syndrome. Of these, 15% are hemorrhagic and may be caused by intracerebral hemorrhage, subarachnoid hemorrhage, or subdural hemorrhage, while 85% are cerebral infarction. Cerebral infarction in this setting is defined as an area of the brain not receiving adequate blood flow and therefore resulting in neurologic function and ultimate cell death. Of the patients who present with infarction, 41% have an unknown etiology; 21% are lacunar in nature, or small artery or arteriolar occlusions of the perforating vessels in the deep white matter or diencephalon; 16% are cardiogenic in origin with an embolus originating in the heart; 11% are caused by large artery (typically the carotid artery) atherosclerotic disease; and 11% are found to have tandem arterial pathology with atherosclerotic lesions of the carotid artery, vertebral arteries, or intracranial arteries.

Lacunar strokes are small infarcts in deep noncortical white matter and brain stem that result in the occlusion of penetrating branches of cerebral arteries. The term 'lacune' refers to the crescent- or moon-shaped tiny stroke that results from occlusion of these vessels. These lesions were seen on pathologic evaluation and now can be seen on magnetic resonance imaging (MRI) studies after infarction. These may be due to lipohyalinosis secondary to hypertension of small arterioles (on the order of 200 μm) and may also be the source of intracranial hemorrhage when the vessel weakens and the presenting diagnosis may be that of an intraparenchymal brain hemorrhage. Lacunar strokes tend to have a standard acute presentation with fairly rapid resolution depending on the exact size of the infarction. This tends to be a diagnosis of exclusion based on the neurologic syndrome and ruling out other sources of intracranial stroke.

In addition to thromboembolic occlusions, vessel dissection may be the etiology of stroke. Dissection occurs when the intimal layer of a blood vessel is damaged, allowing blood to collect between the intima and media, resulting in narrowing of the arterial lumen. This can result from trauma or neck manipulation, but may also arise spontaneously. In these patients, vertebral and carotid dissections may lead to distal emboli and cerebral infarction. Treatment of these patients typically involves anticoagulation with heparin, followed by longer-term anticoagulation with antiplatelet therapy or warfarin. The vessel injury tends to stabilize over time and in many individuals will in fact heal itself. There are situations in which vessel dissection and occlusion can occur, and urgent revascularization may need to be considered in these patients with either an endovascular or a surgical approach.

Patients with atherosclerotic disease of the internal carotid artery (ICA) may experience a transient ischemic attack (TIA), with or without amaurosis fugax, or a stroke. In many cases, these patients can be identified without symptoms. Once a carotid lesion has been identified, careful consideration should be given to whether it would be indicated to perform carotid endarterectomy or carotid artery stenting to accommodate revascularization.

Moya-Moya syndrome is a poorly understood condition in which there is a progressive arteriopathy with narrowing of the proximal intracranial vessels, and, in response to this, the distal vessels proliferate in density and give the appearance on cerebral arteriogram of a 'puff of smoke' or Moya-Moya vessels. This can occur in children who present more frequently with cerebral infarction, and in adults who present more frequently with intraparenchymal brain hemorrhage. For patients who present with TIA or infarction, surgical revascularization may be considered with either an extracranial-to-intracranial bypass graft or an encephalodural angiosynosis procedure (EDAS), in which the superficial temporal artery is placed on the brain's surface and as a result small vessels sprout to supply the brain tissue with vessels over time.

In addition to arterial causes of infarction, venous sinus thrombosis is a situation of hyperperfusion of an area of a brain, resulting in edema or hemorrhage. This can be seen with an increased incidence in certain disease states or with certain medications such as oral contraceptives. Patients with venous sinus thrombosis are typically managed with anticoagulation and, at times when extensive thrombosis is present, may require endovascular clot lysis.

For patients who experience acute onset of neurologic deficit and are found to have arterial occlusion in the brain, intravenous tissue plasminogen activator (tPA) may be indicated in an attempt to dissolve the clot. An additional strategy is to use endovascular techniques to directly manipulate and remove the clot and provide for revascularization. In both these situations, time is of the essence, as a longer interval

of occlusion results in a greater chance of cerebral infarction. For patients with arterial infarctions, it has been well defined that there is a 23% mortality rate, with 26% of patients discharged to a nursing home. Three percent of patients were discharged to a rehabilitation unit, and 48% of patients were able to return home with some degree of neurologic deficit or a complete recovery.

When patients present to the emergency room with a new neurologic deficit, a computed tomography (CT) scan should be obtained urgently. If there is no evidence of hemorrhage, then heparin therapy should be strongly considered. With current imaging techniques, it is also possible to perform computed tomographic angiography (CTA) to evaluate the patency of the vessels. In some institutions, MRI study is performed emergently as well in order to establish perfusion of brain tissue, as well as early changes in the parenchymal water content indicative of the extent of infarcted cerebral tissue.

Risk factors associated with cerebral infarction include hypertension, hypercholesterolemia, smoking history, diabetes, and family history. In patients with TIAs or infarction, risk modification should be accomplished, as well as cholesterol lowering and blood pressure management with medications.

Cardiac source of brain embolism accounts for approximately 20% of all cerebral infarction. While there is no specific neurologic feature that can diagnose these patients, a complete cardiac evaluation is indicated, including an echocardiogram, electrocardiogram, and Holter monitoring to evaluate for any arrhythmias. Depending on results of the evaluation, anticoagulation of these patients may be indicated, especially if an arrhythmia of atrial fibrillation is discovered.

Intracranial Vascular Diseases

Intracranial Aneurysms

Intracranial aneurysms tend to occur at division points of major arterial branches of the brain blood vessels. They are typically referred to as 'berry' aneurysms, based on their saccular nature. Fusiform aneurysms may occur, in which the entire diameter of the arterial wall is diseased and produces a diffuse widening of the artery. Saccular aneurysms can present with rupture, producing subarachnoid or intraparenchymal hemorrhage. Unruptured aneurysms may be discovered as incidental findings or as a result of mass effect-causing symptoms by pressing on sensitive neurological structures.

Ruptured aneurysms For ruptured aneurysms, early treatment (within 24–48 h) is usually indicated. At the time of a subarachnoid hemorrhage from an intracranial aneurysm, patients may experience 'the worst headache of their life,' have focal neurologic deficits, or present in coma. Approximately 15% of patients with subarachnoid hemorrhage die at the time of the hemorrhage, with a total of 45–50% mortality from ruptured aneurysms within 2–3 weeks of the initial hemorrhage. Of the survivors, one-third of the patients make a good to excellent recovery, while one-third of the patients remain impaired and the final third of patients have varying degrees of neurologic deficit but may return to normal levels of activity.

Once an aneurysm ruptures, there is a threat of rerupture. This occurs with an incidence of 4% in the first day after the initial hemorrhage, and approximately 1.5% per day thereafter up to 2 weeks, yielding a 26.5% chance of a second hemorrhage over this interval. To prevent rehemorrhage, early reobliteration with surgical techniques to clip the aneurysm and seal off the base of the aneurysm or endovascular techniques to place a coil device or other agents inside the aneurysm are typically utilized (**Figure 1**).

Following subarachnoid hemorrhage, vasospasm may occur. It is believed that the blood distributed in the subarachnoid space at the time of hemorrhage induces inflammation and constriction of the cerebral vessels. Vasospasm typically occurs 5–7 days after the subarachnoid hemorrhage and carries with it a risk of potential serious neurologic morbidity from infarction. With reduced diameter of vessels, low tissue perfusion may ensue, resulting in infarction. To treat vasospasm once the aneurysm is obliterated, blood pressure may be elevated to enhance cerebral perfusion. In addition, central venous hypervolemia may be utilized to assist with maximizing cardiac output in an attempt to maximize cerebral blood flow. Patients are typically hemodiluted to a hematocrit of 32% in an attempt to maximize blood flow by minimizing the viscosity of blood without impairing the oxygen-carrying capacity.

A final problem that may develop after subarachnoid hemorrhage is hydrocephalus. This can occur acutely and be managed with ventricular drainage at the time of presentation. Hydrocephalus may also occur in subacute or chronic form, which may require ventricular drainage or permanent ventricular shunting.

Unruptured aneurysms When patients are discovered to have aneurysms that have not ruptured, there is time for discussion regarding whether or not the lesion should be treated. This decision is often based on the size of the aneurysm (typically, lesions smaller than 4–5 mm are not treated), as well as the age and overall health of the patient. Endovascular and surgical techniques are used to obliterate

Figure 1 (a) Intra-operative view of an aneurysm arising at the junction of the left internal carotid artery and anterior choroidal artery. (b) The aneurysm is obliterated by placement of a surgical clip.

Figure 2 Angiogram (lateral view, left vertebral artery injection) of large occipital lobe arteriovenous malformation appearing as a tangle of vessels.

unruptured aneurysms; which technique is chosen is often based on the age of the patient, the location of the lesion, and the predicted risk of treatment. Aneurysms are typically given a size range of small (less than 8–9 mm), medium (10–15 mm), large (15–25 mm), or giant (greater than 25 mm). The risk of treating intracranial aneurysms does correlate to some extent with the size of the lesion as well as the age of the patient.

Vascular Malformations

Arteriovenous malformations Vascular malformations of the central nervous system are typically subdivided based on their histopathology and pathophysiology. True arteriovenous malformations (AVMs) of the brain are thought to be developmental in origin. These lesions are typically in the brain parenchyma and involve a tangle of arteries and veins with intervening brain tissue between these vessels (Figure 2). The vessels are not normal in their arterial and venous structures, and there is great variability in the histology of these structures. The brain tissue between these vessels may or may not be functional brain tissue, and this has to be carefully considered prior to recommending any form of treatment. AVMs typically present when patients have a hemorrhage from the lesion or a seizure. The lesions are also found incidentally. Once an AVM has been identified, careful consideration is given to treatment, based on balancing the risk of treatment against the risks of the natural history of the disease. Treatment modalities of open surgery, embolization followed by open surgery, and radiosurgical techniques are utilized to treat AVMs. The natural history of AVMs is such that once a hemorrhage from an AVM has occurred, the rehemorrhage rate is 6% in the first year after that hemorrhage and drops to approximately 4% per year thereafter. For patients who have not had a prior hemorrhage, it is felt that the hemorrhage rate is somewhat lower but occurs at a rate of somewhere between 2 and 4% per year for that individual. Therefore, the decision as to whether or not to treat an AVM must be made based on balancing these rupture rates against the risk of intervening to remove or radiate the lesion. As noted earlier, treatment modalities for AVMs include transarterial embolization, surgical resection, or radiosurgical techniques. Radiosurgery is a technique in which a focused beam of radiation is used to deliver a high dose of radiation to the AVM, thereby inducing an injury response that occurs over several years. Over this interval the vessels thicken and eventually obliterate on angiography.

Dural arteriovenous malformations Dural AVMs are thought to be acquired lesions. It is believed that they occur in response to a certain degree of venous thrombosis. Once a venous occlusion has occurred in or near one of the major draining sinuses of the brain, it is thought that angiogenic factors are produced which allow for development or opening of naturally occurring shunts from the arterial to the venous system on the dura. The dura is the leather-like structure that lines the inside of the skull and covers the brain. Dural AVMs can occur anywhere near a major sinus. A dural AVM may cause a bruit or may cause intracranial hemorrhage. Hemorrhage can occur when the venous drainage from the AVM occurs in a retrograde fashion through the normal cortical venous drainage and, therefore, exposes the normal cortical vein to high pressure. Such lesions often require urgent treatment in order to prevent further hemorrhage.

Dural AVMs are typically treated with transarterial or transvenous embolization with or without additional surgery to excise the lesion. If the dural AVM occurs in such a fashion that there is no cortical venous drainage, then they are thought to be a much more benign type of lesion and can be followed clinically or managed based on symptoms, such as to relieve a subjective bruit.

Cavernous malformations Cavernous malformations are lesions that can occur anywhere in the brain and spinal cord. They are best imaged by MRI and are typically occult on standard angiography (Figure 3). They may be familial in certain cases, and there have been several genes associated with familial cases of cavernous malformation (CCM 1, 2, and 3). Cavernous malformations are collections of sinusoidal vessels that are neither artery nor vein. The vessel lumens may thrombose over time or, because of the thin-walled vessels, may hemorrhage. The hemorrhages tend to be more benign than those from true AVMs since these are low-flow lesions under low pressure. While cavernous malformations can be excised surgically, it is believed that supratentorial cavernous malformations have a fairly low hemorrhage rate, and therefore older individuals are often managed expectantly. Cavernous malformations typically present with hemorrhage or seizure. Lesions in the thalamus and brain stem carry a much higher risk of surgical intervention but also may have a higher hemorrhage rate, or at least a higher risk of symptom-producing hemorrhage. This is probably true for the spinal cord lesions as well, and surgical resection must be carefully balanced against the risk of developing a neurologic deficit secondary to surgical intervention. While radiosurgery has been utilized with cavernous malformations, the end point is difficult to evaluate because the lesions do not typically obliterate after radiosurgical treatment. There have been several reports demonstrating a high incidence (25%) of complications after stereotactic radiation.

Figure 3 Magnetic resonance imaging gradient-echo sequence showing a right cerebellar cavernous malformation.

Developmental venous anomalies Approximately 15% of cavernous malformations occur in conjunction with developmental venous anomalies. Developmental venous anomalies are a collection of normal veins that coalesce to form one large draining vein but are not under any arterial shunting. These are thought to be fairly common in the general population (on the order of 2–5%). Developmental venous anomalies in and of themselves are believed not be at risk for rupture and may occur adjacent to cavernous malformations in what has been termed a 'collision lesion.' Typically, developmental venous anomalies should not be treated, as this removes the venous drainage from the area of the brain involved and may result in a venous infarction.

Capillary telangiectasias Capillary telangiectasias are small collections of dilated capillaries that can occur throughout the diencephalon and brain stem. Some authors believe that these lesions may be related to cavernous malformations but seem to have little, if any, potential for hemorrhage and often do not require any treatment. In addition, they are typically deep in the white matter, and therefore treatment would carry with it a substantial risk of neurologic deficit.

Spinal Vascular Diseases

Arteriovenous Malformations of the Spinal Cord

Dural arteriovenous fistulas Vascular malformations can also affect the spinal cord. The most commonly encountered type of vascular malformation of the spinal cord is the dural arteriovenous fistula. As with dural lesions in the intracranial compartment, dural arteriovenous fistulas in the spine are thought to be acquired lesions. They are typically small AVMs on the dural root sleeve that can occur throughout the thoracic and lumbar spinal roots. The venous drainage from these lesions is intradural and, therefore, exposes the spinal cord to elevated venous pressures. It is the elevated venous pressure that is thought to be responsible for the progressive neurologic dysfunction that occurs with these lesions. The extreme example of this is Foix-Alajouanine syndrome, in which there is progressive venous infarction and edema of the entire spinal cord, which in certain cases has resulted in complete tetraplegia and death. When these lesions are discovered early, they may be treated with embolization or, more typically, with surgical occlusion of the AVM on the dural root sleeve in a fairly straightforward fashion to obliterate the venous hypertension.

Glomus type More typical parenchymal AVMs may also occur in the spinal cord. The glomus type of AVM is a true arteriovenous malformation of the spinal cord parenchyma. These lesions often present with hemorrhage or progressive deficit and are very difficult to treat from the standpoint of surgical or radiation techniques. They tend to be high risk, and the incidence of postoperative deficit is high.

Juvenile type A juvenile type of spinal cord AVM is one that appears to be metameric in origin. It is thought to develop concurrently with the involved segment of spinal cord and associated body tissue and, therefore, involves not only the spinal cord but also the surrounding soft tissue and bone. These are typically diagnosed in children and can be quite extensive and difficult to treat.

Perimedullary The final type of AVM of the spinal cord itself is what is termed a perimedullary AVM. These can be direct arteriovenous fistulas on the surface of the spinal cord or small AVMs immediately on the spinal cord's surface. These may be treated with open surgery or endovascular embolization, depending on the relationship to the artery of Adamkiewicz, which typically occurs in the thoracic region and is one of the major feeding vessels to the spinal cord parenchyma.

Traumatic Vascular Diseases

Traumatic Aneurysms

Intracranial aneurysms may also arise following significant open or closed head injury. These are most commonly pseudoaneurysms, meaning that the vessel wall is ruptured and the hematoma is confined in the extravascular space by surrounding cerebral structures. Typical locations for these aneurysms include the distal anterior cerebral artery and the ICA at the skull base. Traumatic aneurysms can be discovered during neuroimaging following the trauma or may present with delayed hemorrhage. Diagnosis can be made with CTA, magnetic resonance angiography (MRA), or conventional angiography. Since the rupture rate is high, surgical or endovascular management is usually indicated.

Carotid-Cavernous Fistulas

Carotid-cavernous fistulas are a type of arteriovenous fistula between the carotid artery and the cavernous sinus. They can occur posttraumatically or spontaneously and are subclassified according to whether the fistula is directly between the cavernous sinus and the ICA or indirectly between the cavernous sinus and meningeal branches of the internal and/or external carotid artery. Symptoms are generally due to venous hypertension, and patients may present with a bruit, ocular chemosis, or pulsating exophthalmos. Diagnosis is usually confirmed by conventional angiography. Progressive symptoms, especially visual deterioration, are an indication for urgent intervention; however, some low-flow lesions may thrombose spontaneously. Treatment is commonly performed endovascularly by transarterial or transvenous embolization.

Spontaneous Intracerebral Hemorrhage

Spontaneous intracerebral hemorrhage without an identifiable structural cause is most commonly caused by hypertensive vasculopathy or cerebral amyloid angiopathy. It tends to affect people over the age of 60 and usually presents as a sudden onset of a focal neurological deficit with a change in level of consciousness. Diagnosis is made by plain CT in the emergency room setting (Figure 4). Hypertensive bleeds tend to be deep and involve the striatum, thalamus, and cerebellum. Spontaneous intracerebral hemorrhages caused by amyloid angiopathy, on the other hand, tend to be lobar. Anticoagulation is a significant risk factor, among others, for intracerebral hemorrhage in the elderly population. Treatment typically involves some combination of anticoagulation reversal, medical management to prevent secondary brain injury, and surgical evacuation of the hematoma.

Cetacean Brains

L Marino, Emory University, Atlanta, GA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Cetaceans are an order of fully aquatic mammals consisting of two modern suborders. These two modern suborders, collectively known as neocetes, include the odontocetes (toothed whales, dolphins, and porpoises) and the mysticetes (baleen and rorqual whales). There are 67 species of odontocetes and 11 mysticete species. The first cetacean suborder, the archaeocetes ('ancient whales') began as fully terrestrial hoofed animals derived from an ungulate ancestor. Archaeocetes later became fully aquatic before they became extinct. Archaeocetes survived from approximately 55 to 33 Ma.

Cetacean brains have evolved substantially over the past 55 My during their adaptation from a terrestrial lifestyle to a semiaquatic existence and finally, approximately 43 Ma, to a fully aquatic lifestyle. Modern cetacean brains are characterized by several features. These include large mass (both in absolute terms and in relation to body mass), changed proportions of structures related to various domains of sensory processing, a high degree of cortical gyrification, an atypical arrangement of cortical surface projection zones known as cortical adjacency, a high degree of hemispheric independence, and a highly unusual neocortical cytoarchitecture.

Gross Structure of the Cetacean Brain

The adult cetacean brain exhibits a number of unusual gross morphological characteristics. As compared with terrestrial mammals the dolphin brain is much more spherical. The brain is greatly widened bitemporally and heightened and stands in contrast to the elongated brains of primates and carnivores. In cetaceans the cranium is telescoped along the beak–fluke axis and the forebrain is foreshortened, leading to a rounded and high brain shape. The brain's natural orientation in the cranial cavity is also unusual. The brain exhibits pronounced mesencephalic, pontine, and cervical flexures, leading to a foreshortening of the forebrain and a rotation of the brain along the body axis almost 90°. This configuration has led many authors to liken the shape of the cetacean brain to that of a boxing glove. The flexures, which are maintained throughout adulthood in cetaceans, are reminiscent of those observed in the embryonic state of terrestrial mammals (see Figure 1).

Cerebral enlargement in cetaceans occurred most exuberantly in the parietal and temporal regions. Whereas primate brains feature large frontal lobes, no homologous frontal lobe region in the cetacean brain has been identified, leading many investigators to substitute the term 'orbital lobe' for frontal lobe when referring to these modest, ventrally oriented hemispheric regions (see Figure 1).

Brain Size

Modern cetacean brains are among the largest of all mammals in both absolute mass and in relation to body size. One of the hallmarks of cetacean brain evolution is the substantial increase in relative brain size and expansion of the cerebral hemispheres. Average brain size for the extinct suborder of cetaceans, the archaeocetes, was 750 g and varied from about 290 to 2240 g. Modern cetacean brain size, which averages approximately 785 g, ranges from 220 g for the adult Franciscana dolphin (*Pontoporia blainvillei*) to 8000 g for the adult sperm whale (*Physeter macrocephalus*), the largest brain on earth.

Brain size is perhaps more meaningfully expressed as an 'encephalization quotient' (EQ), which is a value that represents how large or small the brain of a given species is compared with other species of the same average body weight. When examined relative to body size within the context of EQ, the great enlargement in the brain in cetaceans becomes even more evident. Archaeocete brains were smaller than expected for their body size. Almost all modern odontocetes, on the other hand, possess above-average encephalization levels compared with other mammals and therefore have brains larger than expected on the basis of brain–body allometry. In order to understand the meaning of EQ it is helpful to note that the EQ for modern humans is 7.0. That is, our brains are about seven times larger than one would expect for our body size. Turning to cetaceans, numerous odontocete species possess EQs in the range of 4–5, that is, they possess brains 4–5 times larger than one would expect for their body size. Many of these odontocete values are second only to those of modern humans and are significantly higher than any of the nonhuman anthropoid primates (highest EQ $\sim$ 3.3). We now know that a substantial increase in EQ during cetacean evolution occurred approximately 35 Ma, when average EQ jumped from 0.5 for archaeocetes to 2.0 for the

Figure 1 Dorsolateral view of bottlenose dolphin brain showing the location of the parietal, occipital, temporal, and orbital lobes. Image courtesy of the Comparative Mammalian Brain Collection, The National Museum of Health and Medicine, Armed Forces Institute of Pathology, Washington, DC.

first neocetes (again, early odontocetes and mysticetes). Therefore, although many archaeocetes possessed large brains because they had large bodies, a major increase in the size of the brain relative to the body did not occur until the emergence of the neocetes.

EQs of mysticetes are all below a value of 1, that is, below average, because of an uncoupling of brain size and body size in very large (and aquatic) animals. Nevertheless, the large absolute size of the mysticete brain (and other features, described later) demonstrates that the mysticete brain underwent evolutionary changes similar to those of odontocete brains.

Surface Features

The cetacean telencephalon is arranged into three concentric tiers of limbic, paralimbic, and supralimbic tissue and accounts for much of the total brain volume (e.g., 63% in the Franciscana, *Po. blainvillei*, and 87% in the sperm whale, *Ph. macrocephalus*). The high degree of cortical gyrification and resulting surface area in modern cetacean brains is unsurpassed among mammals, including humans. Endocasts from fossil material indicate that the surface of the archaeocete brain, in contrast, was relatively smooth, providing further evidence that modern cetacean brains have expanded substantially over time. In the bottlenose dolphin (*Tursiops truncatus*) and common dolphin (*Delphinus delphis*), neocortical surface areas have been measured, respectively, as 3745 and 2136 cm^2 and average total brain weights as 1587 and 802 g. These values exceed values for modern humans, with neocortical surface area being approximately 2275 cm^2 and average total brain weight at 1300 g.

Electrophysiological mapping studies of cetacean cortex places primary visual cortex on the vertex of the hemisphere in the lateral gyrus and the primary auditory cortex lateral and directly adjacent to it in the suprasylvian gyrus. Secondary auditory cortex lies lateral to the primary auditory field in the medial ectosylvian gyrus and somatosensory and motor cortices lie immediately adjacent and rostral to the visual and auditory regions (see **Figure 1**). This is a highly unusual arrangement for large mammal brains. This configuration, termed 'cortical adjacency,' means that all of the sensory–motor projection zones of the cetacean brain are confined to one contiguous region of the overall surface, with a vast expanse of non-projection cortical tissue (that can be tentatively described as 'integrative' or 'associative') in the remaining portion of the hemispheres.

Reproportioning of Central Sensory Structures

Auditory Structures

Cetaceans use audition in an extremely complex and multifaceted manner. Therefore, auditory structures are well developed in all cetaceans. Furthermore, auditory structures are relatively larger in odontocetes than in mysticetes, because of the ability of odontocetes to echolocate. The vestibulocochlear nerve in cetaceans is immense in diameter and is composed of relatively more auditory than vestibular fibers. The ventral cochlear nucleus, trapezoid bodies, lateral lemniscus, and inferior colliculi (auditory tectum) are all greatly enlarged in comparison with terrestrial mammals. Whereas in mysticetes the inferior colliculus can be larger or smaller than the superior colliculus (visual tectum), in odontocetes the inferior colliculus is always larger than the visual tectum and can be at least four times the size of the superior colliculus. The auditory tectum projects to a large medial geniculate nucleus in the massive thalamus. Likewise, the primary and secondary auditory projection zones on the cerebral surface are extensive.

It is important to note that auditory structures in the cetacean brain have not expanded at the expense of visual structures. With the exception of the blind river dolphins, visual structures in the cetacean brain are well developed.

Olfactory Structures

One of the hallmarks of cetacean brain evolution that is found to varying degrees in other marine mammals is the reduction of olfactory structures. Olfaction has been completely lost in adult odontocetes. Fetal odontocetes possess small olfactory structures that regress completely by birth. Interestingly, a short olfactory peduncle sometimes remains in adult sperm whales (*Ph. macrocephalus*) and northern bottlenosed whales (*Hyperoodon ampullatus*), which may be consistent with their phylogenetic status in relation to other cetacea. Adult mysticetes, while possessing a vastly reduced olfactory system, have maintained small olfactory bulbs, a thin olfactory peduncle, and an olfactory tubercle.

The reduction of olfactory input has possibly resulted in a reproportioning of the limbic system in cetaceans. Notably, the cetacean hippocampus (archicortex), fornix, and mammillary bodies are all highly reduced while the amygdala is large and well developed. These proportions may reflect the maintenance of substantial nonolfactory sources of input to the amygdala.

Hemispheric Connectivity

As in other mammals, the two hemispheres of the cetacean brain are connected by anterior and posterior commissures and the corpus callosum. In cetaceans, corpus callosum mass is considerably smaller in relation to brain mass than in other mammals. This is partly due to the general allometric rule that larger brains maintain less interhemispheric connectivity. Therefore, because most cetacean brains are quite large they possess small corpora callosa. For example, the human and killer whale (*Orca orcinus*) corpora callosa possess the same cross-sectional area despite the fact that the killer whale brain is over five times the mass of the human brain.

In addition to a relatively small corpus callosum, cetacean brains evince other aspects of hemispheric independence. In most mammals, each eye projects the majority of its nerve fibers to the contralateral hemisphere but also shares some fibers with the ipsilateral side. Cetaceans, on the other hand, exhibit the highly atypical arrangement of total decussation of the optic nerves to the contralateral hemisphere. Furthermore, each hemisphere is connected to a separate blood supply.

Perhaps the best-known behavioral evidence for a high degree of hemispheric independence in cetaceans is unihemispheric sleep. Many investigators have suggested that the relatively weaker interhemispheric connections in cetacean brains may facilitate the unusual unihemispheric sleep patterns exhibited by cetaceans. Early stages of sleep in cetaceans may occur unilaterally or bilaterally. Stage 3 (slow-wave sleep), however, occurs in only one hemisphere at a time and is correlated with unilateral changes in slow-wave electroencephalogram (EEG) activity. The awake hemisphere retains a low level of alertness. A typical bout of sleep in cetaceans involves an alternating pattern of sleep in one hemisphere and then the other. This pattern continues for 2–3 h.

Cortical Cytoarchitecture

The cetacean neocortex is relatively thin, with a width between 1.3 and 1.8 mm, as compared with 3.0 mm in humans. The thinness of the neocortex likely allows for the high degree of cortical gyrification observed in cetaceans. Cetacean neocortex is characterized by a general absence of granularity (leading to an absence of layer IV), a very prominent thick layer I, the presence of large atypical neurons in the dense layer II, and very large pyramidal neurons frequently forming clusters at the border between layers III and V. The general lack of layer IV in cetaceans has important implications for afferentation patterns. In primates and other mammals, major thalamocortical afferents synapse directly on layer IV. In cetaceans, the majority of afferents from the thalamus appear to go through the very thick layer I to synapse on extraverted neurons of layer II. There is some evidence that a small portion of afferents go to layers III and V as well.

For many decades the cetacean cortex was thought to be homogeneous and relatively nondifferentiated in character. However, the most recent findings show that the cytoarchitectural patterns in cetacean cortex are far more varied and complex than generally thought, with a degree of regional differentiation on par with other large-brained mammals. Although areas of less distinct lamination do exist there are various neocortical regions that display considerable degrees of cytoarchitectural differentiation. For instance, despite the modest gross morphological appearance of the frontal lobes, this region is distinctly laminated and comprises several cortical fields. Also, highly distinct vertical modules are observed in the insular cortex and other areas. Therefore, there is a rich diversity of cytoarchitectural fields in most of the lobes. However, the organization that underlies this diversity is different from that in other mammals and likely represents a different functional strategy for cortical processing, compared to other mammals.

Conclusions

The cetacean brain is a highly elaborated brain that represents an intriguing and very different path toward functional complexity, compared to other mammals. Cetacean brains exhibit a unique combination of characteristics that include an encephalization level second only to that of modern humans, a degree of cortical gyrification unmatched by other mammals (including humans), a high degree of anatomical and functional hemispheric independence, and a highly atypical but complex cortical cytoarchitecture. These characteristics are consistent with the long-standing evidence for cognitive and behavioral complexity in cetaceans.

Chemical Senses: Overview

G M Shepherd, Yale University School of Medicine, New Haven, CT, USA

© 2009 Published by Elsevier Ltd.

A fundamental understanding of the chemical senses begins with the common chemical sense, defined as the ability of cells to detect and react to chemical stimuli. This applies to single cell organisms – bacteria and protozoa – sensing the composition of their environment, as well as to cells of the body specialized for sensing particular signals of the *milieu interieur* (oxygen tension, for example, by the carotid body, or the signals of the immune system), and to cells everywhere in their body organs as they interact with other cells in their different functions.

Among the special chemical senses, taste is our most obvious. Every time we put something in our mouth, we detect and discriminate between the basic tastes – sweet, salt, sour, bitter, and, especially in Asian countries, a meaty taste called umami. Molecular receptors for these qualities are being identified. Research on taste mechanisms is being carried out at several levels: the receptors and second messenger mechanisms in the cells of the taste buds in the tongue and pharyngeal cavity, and the neural pathway from the taste buds to the brain stem and on to the thalamus and neocortex. These neural mechanisms give rise to the sensation of taste, which is being studied by traditional psychophysical methods combined with new methods of genetic analysis.

The articles on smell represent the growing general interest in this sense. In invertebrates, several species are emerging as excellent models. The opportunities to identify olfactory receptors, compare and contrast them with those in the vertebrate, and correlate them with processing mechanisms in the olfactory pathway are beginning to be exploited. Earlier work established that the antennal lobe is equivalent to the vertebrate olfactory bulb as the first processing stage in the olfactory pathway. In both, the modules called glomeruli are expressions of a universal principle in processing odor information. It is becoming clear that principles revealed in one model may apply generally. These models include *Manduca*, in which there are receptors, glomeruli, and pathways for both ordinary odors and pheromones. *Drosophila* has emerged as another leading model, particularly amenable to gene manipulations. Honeybees are especially attractive for the correlations between odor maps in the glomerular layer, equivalent to the odor maps in vertebrates, neural processing mechanisms in the antennal lobe and mushroom bodies, and behavior.

In the vertebrates, olfactory research is being carried out over a wide range of levels and disciplines, beginning with the receptors, first identified by Linda Buck and Richard Axel in 1991, and providing a great impetus to redefining olfaction as a molecular sense. The receptors are believed to be the largest family in the genome. Starting as orphan receptors, the variably broad ligand specificities are gradually being identified and correlated with the specificities of the olfactory glomeruli to which their receptor cells project. Microarray techniques hold particular potential for dealing with this large gene family. The receptor cells are distributed within a complex mosaic within the olfactory epithelium in the nose, which is being analyzed by both electrophysiology and cell imaging techniques. This work will help to define at the receptor level the properties of odor detection, adaptation, and discrimination that are the basis for further processing in the olfactory bulb and beyond.

Among the advances provided by the olfactory receptors, their role in the targeting of subsets of receptor cells to individual glomeruli has been among the most insightful. It has enabled the merging of the molecular biology of the receptors with earlier work on the olfactory bulb as a model for the synaptic organization of a cortical structure. Three articles document these advances. Anatomical studies are providing increasing detail on the basic levels of synaptic organization in the olfactory bulb: within the glomerulus, between glomeruli, and at the level of mitral cell–granule cell interconnections. Physiological studies are revealing the functional interactions involved in processing odor stimuli at each of these levels. The distribution of inputs to the olfactory glomeruli from the olfactory receptor cells, as contained in odor maps, establishes the spatial and temporal nature of the processing mechanisms.

In parallel with these studies in the olfactory bulb, studies are being pursued at the level of the olfactory cortex which receives the olfactory bulb output. Here, in contrast to the stereotyped patterns of the bulb, the interconnections and interactions have appeared to be diffuse and random. However, recent studies are revealing new insights into the complexity of organization within the cortex and between the cortex and the olfactory bulb. Physiological studies are showing how the cortex functions as a system for odor discrimination and memory, expressing many properties of higher-level association cortex

in other sensory systems. Taken together, these studies provide insights into the neural mechanisms of odor processing. Despite these advances, study of the neural basis of smell perception faces the difficult task of establishing baseline data for thresholds for different odors in different species. The biggest challenge is obtaining a consensus on this data in humans.

These advances in the biology of smell have given hope that the principles discovered can be used to guide development of effective devices for detecting and discriminating volatile compounds, which has potential applications in a variety of contexts, from quality control in food production to detection of land mines. The biological and physical principles are providing the basis for the development of an overall theory of olfactory processing, equivalent to that for other sensory systems.

An important recent development is the realization that the importance of smell, particularly to humans, may be derived not so much from the smells we sense when we sniff in, such as perfumes, as from the smells we sense when we sniff out, such as during eating. Via this route, smell is combined with the other senses, especially taste and touch, to give the combined sense of flavor. This new research on retronasal smell is described, and the physiological studies of flavor neurons at the highest levels of reception and modulation, in the orbitofrontal cortex and related areas, are described.

A subject in the sense of smell of increasing interest is the role of pheromones, molecules that carry specific social information between members of a species. Classically it has been believed that in vertebrates this information is carried exclusively by the vomeronasal organ projecting to the accessory olfactory bulb, but recent studies have shown that it is carried in parallel by both the main and accessory systems. Current studies of the vomeronasal system are summarized elsewhere in the encyclopedia. An overview of the current state of knowledge about the processing of pheromones by the two systems is given elsewhere in the encyclopedia. The special case of human pheromones has attracted much attention; despite the heavily conditioned nature of human responses to olfactory stimulation, there is increasing evidence for the ability of human body odors, acting as pheromones, to influence mood, hormonal changes, and mate preference.

In summary, work on the chemical senses is being pursued vigorously in many species, with many innovative technical approaches, and at many different levels of organization. This section of the encyclopedia should enable the reader to appreciate the scope of this work and gain a new perspective on the importance of the chemical senses for animal life in general, and humans in particular.

Introduction

Protozoans, while solitary cells, have a variety of sensory systems, among which are those that detect and respond to chemicals in their environment. The chemicals may derive from food sources or from other similar protozoan cells that communicate about mating or differentiation via chemical signals. Highlighted here are four different sensory systems: three in free-living ciliates and one in an amoeboid cell.

Ciliated protozoa are excitable cells that swim, propelled by the beating of their cilia. The most extensively studied of the ciliates for chemosensation are the free-living ciliates, such as *Paramecium* sp., *Tetrahymena*, and *Euplotes*. Studied to a lesser extent are other ciliates, such as *Blepharisma* and *Oxytricha* (*Sterkiella*). These organisms can mate, which previously made them popular for studies of maternal inheritance and nuclear development. They have been studied using microscopy for their swimming behavior, and using electrophysiological techniques for their electrical properties, over many decades, but the advent of molecular technologies, genome projects, and RNA interference (RNAi) techniques has propelled forward the study of these organisms for their chemosensory behavior and other properties. *Paramecium* is discussed here because of the deep understanding of the physiology underlying its sensory responses that result in changes in ciliary motility. *Tetrahymena* is discussed as a species that responds with motility changes similar to those of *Paramecium*, but shows differences in signaling mechanisms, including the end result of secretion rather than locomotion. *Euplotes* has an entirely different sensory system for detecting self- and non-self for growth and mating.

Like the ciliates, amoeboid protozoa also respond to chemical stimuli with a motility response, but, lacking cilia, these cells crawl up the chemical gradients in their search for food (such as bacteria). When the food is exhausted, they begin to signal to each other to congregate into groups in preparation for producing spores to survive the adverse environmental conditions. *Dictyostelium discoideum* is discussed here as one well-studied example of amoeboid chemotaxis.

Paramecium Chemosensory Behavior

Paramecia are free-living ciliated cells that mostly dwell in ponds and streams, but some species can be found in more extreme aquatic environments. *Paramecium* swimming behavior has intrigued scientists, reportedly since the invention of the first microscope, and certainly since the writings of Jennings in the early 1900s; Jennings described the many external stimuli to which *Paramecium* responds, including temperature, pH, inorganic ions, organic compounds, gravity, and touch. Here the focus is on the responses of *Paramecium* to chemical cues. The relevant stimuli differ depending on the species under investigation, but for *Paramecium tetraurelia*, the attractant stimuli appear to signify the presence of food (bacteria) and the repellents signal less than optimal conditions (e.g., pH and ionic strength).

Chemical stimuli that cause populations of cells to congregate or disperse do so by affecting swimming behavior. Cells do not show chemotaxis (directed motility up or down a gradient), but rather show a biased random walk, which can be a very efficient mechanism for accumulating or dispersing small organisms. The cells swim fast and smoothly when moving up a gradient of attractant stimulus, and they swim more slowly and turn frequently when encountering a repellent or leaving an area of attractant. Turning and speed regulation are essential for attraction and repulsion; adaptation of the cell, so that the cell has an immediate response upon entering a new environment, sharpens the response.

Studies of *Paramecium* chemosensory behavior have built upon years of studies of *Paramecium* physiology, and benefit from the genetic and physiological research on behavioral mutants of *Paramecium*.

Physiological Basis of Chemosensory Behavior

The abrupt turn in the swimming path of a cell is caused by a calcium action potential from the opening of ciliary voltage-gated channels. Each action potential raises ciliary calcium above 10^{-6} M, and causes the axonemal structures inside the cilia to change the power part of the stroke, making the cell stop and back up for a fraction of a second. The cell then pivots in place and takes off again, swimming forward in an almost random new direction. This is the turn due to the Ca^{2+} action potential. As a cell depolarizes, it reaches threshold for action potential and thus depolarizations can initiate turns. Elegant studies of membrane electrophysiology by Kaneko, Naitoh, and Eckert showed the genesis of

the ciliary power stroke reversal with the calcium action potential and the control of the voltage-gated calcium channels (Figure 1). These channels are probably exclusively in the cilia, and deciliated cells regain the action potentials after the cilia regrow a fraction of their length.

Figure 1 Physiological steps in the avoiding reaction or turn. (a) Retreat from the stimulus, and resumption of forward locomotion. (b) The sequence of steps corresponding to the numbers in diagram (a). Step 1, stretch of anterior membrane upon collision with obstacle; step 2, local increase in membrane conductance; and step 3, inward receptor current through stimulated membrane. Step 4, electrotonic spread of receptor current, produces step 5, outward current through rest of membrane (arrows show current flow). Step 6, depolarization of cell membrane (receptor potential), produces step 7, increase in calcium conductance. Step 8, inward Ca^{2+} current; step 9, rise in intracellular Ca^{2+} concentration; step 10, cilia reverse beat; and step 11, cell swims backward. Step 12, Ca^{2+} pumped out; step 13, intracellular concentration of Ca^{2+} drops, cilia resume normal orientation; and step 14, cell swims forward. (a) Adapted from Parducz B (1967) Ciliary movement and coordination in ciliates *International Review of cytology* 21: 91–128 and Grell K (1968) Protozoologie. Berlin: Springer. (a, b) Reproduced from Figure 5 Eckert R (1972) Bioelectric control of ciliary activity. *Science* 176: 473–481.

The speed of swimming correlates with the frequency of ciliary beating, and the frequency of beat is controlled by the membrane potential. Machemer's work demonstrated that as the membrane potential is hyperpolarized from resting potential, the ciliary beating increases, and as it is depolarized, the beat frequency decreases, until finally the beat direction appears to reverse because the power stroke is changed. Depolarization beyond this point results in an increased beat frequency, but in the 'reverse' direction.

In the presence of chemical attractant stimuli, cells swim fast and smoothly with few turns, due to hyperpolarization of the membrane potential away from the threshold for action potentials. The resulting behavior sends the cells up the gradient due to the biased random walk. Conversely, cells swim more slowly and turn frequently due to action potentials because they are depolarized if they happen to move away from an attractant stimulus or toward a repellent. Thus, *Paramecium* chemosensory behavior is consistent with the membrane potential control of ciliary beating.

The genetic approach to dissect the excitable membrane of *P. tetraurelia* taken by Kung (and later by Takahashi for *P. caudatum*) led to a valuable set of behavioral mutants. Some mutants cannot reverse their ciliary beat and cannot generate action potentials, whereas some swim forward rapidly under some conditions and others mostly swim backward. Some of these mutants map to the gene for calmodulin and can be cured by injected calmodulin protein or DNA. These mutants have shown us that the calmodulin molecule distinguishes among the channels that it activates, and that mutants in the N-terminal and C-terminal lobes have diametrically opposed phenotypes. For example, one group of 'Cam' mutants with mutations in the C-terminus have defects in calmodulin-activated K-conductances, which should short-circuit the calcium action potential and normally either keep the cell from turning or abbreviate the turn. Without this K-conductance, cells swim backward for long periods of time, because the membrane potential remains depolarized, and show different Ca channel kinetics due to more intracellular Ca^{2+}. Another group of mutants has changes in amino acids in the N-terminus lobe of calmodulin and they can no longer activate a calmodulin-regulated Na channel. Therefore, when cells are in Na solutions and are depolarized, the Na channels do not open and the response to Na, which should be active turning, is curtailed. There are a host of allelic mutants with different changes in the calmodulin gene sequence and at least six conductances that are affected by

calmodulin mutations. Behavioral mutants have made it possible to use the connection between ciliary motion and ion channels to produce easily identifiable phenotypes and to amplify the effects of very subtle mutations so that they can be selected.

Behavioral mutants have shown us that turning is essential for chemoresponse and that a Ca^{2+}/calmodulin-activated K-conductance is involved in the initiation of the hyperpolarization for some stimuli. The mutants have allowed for the elimination of the involvement of other conductances in the onset of the attractant-induced hyperpolarization.

Paramecium Membrane Receptors

Biochemical studies, bioinformatics, and antisense techniques have revealed that the *P. tetraurelia* cell surface receptors for attraction include 7-transmembrane receptors (e.g., for extracellular cyclic adenosine monophosphate (cAMP)) and loosely tethered receptors (e.g., for folate, the receptor of which is anchored to the cell surface through a glyco-lipid addition to the receptor). The mechanisms by which these two very different kinds of receptors send messages inside the cell are not yet known, although there is evidence for tripartite GTP-binding proteins (G-proteins) and small G-proteins. Both classes of G-proteins have been shown to participate in signal transduction for 7-transmembrane receptors and glyco-lipid-anchored receptors in other systems. Additional attractants, such as glutamate, are characterized for their binding kinetics and structure–activity, but the protein receptors have not yet been isolated. All of the receptors appear to activate K^+ channels to initiate hyperpolarization and, therefore, the signal transduction pathways must couple receptors to downstream channels. There is growing evidence for coupling to plasma membrane calcium pumps to sustain the hyperpolarization and for congregation in special lipid domains of the surface membranes, which may serve as platforms for signaling molecules as in other systems.

There is one stimulus for *P. tetraurelia* that does not attract the cells by first binding to a surface receptor. Ammonium chloride diffuses across the cell membrane as ammonia, and once inside the cell, makes the cytoplasm more alkaline. The result is a hyperpolarization, that causes fast, smooth swimming, and attraction, but the mechanism of hyperpolarization is not yet understood.

Ciliary Motion

There is an effort to correlate the physiological findings about hyperpolarization and depolarization with the workings of the axoneme, the cytoskeletal structure that makes the cilium bend and beat. For example, hyperpolarization by reduction in extracellular K has long been known to hyperpolarize the cell (just as it would a neuron) and also leads to an increase in intracellular cAMP. An adenylyl cyclase that has both the characteristics of a cyclase and K channel has been cloned and shown to be very similar to adenylyl cyclases in parasitic protozoa and *Tetrahymena*. The annotated draft genome shows that *P. tetraurelia* has 15 genes that probably code for adenylyl cyclases and all have a K channel subunit.

Cyclic nucleotides cAMP and cGMP have been shown to affect ciliary beat frequency in cells made permeant to extracellular molecules by exposure to detergent. cAMP increases frequency of beating, and cyclic GMP has the converse effect, showing us one link between the hyperpolarization of the cell and the resultant behavioral change. Substrates for cAMP-activated kinase (PKA) have been identified in *P. tetraurelia* and phosphorylation of at least one substrate, associated with an axonemal dynein, correlates with increased beat velocity and swim speed. At least one chemoattractant, glutamate, utilizes cAMP and PKA as a second messenger system that ultimately increases the ciliary beat. Other stimuli appear to utilize other second messengers, such as Ca^{2+}/calmodulin, to accelerate the beat.

Other Ca^{2+}-Dependent Processes in *Paramecium* Chemical Sensing

Nucleotide triphosphates ATP and GTP cause cells to be repelled by depolarizations that arise from Ca^{2+} conductances triggering Ca^{2+}/calmodulin-dependent Mg^{2+} and Na^+ currents. This mechanism is distinctly different from the mechanism of repulsion from high levels of K^+ or Na^+, inosine monophosphate (IMP), or quinine, which cause depolarizations but do not cause oscillations of membrane potential.

Tetrahymena

Tetrahymena thermophila responds to different arrays of chemicals compared with *Paramecium,* possibly reflecting the different niches that the two ciliates inhabit in nature. Both can live in ponds and fresh water, but *T. thermophila* can also live in a wider range of conditions, and has been found in brackish water, thermal springs, and even soil and sewage. Peptides and small proteins attract *T. thermophila,* perhaps aiding in their search for food sources. Comprehensive studies of attractants and repellents are not available for *P. tetraurelia* or *T. thermophila*, but in general the chemicals that elicit attraction for *P. tetraurelia* can be classified as soluble small molecules that are bacterial metabolites, probably signifying

their food source, and attractants for *T. thermophila* are peptides and proteins. Naturally occurring repellents for *T. thermophila* include extremes of pH and ionic strength, IMP, ATP, and GTP, with GTP the most potent; *T. thermophila* shares with *P. tetraurelia* repulsion from GTP and IMP.

A receptor for one of the peptide attractants of *T. thermophila* has been recently identified. It has structural similarity and shared epitopes with the human insulin receptor β-subunit, particularly in the tyrosine kinase domain. Other receptors that have similarity to mammalian proteins based on their binding or physiological response include those that bind β-endorphins and concanavalin A. This is not surprising, since numerous mammalian proteins, including insulin, endothelin, serotonin, histamine, platelet-derived growth factor (PDGF), and epidermal growth factor (EGF), have been identified as stimulators of *Tetrahymena* behavior. Recently, bradykinin has been added to the list of chemoattractant peptides. It is important to note that many chemoattractant peptides are also important for cell survival in *Tetrahymena* sp. Several authors have observed that the nutritional status of the culture studied is critical in determining the response of *Tetrahymena* to stimulus. Under starvation conditions, some of the above-mentioned proteins are chemotatic, whereas in well-fed cultures, these proteins are mitogenic.

Repellents such as GTP cause rapid transient depolarizations and frequent turning, while ATP causes a more sustained depolarization. Pharmacological evidence collected from both the ATP-mediated response and a lysozyme/pituitary adenylate cyclase-activating peptide (PACAP) chemorepellent response implicates a variety of pathways in *Tetrahymena* avoidance reactions, including pathways that signal through G proteins and ultimately enzymes such as phospholipase C and those activated by cAMP.

As for *Paramecium*, many of the intracellular signaling pathways remain unresolved, but the availability of an annotated genome and RNAi technology should reveal many of these control mechanisms.

Euplotes

Euplotes species have a highly developed mating system, and depending on the species, there can be an almost large number of mating types. The mating types and the Mendelian genetics of mating have long been worked out for *Euplotes raikovi* and *E. octocarinotus*. However, it took a dedicated biochemical approach in work on *E. raikovi* to identify in this species the soluble molecules secreted by one mating type that make a complementary mating type receptive to mating. Subsequently, the 'pheromones' and their receptors were identified for both species. Most recently, it has become apparent that the peptide pheromone is a subset of the amino acids of the receptor, with the pheromone secreted into the surrounding medium while the receptor, with an additional transmembrane domain, remains on the plasma membrane. The pheromone can bind to its own receptor or to a different receptor, elaborated on the surface of a complementary mating-type cell. Each cell expresses only one receptor and its cognate pheromone. When the pheromone binds to its cognate receptor, the cells are stimulated to go through the cell cycle and grow, essentially an autocrine response. When receptors are bound in an autocrine manner, intracellular cAMP levels are depressed. Disruption of this autocrine binding results in an increase in basal cAMP levels and suppression of growth. When the pheromone binds to a heterologous receptor, that cell is arrested in the cell cycle and becomes mating reactive. Since both 'self' and 'non-self' pheromone may be present simultaneously, the ratio of bound 'self' versus 'non-self' is critical in determining the response. Ultimately, ion currents and thus behavior are modified, enhancing the opportunity for a cell to contact a member of another mating type. Perhaps this is a mechanism to keep cells from mating when their nuclei are not in the proper stage to enter meiosis prior to exchange of haploid nuclei with a partner, or from expending unnecessary energy searching for mates when they are not available. Pheromones from *E. octocarinatus* for 10 mating types drive a similar orientation of cells to congregate in close proximity on the substrate because these pheromones also act as chemoattractants.

Interestingly, as in *Tetrahymena*, *E. raikovi* pheromone receptors can bind to a mammalian protein. Rather than insulin or other growth factors, the cytokine interleukin-2 (IL-2) can cross-react with the Er-1 pheromone receptor. IL-2 blocks Er-1-mediated response, and, conversely, Er-1 can associate with a mammalian IL-2 receptor, although it cannot replace IL-2 in a functional manner; whereas very little sequence homology can be noted by comparing sequence data, structural similarities between receptors exist.

Further study of the relationships between *Tetrahymena* and *Euplotes* species and the mammalian signaling molecules that stimulate these ciliates should provide valuable insight into the origin of many metazoan signaling pathways.

Dictyostelium

Many parallels have been drawn between *Dictyostelium* amoebae and neutrophils because both show chemotaxis (directed movement) of polarized cells

up very shallow gradients of stimuli. These amoeboid cells can respond to gradients that change as little as 2% from front to back of the cell, regardless of absolute concentration. These cell types share many of the same mechanisms for polarized movement, and even share a stimulus. *Dictyostelium discoideum* amoebae are attracted to cAMP, nutrients like folic acid, and platelet-activating factor (PAF). Neutrophils respond to bacterial cues like the formyl peptide fMLP, chemokines, complement factor C5a, and PAF. Upon loss of their bacterial food source, *D. discoideum* cells begin to respond to a gradient of cAMP from pulses of the stimuli given off by other cells, and eventually they move together to form a multicellular slug. Neutrophils respond to gradients that indicate the presence of bacteria and infection.

The cells that encounter a gradient of attractant develop a distinct front (pseudopod) and back (uropod) and proceed to crawl up the gradient. Actin polymerization at the anterior leading front edge of the cell, retraction of the back (uropod) through a myosin filament formation, and suppression of pseudopods between the leading edge and back are all necessary for efficient chemotaxis, that is, directed crawling up the gradient. The attractant stimuli bind to 7-transmembrane G-protein-coupled receptors, which then activate their associated tripartite G-proteins (α-, β-, and γ-subunits). The G β- and γ-subunits are crucial to carry on the signaling for chemotaxis. Curiously, the first components of the signaling pathways (receptors and G-proteins) are not redistributed as a cell encounters a gradient of attractant, and yet the cell must reorganize its shape (cytoskeleton) and somehow a front and back of the cell must form. This appears to occur due to an uneven distribution of PtdIns(3,4,5)P_3 (PIP_3), with more PIP_3 at the front. If the gradient changes, there are receptors along the entire surface to detect this change and redirect more PIP_3 to the new leading edge. To generate this uneven distribution of PIP_3, PI3K that phosphorylates PIP_2 to create PIP_3 translocates from the cytoplasm to the plasma membrane at the leading edge, and phosphatase and tensin homolog deleted on chromosome 10 (PTEN), the phosphatase that degrades PIP_3, moves to the back of the cell. This polarized distribution of these enzymes results in the concentration of PIP_3 at the leading edge, where proteins that bind to PIP_3 through plekstrin homology (PH) domains are recruited. Cytoplasmic regulator of adenylyl cyclase (CRAC) is among the PH proteins, and is required for receptor activation of the adenylyl cyclase (**Figure 2**).

Upon attractant stimulation, filamentous actin extends into the cell's leading edge, enhancing pseudopod formation and orienting the cell to crawl toward the attractant stimulus source. The sculpting of the actin cytoskeleton to form actin filament-filled pseudopods for forward motility is perhaps better known in neutrophils, but *D. discoideum* and neutrophils share molecular mechanisms here as well. Actin polymerization and branching occur in the leading edge to fill out the pseudopod and make forward chemotaxis movement possible. The localized polymerization depends on a cascade of events that begin with small G-proteins. The actin polymerization depends on a protein complex (Arp2/3) that is activated by two proteins (Wiskott–Aldrich syndrome protein (WASP) and the related WAVE/SCAR protein). These proteins, in turn, require Rho-family GTPases (small G-protein) Rac and Cdc42 for their activation. Where active Rac is found, the actin polymerization necessary for pseudopod formation will occur, and guanine nucleotide exchange factors

Figure 2 Localization of signaling events in a chemotaxing cell. The uropod is to the right and leading edge to the left. Note the uneven distribution of components for controlling the contractile actin/myosin filaments regulated by Rho in the uropod and the F-actin polymerization for forward motility controlled by PI3K and Rac in the leading edge. Also note the negative feedback regulation from front to back. Meili R and Firtel RA (2003) Two poles and a compass. *Cell* 114: 153–156.

(GEFs) are responsible for activating G-proteins like Rac. The connection of active Rac to the leading edge and its elevated levels of PIP_3 is that PIP_3 can activate some GEFs as can activated receptors. Also, once Rac is activated at the leading edge, it appears to feed back to recruit more PIP_3.

Just as important for successful chemotaxis as actin filament formation in the leading edge is myosin filament formation concentrated at the back of the cell. Myosin II provides power to retract the back end of the migrating cell and also to suppress pseudopod formation along the sides of the cell. Myosin filament formation in the uropod is regulated by the enzyme Akt/PKB, one of the PH domain proteins that is recruited to the PIP_3 of the leading edge, and by cGMP-binding proteins. Akt/PKB phosphorylates p21-activated kinase, which in turn regulates assembly of nonmuscle myosin II in the uropod. The second messenger cGMP has been known for some time to increase upon chemotaxis stimulation, and it appears that its role is both to induce myosin filament formation in the uropod and to activate myosin heavy chain kinase so as to inhibit filament formation in the leading edge.

The *D. discoideum* cells that are moving together by chemotaxis are able to 'count' their cell numbers to form the optimal aggregate size by secreting and detecting counting factor (CF). CF feeds into the signal transduction pathway via the cAMP receptor to effect cytoskeletal alterations that underlie directional motility. CF intersects the previously described pathways at the level of Akt/PKB translocation to the leading edge of the stimulated cell, to control how many cells aggregate together.

Conservation of the signaling pathways involved in the cytoskeletal rearrangements underlying directed motility between *D. discoideum* and neutrophils is remarkable, but there are obvious parallels and common molecular players in the change of cell shape in early developing neurons and in growth cone motility. Studies of *D. discoideum* and neutrophil chemotaxis also highlight the role of adaptation in efficient directional motility and the desensitization/resensitization of receptors.

Chemoaffinity Hypothesis: Development of Topographic Axonal Projections

T McLaughlin and D D M O'Leary, The Salk Institute, La Jolla, CA, USA

Introduction

A critical function of the vertebrate nervous system is to interpret the environment through the connections of various sensory organs. To accomplish this task, the incoming information must be organized in an efficient manner. Perhaps the most efficient organization is achieved through the use of topographic maps that are present throughout the organism to process sensory information. A topographic map is a projection from one set of neurons to another wherein the receiving set of cells reflects the neighbor relationships of the projecting set. In the nervous system of higher vertebrates, topographic maps are common and include sensory body maps, tonotopic maps, and maps of visual space. Furthermore, topographic maps persist in some form throughout the circuitry, from first-order to higher-order connections.

Axon guidance is critical to the formation of appropriate neural connections. However, once the primary growth cone reaches the tissue that it will innervate, the problem switches from finding the correct linear path to finding the correct point in a two- (or three-) dimensional space. This latter problem, known as target recognition, has long been postulated to be under the control of gradients of axon guidance molecules. The chemoaffinity hypothesis, formally proposed half a century ago by Roger Sperry, outlines a conceptual framework by which neural connections can develop a topographic map. The predominant model for studying map development has been the primary visual projection formed by the axons of retinal ganglion cells (RGCs) to their major midbrain target, the optic tectum (OT) of fish, amphibians, and chick, or the superior colliculus (SC) of mammals. The representation of the retina onto the OT or SC can be simplified to the mapping of two sets of orthogonally oriented axes: the temporal–nasal (TN) axis of the retina along the anterior–posterior (AP) axis of the OT or SC, and the dorsal–ventral (DV) axis of the retina along the lateral–medial (LM) axis of the OT or SC (corresponding to the ventral–dorsal OT axis in nonmammalian vertebrates).

Studies of amphibians and fish, as well as invertebrates, have provided much insight into mechanisms of topographic map development and will certainly continue to have substantial impact on the field. However, this article will focus on chicks and mice because of their similarities in map development, their closer relationship to human biology, and the greater availability of relevant genetic experimentation.

The Chemoaffinity Hypothesis

The chemoaffinity hypothesis, formally proposed by Roger Sperry in 1963, presaged the dawning of the era of molecular mechanisms of map development. Sperry expressed his hypothesis in the following passage:

> I still go back to my initial interpretation proposing an orderly cytochemical mapping in terms of two or more gradients of embryonic differentiation that spread across and through each other with their axes roughly perpendicular. These separate gradients successively superimposed on the retinal and tectal fields and surroundings would stamp each cell with its appropriate latitude and longitude expressed in a kind of chemical code with matching values between the retinal and tectal maps.

His critical suggestion was that these molecular tags were associated with the neural tissue (e.g., membrane bound) and might be distributed in complementary gradients that mark corresponding points in both the sensory (e.g., retina) and target structures (e.g., OT or SC). Although Sperry based this hypothesis on his studies of regeneration of the retinotectal projection in newts and frogs, it provided the fledgling field of map development with direction. The basic foundation of the chemoaffinity hypothesis has largely been borne out, but subsequent experimental studies and mathematical models have refined it substantially to add multiple gradients of attractants and repellents and to more accurately account for the sequential phases of complex behaviors exhibited by RGC axons during map development in the OT or SC of higher vertebrates.

Based on the chemoaffinity hypothesis, each point in the OT or SC would have a unique molecular address determined by the graded distribution of topographic guidance molecules along the two tectal axes, and similarly each RGC would have a unique profile of receptors for those molecules that would result in a position-dependent, differential response to them by RGC axons. Over several decades following Sperry's hypothesis, the specificity of the projections of RGC axons to tectal cells was investigated further by the tracing of axonal projections following experimental manipulations, first in the regenerating retinotectal system of fish and amphibians, and later in the developing retinotectal or retinocollicular

projections with the development of high-resolution axon tracing techniques that work effectively in chicks and mammals. This body of evidence supported the basic hypothesis that the establishment of topographic projections involves the positional marking of RGC axons and their target sites in the OT or SC.

Prior to the discovery of the first topographic guidance molecules, the ephrins, the most compelling evidence for their existence came from the work of Friedrich Bonhoeffer and colleagues, who developed and used elegant *in vitro* assays, most prominently the membrane stripe assay. These assays were the first demonstrations of the presence of membrane-associated molecules that meet the criteria for topographic guidance molecules, and they were instrumental in these molecules' eventual identification.

Discovery of Graded Molecular Guidance Cues

Many labs using numerous approaches have carried out searches for topographic guidance molecules. Several cell surface molecules, such as TRAP and TOP_{AP}, with graded or restricted patterns in the retina, OT, or SC consistent with a role in mapping, were identified prior to the mid-1990s, but functional studies have yet to show such a role. The first description of graded molecules that proved to have properties of topographic guidance molecules came only in the mid-1990s with the cloning of two related genes, ephrinA2 (originally called Eph Ligand Family-1, or ELF-1) and ephrinA5 (originally called repulsive axon guidance signal, or RAGS), both of which are ligands of the receptor tyrosine kinase, EphA3 (originally named MEK4), expressed in a graded pattern by RGCs.

Eph receptors and ephrin ligands were not only the first topographic guidance molecules to be discovered, but they also have been defined to have prominent roles in both AP and DV mapping, and many family members are involved. The Eph family is the largest known family of receptor tyrosine kinases, comprising 14 Ephs and eight ephrins in mouse and 15 Ephs and nine ephrins in chick. Signaling through Ephs and ephrins has been implicated in a wide variety of biological processes. Ephs and ephrins are separated into two subclasses based on homology, the EphA/ephrinAs and EphB/ephrinBs, within which receptor–ligand binding and activation are promiscuous; some minimal cross-talk occurs between subclasses. EphAs and EphBs, as well as ephrinBs, are transmembrane proteins; ephrinAs are glycosylphosphatidylinositol (GPI)-linked to the cell membrane.

Ephs and ephrins can signal bidirectionally into either the Eph- or ephrin-expressing axon, and in some instances, Eph and ephrin signaling can be bifunctional, resulting in opposing axonal responses (i.e., attraction or repulsion), depending on the context. As described below, EphAs and ephrinAs act bidirectionally in AP mapping, whereas EphBs and ephrinBs act both bidirectionally and bifunctionally in DV mapping. A few other receptor–ligand pairings have also been implicated in mapping; most notably, Wnt3 and its receptors Ryk and Frizzled have been implicated in DV mapping.

An interesting historical note is the cloning of repulsive guidance molecule (RGM). RGM is the molecular activity that Bonhoeffer and colleagues believed to be the repellent membrane-associated molecule enriched in posterior membranes defined using the membrane stripe assay, as well as a growth cone collapse assay. In fact, the search for RGM resulted in the discovery of RAGS (ephrinA5), a molecule with very similar properties (i.e., GPI linked, similar size, repellent for RGC axons, and expressed in a similar gradient in the OT or SC). However, RGM knockout mice do not exhibit mapping defects, although some findings using ectopic expression in chick retina of an RGM receptor, neogenin, have suggested a role for it in AP mapping.

Mechanisms of Map Development

Determining the process by which RGCs establish topographic connections is critical for defining the roles of graded guidance molecules in map development and creating conceptual or computational models of the process. Frogs, fish, chicks, and rodents have been the vertebrates predominantly studied as models for development of retinotopic maps (Figure 1). These species exhibit important differences in the development of the visual system and retinotopic maps, as well as substantial differences in the absolute size of the OT or SC; for example, the two-dimensional area of the chick OT is more than a thousand times greater than that in frog and fish during the initial events in map development. Although each species has unique features that can be exploited, they have substantial differences in mechanisms employed by RGC axons to target their correct termination zone (TZ) and therefore also in the actual roles of topographic guidance molecules in controlling these axon behaviors.

Multiple Phases in the Development of a Topographic Map

Development of retinotectal topography in chicks and rodents is a multistep process (Figure 1(b)). RGC axons enter their midbrain target at its anterior edge and extend posteriorly parallel to the AP axis of the OT or SC. In birds and mammals, essentially all RGC axons extend well posterior to the topographically appropriate location of their future TZ. Thus,

Figure 1 (a) Photographs, at critical ages during topographic map formation, of the primary model systems currently used for the examination of retinocollicular and retinotectal map development. All photographs are at the same scale. The mouse superior colliculus (SC), on the dorsal surface of the midbrain (bracket, 2 mm), is approximately as large as an entire developing zebra fish, and the chick optic tectum (OT) is approximately the size of an entire Xenopus tadpole at these ages. The Xenopus and zebra fish OT sizes are denoted by the small white bars adjacent to the brain. The mouse and zebra fish are used commonly for the potential genetic manipulations available in these organisms. Chick and Xenopus are especially useful for overexpression, mis-expression, and knockdown studies. Retinal ganglion cells from these organisms can be cultured and manipulated *in vitro*. (b, c) Mechanisms and molecules controlling retinotopic mapping in (b) mouse and chick and (c) frog and zebra fish. The names and distributions of molecules and activities demonstrated *in vivo* to control, in part, the mapping mechanisms used at each stage are listed. The gradients may represent the consensus distribution for a combination of related molecules (e.g., EphAs), which are not listed individually due to distinctions in the individual members expressed and the precise distributions between species. Molecules and activities other than those listed are likely to participate in topographic mapping. (b) In mouse and chick, retinal ganglion cell (RGC) axons enter the SC and OT, respectively, over a broad LM extent and significantly overshoot their future termination zone (TZ, circle). Interstitial branches form *de novo* from the axon shaft around the anterior–posterior (AP) position of the future TZ. Branches are directed along the lateral-medial (LM) axis of the OT or SC toward the position of the future TZ, where they arborize in a domain encompassing the forming TZ. The broad, loose array of arbors is refined to a dense TZ in the topographically appropriate location. (c) In frog and fish, the RGC growth cone extends to the TZ, where it forms a terminal arbor through a process of backbranching from the area immediately behind the growth cone. The tectum expands as terminal arborizations elaborate and refine into a mature TZ. cb, cerebellum; ctx, cortex; D, dorsal; fb, forebrain; hb, hindbrain; N, nasal; T, temporal; V, ventral. Modified from McLaughlin T, Hindges R, and O'Leary DDM (2003) Regulation of axial patterning of the retina and its topographic mapping in the brain. *Current Opinion in Neurobiology* 13: 57–69.

the growth cones of RGC axons in birds and mammals do not target their future TZ but instead extend a millimeter or more posterior to it. In addition, RGC axons from the same retinal location enter and grow across the OT or SC with an aberrantly broad distribution over its LM axis. Branches form *de novo* from the axon shaft hundreds of micrometers or even millimeters behind the growth cone. These interstitial branches form roughly perpendicular to the primary axon and preferentially extend along the LM axis toward their future TZ.

In summary, the topographically ordered connections of the mature projection are established by primary branches of RGC axons that form *de novo* interstitially along the length of RGC axons. These branches form along the shaft of the primary axon with a topographic bias for the correct position along the AP axis, which is the first indication of a topographic response. They subsequently extend along the LM axis to the appropriate site of the future TZ, where they go on to arborize.

AP Mapping

Historically, models of topographic mapping have been based on the action of molecular activities that promote axon growth. However, with the identification in the late 1980s by Bonhoeffer and colleagues of repellent activities concentrated in posterior chick OT that preferentially affect temporal RGC axons, it became clear that topographic mapping was controlled in a fashion different from that previously recognized. These findings eventually resulted in the incorporation of repellent activities into models of topographic mapping, but until recently these models focused on guiding RGC axons to their correct TZ. These models were based on a gradient-determined repulsion, in which an RGC axon would stop its growth when it reached a threshold level of repulsion found at the AP position of the future TZ. Although such models could explain retinotectal map development in amphibians and fish (**Figure 1(c)**), they can not account for aspects of map development along the AP axis in chick OT and rodent SC, including the initial AP overshoot of RGC axons and the subsequent topographic branching interstitially along the axon shaft.

Models for AP mapping in rodent SC and chick OT must explain the topographic bias in the formation of interstitial branches, which is arguably the key feature of AP map development. Models that in principle can account for topographic branching have been proposed recently, including models based on parallel gradients of a branch-repellent (or inhibitory) activity and a branch-promoting activity. However, the field has gravitated toward a model based on opposing gradients along the AP axis, each of which inhibits branching. This model is consistent with the gradients and actions of topographic guidance activities defined over the past few years and, it is important to note, can account for the phases exhibited by RGC axons during map development. As described below, the opposing gradients are based on opposing graded expression of EphAs and ephrinAs along both the TN retinal axis and the AP OT or SC axis, with one repellent gradient caused by EphA forward signaling and the other by ephrinA reverse signaling.

RGC axons respond differentially, in a manner relating to their origin along the TN retinal axis, to opposing gradients of repellent activities along the AP axis of the OT or SC. The low-to-high AP gradient of repellent activity has been shown by many complementary studies to be due to EphA forward signaling, controlled by a high-to-low TN gradient of EphA receptors on RGC axons and a low-to-high AP gradient of ephrinAs in the OT or SC (**Figure 2**). These studies include manipulating expression of EphA receptors by RGCs and of ephrinAs in the target. Recent experimental data have provided evidence that the opposing gradient of repellent activity is caused by ephrinA reverse signaling controlled by a low-to-high TN gradient of ephrinAs on RGC axons and a high-to-low AP gradient of EphAs expressed in the SC. The critical findings are that retinal axons are repelled by EphA7 in the "Bonhoeffer" stripe assay, a repulsion blocked by ephrinA5-fc that blocks EphA function, and that EphA7 knockout mice have retinocollicular mapping defects consistent with the loss of the high-to-low AP graded expression of EphA7 in the SC (EphA7 is not expressed by RGCs). Because ephrinAs are anchored to the cell membrane by a GPI linkage and lack an intracellular domain, to reverse signal they must associate with transmembrane proteins capable of activating intracellular signaling pathways. Recent studies have shown that the p75 neurotrophin receptor mediates the repellent effect of ephrinA reverse signaling on RGC axons on binding EphAs, and is required for appropriate development of the retinotopic map in the SC.

DV Mapping

Topographic specificity along the LM axis emerges through the bidirectional guidance of branches that form along RGC axons with an AP bias as described above. Branches that extend from RGC axons located lateral to their future TZ grow medially whereas branches that extend from RGC axons located medial to their future TZ grow laterally. Branches that reach

Figure 2 Distribution of Ephs and ephrins in the retina and optic tectum (OT) and superior colliculus (SC) of chick and mouse, respectively. The charts represent generalized patterns for individual Ephs and ephrins in the retina and OT or SC during critical stages in the development of the retinotopic map (E15–P7 in mouse and E6–E14 in chick). The charts are likely incomplete, and the distributions for several molecules are dynamic during development. The sizes and shapes of the gradients are generalized, and relative expression levels should not be inferred. A, anterior; D, dorsal; L, lateral; M, medial; N, nasal; P, posterior; T, temporal; V, ventral. Modified from McLaughlin T and O'Leary DDM (2005) Molecular gradients and development of retinotopic maps. *Annual Review of Neuroscience* 28: 327–355.

the area of the nascent TZ selectively form complex arbors. Therefore, not only is this guidance of interstitial branches a critical feature for DV retinotopic mapping, but the molecular mechanisms that control it must account for the bidirectional guidance along the LM axis of the OT or SC of branches of axons that have the same retinal origin and presumably express the same set of receptors at similar levels.

Studies of the molecular control of DV mapping have implicated EphB and ephrinBs, exhibiting both bidirectional signaling and bifunctional action, as well as Wnts and their receptors. In retina, EphB receptors are expressed by RGCs during map development in an overall low-to-high DV gradient, complemented by an overall high-to-low DV gradient of ephrinBs. In both chick OT and mouse SC, ephrinB1 is expressed in a low-to-high LM gradient, complemented by an overall high-to-low LM EphB gradient (Figure 2). Analyses of EphB2 and EphB3 mutant mice, with and without reverse signaling intact, show aberrant LM mapping due to defects in the guidance of interstitial branches and show that ephrinB1 acts as a branch attractant via EphB2/B3 forward signaling. Electroporation studies in chick corroborate these findings, and in addition show that high levels of ephrinB1 repel branches. Taken together, these studies show that in mice and chicks, ephrinB1 can act through EphB forward signaling as both an attractant and a repellent: a branch located lateral to its nascent TZ is attracted up the gradient of ephrinB1 toward it, whereas a branch located medial to its nascent TZ is repelled down the ephrinB1 gradient toward it. The primary axon is not influenced by ephrinB1, but instead the effects of eprhin-B1 are specific to interstitial branches and are context dependent: The location of the branch on the ephrinB1 gradient in relation to the location of its future TZ and its EphB level determine its response. In frogs, ephrinB reverse signaling has also been implicated in retinotopic mapping, but such a role has yet to be shown in mice and chicks (Figure 1(c)).

In principle, EphBs and ephrinB1 could account for DV mapping through their actions as bifunctional (i.e., attractant and repellent) and bidirectional (i.e., EphBs and ephrinBs both can act as receptors) guidance molecules. However, recent evidence suggests that Wnt signaling is also involved in DV mapping. Wnt3 is expressed in a high-to-low medial-lateral gradient in chick OT and mouse SC, and Wnt receptors, Ryk and Frizzled family members, are expressed in an overall low-to-high DV gradient by RGCs. Functional studies show that Ryk mediates RGC axon repulsion by higher levels of Wnt3 whereas Frizzled receptors mediate an attractant effect of lower levels of Wnt3 on dorsal RGC axons. Thus, the 'morphogen' Wnt3 appears to act as a topographic guidance molecule in the OT and to cooperate with EphB-ephrinB1 to regulate DV mapping. In zebra fish, Sema3D has also been implicated in DV retinotopic mapping by repelling ventral RGC axons from ventral OT.

Refinement of the Retinotopic Map

As described above, in mice and chicks, all arbors are formed by interstitial branches that preferentially arborize at, or in the vicinity of, the topographically appropriate location of the nascent TZ. In frogs, refinement of individual arbors involves a combination of directed branch dynamics; further, the continued but disparate growth of the retina and OT requires a continuous small-scale remodeling throughout life. These processes act to shape and refine developing arbors and are likely dependent on trkB/brain-derived neurotrophic factor (BDNF) interactions and neural activity. Compared to map remodeling in chicks or mice, refinement in fish and frogs is a precise shaping of arbors rather than major remodeling of a topographically diffuse projection that involves the elimination of substantial lengths of a primary axon and entire arbors that it might have formed along the eliminated segment.

In chicks and mice, the initial collection of arbors is loosely organized around the topographically appropriate position of the future TZ and requires a substantial degree of remodeling to develop the precise connections evident in the mature retinotopic map. Remodeling requires the removal of inappropriately located branches and elimination of overshooting portions of RGC axons. In mice, the remodeling of the retinocollicular projection occurs before the onset of vision but is coincident with a period of correlated spontaneous waves of activity that propagate across the retina. These waves are generated by networks of connections between RGCs and amacrine cells, a type of retinal interneuron, and correlate the activity of neighboring RGCs, thereby relating an RGC's position to its pattern of activity. These amacrine cell–RGC circuits are cholinergic and can be selectively disrupted by deletion of the $\beta 2$ subunit of the nicotinic cholinergic receptor. Analysis of $\beta 2$ knockout mice, which lack retinal waves but retain wild-type levels of RGC activity, show that correlated patterns of RGC activity are required for the large-scale remodeling of the retinocollicular projection into a refined map. Further, these studies demonstrate that a later resumption of correlated activity does not lead to proper map refinement, thereby revealing a brief early critical period for retinotopic map remodeling in mice.

Concluding Statements

From studies to date, it is clear that other receptor–ligand pairings are required to generate proper retinotopic maps. Several groups have carried out forward- and reverse-genetic screens to identify additional candidate genes involved in retinotopic mapping, or screens that could produce candidate genes as a by-product. For example, the large-scale Tubingen genetic screen in mutagenized zebra fish was designed in part to identify genes involved in RGC axon pathfinding and mapping. This near-saturation screen has resulted in the identification of about a hundred mutants, representing scores of genes; a subset of these mutants have defects in DV or AP mapping in the retinotectal projection. These mutants are being investigated further. In addition, microarray screens have identified many known and unknown genes expressed in gradients or restricted patterns along the TN or DV axes of the developing mouse retina, some of which will be found to be involved in retinotopic mapping.

It is interesting that Sperry's chemoaffinity hypothesis was, in part, a response to contemporaneous views that axonal projections could self-organize. Though it is clear that topographic guidance molecules are critical for mapping, the role that a system plays in its own development is an intriguing and understudied facet of mapping. It seems likely in many systems that the projecting axons themselves affect the development of the projection. For example, RGC axons may alter the expression levels and distributions of guidance molecules as they elaborate arbors in the target due in part to the presence of guidance molecules on RGC axons, including multiple ephrins and Ephs on RGC axons. Thus, guidance information itself is dynamic, and patterned activity has a role in mapping – therefore the progressive development of the topographic map may feed back on itself in multiple ways and influence its own development.

Cholinergic Neurotransmission in the Autonomic and Somatic Motor Nervous System

T C Westfall, St. Louis University School of Medicine, St. Louis, MO, USA

© 2009 Published by Elsevier Ltd.

Introduction

Acetylcholine is the principal neurotransmitter at all autonomic preganglionic nerve terminals (sympathetic and parasympathetic), all postganglionic parasympathetic neuroeffector junctions, a few postganglionic sympathetic neuroeffector junctions (e.g., eccrine sweat glands), the somatic motor nerve neuromuscular junction, and cholinergic synapses in the central nervous system (CNS). The synthesis, storage, release, and inactivation of acetylcholine are similar at all these structures. This is probably also true for nonneuronal cholinergic systems in various parts of the body (e.g., human airway). The neurochemical events involved in the life cycle of acetylcholine are depicted in Figure 1.

Synthesis of Acetylcholine

Choline and Choline Transport

Critical to the synthesis of acetylcholine is the availability of choline. There is little *de novo* synthesis of choline in cholinergic neurons; therefore, choline is provided mostly from the diet. Choline is a dietary component essential for normal function of all cells, not just cholinergic neurons. Choline or its metabolites ensure the structural integrity and signaling functions of all cell membranes; it is the major source of methyl groups in the diet, and it obviously directly affects cholinergic neurotransmission. Cholinergic neurons have especially large requirements for choline because they use choline not only for membrane synthesis but also for acetylcholine synthesis. Choline is taken up from the extracellular space by two transport systems. First is the ubiquitous low-affinity, sodium-independent transport system that is inhibited by hemicholinium 3 with a K_i of about $50\,\mu mol\,l^{-1}$. Second is the high-affinity, sodium- and chloride-dependent, hemicholinium 3-sensitive ($K_i = 10–100\,nmol\,l^{-1}$) choline transport system. The latter form is found predominantly in cholinergic neurons and is responsible for providing choline for acetylcholine synthesis. Once acetylcholine is released from cholinergic neurons following the arrival of action potentials, acetylcholine is hydrolyzed by acetylcholinesterase (AChE; see the section titled 'Enzymatic hydrolysis: AChE') to free acetate and choline. Choline is recycled after reuptake into the nerve terminal of cholinergic cells and utilized for acetylcholine synthesis. Under many circumstances, this reuptake and availability of choline appear to serve as the rate-limiting step in acetylcholine synthesis. Acetylcholine synthesis and release are sustained during persistent and prolonged neuronal stimulation, as long as choline is available and the transporter is functional. The low-affinity choline uptake transporter is used to synthesize membrane phospholipids. These lipids are reservoirs from which choline can also be used by choline neurons for acetylcholine synthesis.

Despite the fact that the high-affinity choline uptake system was first described in the1960s, the gene for the high-affinity choline transporter (CHT_1) has only recently been cloned from a variety of species: *Caenorhabditis elegans*, mouse, *Torpedo*, *Limulus*, and humans. It is interesting that CHT_1 is not homologous to neurotransmitter transporters but is homologous to the Na^+-dependent glucose transporter family. With the molecular identification of the CHT_1, it was discovered that it does not predominantly reside at the nerve terminal plasma membrane but rather in intracellular vesicular structures. It has been observed that CHT_1 co-localizes with synaptic vesicle markers such as vesicle-associated membrane protein 2 and vesicular acetylcholine transporter (VAChT), at least when expressed in a cholinergic cell line. Although information is still incomplete, it has been hypothesized that arrival of action potentiates in nerve terminals results in exocytosis of synaptic vesicles, release of acetylcholine into the synaptic cleft, and increased trafficking of CHT_1 to the plasma membrane, where it functions to take up choline after hydrolysis of acetylcholine. Because choline transport is rate-limiting for acetylcholine synthesis, increased availability of choline via its transport by CHT_1 would favor an increase in acetylcholine stores to maintain high levels of transmitter release during neuronal stimulation. This also suggests that the availability of CHT_1 at the cell surface is dynamically regulated in a manner very similar to the regulation of the exocytosis of synaptic vesicles. Much recent information has been obtained on how trafficking of CHT_1 between the cell surface and subcellular compartments can regulate choline uptake activity. Nevertheless, the precise mechanisms involved in maintaining the distribution of CHT_1 predominantly in intracellular vesicles rather than at the terminal surface like other neurotransmitter transporters is unclear.

Figure 1 Schematic representation of a cholinergic neuroeffector junction showing features of the synthesis, storage, and release of acetylcholine (ACh) and receptors on which ACh acts. The synthesis of ACh in the varicosity depends on the uptake of choline via a sodium-dependent carrier. This uptake can be blocked by hemicholinium. Choline and the acetyl moiety of acetyl coenzyme A (AcCoA), derived from mitochrondria, form ACh, a process catalyzed by the enzyme choline acetyltransferase (ChAT). ACh is transported into the storage vesicle by another carrier that can be inhibited by vesamicol. ACh is stored in vesicles along with other potential cotransmitters (Co-T) such as adenosine triphosphate (ATP) and vasoactive intestinal polypeptide at certain neuroeffector junctions. Release of ACh and the Co-T occurs on depolarization of the varicosity, which allows the entry of Ca^{2+} through voltage-dependent Ca^{2+} channels. Elevated $[Ca^{2+}]_{in}$ promotes fusion of the vesicular membrane with the cell membrane, and exocytosis of the transmitters occurs. This fusion process involves the interaction of specialized proteins associated with the vesicular membrane, called vesicle-associated membrane proteins (VAMPs) and the membrane of the varicosity, called synaptosome-associated proteins (SNAPs). The exocytotic release of ACh can be blocked by botulinum toxin. Once released, ACh can interact with the muscarinic receptors (mAChRs), which are G-protein-coupled receptors, or nicotinic receptors (nAChRs), which are ligand-gated ion channels, to produce the characteristic response of the effector. ACh can also act on presynaptic mAChR or nAChR to modify its own release. The action of ACh is terminated by metabolism to choline and acetate by the enzyme acetylcholinesterase (AChE), which is associated with synaptic membranes. ADP, adenosine diphosphate; ATPase, adenosine triphosphatase. From Westfall TC and Westfall DP (2006) Neurotransmission: The autonomic and somatic motor nervous systems. Choline Acetyltransferase

The synthesis of acetylcholine occurs within the cytoplasm of cholinergic nerve terminals by a reaction in which choline is acetylated with acetyl coenzyme A (CoA) by the enzyme choline acetyltransferase. Acetyl CoA is derived mainly from glycolysis and is ultimately produced by the enzyme pyruvate dehydrogenase. The synthesis of acetyl CoA occurs at the inner membrane of mitochondria, and it is transported by citrate to the cytoplasm, where citrate is freed by citrate lyase.

Choline acetyltransferase is synthesized in the perkaryon and transported along the length of the axon to the terminal by axoplasmic flow.

Storage of Acetylcholine

Following its synthesis in the cytoplasm of the nerve terminal, acetylcholine is transported into synaptic vesicles by VAChT, which uses a proton electrochemical gradient to move acetylcholine to the inside of the organelle. Hydrophobicity algorithm prediction of secondary structure of VAChT suggests a protein comprising 12 transmembrane domains, with hydrophilic N- and C-termini in the cytoplasm. Sequence homology places VAChT into a family of transporter proteins that includes two vesicular monoamine transporters. An adenosine triphosphatase that pumps protons into the vesicle provides the energy necessary for the transport. Transport of protons out of the vesicle is coupled to uptake of acetylcholine into the vesicle and against a concentration gradient via an acetylcholine antiporter. Two types of vesicles appear to exist in cholinergic terminals: an electron-luscent vesicle (40–50 nm in diameter) and dense core vesicles (80–150 nm). The vesicle core contains both acetylcholine and adenosine triphosphate (ATP), which are dissolved in the fluid phase with metal ions (Ca^{2+} and Mg^{2+}) and a proteoglycan vesiculin. In some cholinergic terminals, there are also peptides such as vasoactive intestinal polypeptide (VIP) that act together with ATP and acetylcholine as cotransmitters. The peptides are thought to reside in the larger dense-core vesicles. Vesicular membranes are rich in lipids (cholesterol and phospholipids) as well as proteins.

The VAChT allows for the transport of acetylcholine agonist, which has a considerable concentration gradient and is saturable and adenosine triphosphatase-dependent. Vesamicol is a drug which inhibits the transport of acetylcholine via targeting the acetylcholine H^+ antiporter channel. Vesamicol leads to a reduction in acetylcholine storage and interferes with neurosecretion. Although not precisely known, the content of synaptic vesicles is estimated to range from 1000 to more than 50 000 molecules per vesicle. There may also be large amounts of acetylcholine in the extravesicular cytoplasm.

Release of Acetylcholine

Release of acetylcholine and cotransmitters (e.g., ATP and VIP) occurs on depolarization of the nerve terminals and takes place by exocytosis. Depolarization of the terminals allows the entry of Ca^{2+} through voltage-gated Ca^{2+} channels. Elevated Ca^{2+} concentration promotes fusion of the vesicular membrane with the plasma membrane, allowing exocytosis to occur. The molecular mechanisms involved in the release and regulation of release have been the subject of intense study but are still not completely understood. As mentioned, acetylcholine, like other neurotransmitters, is stored in vesicles located at special release sites, close to presynaptic membranes and ready for release on the appropriate stimulus. The vesicles initially dock and are primed for release. A multiprotein complex appears to form and attach the vesicle to the plasma membrane close to other signaling elements. The complex involves proteins from the vesicular membrane and the presynaptic neuronal membrane, as well as other components that help link them together. It has been established that these various synaptic proteins, including the plasma membrane protein syntaxin and synaptosomal protein 25 kDa (SNAP-25), and the vesicular membrane protein, or synaptobrevin, form a complex. This complex interacts in an ATP-dependent manner with soluble *N*-ethylmalemide-sensitive fusion protein and soluble SNAPs. The ability of synaptobrevin, syntaxin, and SNAP-25 to bind SNAPs has led to their designation as SNAP regulators (SNARES). It has been hypothesized that most, if not all, intracellular fusion events are mediated by SNARE interactions. Important evidence supporting the involvement of SNARE proteins in transmitter release comes from the fact that botulinum neurotoxins and tetanus toxin, which block neurotransmitter release, proteolyze these three proteins.

Two pools of acetylcholine appear to exist. One pool, the 'depot' or 'readily releasable' pool, consists of vesicles located near the plasma membrane of the nerve terminals and is filled with newly synthesized transmitter. Depolarization of the terminals causes these vesicles to release acetylcholine rapidly or readily. The other pool, the 'reserve' pool, seems to replenish the readily releasable pool and may be required to sustain acetylcholine release during periods of sustained or intense nerve stimulation.

Regulation of Acetylcholine Neurotransmission

It is now well accepted that receptors are located on perkaryon, dendrites, and axons of neurons when they may respond to neurotransmitters or neuromodulators released from the same neurons (autoreceptors) or adjacent neurons or cells (heteroreceptors). Cholinergic nerve terminals also contain autoreceptors and heteroreceptors.

Acetylcholine neurotransmission is therefore subject to complex regulation by mediators including acetylcholine itself acting on M_2 and M_4 autoinhibitory receptors and nicotinic acetylcholine excitatory receptors. Acetylcholine-mediated inhibition of acetylcholine release via muscarinic cholinergic receptors M_2 and M_4 is thought to represent a physiological

negative feedback control mechanism. Acetylcholine released from cholinergic neurons may also alter the release of other neurotransmitters. For instance, at the neuroeffector junction in the myenteric plexus in the gastrointestinal tract or sinoatrial node of the heart, postganglionic sympathetic and parasympathetic terminals lie in juxtaposition to each other. The release of acetylcholine not only produces autoinhibition of its own release but may attenuate the release of norepinephrine via an inhibitory action of muscarinic heteroreceptors located on sympathetic terminals. The reverse is also true: after its release of sympathetic nerve terminals, norepinephrine can inhibit the release of acetylcholine by an action of α_{2A} and α_{2C} heteroreceptors on parasympathetic nerve terminals. Muscarinic and nicotinic auto- and heteroreceptors also represent drug targets, or targets for locally formed autacoids, hormones, or transmitters.

Inactivation of Acetylcholine

Enzymatic Hydrolysis: AChE

Subsequent to its release from cholinergic neurons, acetylcholine is subjected to a number of inactivation processes, including (1) diffusion from the site of release, (2) dilution in extracellular fluids, (3) binding to nonspecific sites, and (4) enzymatic destruction. The most important of these by far is the enzymatic destruction of acetylcholine to its hydrolysis products, acetic acid and choline. The reaction is catalyzed by AChE. While AChE is found in cholinergic neurons (dendrites, perikarya, and axons), it is distributed more widely than cholinergic synapses. It is highly concentrated at postsynaptic sites, especially at the neuromuscular junction. AChE exists in red blood cells and the placenta as well as nervous tissue. A second enzyme is butyrylcholinesterase (BuChE). BuChE exists in intestine and skin and abundantly in plasma. AChE can be distinguished from BuChE by selectivity of acetylcholine over butyrylcholine hydrolysis.

BuChE shows a wider substrate capacity than AChE does. Almost all the pharmacological effects of AChE drugs are due to the inhibition of AChE, with a consequent accumulation of endogenous acetylcholine in the vicinity of the nerve terminal. Distinct but single genes encode AChE and BuChE in mammals, and the diversity of molecular structure of AChE arises from alternate messenger RNA processing. Complementary DNAs for several species, including *Torpedo*, *Drosophila*, nematode, rat, mouse, and human AChE, as well as mouse, rabbit, and human BuAChE, are known.

The contact between acetylcholine and the surface of AChE occurs at two places on the protein, One is the anionic site, which is negatively charged and stereospecific. It attracts the positively charged nitrogen atom of acetylcholine and binds the attracted methyl groups by Van der Waals forces. The other site is the 'esteratic' site, which combines the electrophilic carboxy carbon atom of the acetyl group and the serine hydroxyl group of the esteratic site (the nucleophilicity of which is enhanced by the histadine imidazole group).

The three stages for the hydrolysis are as follows: (1) equilibrium is established between the enzyme and acetylcholine, forming an enzyme substrate complex; (2) the complex reacts to release choline and leaves an acetylated enzyme; and (3) the acetylated enzyme reacts with water to give acetic acid and regenerated enzyme with a $t_{½}$ of approximately 40 μs.

Although the principal function of AChE is to inactivate acetylcholine at cholinergic neuronal junctions, it has been reported to have multiple biological functions that are not obvious. These include neritogenesis, cell adhesion, synaptogenesis, amyloid fiber assembly, and activation of dopamine receptors, hematopoiesis, and thrombopoiesis, to name but a few.

Cholinergic Receptors

Once released from cholinergic neurons, acetylcholine produces its physiological or pharmacological effects by first interacting with specific receptors. The various responses are mediated by the interaction of the transmitter with different types of receptors located in different organs, tissues, or cells. There are two general types of cholinergic receptors: muscarinic and nicotinic. The original classification was based on acetylcholine's mimicking the effect of the alkaloid muscarine (muscarinic) or nicotine (nicotinic). Multiple subtypes are now known to exist. Originally the subtypes of receptors were defined by the rank order of potency of agonists and the specificity of antagonists (e.g., atropine as an antagonist of muscarinic receptors and hexamethonium or curare as antagonists for nicotinic acetylcholine receptors (nAChRs)). More recently, the various subtypes have been identified by molecular cloning of the genes.

nAChRs

The nAChRs are members of a superfamily of ligand-gated ion channels (ionotropic receptors). They primarily exist at the neuromuscular junction, autonomic ganglia and adrenal medulla, parasympathetic and sympathetic nerve terminals, and central nervous system. These receptors are the physiologic target of the neurotransmitter acetylcholine as well as naturally occurring alkaloids and synthetic drugs. The nAChR

Table 1 Characteristics of subtypes of nicotinic acetylcholine receptors

Receptor (primary receptor subtype)[a]	*Main synaptic location*	*Membrane response*	*Molecular mechanism*	*Agonists*	*Antagonists*
Skeletal muscle (N_m) $(\alpha_1)_2\ \beta_1\ \varepsilon\ \delta$ Adult $(\alpha_1)_2\ \beta_1\ \gamma\ \delta$ Fetal	Skeletal neuromuscular junction (postjunctional)	Excitatory; endplate depolarization; skeletal muscle contraction	Increased cation permeability (Na^+; K^+)	ACh Nicotine Succinylcholine	Atracurium Vecuronium d-Tubocurarine Pancuronum α-conotoxin α-bungarotoxin
Peripheral neuronal (N_N) $(\alpha_3)_2\ (\beta_4)_3$	Autonomic ganglia; adrenal medulla	Excitatory; depolarization firing of postganglion neuron; depolarization and secretion of catecholamines	Increased cation permeability (Na^+; K^+)	ACh Nicotine Epibatidine Dimethylphenylpiper-azinum	Trimethaphan Mecamylamine
Central neuronal (CNS) $(\alpha_4)_2\ (\beta_4)_3$ (α-btox-insensitive)	CNS; pre- and postjunctional	Pre- and postsynaptic excitation Prejunctional control of transmitter release	Increased cation permeability (Na^+; K^+)	Cytisine, epibatidine Anatoxin A	Mecamylamine Dihydro-β-erythrodine Erysodine Lophotoxin
$(\alpha_7)_5$ (α-btox-sensitive)	CNS; pre- and postsynaptic	Pre- and postsynaptic excitation Prejunctional control of transmitter release	Increased permeability (Ca^{2+})	Anatoxin A	Methllycaconitine α-Bungarotoxin α-Conotoxin IMI

[a]Nine individual subunits have been identified and cloned in human brain which combine in various confirmations to form individual receptor subtypes. The structure of individual receptors and the subtype composition is incompletely understood, however. Only a finite number of naturally occurring functional nAChRs constructs have been identified to date. α-btox, α-bungarotoxin. Adapted from Westfall TC and Westfall DP (2006) Adrenergic agonists and antagonists. Table 2 Characteristics of muscarinic acetylcholine receptor subtypes

Receptor	*Size: chromosome location*	*Cellular and tissue location*[a]	*Cellular response*[b]	*Functional response*[c]
M_1	460 aa 11q 12–13	CNS; most abundant in cerebral cortex, hippocampus, and striatum Autonomic ganglia Glands (gastric and salivary) Enteric nerves	Activation of PLC; ↑ IP_3 and ↑ DAG → ↑ Ca^{2+} and PKC Depolarization and excitation (↑ sEPSP) Activation of PLD_2 ↑ AA Couples via $G_{q/11}$	Increased cognitive function (learning and memory) Increased seizure activity Decreased dopamine release and locomotion Increased depolarization of autonomic ganglia Increased secretions
M_2	466 aa 7q 35–36	Widely expressed in CNS, heart, smooth muscle, autonomic nerve terminals	Inhibition of adenylyl cyclase ↓ cAMP Activation of inwardly rectifying K^+ channels Inhibition of voltage-gated Ca^{2+} channels Hyperpolarization and inhibition Couples via G_i/G_o (PTX sensitive)	Heart: SA node: slowed spontaneous depolarization; hyperpolarization ↓HR AV node: decrease in conduction velocity Atrium: ↓ refractory period, ↓ contraction Ventricle: slight ↓ contraction *Smooth muscle:* ↑*Contraction* *Peripheral nerves:* Neural inhibition via autoreceptors and heteroreceptor) ↓ Ganglionic transmission. *CNS:* Neural inhibition ↑ Tremors; hypothermia; analgesia
M_3	590 aa Iq 43–44	Widely expressed in CNS (< than other mAChRs) Abundant in smooth muscle and glands Heart	Activation of PLC; ↑ IP_3 and ↑ DAG → ↑ Ca^{2+} and PKC Depolarization and excitation (↑ sEPSP) Activation of PLD_2 ; PLA_2; ↑ AA Couples via $G_{q/11}$	Smooth muscle: ↑ contraction (predominant in some, e.g., bladder) Glands: ↑ secretion (predominant in salivary gland) Increases food intake, body weight fat deposits. Inhibits dopamine release Synthesis of NO
M_4	479 aa 11p 12–11.2	Preferentially expressed in CNS, particularly forebrain	Inhibition of adenylyl cyclase ↓cAMP Activation of inwardly rectifying K^+ channels Inhibition of voltage-gated Ca^{2+} channels Hyperpolarization and inhibition Couples via G_i/G_o (PTX sensitive)	Autoreceptor and heteroreceptor mediated inhibition of transmitter release in CNS and periphery. Analgesia; cataleptic activity Facilitation of dopamine release
M_5	532 aa 15q 26	Expressed in low levels in CNS and periphery. Predominant mAchR in dopamine neurons in VTA and substantia nigra	Activation of PLC; ↑ IP_3 and ↑ DAG → ↑ Ca^{2+} and PKC Depolarization and excitation (↑ sEPSP) Activation of PLD_2, PLA_2; ↑ AA Couples via $G_{q/11}$	Mediator of dilation in cerebral arteries and arterioles (?) Facilitates dopamine release Augmentation of drug-seeking behavior and reward (e.g., opiates, cocaine)

[a]Most organs, tissues, and cells express multiple mAChRs.

[b]M_1, M_3, and M_5 mAChRs appear to couple to the same G-proteins and signal through similar pathways. Likewise, M_2 and M_4 mAChRs couple through similar G-proteins and signal through similar pathways.

[c]Although multiple subtypes of mAChRs coexist in many tissues, organs, and cells, one subtype may predominate in producing a particular function, or there may be equal predominance.

mAChR, muscarinic acetylcholine receptor; PLC, phospholipase C; IP_3, inositol-1,4,5-triphosphate; DAG, diacylglycerol; PKC, protein kinase C; EPSP, excitatory postsynaptic potential; PLD_2, phospholipase D; AA, arachidonic acid; CNS, central nervous system; PLA, phospholipase A; cAMP, cyclic adenosine monophosphate; SA node, sinoatrial node; AV node, atrioventricular node; HR, heart rate; PTX, pertussis toxin; VTA, ventral tegmental area.

Table 3 Summary of peripheral cholinergic receptors and responses

Organ	*Response*	*Receptor*
Eye		
Sphincter (circular) muscle of iris	Contraction (miosis)	M_3, M_2
Iris	Contraction (accommodation)	M_3, M_2
Ciliary muscle		
Heart		
SA node	Decrease in rate (negative chronotropic)	$M_2 \gg M_3$
Atria	Decrease in contractile strength (negative inotropic)	$M_2 \gg M_3$
	Decrease in refractive period	
AV node	Decrease in conduction velocity (negative dromotropic effect)	$M_2 \gg M_3$
	Increase in refractory period	$M_2 \gg M_3$

(Neuromuscular junction)	Contraction	N_M or N_2

[a]Most blood vessels are not innervated by parasympathetic nerves but have M_3 receptors on endothelial cells.

is a pentamer consisting of five subunits around a central ion channel pore. Several subunits have been identified: α, β, γ, δ, and ε. All these subunits share 35–50% homology with one another. Depending on the location of the receptor, it has a different combination of subunits. At the neuromuscular junction (N_1 or N_m), the AChR is composed of two α (α_1) subunits; one β (β_1); one δ; and in embryonic or denervated muscle, one γ subunit. In the adult innervated muscle, the γ is replaced with one ε subunit. Functional neuronal nAChRs (CNS N_n) also exist as pentamers composed of two α and three β subunits. Eight human α subunits (α_2–α_7, α_9, and α_{10}) and three β subunits (β_2–β_4) have been cloned. Both the muscle and the neuronal nAChR share structural and functional properties with other ionotropic receptors, such as γ-aminobutyric acid A receptor, 5-hydroxytryptamine type 3, and glycine receptors. Autonomic ganglia (N_2) and the adrenal medulla form homomeric α_7 and heteromeric α_3/β_4, with $(\alpha_3)_2$ $(\beta_4)_3$ being the most prevalent.

The α subunits are responsible for binding acetylcholine, and the conformational change in the α subunits is responsible for permitting ion flow through the central pore of the receptor. The pentameric structure of the CNS–neuronal receptor and the large molecular diversity of its subunits (α_2–α_8, β_2–β_4) suggest there could be a large number of nAChRs with different physiological properties. They may subserve discrete functions and obviously represent multiple drug targets. The stoichiometry of the nAChR in brain is the subject of intense study. Selective ligands are becoming more and more prominent, but it is not yet possible to make a pharmacological classification based on subtypes. The characteristics of subtypes of nAChR are described in Table 1.

Muscarinic Acetylcholine Receptors

There are five distinct subtypes of muscarinic acetylcholine receptors (mAChRs), M_1–M_5, each produced by a distinct gene and all members of the family of G-protein-coupled receptors (metabotropic receptors). Like the different nAChRs, M_1–M_5 have distinct anatomical locations in the periphery and CNS and different chemical specificities. The mAChRs have been shown to be present in virtually all organs, tissues, and cell types, but various subtypes predominate in various tissues and organs (e.g., M_2 in the heart, M_3 in the detrusor muscle of the bladder). The mAChRs are located in smooth muscle, exocrine and endocrine glands, and the myocardium. They mediate the actions of acetylcholine in organs and tissues innervated by postganglionic parasympathetic nerves and postganglionic sympathetic nerves innervating eccrine sweat glands. They are also present at sites that lack parasympathetic nerves (e.g., most blood vessels). Table 2 summarizes the effects produced by activation of mAChRs. In the CNS, mAChRs are involved in regulating a large number of cognitive, behavioral, motor, and autonomic functions although some of these are also influenced by nAChRs.

Effects produced by activating mAChR are coupled through G-protein-induced changes in membrane-bound effectors and production of second-messenger molecules. The M_1, M_2, and M_3 receptor subtypes couple through the pertussis toxin-insensitive G_{11} and G_{13}, resulting in stimulation of phospholipase C activity. This results in the hydrolysis of membrane phosphatidylinositol 4,5 diphosphate to form inositol triphosphate (IP_3) and diaceylglycerol. IP_3 causes release of intracellular Ca^{2+} from the endoplasmic reticulum, which results in smooth muscle contraction as well as secretion from the appropriate cell. Diaceylglycerol activates protein kinase C, resulting in phosphorylation of numerous proteins and various physiological responses. Activation of M_1, M_2, and M_3 receptors also results in the activation of phospholipase A_2, leading to the release of arachidonic acid and consequent eicosanoid synthesis.

Stimulation of the M_2/M_4 receptors leads to interaction with G_i and G_o proteins, which results in inhibition of adenylyl cyclase and the resultant decrease in cyclic adenosine monophosphate, activation of inwardly rectifying K^+ channels, and inhibition of voltage-gated Ca^{2+} channels. Functional consequences are hyperpolarization and inhibition of excitable membranes.

Physiological Responses Produced Following Increases in Cholinergic Neurotransmission

Table 3 depicts the physiological responses due to increases in cholinergic neurotransmission or stimulation of parasympathetic neurons.

Cholinergic Pathways in CNS

Acetylcholine as a Central Nervous System Transmitter

Historically, acetylcholine (ACh) was considered to be the most important central nervous system (CNS) transmitter. As early as 1936, Quastel demonstrated that ACh was synthesized in the brain. Indeed, ACh was the first substance to be proposed to act as a CNS transmitter in the pioneering work of Marthe Vogt and Feldberg in the 1940s and 1950s, largely based on prior lessons obtained with this substance in the peripheral nervous system by a number of outstanding pharmacologists, ranging from Otto Loewi to Sir Henry Dale. Later, Fatt, Katz, and collaborators provided evidence for a quantal release of ACh in the neuromuscular junction, laying the foundations for the idea that this transmitter substance was somehow 'packaged' in nerve terminals. The realization that this was the case came about with the ultrastructural finding in 1955 of synaptic vesicles in CNS nerve terminals by De Robertis and Bennett, and also Palay and Palade, and the compelling demonstration that isolated synaptic vesicles obtained from subcellular fractionation were enriched in ACh content, as shown by De Robertis in Buenos Aires and Whitaker in Cambridge. These studies not only were important for the realization that ACh was a bona fide CNS transmitter but they also provided strong foundations to the chemical synaptic transmission hypothesis, a concept currently applied to a wide variety of so-called classical (e.g., amines, aminoacids) and nonclassical transmitters (e.g., peptides).

CNS Cholinergic Synapses

Contrary to historical expectations, current methods have demonstrated that cholinergic synapses do not account for the majority of transmitter-specific synapses in the CNS. In the cerebral cortex, for example, cholinergic synapses account for about 5–7% of the total synaptic population. However, considerable variations in the number of cholinergic synapses across the CNS should be expected, given the degree of differential concentrations of the ACh-synthesizing enzyme (choline acetyltransferase, ChAT) in diverse brain areas. ChAT is localized mainly in the cytosolic compartment. The CNS cholinergic synapses are endowed with the expected set of organelles (e.g., mitochondria, synaptic vesicles) and molecules (e.g., classical synaptic proteins), but in addition they contain 'signature' proteins such as the high-affinity choline transporter (CHT1) and the vesicular acetylcholine transporter (VAChT). These two proteins endow cholinergic synapses with their physiological specifications. CHT1 plays an essential role in maintaining the required level of ACh synthesis, as it is the availability of choline rather than the ChAT enzymatic activity that is the rate-limiting factor for the synthesis of ACh. As expected, CHT1 is localized in synaptic membranes to facilitate the incorporation of the choline precursor.

Dietary levels of choline have been shown to have an important impact on the replenishment of ACh stores in the CNS. Besides its predicted synaptic membrane localization, CHT1 is abundantly present in synaptic vesicles. This is somewhat perplexing, as ChAT is primarily a cytosolic enzyme and the bulk of the ACh synthesis is known to occur in the cytoplasm. This location might be a consequence of the retrieval of synapses after exocytosis, but the vesicular CHT1 might also play a role in mobilizing choline from vesicles to cytoplasm and vice versa. The VAChT is heavily localized in membranes of synaptic vesicles of cholinergic presynaptic endings. Its function is the straightforward uptake of newly synthesized cytoplasmatic ACh into the vesicular stores. The ACh-enriched vesicles are thus ready for release on demand. The newly synthesized ACh appears to be the first to be released, probably from vesicles closer to the synaptic membranes, while more distant vesicles containing 'older' ACh pools are seemingly located in the cholinergic presynaptic terminal further away from the point of synaptic contact. The cholinergic synaptic vesicles, from the early De Robertis descriptions, are recognized as being small, clear, and roundish. Figure 1 represents the main features of CNS cholinergic synapses.

After the identification of the CNS cholinergic neurons and their projections (see later), it was proposed that their terminations at target sites, particularly in the cerebral cortex, were nonsynaptic in nature. In other words, it was assumed that CNS cholinergic presynaptic boutons release ACh diffusely in a 'cloud-like' modality. The idea of 'volume' or 'extrasynaptic' transmission of acetylcholine in the CNS was born out of the prevalent notion that CNS terminations containing monoamines are apparently nonsynaptic, in a manner reminiscent of the peripheral autonomic axonal terminations. The cholinergic cortical terminations were, therefore, included in the category of nonsynaptic neurons due to the lack of evidence for

synaptic specialization in ChAT-immunoreactive (IR) boutons when observed by electron microscopy. However, Mesulam and collaborators, using ChAT antibodies, noted that cholinergic boutons in the cerebral cortex of the human brain mainly displayed symmetric synaptic contacts. A more comprehensive ultrastructural study in the rat neocortex, applying improved protocols for tissue preservation and utilizing antibodies against VAChT, revealed that the cortical cholinergic presynaptic boutons in their majority establish classical synaptic contacts with symmetric membrane specializations (parallel membranes of equal thickness in the pre- and postsynaptic sides of contacts). These classical synaptic contacts occur preferentially in dendritic shafts and differ in their termination pattern from the bulk of 'noncholinergic' presynaptic boutons. Cholinergic presynaptic boutons are seldom observed contacting neuronal cell bodies and only occasionally contacting dendritic spines. These latter synapses are exclusively of an asymmetric nature (i.e., the postsynaptic membrane is notably thicker than the opposing presynaptic membrane). Figure 2 illustrates the typical ultrastructural characteristics of cholinergic (VAChT-IR) presynaptic sites (boutons) in layer V of the rat parietal cortex.

Main CNS Cholinergic Pathways

Although the existence of CNS cholinergic neurons was well accepted, it took nearly half a century for their unequivocal identification. Early attempts to define CNS systems operating with ACh applied immunohistochemical methods to reveal the presence (activity) of acetylcholinesterase (AChE), the ACh-inactivating enzyme, a procedure which was pioneered by Shute and Lewis at Cambridge University. This method revealed cell groups that later proved to be indeed cholinergic in nature, but it had the intrinsic problem that it demonstrated both 'cholinergic' and 'cholinoceptive' neurons. This approach was modified later by Butcher and collaborators when they introduced the so-called pharmaco-histochemical technique. This technique involved the inhibition of AChE, followed, after few hours, by the AChE histochemical reaction, to demonstrate newly generated AChE in cell body groups, thus avoiding the confounding images of AChE-positive neurites in the CNS tissue. While this approach was of some value, the problem remained that it also revealed several AChE-positive cells which were not cholinergic in nature. We now know that there is not a 100% correlation between ChAT-IR and AChE-positive histochemical reactions in CNS neurons. Notable examples are the conspicuous presence of AChE-positive material in dopaminergic substantia nigra and noradrenergic locus coeruleus neurons in the absence of ChAT immunoreaction. The chemical isolation of ChAT allowed the generation of reliable polyclonal and monoclonal antibodies, which opened the door for the reliable demonstration of the main groups of CNS cholinernergic neurons. Thus, a number

(2001) Cholinergic nerve terminals establish classical synapses in the rat cerebral cortex: Synaptic pattern and age-related atrophy. *Neuroscience* 105(2): 277–285, with permission from Elsevier.

of reports arose during the early 1980s, applying immunohistochemistry to depict the localization of CNS ChAT-IR cell bodies and fiber tracts. At the time, the Swedish histochemists Fuxe and Dahlstrom introduced a letter and number nomenclature to define the catecholaminergic pathway. This proved popular and was widely accepted. Mesulam and collaborators, following the same principles, applied a Ch and number nomenclature to define CNS cholinergic nuclear organizations, as revealed with anti-ChAT monoclonal antibodies. These studies were the most exacting and comprehensive and provided a useful guide for further investigations, although the Ch classification is not universally applied. Following these developments, a number of lesion and track-tracing experiments revealed the existence of a variety of CNS pathways and local circuit cholinergic neurons. The main cholinergic cell groups and pathways are represented in Figure 3 in a parasagittal view of the rat CNS, where the prominent and extensively studied basalocortical and septo-hippocampal pathways are highlighted in gray.

In summary, these immunohistochemical investigations demonstrated that the ventral telencephalon displays a continuous stream of cholinergic cell bodies, notably in the olfactory tubercle, islands of Calleja, all components of the diagonal band, medial septum, nucleus preopticus magnocellularis, and the innermost region of the globus pallidus. These neurons are usually referred to (as an ensemble) as the basal forebrain cholinergic system. In rodents, the ChAT immunoreactive neurons distributed loosely in the innermost third of the globus pallidus represent the nucleus basalis, which is responsible for the large majority of cholinergic input to the cerebral cortex. The rodent cerebral cortex contains in addition a few homogenously dispersed, local circuit, fusiform cholinergic cell bodies. The organization of this 'basalocortical' pathway is very different from that of the

Figure 3 Schematic sagittal view of the rat CNS, representing the main cholinergic pathways, as discussed in the text. OB, olfactory bulb; AON, anterior olfactory nucleus; DB, diagonal band; S, septum (cholinergic neurons restricted to medial division); CG, cingulated cortex; CP, large interneurons in the caudate putamen; H, hippocampus; BN, nucleus basalis; A, amygdala; TH, thalamus; Ar, arcuate nucleus; PPT, peduculo-pontine tegmental nucleus; LDT, lateral doral tegmental nucleus; C, cortex; IP, nucleus interpenducularis; MH, medial habenula; OT, olfactory tubercle. For clarity, cholinergic motor neurons and cholinergic preganglionar neurons are not represented. The gray bands represent the major forebrain basalocortical and septal–hippocampal cholinergic pathways. human brain. In the human brain, the equivalent cholinergic group is composed of large (ergo 'magnocellularis') multipolar neurons located in a flattened nuclear organization lying below the anterior commissure. This organization would correspond to the neuronal group, which is nowadays referred to as the nucleus basalis magnocellularis of Meynert, or simply the nucleus of Meynert. However, it has to be stressed that this nomenclature is only applicable to the human brain and to subhuman primate brains. The rodent structure should be referred to simply as the nucleus basalis. These nuclei, both in rodents and humans, correspond to Ch4 in Mesulam's classification. A possible explanation of this differential organization of the nucleus basalis in primates and rodents might reside in the fact that in rodents the globus pallidus is split where the medial division of the globus pallidus becomes the entopenducular nucleus (also containing cholinergic neurons), while the external division becomes the globus pallidus. In consequence, in rodents, this component of the basal forebrain cholinergic neurons does not find the obstacle of the anterior commissure barrier, invading the innermost third of the globus pallidus in a diffuse manner. In the rodent, the most caudal portions of the nucleus basalis become a flattened neuronal group located between the optic tract and the last portion of the corpus striatum. Much attention has been paid to this nuclear organization, as it has been reported to be compromised in Alzheimer's disease (AD), a disease that, in advanced states, is accompanied by the loss of cortical cholinergic markers (see the section entitled 'CNS cholinergic neurons and AD').

It is well documented that the nucleus basalis innervates all areas of the neocortex in a topographic-specific manner, that is, more rostral regions of the nucleus basalis will supply cholinergic fibers to the most rostral cortical regions, and the most caudal to the most caudal. While the 'basalocortical cholinergic pathway' supplies fibers to the entire neocortex, the cingulate and entorhinal cortex most probably is innervated by cholinergic septal and diagonal band neurons. Figure 4 illustrates the appearance and relative density of cortical cholinergic presynaptic boutons as compared to the overall density of presynaptic boutons as revealed by synaptophysin.

The other prominent basal forebrain cholinergic nuclear group is located in two arching bands of neurons meeting at the midline at dorsal aspects of the septal nucleus. This group of neurons is part of a continuum of cholinergic neurons from more rostrally located cholinergic neurons of the diagonal band of Broca. These septal cholinergic neurons project heavily to all regions of the hippocampal formation via the fimbria-fornix; this is referred to as the 'septal–hippocampal' cholinergic pathway.

Figure 4 Immunocytochemical demonstration of cholinergic presynaptic boutons in the cerebral cortex of the rat (parietal cortex, lamina (b) as revealed with anti-VAChT antibodies. The pattern and density of the total population of cortical presynaptic boutons, as revealed with antisynaptophysin antibodies, are illustrated in (a). Scale bar = 20 μm.

These two cholinergic nuclei (basalis and medial septum) are frequently referred to in the literature as 'the' basal forebrain cholinergic neurons; however, the basal forebrain cholinergic system includes other nuclei forming a continuum in that region of the brain (as previously described). These two cholinergic neuronal groups (basolocortical and septo-hippocampal) are heavily involved in higher CNS functions such as attention, learning, and memory, and are compromised in aging and in AD (see the section entitled 'CNS cholinergic neurons and AD').

The largest CNS concentration of cholinergic fibers occurs, without any doubt, in the nucleus caudatus in humans and in the caudoputamen complex in rodents. These fibers and nerve terminals originate in very large local circuit neurons distributed throughout this region of the basal ganglia. Indeed, the highest CNS concentration of ACh and cholinergic markers in general occurs in the basal ganglia. The cholinergic system here plays an important role in mechanisms implicated in movement control and there is good physiological and pharmacological evidence for a dopaminergic/cholinergic balance in this region.

Other less conspicuous cholinergic cell groups are found in the thalamus (midline, intralaminar), epithalamus (medial habenula), and hypothalamus (posterior region and arcuate nucleus), with less defined functions than those of the forebrain cholinergic neurons. The medial habenula nuclei project heavily to the nucleus interpeduncularis via the so-called fasciculus retroflexus. In the brain stem, the motor and autonomic preganglionar neurons of cranial nerves are all of cholinergic nature, as expected from classical physiological studies preceding the advent of immunocytochemistry. In addition to these motor neurons, there is a collection of ChAT-IR neurons distributed in various regions of the brain stem. Thus, there is a diffuse reticular system (lateral reticular nucleus, parvicellular) and several nuclei, including the pedunculo-pontine tegmental (PPT), lateral dorsotegmental (LDT), parabrachial, nucleus trapezoid, superior olive, and the raphe system (nucleus magnus and obscurus). PPT and LDT assembly of cholinergic neurons projects mainly to the thalamus, epithalamus, and tectum, but also sends axons more ventrally to the basal forebrain, lateral hypothalamus, and substantia nigra. Descending branches from the PPT and LDT cholinergic nuclei reach diverse nuclei in the lower brain stem, and long projections from these neurons can reach the spinal cord. In the spinal cord, occasional small cholinergic neurons can be observed in the dorsal horn in addition to the preganglionar nuclei of the lateral horn and the large motor neurons of the ventral horn.

Although a number of cholinergic neuronal pathways have been described, there is still an incomplete account of the physiological roles for the diverse CNS cholinergic projections. The PPT–LDT ascending cholinergic pathways, along with forebrain neurons, appear to play an important role in sleep control mechanisms, whereas there is scant information regarding the possible functions of the brain stem–spinal cord descending cholinergic projections. The latter projections are suspected to participate in pain-control mechanisms.

The Functions and Neurobiology of Basal Forebrain Cholinergic Neurons

For several decades, the CNS cholinergic system was suspected to play an important role in memory. The most influential early studies pointing out such CNS cholinergic functions were carried out by Drachman and collaborators in young human subjects in which the muscarinic antagonist scopolamine, in low doses, brought about memory deficits similar to those observed in aged individuals. On the other hand, the application of the muscarinic agonists in young

volunteers improved the recall of learned verbal material. These observations on the participation of the cholinergic system in memory tasks were corroborated in subhuman primates by Bartus and collaborators, who elaborated "the cholinergic hypothesis of geriatry memory dysfunction." Numerous further investigations in rodents supported the concept of a cholinergic involvement in memory and learning. These functions, attributed initially to the so-called ascending reticular pathway, elaborated in the 1940s by Moruzzi and Magoun, had an important impact on developing physiological–anatomical theories for higher CNS functions. This anatomically ill-defined system was described as responsible for the control of wakefulness, sleep patterns, alertness, and memory. The anatomical–neurochemical identification in the brain stem and basal forebrain of neuronal cell groups and ascending pathways of catecholaminergic, serotoninergic, and cholinergic nature in the 1970s and 1980s allowed a more precise and specific understanding of the contribution of these transmitter systems to these functions. Today, the basal forebrain cholinergic system can be considered to be the rostralmost representation of such a system. There is solid experimental evidence that the basal forebrain cholinergic neurons do participate importantly in attentional, learning, and memory functions. These investigations constitute a very rich assembly of pharmacological, anatomical, and selective lesion studies combined with a wide variety of behavioral tasks. In more recent years, some emphasis has been placed on the attentional functions of cortical cholinergic inputs, thus conditioning learning and memory functions. Nevertheless, a dramatic argument in favor of the idea that ACh is necessary for learning and memory has been provided by the restoration of these functions with the cortical grafting of genetically modified cells producing ACh in rats with learning and memory impairments as a consequence of nucleus basalis lesions. The forebrain cholinergic input to cortex and hippocampus might have important modulatory roles in defining activity-dependent synaptic maps. The most provoking evidence in that direction was provided by Kilgard and Merzenich in 1998. This study demonstrated that episodic electrical stimulation of the nucleus basalis, paired with an auditory stimulus, resulted in a progressive reorganization of the primary auditory cortex in the adult rat, similar to that with behavioral training. While these findings suggest that the basal forebrain plays a role in modifying cortical synaptic sensory representation, additional pharmacological data would be necessary to firmly relate this to a cholinergic function.

Trophic Factor Dependency of Forebrain Cholinergic Neurons

The embryonic development of the basal forebrain cholinergic system is highly dependent on the expression of nerve growth factor (NGF) and the high-affinity NGF receptor TrkA and, to a lesser extent, on the expression of low-affinity $p75^{LNTR}$ receptors. The low- and high-affinity $p75^{LNTR}$ neurotrophin receptors appear to function, depending on the physiological and/or pathological circumstances, in a cooperative or competitive manner. In early postnatal stages, relatively high levels of NGF are expressed, but this expression substantially decreases after birth. In early ontogenic stages, forebrain cholinergic neurons remain highly sensitive to exogenously administered NGF. The expression and release of NGF are very low after neuronal differentiation in adulthood. However, the NGF dependency of cholinergic neurons in mature and fully differentiated CNS remains. The experimental evidence indicates that in the adult CNS, NGF maintains cholinergic neuronal phenotype. The main supply of NGF is thought to be 'target derived,' that is, from the cerebral cortex for cholinergic nucleus basalis neurons, and from the hippocampus for medial septum neurons. Thus, target ablation of the neocortex or hippocampus provokes cholinergic neuronal cell shrinkage but not death. However, transection of the fimbria-fornix can provoke a mixed situation of neuronal atrophy and cell death of cholinergic neurons in the medial septum. The application of exogenous NGF can restore the cholinergic phenotype in both lesion models. Interestingly, NGF application after limited cortical strokelike lesions is sufficient to restore the size and biochemistry of nucleus basalis cholinergic neurons as well as preventing behavioral memory deficits, even when applying NGF after lesions (see **Figure 5**).

Exogenous application of NGF in cortically lesioned adult rats also induces cholinergic synaptogenesis in the remaining, intact neocortex. On the other hand, the blocking of endogenously produced NGF by applying NGF-immunoneutralizing monoclonal antibodies in the cerebral cortex or synthetic TrkA receptor antagonists was shown to remove preexisting cortical cholinergic synapses *in vivo*. In other words, these observations would indicate that the production of small, baseline endogenous NGF in the cerebral cortex regulates the steady-state number of cholinergic synaptic boutons in the adult CNS. As trophic factors have been shown to be produced and liberated in an activity-dependent fashion, it would be reasonable to assume that the number of cortical

Figure 5 The schematic drawing on the left represents the distribution of abundant forebrain neurons intensively immunoreactive to p75 low-affinity NGF receptor, represented as filled circles. The cells in the inner portion of the globus pallidus correspond to cholinergic neurons of the nucleus basalis. Open circles indicate moderately p75 immunoreactive large neurons in the caudate putamen (cholinergic interneurons). The micrographs on the right (a) indicate cholinergic neurons of the nucleus basalis, as revealed by ChAT immunocytochemistry. Note the rich dendritic branching of the cholinergic neurons of the nucleus basalis. The extreme right column illustrates the computer-assisted definition of the cell soma cross-sectional area. The micrographs illustrate the efficacy of NGF to rescue retrogradely shrunken neurons following cortical lesions: (a) and (d) show ChAT-IR nucleus basalis neurons from naive control adult rats; (b) and (e) show gross cell shrinkage of the same neurons after cortical lesions; and (c) and (f) show prevention of cell shrinkage and maintenance of normal phenotype with the administration of microgram amounts of NGF. ACo, anterior cortical olfactory nucleus; c, corpus callosum; CPu, caudate putamen; cs, cingulate striae; lo, lateral olfactory tract; LOT, nucleus of the olfactory tract; n, fimbria fornix; Pir, piriform cortex; RF, rhinal fissure; Rt, reticular nucleus of the thalamus; SCh, nucleus suprachiasmaticus; sm, stria medullaris; 3, third ventricle. Reproduced from Cuello AC (2006) Cholinergic synaptic terminations in the cerebral cortex, trophic factor dependency, and vulnerability to aging and Alzheimer's pathology. In: Giacobini E and Penney JB (eds.) *The Brain Cholinergic System in Health and Disease*, figure 3.2, pp. 33–46. Oxon, UK: Informa Healthcare, with permission from Taylor & Francis.

cholinergic synapses changes constantly in the human brain, based on experience and brain activity. Such a concept would be in line with the classical tenet of Hebb that the strength of synaptic connections was linked to a growth process which takes place with synaptic efficacy.

CNS Cholinergic Neurons and AD

It is possible that CNS cholinergic neurons are somehow involved in a variety of neurodegenerative disorders. However, up to the present, none of these conditions appears as striking as in the case of Alzheimer's disease. In the 1970s, Davis and Maloney and Bowen et al. reported evidence of marked deficits in cortical cholinergic markers (particularly loss of ChAT levels) in AD brain. After the identification of the main CNS cholinergic groups, Whitehouse and collaborators reported losses of 'magnocellular' neurons in the the nucleus basalis of Meynert. These findings were coincidental with "the cholinergic hypothesis of geriatry memory dysfunction" (as discussed previously). At the time, evidence that the loss of substantia nigra dopaminergic neurons was mainly responsible for Parkinsonian symptoms, along with the evidence that the administration of dopamine

precursors could be an effective transmitter-based therapy, brought about by analogy 'the cholinergic hypothesis of Alzheimer's disease.' This proposal provoked a great deal of experimental and clinical research. We now know that the cholinergic involvement in AD is a component of the neuropathology, most likely secondary to the Aβ burden in the cerebral cortex and hippocampus. It is now also well established that the cholinergic depletion occurs at advanced stages of the AD pathology, while at the AD-prodromic stage of mild cognitive impairment (MCI) an upregulation of cholinergic markers takes place instead. Furthermore, transgenic animal models of the amyloid pathology can replicate features of the cholinergic involvement, suggesting a secondary rather than a primary involvement in the disease process. However, as discussed previously, the forebrain cholinergic system is so intimately related to memory processes that it was perceived as a viable therapeutic target. Early attempts at using muscarinic agonists and choline supplements – in the latter case to stimulate ACh synthesis, given (as discussed previously) that the high-affinity choline uptake system is the *de facto* rate-limiting factor – were without substantive effect on memory or other cognitive parameters. Instead, the application of cholinesterase inhibitors (capable of blocking acetylcholinesterases or butyrylcholinesterases in diverse degrees) to block ACh degradation has been used widely as symptomatic therapy in AD. This approach is by no means capable of halting the pathological process (disease modifying), but has proved effective in delaying cognitive decay in a good number of patients, although the efficacy wanes after a year or two of treatment. The cholinergic system is, however, involved in the disease process. The activation of M1 and M3 receptors has been shown to shift amyloid precursor protein (APP) metabolism to a nonamyloidogenic modality, an aspect that has been confirmed repeatedly in experimental models and in the clinic with the application of anticholinesterases. These observations have provided renewed interest in the development of newer, safer, and more efficaceous muscarinic agonists. Knowing the great trophic dependency of forebrain cholinergic neurons on NGF support, clinical attempts have involved applying mouse NGF in the brain of Alzheimer's patients, but with disapponting results. In these patients, the large doses applied and the diffusion of NGF to undesirable targets (e.g., sensory nociceptive fibers and hypothalamic nuclei) produced pain and marked weight loss. As NGF can act on the nucleus basalis also in the somatodendritic region in a paracrine fashion (in contrast with target derived), there is current interest in applying grafts of genetically modified NGF-producing cells, implanted in nucleus basalis neighboring areas of Alzheimer's patients, and, long range, of regulable lentoviral vectors, allowing the *in situ* expression of NGF. New therapeutic approaches to correct the cholinergic deficit might emerge from the realization that this is most probably due to the dysregulation of the protease cascade, which is responsible for the maturation of the NGF-precursor protein (ProNGF) into mature and biologically active NGF and for its degradation.

Introduction

For over a century the neurophysiological activity of acetylcholine (ACh) has been well documented. Although Otto Lowei, in the 1920s, identified ACh as the cardioactive substance released by the vagus nerve, it took many additional years of research to establish that ACh was also a neurotransmitter of the central nervous system (CNS). ACh is synthesized in the neuronal cytoplasm from acetyl coenzyme A and choline by the enzyme choline acetyltransferase (ChAT) (see Figure 1). Most ACh is stored in vesicles located in axon terminals and is released to the synaptic cleft upon depolarization in a process mediated by an elevation in intracellular Ca^{2+}. Following release, ACh is hydrolyzed into choline and acetate by acetylcholinesterase (AChE), which is found on both the pre- and postsynaptic membranes. Two classes of receptors are involved in cholinergic transmission: nicotinic ion channels, which mediate fast postsynaptic transmission, and the muscarinic G-protein-coupled receptors, which play a modulatory role. The nicotinic ACh ionotropic receptor (nAChR) is a pentameric membrane protein composed of four polypeptide chains, designated nAChRs α, β, δ, and γ, which are located throughout the CNS (Figure 2). The muscarinic ACh receptor (mAChR) family includes five members, M_1, M_2, M_3, M_4, and M_5, which also exhibit a subtype-specific topographic distribution within the CNS (Figure 3). The basic differences between these two receptor classes are listed in Table 1.

In the CNS, ACh facilitates many functions, including learning, memory, attention, and motor control, mainly through an extensive network of cholinergic projection pathways originating in the basal forebrain. Dysfunction of these cholinergic pathways plays a role in age-related memory impairments and in the onset of Alzheimer's disease (AD). The following discussions survey the central cholinergic projection neurons and their relation to neurotransmission, and the observations from human brain suggesting that alterations in neurotrophic support of these neurons play a central role in their dysfunction in aging and AD.

Anatomy of the Cholinergic Basal Forebrain

A diverse group of telencephalic structures situated on the medial and ventral aspects of the cerebral hemispheres compose the basal forebrain in the primate brain. Brain tissue stained for cell bodies reveals clusters of neurons with a distinct magnocellular appearance (Figure 4(a)).

In the early 1980s, the Ch1–Ch4 nomenclature was introduced to designate the cholinergic (ChAT-containing) neurons within the basal forebrain. Studies using the nonspecific cholinergic marker AChE and specific markers – ChAT (Figure 4(i)), the vesicular acetylcholine transporter (VAChT), and the high-affinity choline transporter – delimited a continuum of cholinergic neurons within the basal forebrain (Figures 5(a)–5(d)). Cholinergic neurons (25–30 × 25–30 μm) of the medial septum (Ch1) comprise 10% of this region. The diagonal band of Broca comprises the Ch2 (vertical limb) and Ch3 (horizontal limb) subgroups. Ch2 neurons are fusiform in shape, 20–25 × 30–40 μm in size, and approximately 70% of these perikarya are cholinergic. Ch3 neurons have the most diffuse boundaries in the primate brain and are fusiform-shaped (15–20 × 40–50 μm) neurons of which approximately 1–2% are cholinergic. The largest group of cholinergic neurons (90%) constitutes the Ch4 cells of the nucleus basalis (NB), which are fusiform to multipolar in shape and 40–50 × 60–70 μm in size. Topographically, the Ch4 group can be separated into anterior (Ch4a), intermediate (Ch4i), and posterior (Ch4p) subfields. The total number of cholinergic neurons located within the primate NB is approximately 200 000 per hemisphere. The term 'nucleus basalis' may be employed to designate the cholinergic components (Figures 4(b)–4(d) and 4(f)) as well as the noncholinergic components – for example, calbindin (CB; Figures 4(b) and 4(c)), glutamatergic (Figure 4(d)), γ-aminobutyric acid (GABA-)ergic, and galaninergic profiles (Figures 4(g) and 4(h)). The more restrictive Ch4 nomenclature is reserved for the cholinergic neurons located in this region. These cholinergic basal forebrain (CBF) neurons provide the major cholinergic innervation to the hippocampus (Ch1–Ch2; Figure 6), olfactory system (Ch3), amygdala, and cortical mantle (Ch4; Figure 6).

Interestingly, galanin, an inhibitory neuropeptide, co-localizes within the cholinergic neurons of the NB in rodents and lesser apes (rhesus monkeys, gibbons). By contrast, in the great apes (chimpanzees, gorillas, and humans), cholinergic NB neurons are galanin

negative (Figure 7). These cholinergic neurons are innervated by a separate population of galaninergic interneurons (Figure 4(g)) and fibers from extra forebrain sources (e.g., locus coeruleus). These findings suggest that during the evolution of the human brain the galaninergic systems diverged from rodents and lesser apes. Perhaps galanin plays a unique role in the regulation of CBF neuronal tone required for higher cortical function. The unique role of galanin in the human brain is further underscored by the observation that in the late stages of AD, galanin fibers hypertrophy upon surviving cholinergic neurons (Figure 4(h)). It has been suggested that galanin plays a crucial role in cholinergic cell survival and that galanin overexpression is a compensatory mechanism in an attempt to attenuate the progression of cholinergic cell death in AD. Available data also indicate a species difference in the localization of estrogen receptor alpha (ERα)-containing nuclei within the CBF between rodents and some primates. Numerous histochemical and gene expression studies in the rodent indicate that the CBF neurons co-express estrogen receptors. In contrast to the rodent, immunohistochemical studies indicate that ERα does not co-localize with ChAT-containing CBF neurons in the monkey. However, ERα-containing nuclei as well as minor cytoplasmic staining were found within other forebrain areas, including the lateral septum, amygdala, the bed nucleus of the stria terminalis, the subfornical organ, medial and lateral hypothalamic nuclei, and the amygdalo-hippocampal transition

Table 1 Characteristics of muscarinic and nicotinic receptors

Characteristic	*Muscarinic*	*Nicotinic*
Response time to respective agonist (muscarine, nicotine)	Slow (100–250 ms)	Fast (<10 ms)
Receptor type	Metabotropic	Ionotropic
Receptor subtype	M_1, M_3, $M_5 = G_q$-coupled M_2, $M_4 = G_i$ coupled	Nine subtypes
Excitatory/inhibitory	Mixed	Excitatory
Typical antagonists	Atropine, scopolamine	Tubocurarine
Distribution	Parasympathetically innervated cardiac and smooth muscles (heart, iris, stomach, bronchitis bladder, etc.) Salivary, tear, and sweat glands CNS	All striated muscles Postganglionic parasympathetic and sympathetic neurons CNS

zone in the rhesus monkey. Studies performed on human brain tissue revealed ERα- and ERβ-positive neurons (Figure 4(e)) within the NB. However, these reports did not co-localize these receptors with any CBF neuronal marker. Further studies are needed to determine the chemical phenotype of ER-containing neurons within the primate brain and whether cholinergic neurons are regulated via genomic or epigenetic mechanisms.

Anatomy of the Thalamic and Brain Stem Cholinergic Subgroups

Within the upper brain stem a continuous band of ChAT-containing neurons extends from the rostral midbrain to the midpontine levels (Figure 8). These perikarya can be subdivided into two major fields, Ch5 and Ch6. The cholinergic neurons of Ch5 remain mostly within the pedunculopontine nucleus (PPN); this location is analogous to that of the Ch5 group identified in rodents. At the level of the PPN this sector exhibits a compact lateral component which abuts on the lateral lemniscus and a more diffuse medial portion which is interdigitated with the superior cerebellar peduncle, the medial longitudinal fasciculus, and the central tegmental tract (Figure 8). As the Ch5 sector gradually disappears, the more caudal Ch6 subgroup occupies a lateral position in the periventricular gray at a location which corresponds to the lateral dorsal tegmental nucleus. These Ch6

neurons provide cholinergic innervation to the thalamus (e.g., parafascicular nucleus). The medial habenula, a component of the epithalamus, contains densely packed oval-shaped cholinergic Ch7 neurons, which innervate the interpeduncular nucleus. A compact cholinergic cell group, Ch8, lies along the lateral margin of the mesopontine region within the parabigeminal nucleus; these neurons innervate the superior colliculus. A summary schematic diagram of the central cholinergic projection neurons (Ch1–Ch8) is shown in Figure 9. Other cholinergic neurons include the interneurons of the striatal complex, cranial nerve nuclei, reticular neurons, lateral hypothalamus, olfactory tubercle, islands of Calleja, and scattered intercortical cells seen only in the rodent.

CBF Neuron Survival

A growing body of data supports a role for the neurotrophic substance nerve growth factor (NGF) in the maintenance and survival of CBF neurons. NGF is derived from its precursor molecule proNGF (Figure 10), which is the primary form of NGF in the human brain. *In vitro* studies using dissociated rat CBF cultures or organotypic slices show that NGF treatment prevents the degeneration of cholinergic neurons observed in untreated preparations. In a similar vein, the atrophy and loss of these neurons *in vivo*, following neocortical infarction in monkeys or excitotoxic neocortical lesions in rats, are reversed with exogenous NGF treatment. In addition, infusion of NGF prevents loss of cholinergic phenotypic markers as well as septal cholinergic degeneration following septohippocampal axotomy via fimbria–fornix transection. Finally, transgenic mice that express anti-NGF antibodies in adulthood display an age-dependent loss of cholinergic forebrain neurons.

CBF Neurons Express NGF Receptors

The biological actions of NGF are mediated in part by two NGF receptors, the NGF-specific receptor tyrosine kinase TrkA and the pan-neurotrophin $p75^{NTR}$ receptor, which are produced in the CBF neurons (Figures 4(j)–4(l)) and anterogradely transported to the innervation sites of these cell bodies. These receptors mediate the binding, internalization, and retrograde transport of target-derived NGF to CBF perikarya. TrkA is a receptor tyrosine kinase that binds NGF with relatively high affinity ($K_d = 10^{-11}$) when co-expressed with $p75^{NTR}$. After binding of

Figure 5 Sections stained for the immunohistochemical demonstration of choline acetyltransferase-positive neurons and fibers within the monkey forebrain. NGF to TrkA, the receptor activates signal transduction cascades, including mitogen-activated protein kinases (MAPKs), phosphatidylinositol 3-kinase (PI3K), and phospholipase C-γ (PLC-γ) pathways that promote survival and sustain the cholinergic phenotype of CBF neurons by activation of transcription factors that alter gene expression. $p75^{NTR}$ is a member of the tumor necrosis factor receptor family and binds NGF with relatively low affinity ($K_d = 10^{-9}$). Although this pan-neurotrophin receptor lacks intrinsic catalytic activity, it interacts with cytosolic adapter proteins to activate downstream signaling molecules, including c-Jun, N-terminal Jun kinase (JNK), and nuclear factor-κB (NF-κB). Activation of these pathways through the $p75^{NTR}$ receptor *in vitro* elicits either a pro- or antiapoptotic signal that likely depends on the cellular milieu (e.g., cell type, presence or absence of specific binding partners and/or chaperones). The binding partners of $p75^{NTR}$ include sortilin, Nogo receptor, and lingo-1, in addition to TrkA.

Figure 6 Artist's drawing showing the cholinergic innervation from the medial septal/vertical limb of the diagonal band (MS/VDB; Ch1–2) to the hippocampus (Hippo; red) and the nucleus basalis (Ch4) to the cortex and amygdala (Amg; blue) in the human brain.

NGF Signaling in CBF Neurons

It is well established that NGF is retrogradely transported from its production sites in the cortex and hippocampus to the CBF consumer neurons. The mechanism by which NGF retrograde transport proceeds and culminates in cell survival remains to be answered, but a series of observations indicate that NGF-bound TrkA complexes are internalized as specialized 'signaling endosomes' by a process involving dynamin and PI3K. These signaling endosomes

Figure 7 Schematic diagram depicting the relation between acetylcholine (ACh) and galanin within neurons of the primate cholinergic basal forebrain. In the monkey, note that all cholinergic basal forebrain neurons co-localize galanin. By contrast, these neurons are galanin negative in great apes, including humans. In these species, galanin arises from a population of small interneurons (blue) as well as in an extra-forebrain fiber system (not shown), which terminates upon the large cholinergic neurons of the nucleus basalis.

are transported in the minus direction along microtubules, as dynein inhibition or microtubule disassembly blocks the retrograde transport of both NGF and Trk receptors. NGF application to distal axons in compartmentalized sympathetic neurons induces cyclic AMP response element-binding protein (CREB) phosphorylation in an endocytosis-dependent manner. CREB-mediated gene expression is both necessary and sufficient for NGF-dependent survival, indicating that the retrograde transport of signaling endosomes is required for NGF-induced nuclear responses important for cholinergic cell survival. However, there is also evidence that NGF retrograde

Figure 10 Schematic drawing indicating the interaction between nerve growth factor precursor protein (proNGF), NGF, and its high-affinity (TrkA) and low-affinity ($p75^{NTR}$) glycoprotein (gp) receptors and the putative functional expression in cholinergic basal forebrain neurons. The question mark indicates the ongoing controversy regarding whether proNGF binds with the TrkA receptor as well as with $p75^{NTR}$. P-Y refers to tyrosine phosphorylation.

signaling can occur in the absence of signaling endosomes, suggesting the existence of alternative and possibly parallel mechanisms of retrograde signaling.

CBF Alterations during the Progression of AD

CBF projection neurons have received extensive attention due to their dysfunction in AD. Unbiased stereology has demonstrated that the number of cholinergic neurons within the NB containing either ChAT or VAChT remains unchanged in patients clinically diagnosed with mild cognitive impairment (MCI; a putative prodromal stage of AD) or mild AD, as compared to age-matched controls. In the stereology studies, cortical ChAT enzyme activity was stable in the early stages of AD or increased in the superior frontal cortex as well as the hippocampus of patients with MCI. These observations suggest that basocortical cholinergic tone is preserved in MCI and early AD, supporting the notion that cholinergic NB neurotransmission dysfunction is a late-stage event in AD. By contrast, the number of NB perikarya containing either $p75^{NTR}$ or TrkA was reduced ~50% in MCI and mild AD, compared to controls. Intriguingly, there was a significant positive correlation between the number of TrkA- and $p75^{NTR}$-immunoreactive NB neurons and performance on clinical tests of cognition. In a similar mode, the number of $p75^{NTR}$-immunoreactive NB neurons was significantly correlated with performance on the mini-mental state exam (MMSE) and the global cognitive test. These chemoanatomical clinical pathologic studies suggest that a subpopulation of cholinergic NB neurons undergoes a phenotypic silencing of NGF receptor protein expression in the absence of frank cell loss or cholinergic deficits during the early stages of AD, which correlates with cognitive impairment. Thus, pronounced early defects in NGF receptor expression may be an early pathological event that precedes the eventual loss of cholinergic neurons seen in the later stages of AD.

Quantitative immunoblotting experiments revealed that TrkA and $p75^{NTR}$ protein levels in five cholinergic cortical projection sites (anterior cingulate, superior frontal, superior temporal, inferior parietal, and visual cortex) are decreased during the progression of AD. Interestingly, whereas $p75^{NTR}$ protein cortical levels were stable across the diagnostic groups, cortical TrkA protein was reduced ~50% in mild AD compared to individuals with no cognitive impairment (NCI) and with MCI. Moreover, cortical TrkA levels were positively correlated with cognitive performance. Because TrkA signaling is associated with neuronal survival, this specific reduction of cortical TrkA receptor protein may play a pivotal role in the frank loss of cholinergic NB neurons seen in later stages of AD.

Mechanisms of NGF Receptor Alterations in Cholinergic Neurons in MCI and AD

TrkA Signaling in the Cholinotrophic System

The mechanisms underlying TrkA protein reduction in cholinergic NB perikarya in MCI and the projection sites in early AD are unclear. TrkA gene expression is under positive feedback from NGF signaling,

and this pathway most likely is disrupted in AD by diminished retrograde transport of cortical NGF to CBF consumer neurons. This hypothesis is supported by the observation that NGF mRNA levels are not altered in AD, whereas NGF protein levels are stable or increased in the cortex and decreased in cholinergic NB neurons in late-stage AD. Defective retrograde transport of NGF within cholinergic projection neurons occurs in a segmental trisomic mouse model of Down syndrome (Ts65Dn), a congenital neurodegenerative disorder that mimics some of the neuropathology of AD. In aged rats, CBF neurons exhibit a pronounced reduction in NGF retrograde transport, reduced TrkA protein expression, and severe cellular atrophy. This defect may ultimately reduce TrkA protein in cortical projection sites and further perturbations in NGF signaling within CBF neurons. This putative 'off Trk' cycle of deficient NGF receptor signaling through prosurvival signal transduction molecules such as MAPK and PI3K may contribute to the selective vulnerability of cholinergic NB neurons and to deficits in cortical cholinergic tone observed in late-stage AD.

$p75^{NTR}$ Signaling in the Cholinotrophic System

In contrast, the stability of cortical $p75^{NTR}$ protein expression levels across clinical diagnoses (NCI → MCI → AD) occurs despite a reduction in cholinergic NB perikarya containing $p75^{NTR}$ in both MCI and mild AD relative to NCI. Moreover, cortical $p75^{NTR}$ levels remain stable even in severe AD despite a dramatic reduction of $p75^{NTR}$-immunopositive neurons and fibers in the NB in late-stage AD. Gene expression profiling studies of single cholinergic NB neurons reveal that $p75^{NTR}$ mRNA levels are unchanged in end-stage AD compared to age-matched controls. Therefore, the stability of cortical $p75^{NTR}$ levels is not due to compensatory upregulation of $p75^{NTR}$ by remaining cholinergic NB neurons. On the other hand, the preservation of cortical $p75^{NTR}$ may be related to the *de novo* expression of cortical $p75^{NTR}$-immunoreactive neurons in AD. Alternatively, these data could reflect a redistribution of $p75^{NTR}$ from the CBF soma to the nerve terminals, and receptor accumulation at the terminals due to failed retrograde transport in AD. The preservation of cortical $p75^{NTR}$ protein despite a reduction of cortical TrkA protein in AD could result in a relative increase in $p75^{NTR}$-mediated NGF signaling in cholinergic NB neurons. Traditionally, $p75^{NTR}$ is thought to facilitate NGF signaling by producing high-affinity NGF binding sites and increased TrkA responsiveness to NGF. This concept is being revisited, since $p75^{NTR}$ possesses complex autonomous signaling capabilities in response to NGF that, paradoxically, regulate both cell death and cell survival under different experimental paradigms. NGF activation of $p75^{NTR}$ in the absence of TrkA induces apoptosis in neurons and in mature oligodendrocytes. Retroviral infection of mature $p75^{NTR}$-containing oligodendrocytes with TrkA cDNA reverses NGF-induced apoptosis, suggesting that the coexpression of TrkA suppresses $p75^{NTR}$-mediated proapoptotic signaling. Recent data indicate that activation of the JNK pathway is a primary carrier of the $p75^{NTR}$ proapoptotic signal. NGF binding to $p75^{NTR}$ results in the phosphorylation and activation of JNK, which translocates to the nucleus to phosphorylate the transcription factor c-Jun. Phosphorylated c-Jun-mediated transcription activates a proapoptotic cascade involving the release of cytochrome *c* and caspase activation.

CBF Neurons Display Cell Cycle Proteins in MCI and AD

Accumulating evidence suggests that $p75^{NTR}$-mediated apoptosis involves the activation of cell cycle regulatory molecules. For example, in postmitotic, $p75^{NTR}$-containing retinal neurons, NGF-mediated apoptosis is preceded by an increase in mitotic figures as well as by an upregulation of cyclin B2. Cyclin B2 is typically active at the G_2/M cell cycle transition and apoptosis is prevented in a dose-dependent manner by the delivery of a cyclin B2-dependent kinase inhibitor (CDK1), roscovitine. Intriguingly, CBF neurons in MCI and early AD are characterized by the abnormal expression of cell cycle regulatory proteins (proliferating cell nuclear antigen, cyclin D1, and cyclin B1) and evidence of DNA replication. Perhaps increases in $p75^{NTR}$-mediated activity in the face of reduced TrkA signaling contribute to cholinergic NB neurodegeneration by promoting unscheduled cell cycle reentry and apoptosis in AD. It is likely that shifts in the ratio of TrkA to $p75^{NTR}$ receptors may determine whether neurons survive or die when exposed to NGF. As such, the ~50% reduction in cortical TrkA in the absence of significant changes in $p75^{NTR}$ levels at the onset of AD may signify a relative increase in proapoptotic $p75^{NTR}$ signaling in the cholinobasal projection system.

ProNGF and Cholinergic NB Neuron Survival

The physiological consequences of TrkA and $p75^{NTR}$ signaling upon cholinergic NB cell survival may also depend upon their interactions with the NGF precursor protein, proNGF. ProNGF is the predominant form of NGF present in the cortex of aged, intact humans and is increased ~40–60% in the inferior

parietal cortex of patients diagnosed with MCI or mild AD, compared to NCI. The biological consequences of proNGF accumulation in the cortex during the prodromal stages of AD have yet to be determined. An emerging literature suggests that recombinant proNGF binds TrkA and promotes neuronal survival and neurite outgrowth, similar to mature NGF, but is approximately fivefold less active than mature NGF. Although TrkA-mediated proNGF retrograde transport has not been reported, proNGF accumulation in CBF target sites may be due to reduced cortical TrkA levels and/or retrograde transport to cholinotrophic basal forebrain perikarya. Alternatively, evidence from the rodent cortex indicates that proNGF accumulation is under negative feedback from mature NGF levels; as mature NGF levels rise, proNGF levels are reduced (Figure 11(c)). Moreover, levels of matrix metalloproteinase-9 (MMP-9), an enzyme that degrades mature NGF, are increased in the AD cortex suggestive of increased mature NGF degradation. The resulting decrease in mature NGF may facilitate the proNGF accumulation seen in the prodromal (MCI) and AD cortex (Figure 11(d)). Reductions of mature NGF and poor utilization of proNGF and/or signaling of proNGF via $p75^{NTR}$, in combination with reduced TrkA, may result in cholinergic NB neurodegeneration. Significantly, while TrkA levels in the cortex are positively associated with cognitive scores, cortical proNGF levels are negatively correlated with mental performance. Thus, the concomitant reduction of TrkA and accumulation of proNGF in the cortex may be an early pathobiological marker for the onset of AD.

Figure 11 Schematic diagram illustrating putative scenarios for nerve growth factor precursor protein (proNGF)/receptor complexing during the progression of Alzheimer's disease. (a) ProNGF complexes with TrkA to activate cell survival mechanisms in the aged human healthy brain. This binding event is facilitated by the co-expression of $p75^{NTR}$ on the cell surface. (b) Elevated levels of cortical proNGF in the face of reduced cortical TrkA result in increased binding of proNGF to $p75^{NTR}$/sortilin complexes, enhancing the activation of proapoptotic mechanisms during the transition from mild cognitive impairment (MCI) to Alzheimer's disease (AD). (c) Evidence from rodent brain shows that matrix metalloproteinase 9 (MMP-9) degrades mature NGF. Experimental perturbations of MMP-9 activity increase mature NGF levels and reduce proNGF levels, suggesting that proNGF accumulation is under negative feedback from mature NGF levels. (d) MMP-9 levels are increased in the AD cortex, resulting potentially in reduced mature NGF levels, reduced negative feedback on proNGF levels, and proNGF accumulation.

CBF Neurons: Sorting Life from Death

Paradoxically, several investigations indicate that increases in cortical proNGF result in proapoptotic signaling through binding to the $p75^{NTR}$ and other receptor molecules. Data indicate that the proapoptotic effects of $p75^{NTR}$-mediated proNGF signaling are dependent upon interactions between $p75^{NTR}$ and the neurotensin receptor, sortilin. Sortilin is a Vps10p domain trafficking protein that acts as a cell surface coreceptor with $p75^{NTR}$ to mediate proNGF-induced cell death, and blocking this binding event precludes high-affinity binding of proNGF to $p75^{NTR}$. Sortilin binds the 'pro' region of proNGF, and blocking this binding event precludes high-affinity binding of proNGF to $p75^{NTR}$. Moreover, sortilin expression is required for $p75^{NTR}$-mediated apoptosis following proNGF treatments, suggesting that sortilin is a $p75^{NTR}$ binding chaperone associated with its role in the induction of cell death. It is likely that the outcome of $p75^{NTR}$ signaling in response to proneurotrophin depends on the identity of the bound coreceptor. $p75^{NTR}$ may have other receptor chaperone molecules and binding partners, which assist in its role as a 'multitasking' neurotrophin receptor. In this case, if $p75^{NTR}$ and the coreceptor NgR/lingo 1 interact, then an inhibition of axonal growth occurs, as opposed to cell death if sortilin acts as a coreceptor and/or chaperone. It remains to be determined whether sortilin/$p75^{NTR}$/proNGF complexes with motor proteins to form a retrogradely transported ensemble on microtubules, initiating an intracellular cell death response, or whether it is internalized into the somotodendritic compartment of consumer neurons and is anterogradely transported for recycling to the cell surface. Figure 11 diagrams a potential scenario for prosurvival or proapoptotic signaling in cholinergic NB neurons as TrkA levels decline, $p75^{NTR}$ levels remain unchanged, and proNGF levels rise in cortical projection sites during the progression of AD.

Genetic Signature of CBF Neurons

Currently, the molecular and cellular mechanisms underlying CBF dysfunction remain unclear. The advent of single-cell aspiration technology combined with RNA amplification and custom-designed cDNA array technology has provided novel information about the expression levels of several functional classes of mRNAs found in cholinergic NB neurons from normal aged and AD cases. These studies have shown a downregulation of synaptic-related markers (e.g., synaptophysin and synaptotagmin 1) and protein phosphatase 1 and protein phosphatase 2 subunit mRNAs, along with upregulation of cathepsin D acid hydrolase mRNA in AD patients, as compared to normal control cholinergic NB neurons.

Of particular relevance to cholinergic NB neurons was the observation showing a downregulation of trkA, trkB, and trkC expression during the progression of AD (Figure 12). The protein products of trkB and trkC genes mediate the high-affinity binding of

Figure 12 (a) Dendrogram with color-coded scale bar (orange is low expression and green is high expression), illustrating relative expression profiles of $p75^{NTR}$, trkA, trkB, trkC, and choline acetyltransferase (ChAT) derived from individual cholinergic nucleus basalis neurons from persons with no cognitive impairment (NCI), mild cognitive impairment (MCI), and Alzheimer's disease (AD). No significant differences are found for ChAT and $p75^{NTR}$ gene expression. In contrast, statistically significant downregulation (asterisks) of trkA, trkB, and trkC is observed in MCI and AD. Expressed sequence tags identifying extracellular domains (ECD) and tyrosine kinase (TK) domains display downregulation. The decrement of trk gene expression in MCI is intermediate relative to AD, indicating a step-down effect in expression levels from NCI to MCI to AD. (b) Representative custom-designed arrays illustrating expression-level differences between NCI, MCI, and AD. Three individual cases are depicted for each condition.

two neurotrophins, brain-derived neurotrophic factor and neurotrophin-3, respectively. A significant downregulation of trkA was seen in single NB neurons microaspirated from AD and MCI patients compared to normal controls. An intermediate reduction was seen in MCI, with the greatest decrement in mild AD compared to controls. The downregulation of the trk genes was associated with several measures of cognitive decline. By contrast, dysregulation of ChAT and $p75^{NTR}$ mRNA was not found across the three clinical groups examined. Together, these findings suggest a relative selectivity in the alteration of high-affinity neurotrophin receptors within single CBF neurons during the progression of AD, and that neurotrophic dysfunction in these neurons occurs during the earliest stages of cognitive decline.

Cholinergic NB neurons display the classic pathological feature of AD, neurofibrillary tangles (NFTs), which are composed primarily of hyperphosphorylated aggregates of the axonal microtubule-associated protein tau. Using similar single-cell array technology, the expression levels of the six tau isoforms, which are expressed through alternative splicing of a single tau gene on chromosome 17 that contains 16 exons, were assessed within single cholinergic NB neurons. The brain contains three isoforms with three tandem repeats (3Rtau; Unigene annotation MAPT1, MAPT3, and MAPT5) and three isoforms with four tandem repeats (4Rtau; MAPT2, MAPT4, and MAPT6) of 31 or 32 amino acids in the C-terminus of the molecule. Single-cell gene array analysis revealed that the global expression levels of the six tau transcripts and several other cytoskeletal transcripts within individual CBF neurons did not vary among AD and MCI patients and aged controls, consistent with previous reports. Surprisingly, when a 3Rtau/4Rtau ratio was calculated, a significant shift in the ratio was observed in MCI and AD, with a decrement in 3Rtau in relation to 4Rtau levels for all tau transcripts examined. These data suggest a subtle, yet pervasive, shift in the dosage of 3Rtau and 4Rtau within vulnerable CBF neurons in MCI and AD. Interestingly, a similar shift does not occur during normal aging. Shifts in the ratio of tau genes may be a fundamental mechanism whereby normal tau expression is dysregulated, leading to NFT formation. In this vein, hyperphosphorylation of tau in the cortex of transgenic anti-NGF mice (AD11) appears to be linked to NGF deprivation as opposed to a cholinergic deficit, since NGF but not the AChE inhibitor, galantamine, rescues this defect. It is possible that alterations in the NGF/TrkA/$p75^{NTR}$ signaling pathways might disrupt tau isoform stoichiometry, initiating NFT formation and subsequent downstream cytoskeletal neuronal effects within CBF neurons. Taken together, these gene expression studies suggest that a 'shift' in neurotrophic signaling may underlie the differences in cholinergic function in aging and AD.

Therapeutics for Cholinergic NB Dysfunction in AD

Currently there are no treatments to prevent CBF dysfunction in this devastating disease. Several strategies have been employed to influence the neurotransmission or survival of these neurons. Several anticholinesterase inhibitors, including galantamine, have proved only to have modest effects on cognition, and are sometimes associated with unwanted side effects. Esterase inhibitors in combination with an *N*-methyl-D-aspartate (NMDA) receptor agonist (e.g., memantine) have been suggested to provide greater symptomatic improvement in patients with mild AD. Recently, several novel approaches aimed at rescuing CBF neurons based on NGF and its receptors have been under consideration. Various means of delivering NGF or augmenting NGF function in the brain are being developed to deliver neurotrophins to the brain in a fashion that is less invasive, albeit less targeted, than gene therapy. Small peptide analogs of NGF that contain or mimic the putative active region of the NGF β-component should be considered. These molecules possess the potential advantage of crossing the blood–brain barrier due to their low molecular weight, eliminating the need for invasive brain delivery via surgical procedures. Alternatively, the ongoing development of TrkA-specific NGF peptidomimetics has provided the groundwork for another potential approach to improving prosurvival signaling in cholinergic NB neurons in people during the early stages of AD. The importance of defining the neurotrophic molecular mechanisms underlying the selective vulnerability of CBF neurons has gained greater prominence with the findings from a phase I clinical trial demonstrating that *ex vivo* NGF gene therapy improves cognition and induces CBF neuronal sprouting in mild AD. To date, these patients have not shown any adverse affects from these NGF intraparenchymal injections, and early indications are that NGF therapy is efficacious and may even slow the course of the disease.

Introduction

The cholinergic system has received increasing attention from both basic scientists and clinical researchers after the observation that Alzheimer's disease (AD), the most frequent human neurodegenerative disorder, is specifically associated with an early and selective impairment of cholinergic transmission in the brain. Postmortem examinations showed severe neuronal loss in the basal forebrain cholinergic nuclei and a decrease of choline acetyltransferase (ChAT) and cholinesterase activity in the cerebral cortex in AD. Furthermore, anticholinergic drugs induce memory dysfunction in both animal models and humans. Experimental lesions of cholinergic nuclei impair memory function in monkeys. Even in the absence of AD-related neurodegeneration, decline of cholinergic function has been linked to specific cognitive impairment, including working memory, in healthy aging. It has been suggested that the effects of cholinergic lesions on memory are mediated by the primary effect of cholinergic transmission on attention and executive function. Age-associated alterations of the cholinergic system may underlie an increased risk of delirium in aging. Besides its role as a neurotransmitter in the adult brain, several lines of research suggest that acetylcholine (ACh) plays a critical role in cortical development and in establishing synaptic contacts in neuronal networks that will subserve complex cognitive functions in adulthood. However, the cerebral cortex continues to adapt to the environment throughout the entire life span. Cholinergic function plays a critical role in neuronal plasticity in the adult brain. Therefore, cholinergic impairment in AD not only leads to impaired neuronal transmission within the cerebral cortex but also compromises the ability of the brain to compensate for progressive neurodegeneration. Some of the vulnerability of the cholinergic system in aging or AD may be mediated by an amyloid-related decrease of target-specific nerve growth factor. Consistent with the evidence for cholinergic dysfunction, several double-blind placebo-controlled trials have suggested that enhancement of cholinergic function using (acetyl-) cholinesterase inhibitors attenuates cognitive decline in AD. The findings on cholinergic dysfunction, however, have been limited in regard to the time course and the differential involvement of systems and compartments of the cholinergic system. These limitations are partly because evidence was derived from postmortem studies that intrinsically forbid longitudinal observation and are biased toward severe end stages of disease. Therefore, advanced imaging technology was developed to determine the integrity of the cholinergic system *in vivo*. One line of research is based on radiolabeled ligands to specific components of cholinergic transmission together with positron emission tomography (PET). Another approach uses pharmacological intervention with cholinergic and anticholinergic drugs and functional neuroimaging, using PET and functional magnetic resonance imaging (fMRI). Finally, studies have used structural MRI to determine alterations of cholinergic nuclei in the human basal forebrain. Understanding the rationale, implications, and limitations of these approaches requires a basic understanding of the anatomy and biochemistry of cholinergic transmission in the human brain, outlined in the following paragraphs.

The Cholinergic System

Anatomy of the Cholinergic System

According to Mesulam, the cholinergic pathway "is likely to constitute the single most substantial regulatory afferent of the cerebral cortex." Cholinergic projections in the cerebral cortex are involved in arousal, maintenance of attention, and REM sleep. The main source of cholinergic projections to the cerebral cortex are the magnocellular neurons of the nucleus basalis Meynert in the substantia innominata which separates the globus pallidus from the ventral surface of the basal forebrain. Studies in monkeys suggest a corticotopic organization of basal forebrain cholinergic nuclei. The cholinergic nuclei of the basal forebrain can be divided into subpopulations and named by adapting Mesulam's nomenclature. Cell group Ch1 corresponds to the nucleus septi medialis and innervates the hippocampus, cingulate, and retrosplenial cortex. Ch2 corresponds to the vertical limb of the nucleus of the diagonal band of Broca. Both groups are located medially to the nucleus

accumbens septi. Ch3 designates cells associated with the horizontal limb of the diagonal band nucleus and, together with Ch2, innervates the entorhinal and olfactory cortex. The Ch4 group contains the nucleus basalis neurons within the substantia innominata and is the most extensive cholinergic cell group. The Ch4 group can be divided into anterior (Ch4a), intermediate (Ch4i), and posterior (Ch4p) subpopulations. The anterior subpopulation can be divided into medial (Ch4am) and lateral (Ch4al) cell groups. Ch4a extends from the posterior end of the tuberculum olfactorium to the posterior end of the anterior commissure. Ch4i starts at the anterior tip of the thalamus and extends to the posterior end of the ansa peduncularis, Ch4p extends from the posterior end of the ansa peduncularis to the level of the mammillary bodies. In the human brain there are two major pathways from Ch4 neurons to the cortex: the medial pathway supplies the medial frontal cortex and cingulum, and the lateral pathway projects to the dorsal and lateral prefrontal cortex and the temporal, parietal, and occipital neocortex. A cluster of magnocellular cholinergic neurons located in the anterior part of the basal forebrain (ventrolaterally to the anterior commissure) has been named the nucleus subputaminalis (NSP), or Ayla's nucleus. It is interesting that the lateral subdivision of the NSP has been described only in the human brain, not yet in monkey brains, and has been linked to the cortical speech area. Figures 1–6 illustrate the anatomy of the basal forebrain nuclei based on Gallocyanin-stained sections through the basal forebrain of two control cases, a 29-year-old man and a 66-year-old man.

Because all cholinergic nuclei are concentrated in a very small area of the brain, basal forebrain lesions will easily lead to cholinergic deficits. In the same line, anticholinergic effects of medication or other substances will easily lead to cholinergic deficits, particularly in aging and neurodegeneration, in which the cholinergic input into the cortex is already decreased or damaged.

Cholinergic Neurotransmission

Because ACh is among the most biologically potent neurotransmitters of the brain, its synaptic concentration is highly regulated. ACh is synthesized through ChAT from choline and acetyl-Co-A (Figure 7). The cholinesterases (ChEs) inactivate ACh through hydrolyzation (Figure 8).

The primary enzyme is acetylcholinesterase (AChE), but ACh is also a substrate for butyrylcholinesterase. Inferences of the regional distribution of cholinergic projections based on ChE produce too widespread estimates. ChE is widely distributed across the brain, probably as a safeguard against ACh overload within the brain. The localization of cholinergic projections is more precisely inferred from the distribution of the ChAT. ACh acts on two classes of receptors that are characterized by the pharmacological activity of two alkaloids: nicotine and muscarine. The nicotinic ACh receptor is a ligand-gated ion channel eliciting a fast response whereas the muscarinic ACh receptor is G-protein-coupled and elicits a slow response. Both receptor classes exhibit distinct subtypes, are often co-expressed in the same synapse, and occur pre- and postsynaptically.

Targeting the Cholinergic System *In Vivo*

The short description of the anatomy and biochemistry of the cholinergic system in the brain reveals several potential targets for *in vivo* imaging of the integrity of the cholinergic system. Radiochemistry has developed ^{11}C-labeled markers for nicotinic and muscarinic ACh receptors and for AChE that can be applied *in vivo* using PET. Cholinergic drugs together with cognitive tests during functional imaging using fMRI or PET have been used as a stress test to map the altered plasticity of the cholinergic system with aging and neurodegeneration. Finally, *in vivo* MRI has been developed to detect anatomical changes in the basal forebrain that may be related to the integrity of cholinergic neurons. The following paragraphs review the technical background of and findings obtained by these approaches.

Pet Imaging of Cholinergic Receptor Binding and ChE Activity

How can PET measure neuroreceptor binding and density *in vivo*? In a neuroreceptor study with PET, the measured activity will always be a mixture of specifically bound, nonspecifically bound, and unbound radiotracer. Besides the binding kinetics and receptor distribution, peripheral clearance, regional cerebral blood flow (CBF), and transport across the blood–brain barrier will influence the profile of the time–activity curve. Therefore, the use of a simple quantitative measure, such as the ratio of a region of interest to a reference region (believed to represent nonspecific binding), will be inadequate to most receptor studies. Model-based approaches have been developed to relate the time–activity curve of a region of interest (the observed response function) to the arterial time–activity curve (the observed input function) through a defined model. Most of these models are based on the notion of compartments. In its most extended form, the compartment model encompasses three compartments, which are derived from a four-compartment model by collapsing two compartments into one (Figure 9).

A radiolabeled ligand is injected intravenously (compartment 1), resulting in an initial plasma concentration (C_{Pl}) that rapidly decreases because of uptake into brain (and other tissues), resulting in an early equilibrium between vascular and extravascular

Figure 9 Three-compartment model of ligand–receptor binding. Compartment 1 indicates plasma space; compartment 2, nonspecific binding space in tissue; and compartment 3, specific binding space. C_{Pl} represents ligand concentration in plasma; Q_{free} and Q_{unspec}, quantity of free exchangeable and nonspecifically bound ligand rapidly equilibrating with each other; and Q_{spec}, quantity of receptor-bound ligand. $k1$ to $k6$ are the rate constants for the ligand exchange between compartments in the specified directions. For further details, see text. Modified from Holcomb HH, Links J, Smith C, and Wong D (1989) Positron emission tomography: Measuring the metabolic and neurochemical characteristics of the living human nervous system. In: Andreasen N (ed.) *Brain Imaging: Applications in Psychiatry*, pp. 235–370. Washington, DC: American Psychiatric Press.

brain compartments. The extravascular compartment is divided into three parts. The pool of unbound ligand (quantity of free ligand (Q_{free})) is in rapid equilibrium with the nonspecific bound ligand pool (quantity of ligand reversibly bound to nonspecific proteins (Q_{unspec})). Both compartments are considered a single exchangeable tissue pool (compartment 2). The quantity of free exchangeable ligand in compartment 2 (Q_{free}) tends to equilibrate with the quantity (Q_{spec}) of ligand specifically bound to neuroreceptor in compartment 3. The fractional rate constants k_i govern the exchange of ligand between compartments in the specified direction, assumed to follow a first-order reaction kinetic.

Equilibrium is supposed to occur rapidly between the first (plasma) and second compartments (free and nonspecifically bound ligand). In contrast, the equilibration between the second and third compartments (specifically bound ligand) takes considerable time,

depending on ligand–receptor affinity, and may even not occur within scanning time. There are essentially two models to determine neuroreceptor density and binding characteristics. The first measures receptor saturation with increasing ligand concentration and therefore requires equilibration of ligand between the second and third compartments during scanning time (steady-state model). The second measures the time course of specific brain uptake of ligand over time with different concentrations of an unlabeled receptor-blocking substance (kinetic model). This approach does not require equilibration between the nonspecific and specific compartments. Both models to assess neuroreceptor density and binding kinetics are based on several assumptions, some of which may be reasonable but may not be easily validated. Both approaches gave similar values for receptor density with different dopaminergic ligands (Wong: 17 pmol g^{-1}, Sedvall: 15 pmol g^{-1}). The results with respect to receptor binding affinity, however, are not directly comparable between both models, because different ligands are involved and different parameters are measured. In both approaches the tracer kinetic model requires an input function indicating delivery of tracer to the tissue. In some applications for receptor studies, an arterial input function can be replaced by a reference to tissue devoid of specific binding sites. Single scan acquisition allows for assessment of only one single parameter, whereas dynamic scanning to obtain the time course of tissue activity allows simultaneous estimation of multiple parameters.

Reliable quantification of receptor densities in AD using PET and single-photon emission computed tomography (SPECT) will require an appropriate model to rule out effects of cortical atrophy. Correction of PET data for cerebral atrophy based on corresponding high-resolution MRI scans has already been accomplished in a study on the μ-opioid receptor in the amygdala complex and may be routinely available in the future for other PET studies as well.

Cholinergic Markers in PET Table 1 gives an overview of the most important markers for the cholinergic system in SPECT and PET. Although a decreased nicotinic receptor density in AD has been established from neuropathological studies, studies of the cholinergic system can serve as an example of the pitfalls and controversies associated with *in vivo* receptor imaging using PET. Initial labeling of racemic nicotine with positron emitting ^{11}C in 1982 by Långström and thereafter of the nicotine (+)-(R)- and (−)-(S)-enantiomers was followed by attempts to visualize binding to the brain nicotinic ACh receptors with PET in monkeys and in humans. In AD, uptake of ^{11}C-nicotine into frontal and temporal cortices was less than in healthy age-matched controls. These results are consistent with postmortem evidence of fewer nicotinic

Table 1 PET radioligands for the cholinergic system

Compound	*Label*	*Target*	*Main findings*
2-[18F]fluoro-3-(2(S)-azetidinylmethoxy) pyridine (2-F-A-85380)	^{18}F	$\alpha_4\beta_2$-nicotinic ACh-receptor (responsible for addicitive properties of nicotine?)	Applied to humans; no studies in AD so far reported. 88% occupancy of receptor after smoking of 1 cigarette (dependent smokers)
Nicotine	^{11}C	nAChR	Unspecific binding, kinetic model suggests perfusion as main determinant of distribution
Norchlorofluoroepibatidine	^{18}F	$\alpha_4\beta_2$-nicotinic AChR	Studies in baboons but not in humans because of toxicity of epibatidine
N-methyl-4-piperidyl benzilate (NMPB)	^{11}C	mAChR	Reduced cortical uptake in AD
3-R-quinuclidinyl-4-S-iodobenzilate (RS-IQNB)	^{123}I	mAChR	Reduced uptake temporal and frontal in AD; SPECT marker
Tropanyl benzilate (TRB)	^{11}C	mAChR	Slightly decreased binding in frontal cortex in aging
3-(3-(3-Fluoropropyl)thio)-1,2,5-thiadiazol-4-yl)-1,2,5,6-tetrahydro-1-methylpyridine ([18F] FP-TZTP)FP-TZTP	^{18}F	mAChR (M_2)	Greater receptor avidity in ApoE4 carriers, possibly reflecting lower occupancy by ACh
N-methyl-4-piperidyl acetate (MP4A)	^{11}C	AChE	Reductions in AD
N-[^{11}C]methyl-pi-peridin-4-yl propionate ([^{11}C]PMP)	^{11}C	AChE	Reductions in AD, correlations with cognitive performance

ACh, acetylcholine; AChE, acetylcholinesterase; AD, Alzheimer's disease; ApoE4, apolipoprotein E; mAChR, muscarinic acetylcholine receptor; nAChR, nicotinic acetylcholine receptor; SPECT, single-photon emission computed tomography.

ACh binding sites in AD. However, the validity of nicotinic receptor imaging *in vivo* with ^{11}C-nicotine was first questioned by Nybäck and co-workers. They showed in healthy participants that ^{11}C-nicotine uptake did not decline after potential binding sites were blocked by unlabeled ligand, indicating no measurable impact of receptor availability on tracer uptake. The ratio between tracer uptake in temporal cortex and white matter was constant over time (compared with the previously described linearly ascending ratio between specific binding in the putamen and nonspecific binding in the cerebellum), which is not compatible with specific binding characteristics. Finally, the experimental data could be fitted with a two-compartment model, in which tracer uptake was determined solely by blood flow and blood–brain barrier permeation. A specific binding compartment was not required. Nybäck and colleagues concluded from these results that the regional reduction of ^{11}C-nicotine uptake in AD reflects reduced CBF.

In the following years, new compounds were investigated for their potential to specifically detect nicotinic receptor binding *in vivo*. [^{18}F]norchlorofluoroepibatidine was successfully applied in baboon studies but because of toxicity could not be transferred to human studies. More-selective and less-toxic 3-pyridyl ether derivatives have been used successfully for development of a nicotinic ACh receptor (nAChR) ligand. The recently developed radioligands 2-[^{18}F]fluoro- and 6-[^{18}F]fluoro-3-(2(*S*)-azeti-dinylmethoxy) pyridine allow for visualization of brain $\alpha_4\beta_2$-nAChR with PET in humans. This nAChR subtype is expressed throughout the brain in pre- and postsynaptic locations and has been linked to the addicting properties of nicotine. *In vitro* studies on postmortem brain material using different ligands for autoradiography have obtained conflicting results with reductions of this specific nAChR in some but not all studies. The *in vivo* ligand A-85380 has shown its feasibility and validity in a familial form of frontal lobe epilepsy with mutations in the nAChR α4 or β2 subunit but has not yet been applied to AD.

Several tracers have been applied to detect muscarinic AChRs (mAChRs). In postmortem studies these receptors have been found to be decreased with AD. In aging, autopsy studies have been inconsistent, with series with the greatest age ranges and participant numbers indicating more than 50% reductions in muscarinic receptor numbers in the striatum, hippocampus, and frontal cortex between ages 4 and 93 years. However, declines in cortical or hippocampal muscarinic receptors in series between the ages of 60 and 90 years were modest in some studies or not detectable in other studies. The first ligand to map mAChR *in vivo* in the human brain was 3-quinuclidinyl-4-iodobenzilate labeled with ^{123}I (^{123}IQNB) in SPECT. In older normal adults, this tracer showed high radioligand uptake in the basal ganglia and occipital and insular cortex, and low uptake in thalamus and cerebellum. This regional pattern matches the relative distribution of mAChR in autopsy studies. Studies in AD showed a moderate decrease of tracer uptake in posterior temporal and frontal cortices. Unfortunately, the early uptake of ^{123}IQNB is flow-dependent, so scans had to be performed 21 h after injection, making this probe difficult to handle in a clinical setting. Moreover, the spatial resolution of SPECT cameras is generally much lower than the resolution of PET, lowering the potential use of this approach for clinical application or research.

Binding of ^{11}C-tropanyl benzilate (TRB) using PET was slightly but significantly decreased in the frontal cortex with aging. Binding showed a nonsignificant trend of increase in cerebellum and brain stem with aging. The authors interpreted these effects as indicating small decline of receptor density in frontal cortex in healthy aging. TRB has not yet been applied to studying patients with AD or other neurodegenerative disorders.

In one PET study using ^{11}C-labeled *N*-methyl-4-piperidyl benzilate (NMPB), normal aging was associated with a reduction in muscarinic receptor binding in neocortical regions and thalamus. In AD patients, the three-compartment model appeared capable of dissociating changes in tracer transport from changes in receptor binding but suffered from statistical uncertainty, which required normalization to a reference region, therefore limiting its potential use in the study of neurodegenerative processes. After normalization, no regional changes in muscarinic receptor concentrations were observed in AD. These findings are in contrast to an earlier study combining measurement of mAChR with ^{11}C-NMPB and ^{18}fluorodeoxyglucose (FDG)-PET of cortical glucose consumption and ^{99}Tc-hexamethylpropyleneamine oxime (HMPAO)-SPECT of CBF. In this study, AD patients had reduced ^{11}C-NMPB uptake throughout the entire cortex relative to controls, which was more pronounced than reductions in CBF but less pronounced than changes in cortical glucose metabolism.

Application of M2 muscarinic receptor ligand 3-(3-(3-[^{18}F]Fluoropropyl)thio)-1,2,5-thiadiazol-4-yl)-1,2,5,6-tetrahydro-1-methylpyridine ([^{18}F]FP-TZTP) during PET revealed greater M2 receptor avidity in older adults carrying the apolipoprotein E4 (ApoE4) allele, a risk allele for sporadic AD. This alteration might be due to a decrease in synaptic ACh concentration through lower receptor occupancy. Both age and ApoE4 genotype independently led to a greater decrease in receptor avidity following the infusion of the AChE inhibitor physostigmin, probably reflecting the

increased receptor occupancy by the endogenous ligand ACh. Other markers, such as *N*-^{11}C-methyl-3-piperidyl benzilate, have shown reduced mAChR binding in monkey cortical regions with aging but have not been applied to human studies so far.

In summary, in contrast to the nicotinic markers, a wide range of muscarinic markers are available with PET and SPECT, and these markers have been evaluated using kinetic modeling in aging and in AD. Results, however, are not absolutely consistent to date. Effects of aging on muscarinic receptor density appear to be modest at most, with the effects being concentrated in the frontal lobes. In AD, effects appear to be more widespread if they are detected at all. The most interesting finding to date seems to be the study using [18F]FP-TZTP with PET. This study showed an increased binding volume for the ligand, possibly reflecting decreased availability of endogenous ACh in at-risk groups of AD defined by the presence of the ApoE4 genotype.

A promising approach to quantify cholinergic impairment in AD was presented by Iyo and collaborators, who used an ^{11}C-labeled substrate for AChE (*N*-methyl-4-piperidyl acetate (MP4A)) to measure catalytic activity of brain AChE with PET. This lipophilic tracer is taken up into the brain across the blood–brain barrier, where it is hydrolyzed by brain AChE to a hydrophilic metabolite that remains trapped within the brain. The ratio of metabolized to unmetabolized MP4A gives an estimate of AChE catalytic activity. Using this model in a pilot study with five AD patients and eight healthy age-matched controls, the investigators found AChE activity in AD reduced 20–25% in frontal and occipital cortex and 30–45% in temporal and parietal cortex. Subsequent studies using *N*-[^{11}C]methyl-pi-peridin-4-yl propionate as substrate for AChE confirmed an average decrease of 25–33% of mean cortical AChE activity in patients with moderate AD and 9–15% in mild AD. The extent of reduction in enzyme activity *in vivo* was much less than expected from postmortem findings. Still, the changes were more pronounced than were independently measured reductions of regional CBF. These data suggest that cholinergic denervation may be mild to modest in early stages of disease but appears to be independent of reduced CBF. Loss of cholinergic enzyme activity may precede metabolic and blood flow alterations in early AD, when severe functional impairment and final loss of neurons (both leading to decreased uptake of glucose) may not yet be markedly present. One study investigating cortical AChE activity and cognitive performance suggested that AChE activity is predominantly correlated with measures of working memory and attention, much less with measures of delayed short- and long-term memory. These data agree with experimental evidence that cholinergic transmission is predominantly involved in attention and executive function.

The hope that specific receptor imaging might improve clinical diagnosis and treatment of AD has not yet been fulfilled. The complexity of the methods, their limited availability, and inconsistency of results may be the major reasons why no studies have been reported so far using receptor PET as a diagnostic marker or secondary endpoint in pharmacological trials. Another reason may be the complex regulation of the cholinergic system. Surprisingly, an autopsy study based on the religious order population has shown an increase of ChAT activity in people with mild cognitive impairment whereas patients with AD showed a consistent reduction of cortical ChAT activity. In a subsequent discussion, many researchers argued that this finding may indicate that cholinergic lesions occur at a late stage in the development of the disease. A more differentiated discussion, however, has pointed out that some subregions of the basal forebrain cholinergic nuclei appear to be preserved until late stages of disease and might be the source of new cholinergic synapses into denervated brain areas. The stimulus for this sprouting of cholinergic axons might be the progressive loss of target neurons in the most vulnerable brain areas, such as the entorhinal cortex. These data, together with increased muscarinic receptor avidity reported in some studies of mild stages of AD, suggest a dynamic response of the cholinergic system to progressive neurodegeneration and decrease of ACh concentrations. These mechanisms most likely vary with the clinical stage of the disease and therefore make it difficult to identify patterns of receptor changes that are predictive of AD or respond specifically to treatment.

Perspective of neuroreceptor imaging in Alzheimer's disease Future studies using these techniques will have to address several issues. First, they need to more extensively study alterations in cholinergic transmission and ChE activity in preclinical stages and at-risk stages of AD. The finding of an upregulation of muscarinic receptor binding and ChAT activity in patients with mild cognitive impairment and even cognitively healthy people with ApoE4 genotype suggests preclinical compensatory processes whose breakdown may contribute to the clinical manifestation of dementia. Neuroreceptor imaging may contribute to a better understanding of these mechanisms. The binary discussion (early cholinergic involvement in AD as primary event vs. secondary involvement as consequence of degeneration of cortical input areas) may have to be replaced by a more differentiated view appreciating a stepwise involvement of some cholinergic nuclei and

relative preservation of others that may partly compensate for the loss of cortical cholinergic innervation. Second, studies need to determine alterations in cholinergic binding over time to assess the potential use of these measures to map disease progression and treatment effects. Third, studies will have to consider that AD involves not only the cholinergic system but serotonergic, catecholaminergic, and glutamatergic transmission as well, any of which may contribute to both cognitive and behavioral symptoms of dementia.

Functional Imaging of Cholinergic Treatment Effects

The short-acting AChE inhibitor (AChE-I) physostigmine increases working memory performance in young and older healthy participants and at the same time decreases regional CBF in prefrontal areas that are involved in task performance. These findings may indicate that in healthy adults, enhancement of cholinergic function can improve processing efficiency and thus reduce the effort required to perform a working memory task. A study in monkeys showed that application of an AChE-I could restore the reduced response of regional CBF to vibrotactile stimulation with aging. These data suggest that increased reaction time and reduced working memory performance in aging may be related to a functional decline of cholinergic transmission that can partly be restored by the application of AChE-Is. In agreement with monkey studies, two independent PET studies of the ChE-I donepezil showed a reduction of cortical AChE activity associated with neuropsychological effects of treatment in AD patients. These studies confirmed the notion that application of ChE-I inhibits cortical AChE and that this inhibition is associated with an attenuation of cognitive decline. Interpretation, however, is limited because these studies used an open-label design. Reductions ranged between 27% and 39% at therapeutic doses. The use of higher doses of the presently available ChE-I to reach a higher degree of AChE inhibition is limited because of side effects. Intravenous application of physostigmine decreased cholinesterase activity by 50%. Agents with a longer half-life than physostigmine's and higher inhibition potential than the presently available ChE-I approved for AD are needed to test whether even greater inhibition of ChE might lead to better clinical effects.

The ChE-I rivastigmine increased cortical metabolism in treatment responders compared with nonresponders and placebo-treated AD patients. In open-label studies, the ChE-Is reminyl and metrifonate increased metabolism in specific cortical regions in treatment responders compared with nonresponders. One study found relative preservation of cortical metabolism in temporoparietal and frontal association areas after 12 months of treatment with rivastigmine compared with untreated AD patients. These studies suggest that cholinergic treatment increases cortical metabolism in association with cognitive improvement through treatment. Only one of these studies, however, was placebo-controlled. All studies compared treatment responders with nonresponders. However, this approach has the disadvantage that it is difficult to disentangle treatment effects from other factors influencing cognition. Comparing responders with nonresponders shows the cortical substrate of cognitive change, which might only partly be related to treatment (since by definition both comparison groups are treated in the same way). In a recent study, the effect of donepezil on cortical metabolism was determined during rest and passive audiovisual stimulation in a double-blind crossover design. Effects were compared between donepezil and placebo-treated patients independent of clinical response. Resting state glucose metabolism was increased with donepezil in left prefrontal cortex and decreased in right hippocampus. Cortical response to activation was increased in right hippocampus with donepezil compared with placebo, suggesting that decreased hippocampus metabolism during rest with donepezil treatment was reversible and even led to an overshoot activation. The effects were spatially much more restricted than in earlier studies. This may be related to the use of a double-blind design and the fact that patients were not classified according to clinical response.

The first small-scale studies with functional MRI (fMRI) have shown effects of cholinergic treatment on regional activation during a memory task. During face encoding healthy older patients showed higher activity in the fusiform face area than did AD patients. After treatment with donepezil, AD patients showed fusiform activation similar to that of the controls. Exposure to the ChE-I galantamine produced increases in cortical activation during face recognition in patients with mild cognitive impairment. The available data on the effects of cholinergic treatment on the blood oxygen level-dependent response in fMRI are of limited value because there are no studies using a double-blind, placebo-controlled design.

MRI Studies to Detect Atrophy of Cholinergic Nuclei

Hanyu and colleagues were the first to study atrophy of the substantia innominata as a surrogate measure of atrophy in nucleus basalis Meynert. They measured the thickness of the substantia innominata at its smallest extent in a coronal section through the anterior commissure. They found significant decline of the thickness of the substantia innominata in AD

patients compared with controls. Moreover, they found that the thickness of the substantia innominata was inversely correlated with the clinical response to treatment with the ChE-I donepezil. Studying different types of dementia, they found that the reduction of thickness of the substantia innominata was more pronounced in patients with Lewy body dementia than in patients with AD and more pronounced in AD than in vascular dementia. The conclusiveness of the data, however, was limited because the two-dimensional measure of thickness was not accurately located within the substantia innominata and provided only a very rough estimate of atrophy. Recently an automated technique was proposed to determine signal changes within the substantia innominata on the basis of a proton density weighted scan through the basal forebrain. All MRI scans were normalized to a common standard space. Then a three-dimensional region of interest covering the entire extent of the substantia innominata was extracted. Differences in signal intensity across the entire substantia innominata were determined by means of voxelwise statistics. As the locations of nucleus basalis Meynert have not been mapped in MRI standard space before, postmortem MRI and histological sections of the brain of a nondemented older adult were used to transfer the locations of the nuclei of the nucleus basalis Meynert into standard space. These were used as anatomical reference for the signal changes in the substantia innominata from the *in vivo* data. Significant signal reduction was found in anterior lateral and intermediate nuclei of the nucleus basalis Meynert in AD. Moreover, signal reductions were correlated with regional distribution of cortical gray matter loss in AD, suggesting a somatotopic organization of cholinergic projections from the basal forebrain. Recently, a *z*-score approach was developed to determine signal reductions in single participants compared with a reference group of healthy controls. Significant reductions of signal intensity in the substantia innominata similar to those observed in the independent group comparisons were found.

Diffusion tensor imaging (DTI), another MRI modality, may become interesting in the near future for the detection of cholinergic abnormalities. It can be applied to determine the integrity of subcortical fiber tracts *in vivo*. The trajectories of cholinergic pathways in the human brain have been described. Using the Cholinergic Pathways Hyperintensities Scale with T2-weighted MRI scans, Behl and colleagues showed a better response to cholinergic treatment in those AD patients who had more lesions along cholinergic pathways compared with the patients with low cholinergic lesion load, even though overall load in white matter lesions was comparable between groups. It may be of interest in future studies to apply DTI together with basal forebrain scans to determine the selective loss of cholinergic projections from the basal forebrain to the cerebral cortex in AD. AD may serve as an ideal lesion model to study the neuroanatomy and neuropathology of the human cholinergic system. The advances in mapping and understanding alterations of the cholinergic system in AD can then be applied to other human diseases involving the cholinergic system and serve as target for animal models of cholinergic dysfunction.

Imaging the Cholinergic System *In Vivo*: Future Perspectives

What will be the impact of all these techniques to describe cholinergic changes in AD and aging about 3 years ahead? To address this question three potential fields of application should be delineated: (1) clinical routine diagnostic and treatment, (2) clinical trials to establish new treatments (phase II trials), and (3) clinical neuroscience.

It may well be that none of the techniques described in this article will have a direct impact on clinical routine diagnostic or clinical evaluation of treatment efficacy in AD within the next 3 years. Before it is finally applied in clinical routine, a new diagnostic marker goes through three phases:

1. Establishment of the technical characteristics of the marker: reproducibility, effort of acquisition and analysis, analytical sensitivity, and specificity.
2. Establishment of the validity in selected samples: sensitivity and specificity.
3. Controlled diagnostic trial: application in an intent-to-diagnose design, in which patients are selected according to the indication of the diagnostic measure, not the presence or absence of the disease, so that positive and negative predictive values can be determined.

Most of the techniques to determine the functional or morphological integrity of the cholinergic system *in vivo* are presently in phase I: cholinergic receptor PET, fMRI of cholinergic treatment, and structural MRI of the cholinergic nuclei. Only FDG-PET in combination with cholinergic treatment is in phase II, with first clinical trials having applied PET as secondary outcome parameter, but these appear to be all small-scale monocenter studies in highly selected samples. Up to now, no multicenter phase III trial using PET has been undertaken to map the cholinergic system as diagnostic marker or secondary outcome parameter of treatment. One reason for this may be the high costs and limited availability even of FDG-PET for large-scale multicenter clinical trials.

The already completed European Network for Efficiency and Standardisation of Dementia Diagnosis (NEST-DD) and the recently launched US-based AD Neuroimaging Initiative (ADNI) both involve FDG-PET, although not in combination with cholinergic markers or treatment in a prospective design. Retrospective analysis of a subset of the data of the NEST-DD or ADNI may give some insight into the multicenter feasibility of this approach and the effect of cholinergic treatment on cortical metabolism in FDG-PET following a naturalistic design. There are plans now for multicenter molecular imaging studies that include receptor markers of the cholinergic system. Again, these studies will have to involve highly selected samples and therefore will not provide estimates of positive and negative predictive values of these techniques in a clinical population. Another reason these techniques will not likely be applied in clinical routine diagnostics in the near future is the limited budget of national health systems worldwide. From a socioeconomic point of view, the presently available treatment options for AD do not clearly justify the application of a very expensive methodology to give treatment to patients earlier. However, once these techniques have proven their potential to identify those patients who will have maximum benefit from available treatments or once disease-modifying treatments have become available, this situation will change. The costs of these techniques then will be paid off by the early application of disease-modifying treatments that decrease the costs of dementia care.

For the next years, the development of these techniques will probably have some impact on the development of new drugs. Presently, MRI-based volumetric markers are used as secondary outcome parameters in clinical trials on potential disease-modifying effects in AD. The regulatory authorities have indicated that they might accept biological markers as primary endpoints under certain conditions. It has to be shown that the biological marker is related to a clinically relevant outcome, reflects the supposed mechanism of action of the drug, and has high test–retest reliability. At some point receptor PET and imaging of cholinergic nuclei may be part of clinical trials to identify at-risk people and as a secondary endpoint for treatment. Receptor-PET will additionally play an important role in proof-of-concept studies. Receptor PET has already been applied in testing of new compounds and studying the mechanism of action of drugs, such as determining dopamine release and dopamine receptor antagonism of typical and atypical antipsychotics. Imaging cholinesterase inhibition, dynamic changes of nicotinic and muscarinic binding, and the functional consequence of cholinergic changes on brain reserve capacity will help evaluate the mechanism of action of presently available treatments, such as *N*-methyl-D-aspartate antagonists and ChE inhibitors. They may also help estimate the potential of new compounds to modulate the cholinergic system in the human brain *in vivo* before they enter into phase II and III trials.

The most important impact of these techniques in coming years will be their contribution to understanding of the organization and function of the cholinergic system in the human brain. Aging *per se* is associated with a decline of cholinergic markers in the brain. The total number of nucleus basalis Meynert neurons has been shown in the ninth decade to be 20–30% below that in newborns. If the reduction of neuron numbers is approximately linear with age, these data suggest that reduction would be about 3% per decade. However, within a narrow age range in adults (50–80 years), several studies could not detect significant reductions of neuron numbers, suggesting that the 30% reduction from newborns to centenarians may at least partly reflect developmental changes in childhood and adolescence rather than effects of aging. These findings of a limited reduction of cholinergic projections would fit well with the observation that, in contrast to a widely held belief, aging is not inevitably associated with dementia. It would be of high clinical relevance to confirm the postmortem data by a longitudinal imaging approach applying structural and functional markers of cholinergic projections and receptor availability. This would indicate that normal aging preserves a large enough capacity of the cholinergic system to help the brain adapt to environmental and intrinsic factors under normal conditions. In contrast, AD serves as a paradigm that stresses the cholinergic system and allows inferences about its normal function. The focus of research in the coming years will likely increasingly include the role of the cholinergic system in the maintenance of brain plasticity. Research will focus on one hand on the ability of the brain in healthy aging to respond to external and internal stimuli based on the preservation of a minimum of cholinergic function, and on the other hand on the failure of brain plasticity in the presence of severe cholinergic lesions such as in AD. A better understanding of the molecular basis of brain plasticity will help science not only understand the functional basis of learning in its broadest sense (adaption to a constantly changing environment) but also develop treatment paradigms that do not focus only on lowering the impact of pathological events but on increasing the ability of the brain to adapt to pathological changes.

Chromaffin Cells: Model Cells for Neuronal Cell Biology

B G Livett, University of Melbourne, Melbourne, VIC, Australia

© 2009 Elsevier Ltd. All rights reserved.

Techniques for Studying Chromaffin Cells

Functional studies on chromaffin cells were initially carried out *in vitro* (with cat and bovine adrenal glands perfused retrogradely through the central lobular vein) or *in vivo* (with anesthetized rats, cats, or dogs cannulated via the adrenal vein, the inferior vena cava, or the dorsal aorta). More recently, studies have been carried out in cell culture on adrenal chromaffin cells isolated in large numbers by collagenase treatment of intact bovine adrenal glands (Figure 1) and maintained as primary monolayer cultures or as suspension cultures. The accessibility of populations and single chromaffin cells in culture, their spherical shape, and the fact that they are nontransformed cells have made them a popular experimental system for addressing a number of important questions in cell biology.

Technical advances now make it possible to study the release of catecholamines from a single chromaffin cell and even from a single chromaffin granule in real time, using either electrophysiological measurements of membrane capacitance changes, electrochemical measurements of the released catecholamine made with carbon fiber microelectrodes, or fluorescence microscopy of chromaffin cells transfected with fluorescent proteins targeted to the secretory granules. Advances in transfection techniques now permit expression of exogenous proteins in a high percentage of chromaffin cells in primary culture. For example, Semliki Forest Virus has been used to transduce cDNAs encoding various proteins fused to enhanced green fluorescent protein (EGFP) into cultured bovine adrenal cells. Pro-ANF–EGFP, the virally transduced fusion protein generated with atrial natriuretic factor (ANF), is specifically targeted to large dense-core vesicles as shown by its co-localization with acidophilic dyes and chromogranin A, making this a useful system for the study of secretory vesicle dynamics. Expression of aequorin Ca^{2+}-sensitive photoproteins with tailored Ca^{2+} affinities and targeted to subcellular compartments (mitochondria, endoplasmic reticulum (ER)) allows Ca^{2+} signaling to be investigated in cellular regions other than the cytosol. Physical separation of noradrenaline and adrenaline chromaffin cell types by differential centrifugation in density gradients and permeabilization of chromaffin cells with digitonin or with *Staphylococcus aureus* alpha toxin to gain direct access to the exocytotic machinery now make it possible to investigate and manipulate the cellular events involved in stimulation–secretion coupling. Together, these sophisticated techniques permit a detailed investigation of the second messengers and signal transduction events that mediate receptor responses in well-defined populations of normal (i.e., nonneoplastic) cells. Consequently, adrenal medullary chromaffin cells occupy an important place in neuroscience research by providing a primary source of normal excitable cells for cell biological studies.

Synthesis and Storage of Catecholamines in Adrenal Chromaffin Cells and Chromaffin Granules

The adrenal medullary catecholamines are low-molecular-weight dihydroxylated phenolic compounds synthesized from the dietary aromatic amino acids phenylalanine and tyrosine by the sequential actions of cytoplasmic and intravesicular enzymes (Figure 2). The physiologically important catecholamines include epinephrine (adrenaline), norepinephrine (noradrenaline), and dopamine. The relative amounts of epinephrine and norepinephrine differ considerably among mammalian species, with the proportion of epinephrine to norepinephrine increasing after birth. The adult human medulla contains large amounts of epinephrine (0.2–0.8 $mg\,g^{-1}$; 80%) and smaller amounts of norepinephrine (0.04–0.16 $mg\,g^{-1}$; 19%) and dopamine ($<0.01\,mg\,g^{-1}$; 1%). The two principal catecholamines, epinephrine and norepinephrine, are stored in separate chromaffin cell types within large vesicles ($\sim$0.5 μm in diameter), which are commonly referred to as chromaffin granules (Figure 3). The concentration of catecholamines within the chromaffin granules is so high ($\sim$0.6 M, or twice the osmolarity of body fluids) that it is unlikely that they occur in free solution. Rather, there is now good evidence for an intragranular storage complex consisting of the catecholamines complexed with adenosine triphosphate (ATP; $\sim$0.2 M), acidic proteins (chromogranins; pI $\sim$ 5.5), and other secretory products such as enkephalins (Figure 4). In addition, the enzyme that synthesizes norepinephrine from dopamine (dopamine β-hydroxylase; DBH) and the proteolytic enzymes that process proenkephalin to metenkephalin and leuenkephalin and congeners are associated with the chromaffin granules. Actin and α-actinin are associated with the outside (cytoplasmic side) of the chromaffin granule membrane and are thought to interact with cytoskeletal elements to facilitate granule movement and fusion. The resulting release of granule contents into the

Figure 1 Ultrastructural features of isolated adult bovine adrenal chromaffin cells. Two cell types are present: norepinephrine cells (left) containing dense-core vesicles with electron-dense core contracted away from the vesicle membrane (targetlike appearance), and epinephrine cells (right) with evenly filled pleomorphic vesicles. The epinephrine cell types predominate, in agreement with biochemical analyses of these cell preparations showing an epinephrine/norepinephrine ratio of approximately 3:1. From Livett BG (1984) The secretory process in adrenal chromaffin cells. In: Cantin M (ed.) *Cell Biology of the Secretory Process,* pp. 309–358. Basel: Karger.

Figure 2 Pathway for the biosynthesis of catecholamines. The pathway from tyrosine to norepinephrine and epinephrine is shown together with the enzymes and cofactors for each step. The feedback inhibition by norepinephrine on tyrosine hydroxylase (TH) is indicated by the arrow. AADC, aromatic amino acid decarboxylase (sometimes called dopa decarboxylase); DBH, dopamine β-hydroxylase; PNMT, phenylethanolamine-*N*-methyltransferase; SAM, *S*-adenosylmethionine.

capillary lumen occurs by a Ca^{2+}-dependent exocytotic mechanism.

The catecholamines are concentrated within the chromaffin granule by a chemiosmotic mechanism (Figure 5) in which a membrane-bound ATPase drives protons into the chromaffin vesicle, thereby creating an electrochemical proton gradient across the chromaffin vesicle membrane. The chemical part (ΔpH) of the gradient supplemented by the electrical potential ($\Delta\psi$) drives the uptake of catecholamines via a specific carrier molecule (the 'catecholamine carrier'). The second component to the electrochemical gradient – the electrical potential – drives the uptake of nucleotides (e.g., ATP) via a separate carrier. The two chromaffin vesicle membrane proteins involved in this process of amine transport, the vacuolar H^+-ATPase (V_o-ATPase) and the catecholamine transporter, have been isolated and their genes cloned and sequenced. The V_o-ATPase is important in providing the energy for amine accumulation in the vesicles, whereas the amine transporter is thought to provide the selectivity for amine uptake. Of interest, the amine transporter in chromaffin cells shows homology to a class of bacterial drug-resistance transporters having 12 transmembrane domains. Like the multidrug-resistance protein from *Bacillus*, the vesicle amine transporter in chromaffin granule membranes binds reserpine and confers cell resistance to the neurotoxin 6-methyl-4-phenylpyridinium (MPP^+)

Figure 3 Chromaffin vesicles. The intracellular storage granules containing epinephrine or norepinephrine and a variety of proteins and peptides. The subcellular features were highlighted by the freeze-structure technique. An isolated chromaffin cell was quick-frozen and then fractured. Platinum and carbon, sprayed on the fractured surface, formed a replica of the surface relief; the tissue was then dissolved and a transmission electron micrograph was made of the replica. Micrograph made by Wolfgang Schmidt of the University of Innsbruck; provided courtesy of Professor Stephen Carmichael, Department of Anatomy, Mayo Clinic, Rochester, from the online article (see http://webpages.ull.es/users/isccb12/ChromaffinCell/Primer.html) by Stephen Carmichael and Hans Winkler, 'A Primer on Chromaffin Cells,' based on their article in *Scientific American* (1985) 253: 40–49.

by diverting the uptake of this toxin away from the cellular mitochondria and into the chromaffin granules.

Control of Catecholamine Biosynthesis

In vivo, the synthesis of catecholamines within the adrenal chromaffin cells is subject to neural and hormonal regulation. Tyrosine hydroxylase (TH) is the rate-limiting enzyme, and is known to be controlled acutely (minutes) by phosphorylation and chronically (days) by protein synthesis. In humans and animals exposed to stress (e.g., cold, burns, asphyxia, isolation, immobilization, physical exercise, or childbirth), the rate of synthesis of the biosynthetic enzymes and of the catecholamines increases markedly. Short-term stress initially increases the activity of TH by causing it to be phosphorylated in its N-terminal regulatory domain on several serine residues by a number of different Ser/Thr kinases. These include Ca^{2+}/calmodulin-dependent protein kinase II, cyclic adenosine monophosphate (cAMP)-dependent protein kinase A, protein kinase C, two extracellular signal-regulated kinases (ERK-1 and ERK-2), and a number of related kinases. Nicotine, acting via nicotinic receptors, can sustain the phosphorylation of TH at Ser40 for up to 48 h. Sustained phosphorylation and activation of TH are also observed with histamine and angiotensin II. Sustained phosphorylation of TH at Ser40 provides a novel mechanism for increasing TH activity and leads to increased catecholamine synthesis.

In humans, four splice variants of TH are expressed, with different amino acid insertions immediately prior to one of the key phosphorylated Ser residues that regulate TH activity. TH phosphorylation is increased following stimulation of chromaffin cells with a wide variety of agents, including acetylcholine (ACh), nicotine, K^+, histamine, angiotensin II, pituitary adenylate cyclase-activating peptide-27, caffeine, and nerve growth factor. The phosphorylation state of TH affects its V_{max}, its affinity (K_m) for its substrate tyrosine and for its cofactor tetrahydrobiopterin, its affinity (K_i) for catecholamines responsible for feedback inhibition of TH, and its pH optimum.

Following longer periods of stress lasting hours or days, the amounts of the enzymes TH and DBH increase. The *de novo* synthesis of TH and DBH is under neuronal control whereas the synthesis of phenylethanolamine *N*-methyltransferase (PNMT) is under hormonal control. PNMT is induced by adrenocorticosteroids and this hormonal effect can be mimicked by dibutyryl cAMP and, in hypophysectomized animals, by adrenocorticotropin (ACTH). Synthesis of enzyme cofactors plays a very important role in the regulation of catecholamine biosynthesis. The normal tissue levels of the biopterin cofactor are below the K_m for TH, so the increased synthesis of biopterin (by a guanosine triphosphate cyclohydrolase) is required for long-term activation of TH where the amount of TH enzyme increases. Synthesis of cofactors also plays a crucial role in determining the levels of DBH and PNMT. These two enzymes are subject to rapid intracellular proteolysis and their respective cofactors protect against this proteolysis. Synthesis of the cofactors (ascorbic acid for DBH and *S*-adenosylmethionine for PNMT) is regulated by glucocorticoids under hypothalamopituitary (ACTH) control. Hypophysectomy decreases the number of molecules of DBH and PNMT by increasing their rate of proteolysis. Low concentrations of angiotensin II (10^{-10}–10^{-7} M) evoke long-term effects on TH and PNMT gene induction via a Ca^{2+}-protein kinase C-mediated pathway, whereas higher concentrations (10^{-6}–10^{-5} M) are more effective in the short term to produce catecholamine secretion. This suggests that the major physiological function of this peptide hormone in the adrenal medulla is the long-term regulation of gene expression, rather than the short-term regulation of catecholamine or enkephalin secretion. Control of catecholamine gene expression

Figure 4 Synthesis and packaging of the contents of chromaffin vesicles. The primary secretary product of most chromaffin cells, adrenaline (epinephrine), is synthesized from tyrosine in four steps, each catalyzed by a different enzyme (see **Figure 2**). Tyrosine is transported into the cell, changed into dopa, and then into dopamine. The dopamine is carried into the chromaffin vesicles and there is transformed into noradrenaline (norepinephrine), which subsequently leaks out of the vesicles into the cytosol and is converted into adrenaline; the adrenaline is pumped back into vesicles for storage. A second substance stored in the vesicles, ATP, is synthesized in mitochondria from ADP, which is derived from adenosine. Amino acids serve as raw material for the manufacture of chromogranins A and B and enkephalin precursors. Proenkephalin, a long polypeptide chain containing enkephalin sequences, is synthesized on ribosomes along the endoplasmic reticulum. As it passes into the reticulum the preproenkephalin loses a short signal peptide; the shortened molecule (now known as proenkephalin) then moves into the Golgi complex and is packaged in newly formed chromaffin vesicles. There it is processed into smaller pieces, including some free enkephalins. The chromogranins are synthesized by a similar process. The various constituents of the chromaffin vesicle (catecholamine, chromogranins, peptides, ATP) are packaged as a multimolecular complex within the vesicle, to reduce their osmotic activity. Upon exocytosis, the vesicle is recycled and reused. Picture courtesy of Professor Stephen Carmichael, Department of Anatomy, Mayo Clinic, Rochester, from the online article (see http://webpages.ull.es/users/isccb12/ChromaffinCell/Primer.html) by Stephen Carmichael and Hans Winkler, 'A Primer on Chromaffin Cells,' based on their article in *Scientific American* (1985) 253: 40–49.

appears to involve several different transcription factors, with the cAMP/cAMP response element (CRE) complex involved in TH expression and the phorbol ester response element (AP-1) being important in mediating PNMT gene expression in response to angiotensin II and nicotine. With their intricate control of TH activity by multiple phosphorylation and of TH gene expression by multiple transcription factors and upstream regulatory domains, chromaffin cells and the related PC12 cells have provided excellent models in which such cell signaling pathways can be investigated and elucidated.

Figure 5 Uptake of amines and ATP into chromaffin granules. The membrane-bound ATPase drives protons into the chromaffin vesicle, creating an electrochemical proton gradient. The chemical part (ΔpH) of the gradient, supplemented by the electrical potential ($\Delta\psi$), drives the uptake of catecholamines by a specific carrier. Only the electrical potential has been shown to drive the uptake of nucleotides via its carrier (O). The specificity of the two carriers has been established by their sensitivity to different inhibitors. From Livett BG (1984) The secretory process in adrenal chromaffin cells. In: Cantin M (ed.) *Cell Biology of the Secretory Process*, pp. 309–358. Basel: Karger.

Control of Catecholamine Secretion

Neuronal

In the adult, control of secretion from the adrenal medulla is mediated through the splanchnic nerve. Classically this innervation has been regarded as purely cholinergic; however, many findings suggest that this may be too restrictive a view of control of chromaffin cell secretion. Studies in the adult rat and dog have provided evidence that stimulation of specific central loci and certain peripheral pathways can be used to achieve independent control over the secretion of epinephrine and norepinephrine. Changes in the proportions of the two amines released can be brought about by merely altering the pattern of electrical stimulation applied to the whole of the efferent innervation to the adrenal in the calf. Different properties of the epinephrine and norepinephrine cells may also contribute to their differential release. Both nicotinic and muscarinic ACh receptors participate in the secretion of catecholamines from adrenal chromaffin cells, but their relative involvement in the release process depends on the concentration of ACh and upon the species being studied. In the rat, cat, dog, and gerbil, nicotinic receptors play a major role in the secretion of adrenal catecholamines, with only a minor contribution from muscarinic receptors. In bovine adrenal chromaffin cells, only nicotinic receptors are linked to secretion, whereas in the chick, muscarinic receptors are principally involved in the secretory response. Significant evidence is now accumulating that noncholinergic cotransmitters in the preganglionic splanchnic nerve fibers also contribute to the control of adrenal medullary function. In particular, the enzyme responsible for nitric oxide synthesis, neuronal nitric oxide synthase, and pituitary adenylate cyclase-activating polypeptide (PACAP) are expressed in preganglionic cholinergic nerves originating in the spinal cord and innervating chromaffin cells in the adrenal medulla. The role of nitric oxide has yet to be fully elucidated, but PACAP is a powerful secretagog and also substantially potentiates catecholamine secretion evoked by cholinergic agonists or by sympathetic nerve stimulation *in vivo*. PACAP also has long-term effects on both secretion and gene expression in chromaffin cells.

Nicotinic Cholinergic Receptors on Chromaffin Cells

Consistent with their neuronal origin, chromaffin cells express neuronal-type nicotinic ACh receptors (nAChRs). Neuronal-type nAChRs are composed of multiple subunits inserted into the plasma membrane and arranged concentrically to form pentameric ACh-gated ion channels. In the central and peripheral nervous system, multiple subunits selected from $\alpha2$–$\alpha9$ and $\beta2$–$\beta4$ form pentameric complexes, either heteromeric (e.g., $\alpha4\beta2$, $\alpha3\beta4$) or homomeric (in the case of $\alpha7$). In the bovine adrenal medulla, the following subsets of neuronal nAChR subunits have been identified: $\alpha3$, $\alpha5$, $\alpha7$, and $\beta4$. It is likely that the functional receptor responsible for catecholamine release from the bovine adrenal medulla contains $\alpha3$ and $\beta4$ subunits, possibly in combination with $\alpha5$, but the precise contribution of the various subunits is not known with certainty. Further, it is not known whether the $\alpha7$ subunit forms a homomeric receptor or heteromeric complex with the other α and β subunits. However, there is currently much interest in $\alpha7$-containing nAChRs because they respond to short pulses of high concentrations of ACh, exhibit a high Ca^{2+} flux, and desensitize rapidly. It is possible they trigger the initial entry of Ca^{2+} into the chromaffin cell in response to the high concentrations of synaptically released ACh, after which further Ca^{2+} entry via $\alpha3\beta4$-containing nAChRs contributes to the observed prolonged release of catecholamines from the adrenal gland.

Peptide Modulation of Secretion

The adrenal medulla has been a rewarding tissue in which to study the functions of neuropeptides. Many neuropeptides, including PACAP, are endogenous components of the splanchnic nerve that innervate the adrenal medulla or of the chromaffin cells, or

both. In some cases (e.g., calcitonin gene-related peptide (CGRP), substance P (SP), galanin, and some of the PACAP), the peptides are present in terminals of sensory nerve collaterals, rather than the preganglionic innervation. Studies with isolated adrenal chromaffin cells in monolayer culture have shown that many of these peptides (notably SP, somatostatin, and certain enkephalin congeners) do not evoke secretion but can modulate the nicotinic secretion of catecholamines. Two binding sites on the β subunit of the neuronal nAChR contribute to the affinity of SP. SP is an inhibitory neuromodulator of the nicotinic response in adrenal chromaffin cells and at the same time protects against nicotinic desensitization. On the basis of these findings *in vitro*, it was proposed that SP may function *in vivo* to maintain a prolonged adrenal catecholamine output during stress. Support for this idea has come from *in vivo* studies on adult rats, pretreated as neonates with capsaicin to kill sensory nerve fibers containing SP in the splanchnic nerve. Thus SP appears to act as a true postsynaptic neuromodulator – inhibiting the release of catecholamines mediated by the release of ACh from the splanchnic nerve under resting conditions while facilitating nicotinic function (through protection against desensitization) under conditions of stress.

The actions of the other neuropeptides are not as well defined, although it is known that, like SP, they are present in the splanchnic nerve or chromaffin cells or both, and many inhibit the nicotinic response. Opioid peptides are expressed in very high concentrations by chromaffin cells, but are also present in their efferent innervation. Their expression in chromaffin cells has led to clinical trials in which encapsulated chromaffin cells are implanted in the subarachnoid space in human cancer patients to alleviate their intractable pain (see later, and see the section 'Further reading'). In addition, opioid peptides (and ATP) released from chromaffin cells have autocrine feedback effects, inhibiting voltage-operated Ca^{2+} channels in the chromaffin cell membrane through actions on G-protein-coupled receptors. Leuenkephalin and metenkephalin are weak inhibitors of nicotinic response, but do enhance the basal release of catecholamines when present in submicromolar concentrations. Many biologically active fragments of the chromaffin granule protein chromogranin have been identified, including catestatin, chromacin, chromostatin, secretoneurin, neuroendocrine secretory protein 55 (NESP55), and vasostatin; they may have actions outside the adrenal, as well as some local modulatory effects. Chromogranin A (CgA), one of the most abundant acidic glycoproteins ubiquitously present in neuroendocrine/endocrine cells, regulates dense-core secretory granule biogenesis. Catestatin (human CHGA352–372) was tenfold more potent than neuropeptide Y at inhibiting the nicotinic secretion of catecholamines from rat PC12 chromaffin cells. Other studies indicate modulatory effects of CGRP, which can potentiate nicotinic responses on rat chromaffin cells. Neurotensin, vasoactive intestinal polypeptide, and vasopressin have all been reported as endogenous peptides within the adrenal medulla, but whether these have a function there or are a developmental consequence and legacy of the common neural crest origin of the adrenal chromaffin cells and other neuronal cell types is not known. Although the detailed mechanisms and physiological importance of these modulatory effects remain to be elucidated, it is clear that the scope for control of secretion extends beyond the original view of splanchnic nerve stimulation and activation of cholinergic receptors on the chromaffin cells.

Nonneuronal

The adrenal medulla of species such as the rat and calf are not functionally innervated by the splanchnic nerve at birth, and nonneurogenic responses have been elicited in response to stresses such as asphyxia. The onset of neural control of adrenal medullary function in the rat first appears at the end of the first postnatal week and matures fully by approximately 10 days of age. A functional role for the endogenous opioids in dampening nonneurogenic release of catecholamines has recently been proposed that may be of survival value to neonates undergoing stress. In addition, glucagon released from the pancreas in response to hypoglycemic stress is a potent secretagog for adrenal medullary catecholamine release. Nonneural influences have been shown to be responsible for the large mobilization and elevation of plasma catecholamines observed 1 h after administration of insulin to adult rats.

Hormonal control of adrenal catecholamine secretion in the adult has been extensively documented. The secretion induced by histamine, angiotensin II, prostaglandins, adenosine, and other factors is dependent on the presence of extracellular Ca^{2+}, as is that evoked by nicotinic agonists; however, unlike nicotinic agonists, these other agents have receptors that are coupled to G-proteins and are not directly depolarizing. The molecular mechanisms by which these noncholinergic receptors induce secretion are hence a major focus of research on chromaffin cells. In many cases, the density of receptors in the adrenal medulla for these noncholinergic agents is so high that this tissue has been used for the isolation and cloning of the receptor (e.g., the histamine H1 receptor). The

G-protein-coupled receptors may act by indirectly depolarizing the chromaffin cells by opening non-selective cation channels or by closing K^+ channels. This depolarization could then recruit voltage-sensitive Ca^{2+} channels. Muscarinic receptors, which are G-protein coupled, contribute substantially to secretion in nonbovine species and act through this mechanism.

Exocytosis and Endocytosis

Much interest has centered around the identification and possible functions of vesicle, cytoplasmic, and plasma membrane proteins thought to be involved in the 'fusion machine' that constitutes exocytosis in the adrenal medulla (Figure 6). The Ca^{2+}-induced exocytosis occurs in two phases: the first phase involves a MgATP-dependent Ca^{2+}-enhanced priming of the secretory apparatus, and the second phase is a Ca^{2+}-dependent and MgATP-independent step that triggers exocytosis. Roles have been proposed for the soluble protein synexin (also termed annexin V[II]) in promoting Ca^{2+}-dependent membrane fusion of chromaffin granules leading to compound exocytosis; however, clearly many other proteins are also involved, including monomeric G-proteins (such as Rab 3A, ARF6, and RhoA), an inhibitory trimeric G-protein (G_o), and cytoplasmic and cytoskeletal proteins such as Exo1, Exo2, synaptobrevin, scinderin, F-actin, munc18, csp, noc2, protein kinase C, myosin, myosin light-chain kinase, and possibly phospholipase D. Trifaro and colleagues have shown that nicotine and depolarizing agents induce disassembly of the cortical actin cytoskeleton in focal areas underneath the plasma membrane, so removing the proposed barrier to chromaffin granule access to the plasma membrane for fusion–exocytosis. Upon stimulation, the uniform cortical distribution of actin and spectrin redistributes into patches. It is believed that voltage-sensitive Ca^{2+} channels at these sites open and permit Ca^{2+}-induced exocytosis, possibly involving phosphorylation of a 20 kDa myosin light chain in the MgATP-dependent priming process preceding exocytosis. Synaptic vesicle proteins such as synaptobrevin and plasma membrane proteins are then proposed to be involved in the so-called fusion engine responsible for vesicle docking to the plasma membrane. The resulting exocytosis brings about hormone secretion, although the details of this mechanism remain to be fully defined.

Membrane capacitance measurements using patch pipettes not only allow exocytosis to be followed in

Figure 6 Life cycle of a secretory granule in chromaffin cells and in other secretory cells (neurons, endocrine cells). Step 1: Specific granule membrane and plasma membrane proteins cause the granules to dock with special sites on the plasma membrane. The granules become primed, and then with appropriate stimuli their contents are released ('exocytosis') through a pore created by the fusion of granule and plasma membrane. The fusion pore may only be formed transiently, such that the vesicle is rapidly recovered by endocytosis ('kiss-and-run' exocytosis; step 2). Alternatively, following full fusion, the granule membrane may be recovered by endocytosis through clathrin-coated pits (step 3) and recycled through endosomes (step 4). In both cases, the vesicle is restocked with secretory material and then returned to the secretable pool (step 5). Figure kindly supplied by Dr. Mike Cousin, Membrane Biology Group, Division of Biomedical and Clinical Laboratory Sciences, University of Edinburgh, Scotland.

single cells, but also endocytosis. Such studies on chromaffin cells have demonstrated that the endocytotic retrieval of vesicle membrane following fusion with the cell surface may occur in much less than a minute. In some cases the vesicles do not fully fuse with the membrane but are rapidly retrieved in a process called 'kiss-and-run' exocytosis (Figure 6). Such recycling of vesicles is crucial to permit a constant supply of releasable vesicles.

Ca^{2+} Signaling

The primary signal for exocytosis from chromaffin cells is a substantial increase in cytosolic Ca^{2+} just underneath the plasma membrane. As excitable cells derived from neural crest that are obtainable in large numbers for *in vitro* study, chromaffin cells have been an ideal model system in which to investigate Ca^{2+} signaling. They have been particularly useful for studying calcium channel current autoregulation by materials co-released with catecholamines, such as ATP and opiates. Robust secretion requires concentrations of Ca^{2+} in the subplasmalemmal zone of $>10\,\mu M$. Such concentrations are only effectively achieved by extracellular Ca^{2+} influx through voltage-operated Ca^{2+} channels (VOCCs), the opening of which is synchronized by membrane depolarization. Chromaffin cells posses a variety of types of VOCCs, including in most species L, N, and P/Q channels (5–50%), as well as R and/or T channels in rodents; human adrenal chromaffin cells express mostly P/Q types (60%). Detailed studies have characterized the role of cytosolic Ca^{2+}-buffering proteins on the shape of Ca^{2+} signals in chromaffin cells. By use of pulsed-laser imaging of voltage-clamped cells, it has been shown that depolarization induces Ca^{2+} entry at restricted zones, or 'hot spots,' around the cell surface. Combination of this technique with carbon fiber microelectrode voltammetry has shown these Ca^{2+} hot spots are preferred sites for catecholamine secretion. More recent studies have used chromaffin cells transfected with green fluorescent protein, targeted so as to be expressed as a soluble protein in chromaffin granules. By use of confocal or deconvolution fluorescence microscopy, and total internal reflectance fluorescence microscopy (TIRFM), it is now possible to follow in real time the motion of individual vesicles within the living cell, both deep within the cell and at the specialized release zones around the cell surface, and to observe exocytotic events while manipulating Ca^{2+} levels. These sophisticated methods have contributed significantly to our understanding of the molecular events controlling exocytosis.

Chromaffin cells also possess intracellular Ca^{2+} stores, some of which release their Ca^{2+} in response to the second messenger, inositol (1,4,5)-trisphosphate, and others that are responsive to ryanodine receptor agonists such as caffeine. Different receptors give rise to distinct Ca^{2+} signals in part because they differentially recruit these two stores. Expression of the photoprotein aequorin, engineered so that it is targeted to the ER, has shown directly that Ca^{2+} is released from this organelle by a variety of stimuli and then gets taken up again from the cytosol. Depending on the extent of filling, the ER may act as a sink or source of Ca^{2+} that modulates catecholamine release. Targeted aequorin combined with confocal microscopy has shown that entry of Ca^{2+} through calcium channels can refill the ER to nearly millimolar concentrations. Use of Ca^{2+}-sensitive dyes (e.g., fura-2) has shown substantial interactions between external Ca^{2+} entry and store Ca^{2+} mobilization, such that chromaffin cells can generate complex oscillations in cytosolic $[Ca^{2+}]$. Store Ca^{2+} mobilization is also triggered by Ca^{2+} (a process called Ca^{2+}-induced Ca^{2+} release, or CICR), and this occurs in response to Ca^{2+} release from nearby stores or due to external Ca^{2+} entry through VOCCs. Depletion of store Ca^{2+} causes the influx of external Ca^{2+} entry by a process called capacitative Ca^{2+} entry.

Ca^{2+} removal mechanisms have also been extensively studied in chromaffin cells. These cells possess four principal Ca^{2+} removal mechanisms: plasma membrane Ca^{2+}-ATPases, plasma membrane Na^{+}/Ca^{2+} exchangers (NCXs), smooth ER Ca^{2+}-ATPases, and mitochondrial uniporters. They each play a role in removing cytosolic Ca^{2+} after it has been elevated; however, these mechanisms have different affinities and capacities, as well as different cellular locations. Studies on the mitochondrial uniporter and the NCX indicate that these have significant effects not only on the shape of cellular Ca^{2+} responses, but also on the secretory responses they evoke. Expressing aequorin targeted to mitochondria also confirms that large amounts of Ca^{2+} are taken up into the mitochondria following agonist stimulation and that this limits the extent of exocytosis. Some parameters exhibited by chromaffin cells *in situ*, such as cell polarization and clustering of calcium channels, are not maintained in chromaffin cells in culture, and this is a limitation of isolated cells.

Clinical Uses of Chromaffin Cells in Parkinson's Disease and Chronic Pain

Chromaffin tissue containing catecholamines and enkephalins has been used increasingly over the past decade as a source of cells for transplants in both animal models and human disorders (e.g., Parkinson's disease) in attempts to ameliorate behavioral deficits.

In patients with Parkinson's disease, the use of adrenal medullary tissue transplanted into the brain appears to offer an effective, lasting treatment. Implantation of chromaffin cells which synthesize and secrete a number of pain-reducing neuroactive compounds, including noradrenaline and opioid peptides, has also been proposed for the treatment of intractable cancer pain. Bovine adrenal medullary cells encapsulated into microcapsules of alginate-poly-L-lysine with a liquefied inner core have been introduced into the spinal subarachnoid space in humans to relieve pain. Macro- or microencapsulation of the chromaffin cells within semipermeable membranes is expected to protect the transplant from the immune system of the host. The future of such transplants for the treatment of pain in cancer patients and in patients refractory to morphine remains to be fully evaluated, but is a novel approach with considerable potential.

Bovine chromaffin cells have also provided a convenient functional assay for monitoring the relative efficacy of different synthetic α-conotoxins to inhibit the neuronal-type nicotinic ACh receptor. Two of these, α-conotoxins Vc1.1 and RgIA, recently shown to be potent analgesics in rat models of human neuropathic pain, are selective inhibitors of the α9α10 neuronal nicotinic receptor. Conotoxin Vc1.1 is presently undergoing clinical trials for the treatment of chronic neuropathic pain. It remains to be determined if the α9α10 neuronal nicotinic receptor is present in chromaffin cells and, if so, the extent to which its activation by ACh and nicotine contributes to catecholamine secretion.

Chronic (Repeated) Stress: Consequences, Adaptations

M F Dallman, University of California at San Francisco, San Francisco, CA, USA

© 2009 Published by Elsevier Ltd.

Chronic Stress

What is important for the organism? Evolutionarily, the answers are, first, survival to achieve and sustain reproductive age and, second, reproductive success. The hypothamic–pituitary–adrenocortical (HPA) axis is intimately involved with the former requirement, and its overactivity may inhibit the latter while taking care of living for the moment. Glucocorticoid (GC) secretion is regulated by the HPA axis and is key to survival after severe insults that threaten the organism. GC modulates energy availability, immune responses, learning, and memory, as well as many behaviors. The consequences of GC secretion reveal an organism that is better fit for survival under conditions of challenges. This is clearly so in the face of punctate, acute stressors that, once finished, do not recur on a regular basis. However, with chronic or repeated stressors that cannot be coped with through behavioral changes, the persistently increased secretion of GC may limit the ultimate longevity of the organism. In the case of chronic or persistent inescapable stressors, mechanisms have evolved that may diminish the HPA response to the unrelieved, or repeated stressor input. This is reflected by the process of habituation of the HPA output to a given stressor, well studied in rats by using shock, restraint, or cold.

A careful look at responses to a new stressor in chronically stressed rats that are habituated to a chronic stressor reveals that the new HPA response is most often facilitated compared with that of a stressor-naïve animal. This demonstrates that, although central mechanisms of habituation are engaged, the brain remains aware of the persistent challenge, and the HPA axis overresponds to a new threat. This article first describes the recruitment of limbic networks accompanying chronic or repeated stressors and then the habituation to repeated or chronic stressors, using repeated restraint as a model, and the brain sites and HPA responses important during habituation. It discusses experimental manipulations of these sites and what they may reveal about the plasticity of brain responses in the face of chronic or repeated stressors. Finally, it briefly recaps the upside and discusses the long-term downside of perpetual challenges to the organism – the wear and tear of life.

Chronic Stress and Recruitment of a Limbic Network That Biases Subsequent Autonomic, Behavioral, and Neuroendocrine Responses to Stressors

The HPA axis is not the only motor system that is affected by chronic or repeated inescapable stressors. Chronic stressors bias autonomic responses toward excessive sympathetic outflow; they bias behaviors toward the fearful- and anxiety-like spectrum; they alter neuroendocrine responses so that the HPA responses to novel stressors are facilitated although those to many known stressors are habituated with repetition. In rats, the somatotropic and thyrotropic axes are inhibited by chronic or repeated stressors; the gonadotropic axis may be either inhibited or facilitated, depending on the stressor that is chronically or repeatedly applied. These effects of chronic stressors may be a consequence of the stimulatory actions of GC on corticotropin-releasing factor (CRF) synthesis and secretion in the central nuclei of the amygdala (CeA). From the CeA, CRF axons innervate and may activate all monoaminergic cell groups that have been shown to be important, and facilitated, after the engagement of the chronic stress network. It is the altered activity of the monoaminergic networks, as well as direct effects of CRF from the CeA, that is responsible for many of the altered autonomic, behavioral, and neuroendocrine responses that accompany activation of the emotional limbic brain during persistent, inescapable stressors.

Habituation of HPA Responses with Time after Inescapable Stressors

What are the HPA characteristics of habituation? Because habituation is measured by comparison of the amplitude and duration of the first HPA response to a given stressor with those of subsequent responses, it is far easier to demonstrate that habituation occurs after the use of mild to moderate stressors that do not saturate the response characteristics of the HPA axis. Habituation has typically been studied in responses to repeated restraint, intermittent or chronic cold, footshock, social stressors, and variable chronic stress paradigms. Although some are top-down, processive stressors and others bottom-up, systemic stressors, the HPA responses more often than not habituate with repetition or time. It seems likely that with both top-down and bottom-up cases, the animal becomes adapted, behaviorally and

physiologically, to the repeated or chronic stimuli. Indeed, for restraint, there is evidence, as measured by c-fos expression, that afferent input within the brain is reduced with repetition, whereas with the metabolic challenge of cold, the animal gears up its metabolism and food intake to alter thermogenesis and respond appropriately to the challenge, thus reducing afferent input to the brain. Nonetheless, generally there is evidence that, although habituation may occur with chronicity or repetitions of stressors that are not life-threatening, new central networks have been recruited that allow the animals to hyperrespond to presentation of novel stimuli.

Repeated Restraint

Restraint is probably the most-studied stressor in which the process of habituation has been explored. Restraint, unlike immobilization, simply confines animals in a tube in which they can breathe readily and can move somewhat but in which they cannot turn around. The HPA axis response to an initial bout of restraint is transient. When rats are maintained in a restraining tube for hours, adrenocorticotropin (ACTH) and corticosteroid responses peak at 15–30 min and then return to control concentrations despite continued confinement (Figure 1); red lines show responses to restraint during the first encounter with it). It is likely that a portion of the initial response also reflects the stressor of being picked up and placed into the restraining tube. Nonetheless, the HPA response to the stressor seems clearly damped by the adrenal GC feedback signal since in its absence, ACTH concentrations remain high for the full period of restraint. With chronic, repeated restraint, the amplitude of the HPA response decays over days (Figure 1; blue lines show responses to restraint during the fifth encounter). All efferent components of the response are diminished and curtailed, and this is reflected by the markedly reduced c-fos response in the hypothalamic paraventricular nuclei (PVN) to restraint on the fifth day compared with the first. Moreover, the CRF cells in the PVN that express c-fos after repeated restraint appear to be located more ventromedially, compared to the dorsomedial neuronal CRF response that occurs to the first episode of restraint. All the downstream responses are shortened, and their amplitude is generally diminished. However, it is characteristic of chronic stressors that HPA responses are still observed, but their magnitude and duration decrease.

Why Habituation?

Familiarity with the stimulus, in part through GC-mediated learning, memory, and recall, perhaps reveals that it is not life-threatening, although it may be boring and uncomfortable, and that it can be endured. Habituation to the much more severe stimulus of immobilization, in which rats are tightly restrained and cannot move even their heads, is much slower, although it, too, occurs eventually. Habituation also occurs with other stimuli, such as cold, mild electrical shock, social stress, and subsequent presentations of a previously experienced stimulus in a variable stimulus paradigm (in which different stressors are presented twice daily for up to a month). However, if stimuli are perceived as life-threatening, subsequent repetitions may produce augmented, rather than habituated, responses, as reported for exposures to predator odor and immune challenge. Again, it seems highly appropriate to have mechanisms (that are still unclear) that allow continued, and even increased responses to potentially life-threatening events.

Where in the Brain Does Habituation to Restraint Occur?

Many sites in brain have been examined for their potential role in habituating HPA responses to repeated restraint. With the use of c-fos messenger RNA, it seems clear that there is decreased responsiveness to recurrent restraint throughout the afferent limbic and cortical brain networks involved in transmission of the signal to the CRF motor zone, the hypothalamic PVN, probably as a consequence of cortical inhibition of these sites.

How Does Habituation Occur?

Although cytotoxic lesions of the posterior paraventricular thalamus do not affect the duration or amplitude of an initial ACTH response, they do block habituation of ACTH to repeated bouts of restraint, suggesting that this structure is important for, perhaps, the memory of prior restraint (Figure 2). Moreover, injection of a cocktail of mineralocorticoid receptor and GC receptor (GR) antagonists during each period of repeated restraint also decreases the degree of habituation (Figure 3) although they do not affect the initial HPA response to the stressor. Thus, it appears that cells in the posterior paraventricular thalamus that contain GRs (and presumably mineralocorticoid receptors) and that project to both the basolateral amygdala and the prefrontal cortex strongly affect habituation of HPA responses to restraint, although they do not explain the entire habituation response. Similarly, injection of a GR antagonist into the basolateral amygdala, or into the hippocampus, depending on the type of behavior examined, can block subsequent behavioral responses to a stressor. It seems clear that the GCs aid learning

of and memory for emotionally laden events and that without the GC action, appropriate responses to the events do not occur.

Facilitation to Novel Stimuli Occurs with Chronic Stress

What Does Facilitation Look Like?

Although HPA responses to repeated stimuli dwindle with repetition, it is characteristic of rats undergoing chronic challenge that they exhibit greater-than-normal HPA responses to new stressors. The example provided in Figure 4 is of rats given intermittent injections of morphine in escalating doses that allow partial withdrawal twice daily, which is an intense stimulus to the HPA axis. However, facilitated responses to novel stressors are characteristic of most chronic challenges and have been observed in rats, mice, sheep, and humans. Facilitated responses are observed at each level (CRF, ACTH, and corticosterone) of the HPA axis in rats. Facilitation of HPA responses to novel challenges, even in an organism undergoing chronic stress with habituated responses,

Figure 2 Dishabituation of HPA responses to restraint by lesion of posterior PVThalamus: first vs. eighth restraint. makes a great deal of physiological sense since GC responses of normal magnitude to many stressors are essential for the maintenance of life.

Facilitated Responses Require Sustained or Intermittently Repeated Stressors and Elevated Corticosterone Concentrations

Adrenalectomized rats without GC or with low levels of GC replacement do not exhibit facilitated ACTH responses to novel stimuli under conditions of chronic challenge (Figure 5). Although replacement with GC results in normal, monotonic inhibition of ACTH in chronically stressed, compared with control, rats (Figure 5, left panel), GC concentrations must be maintained at values above the normal daily mean for intact, unstressed rats for facilitated responses to novel stress to be observable (Figure 5, right panel). The corticosterone concentrations that permit facilitation are sufficient to entirely inhibit ACTH responses to novel restraint in control animals that were not chronically challenged. Because GC acts at GRs in the anterior pituitary corticotropes to inhibit both synthesis of proopiomelanocortin, the precursor for ACTH, and secretion of the mature hormone, hypothalamic CRF may increase in response to the acute stimulus, but because of the GC-inhibited corticotrope, ACTH secretion may not occur.

How Does Facilitation Occur?

Facilitation is almost certainly explained by the fact that chronic stressors recruit a limbic network, based on activation of CRF in the central nucleus of the amygdala by GC's acting through GRs. The limbic response network prepares the animal to maintain behavioral, autonomic, and neuroendocrine responsiveness in the face of tonically elevated GC that might otherwise suppress these responses. Facilitated HPA responses to new stimuli are blocked by daily injections with a GR antagonist (RU486) during the period of intermittent challenge. They are also blocked by the injection of a CRF1 receptor antagonist before the novel stimulus is presented. Thus, although the intimate details are still not understood, the stress-induced elevations in GC concentrations promote, not only habituation, but also facilitation, through actions on stressor-recruited limbic structures and on limbic neurons to stimulate CRF synthesis.

The Up- and Downsides of HPA Responses to Chronic or Repeated Challenge

The Upside

The HPA responses to chronic challenge are essential for maintaining life. Without the GCs, death occurs or metabolism and mentation are not appropriately regeared to meet the challenge. The persistent and overall increases in GC concentrations above basal values that occur during normal physiological responses to chronic stressors sculpt the organism's repertoire to manage the threat flexibly and

Figure 5 Facilitated ACTH responses to novel restraint require high corticosterone in chronically stressed adrenalectomy (ADX) rats. ACTH, adrenocorticotropin. optimally: (1) Metabolic activity is adjusted to produce more gluconeogenesis so that available essential fuel is abundant, drawing on reserves and also rearranging stored metabolic energy toward the center of the animal, where it provides better physical balance for potential escape behaviors. (2) Behaviors are geared more toward fight, flight, anxiety, and ingestive responses, and there is an increased level of arousal that will more accurately pinpoint any new dangers to be assessed. Habituation, mediated at least in part through the GC response, ensures that the HPA response is calibrated and appropriately damped, once the level of the threat is known and evaluated, so that more-than-adequate GC secretion does not occur. Simultaneously, the same challenge-induced GC responses enable full engagement of the stressor-recruited central brain stress-response network, allowing increased responsivity in other central neural systems to ongoing and potential new threats. The HPA response is finely honed to enable and prepare the organism to deal with the ongoing vicissitudes of life.

The Downside

Greatly elevated concentrations of GC, persisting for too long, may exert deleterious effects that will ultimately decrease the life span of the individual. GCs certainly affect learning and memory, and they do so with an inverted U-shaped dose–response relationship. As in the story of Goldilocks and the three bears, the magnitude of the chronic HPA response must be just right, neither too little nor too much. Effects of inappropriately high GC on learning and recall of memory, hippocampal CA3 apical dendritic branching, neurogenesis, and neuronal apoptosis are generally deleterious. As with all things, there is a Janus-like quality to the GCs. They can either augment or inhibit immune responses. During the stressful breeding season, both salmon returning to spawn and the small male Australian marsupial *Antechinus stuartii* die after fertilizing the eggs of the female, and often with evidence of overwhelming infection, probably due to the very high GCs that accompany their efforts. GCs also stimulate not only the learning and memory of high-density palatable calories but also their intake. This is appropriate and plays a large role in seasonal fattening in birds and animals in the wild. However, in industrialized societies, people living under conditions, not only of heightened persistent psychological challenge, but also of inexpensive and readily available, low-quality, high-calorie foods, run into trouble. Stressor-induced increases in palatable food consumption may result in increased abdominal obesity, cardiovascular disease, and type 2 diabetes. All these are known to strongly contribute to morbidity and mortality.

Thus, although they are required for the survival of challenge, the secreted GCs also greatly increase the rate of wear and tear associated with life and may ultimately shorten life span.

Anatomy of Cingulate Cortex

Subdivisions

The mammalian cingulate cortex occupies a vast territory stretching rostrocaudally along the cingulate sulcus on the medial surface of the cerebral hemispheres (Figure 1(a)). In both human and nonhuman primates, the cingulate cortex consists of the cingulate gyrus as well as the cortex lining the superior and inferior banks of the cingulate sulcus. The name 'cingulate,' derived from the Latin word for belt, reflects the fact that the cingulate cortex encircles the corpus callosum. The cingulate cortex can be divided into the more rostral anterior cingulate cortex (ACC) and the more caudal posterior cingulate cortex (PCC). In primates, the ACC consists of Brodmann's areas 24, 25, 32, and 33, while the PCC consists of Brodmann's areas 23, 29, 30, and 31. The clearest distinction between the ACCs and PCCs is that ACC has a thin agranular layer 4, whereas PCC has a pronounced granular layer 4.

The ACC and PCC can be further subdivided. The ACC consists of at least three distinguishable areas – the perigenual anterior cingulate cortex (pACC), the dorsal anterior cingulate cortex (dACC; sometimes referred to as midcingulate cortex, MCC), and the rostral and caudal cingulate motor areas (CMAs). The PCC comprises at least two distinct areas, the more rostral posterior cingulate cortex proper and the more caudal retrosplenial cortex, which constitutes the entire PCC in rodents.

Although there is a great deal of functional overlap between regions of the cingulate cortex, each of the anatomically defined subdivisions serves discrete functions. The pACC and dACC are thought to process emotional and cognitive information, respectively, while the CMAs process motor information. Although response properties of neurons in the CMAs are similar, electrical stimulation in the more caudal areas CMAd/v has a stronger and more consistent effect on movement than stimulation in CMAr. This difference is consistent with the stronger connections to the motor cortex and spinal cord made by neurons in CMAd/v. Response properties of single neurons within the CMAs are similar to those in supplementary motor cortex (SMA), but SMA neurons respond earlier and more phasically than neurons in the CMAs. These findings suggest that SMA initiates movements while the CMAs contribute to their execution. The PCC differs from ACC by virtue of having a closer linkage to processing spatial information and a less direct role in the generation of voluntary action. Within the PCC, the retrosplenial cortex has been implicated in episodic memory formation and consolidation.

Connections

The cingulate cortex has been described as a neural interface between emotion, sensation, and action. This idea is strongly supported by the presence of anatomical connections linking the cingulate cortex with brain areas closely associated with each of these functions. The centrality of motivational and emotional processing to cingulate function is highlighted by its strong reciprocal connections to the reward centers of the brain, including the orbitofrontal cortex (OFC), the basal ganglia, and, in the case of the ACC, the insula (Figure 1(b)). The ACC is a major target of midbrain dopamine neurons, which respond to a variety of reward-related parameters. In addition, the ACC is reciprocally connected with the amygdala, a collection of nuclei that participates in assigning both positive and negative valence to events. Motivational and emotional inputs to ACC may be directly communicated to the PCC via massive reciprocal connections between these two regions.

Both the ACC and PCC are reciprocally connected with the lateral prefrontal cortex (LPFC), a region implicated in executive control, working memory, and rule learning and expression. The strong connections between the cingulate cortex and the LPFC suggest that the cingulate cortex serves as a gateway for incorporating reward-related information into sensorimotor mappings subserved by the LPFC. Furthermore, the ACC sends strong projections to the locus coeruleus (LC), a brain stem nucleus providing widespread noradrenergic inputs to the rest of the brain. Inputs from the LC to the prefrontal cortex may shift the organism between 'exploit' and 'explore' modes of behavior.

The cingulate cortex also shares strong reciprocal connections with motor structures. These include the primary and supplementary motor cortices and the main cortical regions controlling eye movements, the frontal and supplementary eye fields. The PCC is reciprocally connected with several parietal premotor areas, including 7a, 7m (also connected with ACC), and 7/PG. Both PCC and the caudal CMAs send direct projections to the spinal cord, likely pathways

Figure 1 Anatomical subdivisions of the cingulate cortex and adjacent areas of the cortex. (a) The cingulate cortex anterior to the central sulcus is traditionally known as the anterior cingulate cortex (ACC), while the cingulate cortex posterior to the central sulcus is traditionally known as the posterior cingulate cortex (PCC). The ACC is divided into a rostral perigenual ACC (pACC), a central dorsal ACC (dACC), and the caudal motor regions within the sulcus called the cingulate motor areas (CMAs). The posterior cingulate cortex is generally divided into the more rostral posterior cingulate proper (PCC) and more caudal retrosplenial cortex (Rs). (b) Some, but not all, of the major connections between the anterior and posterior cingulate cortices and other areas in the macaque brain. ACC, anterior cingulate cortex; AMYG, amygdala; Hip, hippocampus; IPL, inferior parietal lobule; LPFC, lateral prefrontal cortex; M1, primary motor cortex; MPC, medial parietal cortex; MTL, medial temporal lobe; OFC, orbitofrontal cortex; PCC, posterior cingulate cortex; SMA, supplementary motor area; VTA, ventral tegmental area.

by which the cingulate cortex most directly controls behavior.

The strong connections between PCC and the parietal cortex suggest that it may play a central role in orienting attention. In fact, the parietal, cingulate, and frontal cortices are often thought to comprise a network specialized for attentional control. Indeed, damage to these areas leads to neglect, a selective deficit in orienting attention. Recent neuroimaging work has suggested that the PCC may participate in selecting locations for enhanced attention while ACC plays a more general, nonspatial role in controlling attention. This idea is supported by the finding that blood flow to PCC increases when spatial attention is shifted contralaterally, whereas blood flow to ACC increases in a nonselective fashion. Cingulate cortex is unique among attentional control areas by virtue of its strong connections to limbic regions, which are thought to be important for reward processing. These connections may serve as a gateway by which reward-related information is integrated with executive processes controlling the allocation of attention.

A final set of important connections is that linking cingulate cortex to structures that form long-term memories. The PCC makes strong reciprocal connections with the hippocampus and the medial wall of the temporal lobe, both of which are associated with consolidation of long-term memories. The ACC shares strong connections with the amygdala, which processes information about emotionally relevant stimuli. Both sets of connections provide a potential mechanism for enhancing long-term memories of motivationally significant events.

Each region of the cingulate cortex is most strongly connected, both anatomically and functionally, to adjacent regions of the cerebral cortex. Thus, pACC, involved in emotional aspects of cognition, is located adjacent to the OFC, which is thought to be the primary cortical site for emotional and motivational information processing. The dACC, concerned with more abstract cognitive processes, is located adjacent to the LPFC and pre-SMA, which are thought to participate in rule representations, working memory, and other abstract cognitive processes. The cingulate motor areas, the most directly motor of the cingulate areas, are adjacent to the primary and supplementary motor areas of the frontal lobe. Finally, the posterior cingulate and retrosplenial cortex, which link rewards with locations in space, are adjacent to the parietal and parahippocampal regions, the chief cortical sites for storing and manipulating spatial representations.

Role of Cingulate Cortex in Behavior

Early Ideas of Cingulate Function

As with many other areas of the brain, early hypotheses of cingulate cortex function were based on the anatomy of the region and its connections. Neuroanatomists in the late nineteenth century identified strong connections from the olfactory bulb to the cingulate cortex, suggesting a prominent role for this area in olfaction. The contrast between the large size of the cingulate cortex and the relative unimportance of olfaction in primates, however, weakened this idea. In 1937, the neuroanatomist James Papez

proposed an emotional role for the cingulate cortex, clearly linked to the widespread importance of olfaction to emotional processing in mammals as well as the strong connections to the cingulate cortex from the hypothalamus, which was then thought to be the source of emotions. Initial support for Papez' model came from Wilder Penfield's studies demonstrating that intracranial electrical stimulation of the hippocampal regions adjacent to the cingulate cortex evoked strong emotional reactions in awake human surgical patients. Additional support for the Papez model came from the results of bilateral cingulotomies on humans with severe depression, schizophrenia, and obsessive–compulsive disorder. Although this procedure, in which the entire cingulate cortex was removed, sometimes alleviated unwanted symptoms, it also resulted in blunted emotions and flat affect.

Early electrophysiological studies of the cingulate cortex used methods that had proven successful in elucidating the functions of primary sensory cortical areas, particularly visual cortex. These early studies, however, showed that cingulate neurons in anesthetized monkeys failed to respond to simple stimuli, such as bars and points of light, which strongly activate neurons in visual cortex. Subsequent studies in awake monkeys have shown that cingulate neurons do respond to large textured patches and other behaviorally salient stimuli, probably because such stimuli attract attention. Although most studies have probed cingulate function using visual stimuli, it is not an exclusively visual structure; neuroimaging studies have revealed PCC activation in response to emotionally relevant (threat-related) auditory stimuli, and these responses depend on the locus of auditory attention. Furthermore, when human subjects are hypnotized, pain-related responses in ACC, but not in somatosensory cortex, are reduced. Collectively, these results suggest that the cingulate cortex is not exclusively a sensory or emotional structure, but instead contributes to cognitive processing of motivationally relevant stimuli and for guiding action.

Role of Cingulate Cortex in Reward-Guided Behavior

Early evidence for the role of cingulate cortex in processing motivational and reward-related information came from studies of intracranial self-stimulation (ICSS) in rats. In the ICSS paradigm, a rat can press a lever to receive direct electrical stimulation from an electrode placed in its brain. The extent to which the rat presses the lever serves as an index of the reinforcing effects of activating this region. The strongest ICSS is evoked by stimulation of the medial forebrain bundle (MFB) or the ventral tegmental area (VTA) in the midbrain. ICSS can also be elicited by stimulation in the ACC and the retrosplenial cortex, as well as in areas connected to the cingulate cortex, including the hippocampus, the orbitofrontal cortex, and entorhinal cortex. While MFB and VTA stimulation causes rats to forsake food to the point of starvation, stimulation in cingulate cortex and related structures has much weaker effects on behavior. Notably, the rate of ICSS elicited by cingulate stimulation does not depend on electrical current or pulse frequency, as it does in the MFB or VTA. Also, unlike VTA and MFB, rates of ICSS elicited by cingulate activation gradually increase over time. One possible explanation for the gradually increasing rates of ICSS in cingulate cortex is that the stimulation slowly potentiates the formation of memories linking the animal's behavioral response with the stimulation. These results suggest that cingulate cortex does not simply generate a reward signal, but rather guides the formation of associations between rewards and sensory-guided actions.

Role of Cingulate Cortex in Selecting Action

Electrophysiological and pharmacological studies strongly implicate cingulate cortex in motor planning, possibly by binding reward-related information to action. One important example of the motor functions of cingulate cortex comes from a study of rhesus monkeys performing a task in which the links between sensory cues, rewards, and motor responses were systematically altered. Monkeys were presented with one of two cues that instructed one of two motor responses (either saccade or maintain fixation), and each motor response either was or was not associated with a reward. All combinations of parameters (sensory cue, motor response, mapping rule, and reward) were tested. In this task, ACC neurons represented both the motor plan and the reward contingency but almost never represent the pure sensory attributes of the cues.

One important question about the motor role of the cingulate cortex is the degree to which motor signals within cingulate cortex are abstract versus specific to a particular action. One study of a human patient with an ACC lesion supports the idea that motor coding in cingulate cortex is specific to a particular type of movement. This patient performed poorly on a Stroop task when manual responses were required, but was not affected when the task required verbal responses. This finding is also consistent with reports that electrical stimulation of cingulate cortex during surgical procedures can elicit uncontrolled hand movements. Together, these results demonstrate that motor representations within the cingulate motor areas are effector specific.

One important aspect of motor selection subserved by the cingulate cortex is the correct sequential ordering of responses. When monkeys perform a series of actions to obtain a single reward, many neurons in the

ACC fire selectively before only one of the actions but do not fire when rewards are given randomly. These results imply that one role of the ACC may be to control the order or timing of behavioral sequences.

Role of Cingulate Cortex in Monitoring Behavioral Outcomes

A substantial body of research has investigated the role of the cingulate cortex in monitoring errors and in evaluating and resolving conflict. These studies follow from the observation that negative electrical potentials are generated within the ACC when subjects make errors in many psychological tasks. This error-related negativity, or ERN, appears around 100 ms after the initiation of an incorrect motor response. A second ERN occurs about 250 ms after the subject is told she has made an error. Because the ERN arises after the behavioral response, it must reflect the consequences of an action rather than its planning or initiation. Moreover, since the ERN is generated independently of the modality of the motor response, it likely reflects abstract cognitive processing rather than movement-specific computations.

Subsequent studies have shown that an ERN is also generated on trials in which there is a high probability of error, but no error actually occurs. These trials are characterized as having high conflict, defined as the tension between two or more incompatible competing motor responses. For example, in a Stroop task, subjects must mediate between the habitual tendency to read the word and the instructed task of naming the color in which the word is printed (Figure 2(a)). When the word and the color are incongruent, these two responses conflict with each other. Conflict signals may trigger an executive control function that initiates increased effort to improve performance on subsequent trials. In support of this idea, behavioral studies have shown that trials with larger ERNs are more likely to be subsequently corrected and that subjects performing high-conflict tasks show the greatest increases in reaction time following trials with the greatest ERN.

These observations are supported by several functional magnetic resonance imaging (fMRI) studies showing hemodynamic responses believed to reflect the same processes that generate the ERN. However, two electrophysiological studies have failed to find any evidence for explicit conflict signals in the activity of single ACC neurons. Together, these observations raise the possibility that the cingulate cortex does not explicitly encode response conflict, but instead encodes all possible motor actions and their likelihood of yielding reward. Because high-conflict conditions may be associated with multiple motor plans, which would recruit multiple overlapping groups of neurons, this might lead to what appears to be a conflict-related BOLD signal. Nonetheless, the precise role of cingulate cortex in conflict monitoring remains unclear.

Figure 2 Behavioral monitoring in ACC. (a) Examples showing the low- and high-conflict conditions of the Stroop task. The Stroop task requires subjects to name the color while ignoring the word. The high-conflict condition (right, incongruent word/color) evokes an increased BOLD response in the dorsal ACC. (b) Cartoon indicating the trial structure of the task used by Shima and Tanji. Subjects can perform one of two actions (turn or push a handle). One action is consistently rewarded (i and ii). At some point, the rewarded action is switched (iii). A normal subject will alter the strategy at this point to begin receiving rewards again (iv). Monkeys with reversible ACC lesions fail to reliably adopt the new strategy. Recent work has shown that monkeys with permanent ACC lesions can adopt the new strategy for a few trials, but soon revert to the former strategy (v).

Both electrophysiological and neuroimaging studies consistently report that cingulate cortex seems to be more active when subjects actively search for the optimal strategy to solve a task than when they simply follow arbitrary rules. Enhanced activity is seen in ACC in tasks that require unspecified responses (e.g., word-generation tasks) or in monkeys when movements are triggered internally rather than in response to explicit external cues. Moreover, neurons in ACC are more active when monkeys endeavor to learn the order in which they must press three squares on a computer screen than after they have learned the sequence. Similarly, BOLD activity in ACC is much stronger when human subjects monitor the monetary payoffs associated with pressing buttons and try to maximize their yield than when they merely follow explicit instructions.

Role of Cingulate Cortex in Assigning Motivational Significance to Potential Actions

One model of cingulate cortex function that may account for most of the foregoing observations purports that the general function of cingulate

circuitry is to link reward information to potential sensory-guided actions. This model is supported by the findings (described above) that cingulate cortex participates in both sensory and motor processing and, moreover, appears to integrate reward information into the context of ongoing sensorimotor transformations. According to this view, cingulate cortex provides a functional linkage between limbic areas and cortical sensory and motor areas.

One landmark study supporting this model demonstrated that cingulate cortex participates specifically in reward-based guidance of action. In this study, monkeys grasped a joystick that they could either lift or turn on each trial (Figure 2(b)). One of these actions was rewarded and the other was not. The only way the monkey could identify which action was rewarded was to monitor the consequences of their actions. When reward value associated with one action declined, the monkey could switch to the other action to receive a larger reward. Reward-related switches in behavior elicited high firing from neurons in CMAs. Moreover, temporary lesions in this area abolished the animal's ability to modify its behavior based on changing rewards. Later work has shown that permanent lesions to the ACC do not specifically impair the ability to modify behavior in response to changing outcomes, but instead disrupt the ability to sustain new behavioral strategies following the reward-guided switch. These results suggest that the ACC specifically participates in the reward-based consolidation of new behavioral strategies.

Further support for a role for cingulate cortex in integrating reward outcomes into ongoing sensorimotor transformations comes from the finding that ACC does not represent abstract stimulus–reward mappings when they have no influence on the selection of motor responses. In one study, monkeys were trained to perform two different tasks. One task was a variant of the reward-based switching task, as described above, in which monkeys performed one of two actions (lift or turn a handle) in response to a reward. The other task was a visual discrimination task in which monkeys learned to associate one of two stimuli with a reward and then select the

Figure 3 Visuospatial information encoded by neurons in PCC is modulated by reward variables. (a) Neurons in PCC have large contralateral response fields. Color map showing average response of a single neuron following saccades to points in a grid of locations, size 40×40 degrees. Responses are greater when saccades are directed to the upper-left quadrant (response field, RF). (b) PCC neurons encode reward size associated with saccades into their RF. Peri-stimulus time histograms (PSTHs) showing the temporal evolution of the average response of a single PCC neuron in a free choice task. Responses are significantly greater on high reward trials (black line) than on low reward trials (gray line). This modulation affects both the decision period and the postsaccade period of the trial. (c) PCC neurons encode reward uncertainty, or risk, even when average expected payoff is identical. PSTHs showing the average response of a single PCC neuron in a free choice task. Responses are greater when subject chooses to shift gaze to the risky target (black line). (d) PCC neurons respond following unexpected rewards. PSTH showing average response of a single PCC neuron when an unexpected reward is delivered. rewarded stimulus. ACC-lesioned monkeys were specifically impaired in their ability to perform the reward-based switching task but their performance was unaffected in the visual discrimination task.

Reward-related computations within cingulate cortex are not limited to the ACC. Neurons in the PCC, for example, represent the subjective value of rewards associated with orienting toward particular locations in space (**Figure 3**). PCC neurons respond after the illumination of targets, saccade onset, and following reward delivery. Because PCC neurons respond in proportion to the size and probability of rewards, as well as subjective preference for uncertain rewards associated with orienting to a visual target, it has been hypothesized that firing rate in PCC is proportional to the subjective utility of a location in space. The responses of PCC neurons to events within a trial may reflect continuous updating of the subjective utility of the preferred location. Collectively, these results suggest that PCC, like ACC, participates in connecting information about rewards to ongoing sensorimotor transformations.

Conclusion

The cingulate cortex has long been viewed as a large and mysterious terra incognita. Nonetheless, a great deal of knowledge has been gained in recent years. This knowledge, derived from single-unit electrophysiology, lesion studies, fMRI, and event-related potential (ERP) studies, implicates the cingulate cortex in the use of reward information to optimize the process of selecting actions based on sensory information.

Circadian Function and Therapeutic Potential of Melatonin in Humans

The Circadian Function and Therapeutic Potential of Melatonin in Humans

Melatonin is a neurohormone produced by the pineal gland, almost exclusively at night. It was discovered in 1958 by Aaron Lerner, a dermatologist and chemist, who was interested in pigmentation disease. Although melatonin does not have skin-lightening effects in humans, Lerner's work in amphibians eventually led to the discovery that endogenous melatonin production is a central part of the biological timing system. Almost 50 years after its isolation and identification from bovine pineal glands, this neurohormone is now recognized as the best biomarker for endogenous circadian phase. Commercially synthesized from chemical reagents, exogenous melatonin is available for human use, either over-the-counter or by prescription, depending on the country of sale.

The following, complemented by several articles in a 2005 volume of the *Journal of Biological Rhythms* dedicated to human circadian rhythms, provides a comprehensive review of the circadian aspects of melatonin. Work in this area is increasing exponentially. Accordingly, we have included very recent findings, including some as yet unpublished. These findings extend the relevance of this contribution beyond that of a historical review.

Melatonin and 6-Sulfatoxymelatonin

Development of melatonin assays in the 1970s opened up new possibilities for human studies of circadian rhythms. The principal metabolite of melatonin is 6-sulfatoxymelatonin. A convenient way to estimate the total amount of melatonin production in a 24 h period is to collect urine overnight and measure this metabolite, provided that metabolism of melatonin by the liver is within normal limits. However, frequently assessed plasma or salivary levels allow for a more highly resolved use of melatonin as a phase marker.

Melatonin Gas Chromatographic-Mass Spectrometric Assay and Radioimmunoassays

As measured by the 1978 gold-standard gas chromatographic-mass spectrometric (GCMS) assay, melatonin levels in normal humans are less than $10\,\mathrm{pg\,ml^{-1}}$ during the day and increase to several times that amount at night. Melatonin levels are almost always reported in picograms per milliliter, although occasionally picomoles per liter ($43\,\mathrm{pmol\,l^{-1}} = 10\,\mathrm{pg\,ml^{-1}}$) have been substituted. The GCMS assay uses negative chemical ionization and a deuterated internal standard, and it has the greatest precision, accuracy, and sensitivity of any assay. It has directly and indirectly validated the radioimmunoassays (RIAs) that are widely used today because of their convenience and efficiency. One of the first applications of the GCMS assay was to show that virtually all of the circulating levels of melatonin are derived from the pineal gland, thus validating the measures of plasma and salivary melatonin as markers of pineal function. In particular, the timing of endogenous melatonin production can be used as a marker for the phase of the circadian pacemaker (located in the suprachiasmatic nucleus (SCN)).

Bright (High-Intensity) Light

The GCMS assay was also employed in the discovery that light can suppress melatonin production in humans. Humans require brighter light for melatonin suppression than other animals. In addition to melatonin assay methodology, this explains why light suppression of melatonin in humans was not reported until 1980, although it was attempted earlier. The interspecies difference was thought to be adaptive, that is, to be a short-term response to a previous history of light exposure. Several studies have since shown that the intensity of recent ambient light exposure determines the degree of suppression of melatonin to light – the brighter the light, the greater the suppression of melatonin production.

Melatonin Suppression Test

Intensity-dependent suppression of melatonin by light is the basis for the melatonin suppression test (MST). Originally, subjects were exposed to 500 lux light between 2 and 4 a.m. This intensity was used in order to compare the degrees of partial suppression between individuals or groups of individuals (such as manic-depressive patients). Variations of this test have been applied in a number of different ways. Although it is assumed that sensitivity to light as determined by this test reflects the overall sensitivity of the circadian system to light, as presently operationalized this test does not appear to be useful in determining the patency of the retinohypothalamic innervation of the

SCN of the hypothalamus in blind people, due in part to a lack of sensitivity and specificity of this test as a biomarker in the blind.

Suppression of melatonin by light has at least four important implications. First, humans might have biological rhythms that are regulated by exposure to (bright) outdoor light, remaining relatively unperturbed by ordinary-intensity indoor light. Second, bright artificial light might be substituted for sunlight to experimentally, and perhaps therapeutically, manipulate biological rhythms in humans. Third, totally blind people with no light perception might have abnormal circadian rhythms. And fourth, measurement of the melatonin rhythm in sighted people should be done under dim light to avoid masking its true circadian phase.

Seasonal Affective Disorder, or Winter Depression

Based on these implications, the administration of bright light was first used as a treatment in patients with both nonseasonal and seasonal depression. However, more than 25 years later, much still remains to be known about light's efficacy, optimal treatment parameters, and mechanism of action in nonseasonal depression. On the other hand, bright light is now established as the treatment of choice for winter depression, or seasonal affective disorder (SAD). In fact, the most common use of bright light is for the treatment of SAD, although it is also used for treating advanced and delayed sleep phase syndromes, jet lag, and shift-work maladaptation. SAD and winter depression are two terms that are used interchangeably because there do not appear to be other types of mood disorders that recur at the same time each year in patients studied longitudinally – despite the fact that cross-sectional studies show fall and spring peaks in depression and an increased incidence of mania in the summer.

Phase Shift Hypothesis

The leading hypothesis for SAD and the antidepressant mechanism of bright light is the phase shift hypothesis (PSH). According to the PSH, winter depression is at least partly related to a misalignment between circadian rhythms and the sleep/wake cycle that occurs because of the shorter winter days. The prototypical patient with SAD is thought to become phase-delayed in the winter, cueing to the later dawn. Thus, their circadian rhythms, which are tightly coupled to the SCN, shift later with respect to their sleep/wake cycle. Some atypical patients with SAD may be cueing to the earlier dusk and phase advance in the winter. In either case, bright light should be scheduled to provide a corrective realignment. For most (phase-delayed) patients, the optimal timing of light is in the morning, immediately on awakening. The usual intensity is 10 000 lux of ordinary (cool white) fluorescent light, delivered by a light box set at a precise distance from the eyes; 1–2 h of light may be necessary for several days until the antidepressant response is complete, and then the duration of exposure can be reduced. Too much light can also overly phase shift circadian rhythms, causing a misalignment in the opposite direction, which might be the case if patients relapse after a brief response. If morning light is not at all efficacious, a trial of evening light (7–9 p.m.) is in order. Light exposure at both times is not recommended because the phase advance from morning light will be counteracted by the phase delay due to evening light.

Dim Light Melatonin Onset as a Marker for the Phase of the Endogenous Circadian Pacemaker

In sighted people, the best marker for circadian phase is the dim light melatonin onset (DLMO). Suppression of melatonin production by light is to be avoided when using the endogenous melatonin profile as a marker for the underlying phase of the endogenous circadian pacemaker. Removing this masking effect by collecting samples under dim light (light intensities of less than 10–30 lux that begin 1–2 h before the earliest expected rise in melatonin levels) increases the reliability that the melatonin profile is reflecting the true phase of the endogenous circadian pacemaker. The DLMO does not represent the time that melatonin rises under naturalistic lighting conditions, in which the melatonin profile reflects both the timing of the endogenous circadian pacemaker and the gating effect of darkness (suppressant effect of light). The naturalistic profile represents the melatonin signal that is actually presented to the individual living under conditions of ambient light. If a function for endogenous melatonin production in humans is identified, it will be best understood as mediated by the melatonin profile assessed under naturalistic lighting conditions.

Dim Light Melatonin Offset and Melatonin Synthesis Offset

In blind individuals (and in sighted people) studied under naturalistic conditions, the margins of the active phase of melatonin are the melatonin onset (MO) and melatonin offset (MOff). The three features of the melatonin profile that most easily lend

Figure 1 The three features of the melatonin profile that most easily lend themselves for marking circadian phase in sighted people: the dim light melatonin onset (DLMO), dim light melatonin offset (DLMOff), and melatonin synthesis offset (SynOff). PAD, phase angle difference.

themselves for marking the circadian phase in sighted people are the DLMO, dim light melatonin offset (DLMOff), and melatonin synthesis offset (SynOff). These are illustrated in Figure 1. The operational definition of the plasma DLMO (and the DLMOff) is usually the interpolated clock time when levels continuously rise above (or fall below) the threshold of 10 pg ml^{-1}. Saliva concentrations at these times are about one-third those of plasma; the corresponding salivary threshold is therefore 3 pg ml^{-1}. For both saliva and plasma, samples are ideally collected every 30 min.

The SynOff, which is the time when melatonin levels begin to decline, is recommended for assessing the putative second oscillator. For many years, some investigators thought that the human melatonin profile was regulated by two oscillators, which may be true for rodents and other organisms. According to the two-oscillator model, the SynOff is regulated by a separate pacemaker that is cued to dawn. Although the issue has yet to be resolved, there appears to be increasing consensus that if there are two oscillators in humans, they are tightly phase-locked under most circumstances. Therefore, the measurement of any of these markers should provide the same information about circadian phase. In sighted people, the DLMO is the marker of choice because collecting samples usually does not interfere with sleep and can be done at home (using saliva).

Phase Angle Difference, Circadian Misalignment, and Phase Typing

Phase angle difference (PAD) is the time interval between two circadian rhythms, for example, between the DLMO and midsleep. On average, the interval between the 10 pg ml^{-1} plasma DLMO and the midpoint of sleep is 6 h (PAD 6), and the interval between the 2 pg ml^{-1} DLMO ($DLMO_2$) and the midpoint of sleep is 7 h (PAD 7). (Unless otherwise specified, DLMO refers here to the 10 pg ml^{-1} plasma threshold.) PAD 6 appears to represent the optimal mood in SAD patients, before and after treatment with low-dose melatonin (Figure 2). PAD 6 has also been used to operationally define phase-advanced (PAD $6 > 6$ h) and phase delayed (PAD $6 \leq 6$ h) types; the former characterizes people with a DLMO that is phase advanced with respect to sleep, and the latter (typical of patients with SAD) characterizes individuals with a DLMO that is phase delayed with respect to sleep. Phase-delayed SAD patients are optimally treated with bright light in the morning and/or low-dose melatonin in the afternoon/evening; phase-advanced SAD patients are optimally treated with bright light in the evening and/or low-dose melatonin in the morning. Phase typing based on PAD 6 may prove to be useful in the diagnosis and treatment of other disorders as well; however, the circadian component in nonseasonal depression is not likely to be as important as it is in SAD, in which it may explain as much as 65% of the variance in depression ratings (Figure 2).

Zeitgeber Time

The time interval between the DLMO and the entraining zeitgeber (environmental time cue) is the zeitgeber time (ZT) of the DLMO. This can also be used to estimate the phase angle of entrainment (PAE). By tradition, the time interval between waketime (lights on) and the DLMO is the DLMO ZT. On average, the DLMO occurs 14 h after waketime. Thus, the average DLMO ZT is 14.

Phase Angle of Entrainment and Circadian Period

The DLMO ZT can be used to estimate the PAE. However, this assumes that the conveniently measured sleep variable, waketime, faithfully represents the phase of reference for the primary zeitgeber, the light dark cycle, an assumption grounded in the fact that the sleep/wake cycle superimposes structure on the perceived light dark cycle. As more is understood about the circadian response to light (and dark), this reference phase will be calculated with greater accuracy. At present, however, we must deal as best we can with the fact that waking up into bright sunlight results in a shorter PAE (DLMO ZT) than awakening before dawn, a fact that complicates extending findings from studies in which animals with shorter intrinsic periods (taus) entrain to a 24 h zeitgeber with a shorter PAE. (Unless otherwise specified, intrinsic tau is assumed here to be greater than 24 h, which is

Figure 2 Mood in prototypical SAD patients after treatment with low-dose melatonin given in the afternoon/evening to provide a therapeutic phase advance. PAD 6 appears to represent optimal mood in SAD patients. PAD, phase angle difference; SIGH-SAD, Structured Interview Guide for the Hamilton Depression Rating Scale, for Seasonal Affective Disorder.

clearly the case for the majority of humans.) The animal studies were conducted under conditions in which the light/dark cycle was much more strictly controlled than the measurement of DLMO ZT in humans exposed to their usual light/dark cycles. However, under laboratory conditions, sighted humans with shorter taus have also been shown to have shorter PAEs, a finding consistent with what was found in blind people entraining to a daily dose (10 mg) of melatonin. PAE has also been estimated in humans using the melatonin/sleep onset interval (MSI). Another consideration is that PAD is most meaningful when measured under naturalistic conditions, whereas PAE is most useful when measured under controlled lighting and stabilized sleep/wake experimental conditions.

Circadian Time

The clock time of the DLMO is of importance, and so is its circadian time (CT). By tradition, CT 0 is waketime (lights on). Because the DLMO occurs 14 h on average after waketime, the 10 pg ml^{-1} plasma DLMO is designated CT 14. It is heuristically useful (if not always empirically demonstrable) to refer to the DLMO as CT 14. This is particularly useful for understanding the phase-shifting effects of light and melatonin, that is, at what time these phase-resetting agents cause phase advances versus phase delays.

CT and ZT are sometimes used interchangeably. CT is more appropriately used in free-running blind people, whereas ZT is more appropriately used under conditions of entrainment, the usual circadian status of sighted individuals. However, designating the DLMO as CT 14 in sighted people is also useful for assessing the phase of the light and melatonin phase response curves (PRCs). It has been known for almost 2 decades that scheduling these phase-resetting agents according to CT rather than clock time optimizes their effects because CT takes into account individual differences in circadian phase.

The Light and Melatonin Phase Response Curves

As already mentioned, morning light causes phase advances, and evening light causes phase delays in entrained individuals. These times account for two points on the light PRC, which is usually plotted according to CT. Light and melatonin PRCs are provided in Figure 3. Research in this area is active, and the precise shapes of these curves will probably be refined over the next few years. In essence, however, there is a 12 h zone for phase advances and a 12 h zone for phase delays; that is, a phase-resetting agent will cause phase advances when initiated at any time within its PRC's phase-advance zone and will cause phase delays when initiated at any time within its PRC's phase-delay zone. Until more is known about

Figure 3 Light and melatonin phase response curves (PRCs). Copyright (1998) From The human phase response curve (PRC) to melatonin is about 12 h out of phase with the PRC to light. *Chronobiology International* by Lewy AJ, Bauer VK, Ahmed S, et al. Reproduced by permission of Taylor & Francis Group, LCC., http://www.taylorandfrancis.com.

these PRCs, it is at least heuristically useful to consider them to be 12 h out of phase with one another and to consider the crossover times to be CT 6 and CT 18, 8 h before and 4 h after the DLMO, respectively. For a person whose DLMO is at 8 p.m., these convert to clock times of noon and midnight, so a useful mnemonic is that the phase advance zone for light (the phase delay zone for melatonin) occurs during the morning hours, whereas the phase delay zone for light (the phase advance zone for melatonin) occurs during the afternoon/evening hours (Figure 4).

Figure 4 Phase advance and delay zones for a person whose DLMO is at 8 p.m.: (a) the phase advance zone for light occurs during the morning hours and the phase advance zone for melatonin occurs during the afternoon/evening hours; (b) the phase delay zone for light occurs during the afternoon/evening hours and the phase delay zone for melatonin occurs during the morning hours. Reproduced from Lewy AJ and Sack RI (1996) The role of melatonin and light in the human circadian system. Amsterdam: Elsevier, with permission from Elsevier.

Blind Free-Runners

Approximately 15% of legally blind people are totally blind (unable to detect light). Most totally blind individuals free-run and are called bind free-runners (BFRs). BFRs have observed taus that are usually slightly greater than 24 h (24.1–25.0 h). Almost all BFRs can be entrained to a daily dose of melatonin. A BFR will stop free-running when the exogenous melatonin dose comes into contact with the entrainment point on the melatonin PRC, which for most BFRs is in the advance zone. Tau appears to be related to an inherited trait determined by clock genes. Although not proved, it is convenient to think of people with shorter intrinsic taus as morning types and to think of people with longer intrinsic taus as evening types. Some people have taus slightly shorter than 24 h; they are most assuredly morning types.

Low physiological doses appear to be sufficient for entrainment and may be more effective than some higher doses, presumably because of spillover of these high doses onto the wrong zone of the melatonin PRC. For example, higher doses taken on the advance zone always results in a phase advance, but spillover on to the delay zone reduces the magnitude of the phase advance. Spillover, and other pharmacokinetic parameters, may explain why not all BFRs have been shown to be entrainable to a daily dose of melatonin. Another explanation for failure to entrain has been the finding that initiating treatment on the delay zone will reduce the likelihood of entrainment even after the MO

has transited through a complete 24 h circadian beat cycle (defined later); however, this finding is inconsistent with animal studies and has not been replicated by other research groups (for any doses of melatonin). In any event, low doses (0.5 mg) almost always result in the entrainment of BFRs. They are optimally given around 6 p.m. to entrain most BFRs to the normal phase. BFRs with taus <24 h require melatonin at waketime to be entrained at the normal phase. Low doses are effective at both of these administration times, which has the added benefit of minimizing the soporific side effect that sometimes occurs immediately after taking melatonin. A melatonin dose–response curve has recently been described and appears in Figure 5; the daily phase advance for the lowest entraining dose of melatonin was calculated by subtracting 24 h from tau at entrainment phase (TEP).

As already mentioned, the measurement of MOs is particularly important in doing research in blind people and may have clinical relevance as well. Assessing the MO is essential when determining the CT of exogenous melatonin administration. In research studies, exogenous melatonin is not administered on days when endogenous melatonin levels are assessed. The CT of administration can still be estimated in the following way: if a BFR's MO occurs at 3 a.m. the day before restarting treatment at 6 p.m., melatonin given at 6 p.m. will be on the delay zone (CT 5) of the melatonin PRC (the delay zone begins at CT 6, which is 8 h before the MO). Thus, we can be virtually certain that the BFR has escaped entrainment.

Relative Coordination to Weak Zeitgebers, the Two-Point Tau, the Tau Response Curve, and Tau at Entrainment Phase

A circadian beat cycle in a BFR is completed when the MO transits through 24 h. Every BFR studied to date with high resolution (an MO assessment approximately every 2 weeks through a complete circadian beat cycle) shows relative coordination to as-yet-unidentified weak zeitgebers (Figure 6). The pattern of response in all BFRs is the same; as the MO drifts across the day, the two-point tau between each successive pair of MOs is longer than the BFR's average tau, and as the MO drifts across the night, the two-point taus are shorter than average. These two-point taus can be plotted against the average clock time of the two MOs to produce a tau response curve (tauRC). Figure 7 provides tauRCs from two BFRs. The pattern of response to the weak zeitgebers (which may include social cues) is the same for all BFRs; however, the range of oscillation (the difference between the shortest and longest two-point taus)

Figure 5 Melatonin dose–response curve. TEP, tau at entrainment phase. Copyright (2005) From Melatonin free-running blind people according to a physiological dose response curve. *Chronobiology International* by Lewy AJ, Emens JS, Lefler BJ, Yuhas K, and Jackman AR. varies markedly between individuals. Identification of the weak zeitgebers and demonstration that they are regular in strength and timing will validate the use of range of oscillation not just as a bioassay of responsivity but of an individual's sensitivity to the weak zeitgebers. The tauRC of a BFR can also be used to calculate TEP, which is important in calculating the physiological dose–response curve for melatonin. TEP is the two-point tau a BFR would be expected to have while free-running through the clock time of the now-entrained MO.

Figure 6 Pattern of response in blind free-runners (BFRs), with melatonin onset (MO) assessment approximately every 2 weeks through a complete circadian beat cycle. A different symbol is used for each BFR. Reproduced from Emens JS, Lewy AJ, Lefler BJ, and Sack RL (2005) Relative coordination to unknown weak zeitgebers in free-running blind individuals. *Journal of Biological Rhythms* 20(2): 159–167.

Natural Entrainment

As already mentioned, most totally blind people are BFRs. Some totally blind people, however, appear to naturally entrain to the unknown weak zeitgebers. A more rigorous operational definition is required for natural entrainment than for entrainment to melatonin. In order to designate a blind person as naturally entrained, a tau very close to 24.00 h must be ruled out, as well as a transient short tau, observed as the MOs move through the short-tau zone during relative coordination. Recent evidence suggests that, among adults, males are less likely to be naturally entrained than females, a potential difference in sensitivity to the weak zeitgebers that is apparent after puberty (in fact, there is a suggestion that prepubertal males may be more likely to be naturally entrained than females). Furthermore, the range of oscillation in adult female BFRs is significantly greater than in adult males. These findings led to the prediction that sighted adult females would have an advanced PAE compared to adult males. This is based on the fact that human intrinsic tau is usually greater than 24 h, thus requiring a daily phase advance for entrainment; more sensitivity to the overall set of zeitgebers would therefore result in an earlier PAE. These findings are consistent with those in *Octodon degus*, a diurnal rodent, in whom social cues and pheromones have been shown to be sex-specific.

The Function of Endogenous Melatonin in Humans

The precise circadian function of endogenous melatonin production remains to be demonstrated. This

Figure 7 Tau response curves for two blind free-runners (BFRs). The pattern of response to the weak zeitgebers is the same for all BFRs; however, the range of oscillation (the difference between the shortest and longest two-point taus) varies markedly between individuals. MO, melatonin onset.

function, as postulated in the first description of the human melatonin PRC, is dependent on the acute suppressive effect of light, which has been retained in humans who do not seem to have marked seasonal differences in the duration of the naturalistic profile. Taking into account that a truly useful circadian melatonin signal must come from a person who is entrained to the light/dark cycle, the main function of endogenous melatonin in humans may be to synchronize the third trimester fetus and the suckling infant to the mother. At about 3 months of age, the retinohypothalamic tract is fully functional and the infant can independently synchronize to the light/dark cycle. This would be an important area for future research.

Circadian Gene Expression in the Suprachiasmatic Nucleus

M U Gillette and S-H Tyan, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Introduction

Regulated expression of a core set of clock genes is the basis of circadian timekeeping in vertebrates, as in other organisms. Clock genes are defined as being necessary to generate normal circadian rhythms, near 24 h oscillations in biological processes. With the enlargement of the brain in vertebrates, control of circadian rhythms became centralized. In lower vertebrates, such as fishes, lizards, and some birds, the pineal gland, near the surface of the brain, is directly photosensitive and exerts significant circadian control. In mammals, the pineal is overlain by enlarged cerebral hemispheres and is no longer photoreceptive. The central circadian clock of mammals resides within the suprachiasmatic nucleus (SCN) of the hypothalamus.

Clock genes are under study in the range of vertebrate taxa, but have been most fully studied in the mammalian SCN. Rhythmic expression of clock genes within the SCN is required for the production of circadian rhythms throughout the brain and body. Circadian clock genes also are expressed rhythmically in the cells of most tissues. Clock gene expression modulates myriad processes that oscillate daily at levels from behavior to tissue-specific cellular function. States of sleep and arousal, release of neuroendocrine hormones, autonomic control of organs, contractile strength of muscle, and production of liver enzymes all oscillate with circadian rhythmicity. Regulated clock gene expression within the SCN enables this central clock to act as the conductor to the orchestra of local body clocks. In concert, these circadian clock-driven oscillations enable the organism to anticipate predictable changes in the environment, to coordinate diverse internal processes, and to align itself adaptively with the major variable in its environment, the cycle of night and day.

Circadian rhythms emerge from cell-autonomous processes, posttranslational modifications (PTMs) of clock proteins that regulate transcriptional-translational feedback loops of clock genes. These cellular processes together form a dynamic timekeeping mechanism with a near-24 h period. Interlocking positive and negative feedback loops wherein clock proteins alternately activate or repress transcription is the apparent basis of the circadian clocks in plants and diverse animals, including mammals. Key to the oscillatory process is the tight regulation of proteins encoded by clock genes; during their lives within the circadian cycle, clock proteins associate dynamically with other clock proteins to form macromolecular assemblies, move between different subcellular compartments, and undergo extensive changes in post-translational state and stability.

The regulated expression of clock genes and proteins underlies the three primary components of the circadian system as it functions within the organism: the central clock, which generates the circadian time base in the SCN; input pathways, by which light entrains the SCN clock to the day–night cycle; and output pathways from the SCN, which transmit timing information beyond the central clock.

1. Within the central clock, clock genes and proteins form the core timekeeping mechanism. Some clock proteins are transcription factors that regulate their own transcription and that of other clock genes. Others are kinases, enzymes that add phosphate groups, reversible PTMs that profoundly alter the functioning and associations of substrate clock proteins.
2. The input pathways, which transmit signals to the SCN, adjust and align the clock's time base. This requires that incoming signaling pathways engage the molecular clockwork. Thus, neurotransmissions to the SCN initiated by light at the retina must activate signal transduction events that target clock proteins and genes.
3. The output pathways, which transmit signals from the clock, are initiated by clock proteins via effects on transcription of genes that are not part of the timekeeping mechanism. These clock-controlled genes enable the central clock to communicate time-of-day information to the brain and body. Outputs include neural and humoral signals from the SCN that are regulated by the clock and bear time-of-day information to peripheral clocks. There, clock proteins drive the expression of tissue-specific output genes throughout the genome. This enables peripheral clocks in the diverse cells of the body to regulate local circadian functions in tissue-specific ways.

This review evaluates present understanding of the expression of circadian clock genes in the mammalian SCN. This is an area of rapid flux; insights are still developing. Extrapolations have been made from the well-studied *Drosophila* model, but must be regarded cautiously, with the recognition that functional differences in some clock elements are emerging. We consider (1) putative circadian clock genes, (2) SCN clockwork mechanisms, (3) the structural and

functional features of clock proteins, (4) patterns of clock gene expression in the SCN, (5) the regulation of clock mRNA/protein expression and function, and (6) the effects of light.

Putative Circadian Clock Genes

Cross-species genomic comparisons of putative clock genes suggest striking similarities in the molecular circuits within timekeeping mechanisms across diverse circadian clockworks. The regulatory circuits are proposed to comprise interacting proteins – transcription factors together with their modifying kinases and phosphatases. These clockwork elements form similar transcriptional-translational feedback loops in phylogenetically distant organisms. Elements of such molecular circuits have been found in unicellular photosynthetic blue-green algae (*Cyanobacteria*), the bread mold (*Neurospora*), the fruit fly (*Drosophila*), the flowering plant (*Arabidopsis*), a number of rodents (rat, hamster, and mouse) and humans (*Homo*). Within animal lineages, the principal clock genes are largely conserved. Where differences appear, they can be traced deep into basal lineages; some clock genes are more similar between mouse (*Mus*) and honeybee (*Apis*) than between bee and fruit fly. This indicates that circadian clocks are ancient and that clockwork elements have been under high selective pressure to be conserved during evolution.

Circadian clock genes are identified by phenotypic profiles as those genes necessary for the generation of circadian rhythms. Key loci are defined by gene mutations, genetic deletions, or molecular manipulations that alter the period by $\geq$3 SD (standard deviations) from mean wild-type rhythms or completely abolish circadian rhythms (Table 1). Although our understanding is growing, the roles of putative clock elements in circadian rhythm generation are less well-established in mammals than in more tractable genetic models, such as *Drosophila*. Orthologs of some fly clock genes exist in mammals and probably perform similar roles in timekeeping. However, mammals may express multiple paralogs, distinct genes with high sequence similarity, probably evolved from a single ancestral gene. For example, *Drosophila Period* (*dPer*), the first animal clock gene identified, exists as a single gene, an ortholog of three paralogous mammalian *Period* genes (*Per1, 2, 3*). Of the three, *Per2* is thought to function as the core clock element, whereas *Per1* probably acts in the input pathway and *Per3* contributes to output functions. Other putative mammalian clock genes are ancestrally distant from those in the fly. New evidence indicates that mouse *Cryptochrome* (*mCry*) *and Timeless* (*mTim*) genes are divergent in sequence and expression pattern from related genes in *Drosophila* but are similar to *Apis*. These differences complicate deciphering timekeeping circuits in mammals.

A working model for the SCN clock has been developed based on overall similarities to the fly model of the structure and regulatory features of putative mammalian clock genes and proteins, their temporal expression patterns, and their functional characteristics. The circadian clock in the SCN is predicted to emerge from interactions among 10 transcription factors encoded by putative clock genes: *CLOCK* (*Clk*), *Bmal1/Mop3* (hereafter, *Bmal1*), *Period* (*Per 1, 2, 3*), *Cryptochrome* (*Cry 1, 2*), *Timeless* (*Tim*),*Rev-erbα* (orphan nuclear receptor), and *Ror* (retinoid orphan receptor). Two putative clock genes encode kinases: *casein kinase I epsilon* (*CKIε*) and *glycogen synthase kinase 3 beta* (*GSK3β*). No phosphatases have yet been identified as mammalian clock elements; however, the strong evidence for clock genes encoding protein kinases in mammals predicts that counterbalancing phosphatases also form the core clock mechanism. An additional feature is that clock elements must be expressed appropriately in temporal and spatial domains. Thus, present models are incomplete and limited by our knowledge, but they are

Table 1 Mutation phenotype and SCN expression patterns of clock genes

Gene	*Mutation phenotype*	*Peak mRNA expression*	*Peak protein expression*
Clock	Longer period (+4 h); arrhythmicity in DD	Constitutive	Constitutive

Cry2	Longer period (+1 h)	CT 8–16	CT 12–16

DD, constant darkness; ODN, oligodeoxynucleotide; SCN, suprachiasmatic nucleus.

useful for conceptualizing this complex dynamic process.

Thus far, relatively few clock components have been found in mammals. We might ask if there are new clock components to be discovered: doubtless there are. New candidate clock genes are being reported as potential components of core clock mechanisms. In addition, microarray data have shown that approximately 10% (hundreds of genes) of all detectable transcripts in mice tissue express circadian patterns. Large-scale genomic approaches will likely reveal new candidate genes for testing functionally, which will no doubt cause us to revise core clock mechanisms.

Suprachiasmatic Nucleus Circadian Clockwork Mechanisms

Fundamental to circadian clocks is that different sets of clock proteins act as positive and negative regulators of clock gene expression (Figure 1). This relationship sets up positive and negative feedback loops, dynamic relationships that characterize biological oscillators of many types. Because circadian clock gene expression requires regulating multiple transcriptional, translational, posttranslational, and translocational processes, the time domain of the circadian clock is long relative to other biological oscillators.

Figure 1 A model of positive and negative transcriptional feedback loops formed by clock proteins within cells of the SCN. When CLK and BMAL1 together bind to E-box sequences in promoters of other genes, they activate transcription. This forms a positive loop, enhancing transcription. In this model, they activate transcription at *Per, Cry,* and *Tim* genes producing mRNAs (small oscillatory lines). These mRNAs are translated in the cytoplasm into PER, CRY, and TIM proteins, which eventually translocate to the cell nucleus. This process is thought to be driven by posttranslational modifications (PTMs) and protein–protein interactions that stabilize the proteins and favor nuclear localization. Within the nucleus, PER, CRY, and TIM associate with the CLK-BMAL1 complex at E-boxes of the *Per, Cry,* and *Tim* gene promoters. This represses transcriptional activity at these genes, closing the negative loop of clock gene regulation. The affinity of the complex changes the association of PER, CRY, and/or TIM, which dissociate from the complex. Upon release, they may be ubiquinated and then degraded. This tips the balance toward the positive feedback loop and the cycle repeats. The period of each cycle is ~24 h.

The proposed mammalian clockwork mechanisms follow. The protein products of the putative clock genes *Clk* and *Bmal1,* CLK and BMAL1, respectively, regulate a positive feedback loop. Under appropriate conditions, these proteins dimerize, translocate to the cell nucleus, bind to E-box (CACGTG)-containing *cis*-regulatory sequences in target genes and initiate transcription. BMAL1 transcriptional activation requires a coactivator, acetylate 3. Recently, CLK itself was found to be a histone acetyl transferase. Among the genes that CLK and BMAL1 activate are the putative clock genes of the *Per* and *Cry* families. In *Drosophila,* target clock genes include *Timeless* (*dTim1*), but it is not known whether they activate mammalian *Timeless* (*mTim*).

Transcription-translation of the *Per* and *Cry* genes initiates a negative feedback loop. PER and CRY accumulate in the cell cytoplasm for part of the circadian cycle. Conformational changes induced by protein–protein interactions and/or PTMs expose nuclear localization sequences (NLS) and target the cell nucleus with these proteins. Nuclear transport/shuttling mechanisms for clock proteins are not understood. Within the nucleus, PER and CRY form multimeric complexes with CLK:BMAL1, still bound to the E-boxes in *Per* and *Cry* promoters. This leads to a reduction in histone acetyltransferase activity, which decreases histone H3 acetylation and transcriptional activation, thereby inhibiting the positive loop. This important control point leads to the cessation of production of mRNA from the *Per* and *Cry* genes, and their proteins are degraded. This closes a negative feedback loop. The loss of CRY and PER proteins poises the system to reenter the positive loop phase. TIM can interact with PER1 to inhibit CLK:BMAL1-activated transcription in cultured cells. Although there is evidence that TIM is necessary for SCN circadian rhythms, it has not yet been shown to act within the negative loop in the SCN clock.

A second bidirectional set of feedback loops is present in mammals, as in flies. These positive and negative loops center around the regulation of and by an orphan nuclear receptor, REV-ERBα. In the positive loop, CLK:BMAL1 binding at an E-box enhancer of the *Rev-erbα* gene activates transcription. The resulting protein, REV-ERBα, initiates the negative loop by binding to retinoic acid-related orphan receptor response elements (ROREs) in the promoter of *Bmal1,* and possibly *Clk* and *Cry1*, thereby repressing transcription. PER:CRY complexes also feedback negatively on the CLK:BMAL1 complex at the E-box site, inhibiting transcription of *Rev-erbα*. As levels of REV-ERBα, decrease, ROR is thought to displace

REV-ERBα on RORE sites, turning on *Bmal1* transcription. Rising levels of PER and CRY again lead to increased BMAL1 expression by repressing *Rev-erbα*, completing an oscillatory loop. These loops are thought to enhance the stability and robustness of the circadian oscillator.

Transcriptional-translational feedback loops do not alone account for an oscillatory cellular clockwork. The critical drive for the dynamics of temporal and spatial oscillation in clock-protein transcription factors resides in their PTM. PTMs can include phosphorylation/dephosphorylation, limited proteolysis, ubiquitination, sumoylation, methylation, and glycosylation. PTMs of clock proteins cause conformational changes in three-dimensional protein states that determine key events in the life of the protein: subcellular localization, intermolecular interaction, translocation, and degradation. Each clock protein is likely to have multiple effectors of PTM. PER2 is phosphorylated both by CKIε and GSK3β. Mutation within the CKIε recognition site of PER2 significantly alters circadian behavioral rhythms, including human sleep–wake cycles. GSK3β is expressed in the SCN and liver of mice, where it exhibits robust circadian oscillation in phosphorylation state, and it phosphorylates PER2 in COS1 cells. Doubtless additional clock genes will be identified that regulate PTM of other clock proteins.

Structural and Functional Features of Clock Proteins

Structural motifs and functional domains of clock proteins are substrates for protein–protein interactions, PTM, and regulation of subcellular distribution (Figure 2). PERs are the most thoroughly studied of the core clock components. In dPER, intermolecular interaction of the two PAS domains (PAS-A and PAS-B) is necessary for PER homodimer formation. All three mammalian PERs contain the PAS-A and PAS-B dimerization domains, nuclear export signal (NES) domains, and CKIε-binding motifs. Studies of a natural period variant in hamster, *tau*, found that it encodes an altered CKIε. CKIε regulates protein stability and subcellular localization of PER. Substituting serine for glycine in the CKIε substrate site of human PER2 shortens the circadian period, possibly by altering degradation or accelerating nuclear entry. CKIε actively regulates the intracellular location of PER by masking or unmasking the nuclear localization signal (NLS) domain, which is adjacent to the CKIε-binding motif in all three PERs. PERs also contain cytoplasmic localization domains (CLD), which are mediators of nucleo-cytoplasmic shuttling. CLDs of PER1 and PER2 are suggested to be nonfunctional. Indeed, mPER2 shows predominantly nuclear staining in the SCN.

Figure 2 Schematic representation of structural and functional features of mouse clock proteins. A and B represent the PAS-A and PAS-B domains, respectively, sites of protein–protein interactions that enable the formation of dimers and macromolecular assemblies. bHLH, basic helix–loop–helix DNA-binding domains; CKI, casein kinase Iε recognition motif; CLD, cytoplasmic localization domain; CRY, cryptochrome-binding domain; NES, nuclear export signal; NLS, nuclear localization signal; PAS, Period-Arnt-Single-minded transcription factor domain; Poly Q, poly-glutamine-rich sequence.

CRY1 and CRY2 contain N-terminal chromophore-binding domains but exhibit structural divergence in C-terminal extension domains. This suggests that C-terminal domains have unique functions in each CRY. CRY acts as a repressor by directly interacting with the CLK-BMAL1 heterodimer in the nucleus. Thus, the nuclear localization and interaction with this heterodimer are essential for CRY function. An NLS has been found in the N-terminal chromophore-binding sequence in CRY1 and a functional NLS was identified in the C-terminal extension domain in CRY2. How CRY localization is regulated is unknown, but it is likely that PER-binding unmasks the NLS or masks the CLD of CRY.

Intracellular distribution and PTM are also affected by the interactions of PERs with CRYs. The two PAS domains are required for PER–PER and PER–CRY dimerization. PER–CRY dimerization appears important for the nuclear accumulation of both proteins; *Cry1*/*Cry2* double-mutant mice show weak nuclear localization of PER1 and PER2. Moreover, PER–CRY dimerization prevents their degradation through the ubiquitin–proteasome pathway.

CLK and BMAL1 proteins each have one basic helix–loop–helix (bHLH) DNA-binding domain and two PAS dimerization domains. CLK and BMAL1 also contain conserved NES and NLS domains, adjacent to the PAS-A and bHLH domains, respectively. CLK may be regulated by protein kinase G type II (PKG-II) at the end of the night, when they co-immunoprecipitate from SCN extracts. BMAL1 is phosphorylated *in vitro* by two kinases, CKI and mitogen-activated protein kinase (MAPK). MAPK phosphorylates Ser-527, Thr-534, and Ser-599 in BMAL1. A conserved CKI substrate consensus motif exists in the C-terminus of BMAL1, but phosphorylated residues have not been determined. These two kinases may compete to regulate BMAL1 function because their phosphorylation motifs overlap. Transactivation studies support this hypothesis – MAPK-mediated phosphorylation decreases CLK–BMAL1 transcriptional activity, whereas CKI-mediated phosphorylation induces it.

Figure 3 Schematic of circadian expression patterns in the SCN: (a) clock gene mRNAs; (b) clock proteins. Relative mRNA and protein levels of clock gene transcription factors oscillate over the circadian cycle. An exception is those products of the gene *Clock*, which are constitutive. The mRNAs of negative elements are generally high in the daytime; transcripts of *Bmal1*, a positive element, peak in the nighttime. The mRNAs of most clock genes are nearly immediately translated, so the oscillations in clock proteins are offset from mRNA rhythms by ~4 h. BMAL1 peaks midday, whereas proteins of negative elements peak from late day to early night. Horizontal bars: yellow indicates daytime (ZT 0–12 h); black indicates nighttime (ZT 12–24 h).

Patterns of Clock Gene Expression in the Suprachiasmatic Nucleus

Temporal patterns of putative clock mRNA and protein expression have characteristic relationships to phases of the day–night cycle (Figure 3). Most show oscillatory circadian patterns that map to specific phases of the ~24 h cycle. Time of the SCN clock in animals under light–dark conditions is expressed as zeitgeber time (ZT) because the regular daily appearance of light acts as a time-giver. Subjects usually are entrained to a 24 h cycle with 12 h of light (day) and 12 h of darkness (night). Under constant environments, including darkness, phase-relationships persist. The period of these clock-driven oscillations is *circa*, not exactly, 24 h. Reckoning circadian time (CT) includes correcting for the non-24-h period.

Proteins of the positive loop exert primary influence during the daytime. In anticipation, *Bmal1* mRNA increases during the nighttime (CT 15–18), peaks just before dawn (CT 23), and then drops sharply. BMAL1 protein is present in the first half of the day (CT 0–8). *Clk* mRNA and protein are constitutively expressed in the SCN. For CLK and BMAL1 to dimerize, they need to be in the same physical space. Dimerization dynamics are unknown; however, shortly after BMAL1 starts to accumulate, mRNAs of the elements of the negative loop appear (Figure 3). This is

consistent with a model wherein CLK–BMAL1-driven transcription forms the positive loop, activating the transcription of clock genes in the negative loop (Figure 1).

Daytime activation of transcription of elements of the negative loop imposes critical negative feedback that enables the oscillation. The transcription of *Per, Cry,* and *Tim* peaks during the mid- to late circadian day, in antiphase to the *Bmal1* peak (Figure 3). *Per* mRNAs and proteins exhibit robust circadian patterns, with protein lagging mRNA rhythms by ~4 h. Proteins of the negative loop – PER 1, 2, and 3; CRY 1 and 2; and possibly TIM – appear in the late day, with most peaking near the day–night transition. PER-CRY heterodimers are reported to accumulate in the nucleus at night, when they are predicted to interact with CLK–BMAL1 to repress *Per* and *Cry* transcription. However, most *Per* and *Cry* mRNA appears to decrease in the second half of the day. This inconsistency has not been resolved, but it may reflect sampling methods.

Within the SCN, clock gene expression varies regionally. Regions are distinguished as (1) the ventromedial core, receiving inputs from the retina and other afferent regions and expressing vasoactive intestinal peptide (VIP); and (2) the dorsomedial shell, projecting from SCN to the nearby hypothalamus and expressing arginine vasopressin (AVP). In mouse, *Per1* mRNA undergoes circadian oscillation in the shell region, preceding shell *AVP* mRNA rhythms by ~4 h. PER2 rhythms in diurnal rodents peak between ZT 10–18 in the dorsal, ventral, and lateral regions but not centrally. At trough times, PER2 is primarily in the dorsal SCN. PER1 is more widely distributed at its peak, but, as with PER2, it is less dense in the core.

Regulation of Clock mRNA and Protein Expression and Function

Dynamic regulation of clock gene mRNA and protein state is necessary to generate ~24 h oscillations. Regulation of mRNA may include RNA processing (capping, splicing, and polyadenylation), export, decay, and translation, as well as alternative transcriptional start sites. Changes in RNA processing could change clock state by altering the RNA expression pattern or RNA stability. Multiple transcriptional initiation sites and splice variants have been identified for mammalian *Bmal1* and *Bmal2*. Human BMAL2 isoforms exhibit differential transcriptional activity *in vitro*, suggesting that alternative splicing may regulate clock function. In addition, *Tim* may have multiple splice forms because multiple transcript and protein species have been reported.

Protein state is regulated by PTM and protein–protein interactions. Of possible PTMs that can regulate proteins, phosphorylation has been studied most. Changing the equilibrium between phosphorylation–dephosphorylation states may be a key determinant of clock proteins by altering (1) stability in the cytoplasm, (2) transcriptional activator-repressor activity, and (3) nuclear entry. CKIε–mediated phosphorylation of PER2 affects its stability. The phosphorylation state increases PER turnover by altering the rate of ubiquitination, which targets proteins for degradation. In addition to stabilizing clock proteins, phosphorylation is important for regulating transcriptional activator–repressor activity. In cultured mammalian cells, repressing CKI expression decreases BMAL1-dependent transcriptional activity at the *Per1* promoter. MAPK also alters the BMAL1-dependent transcription. Not surprisingly, dephosphorylation has been reported to impact activity of dPER; increased phosphatase PPA2 activity leads to stable, constitutive nuclear expression, but has not been examined in mammals. Nuclear localization of PER2 is affected by CKIε-mediated phosphorylation. In COS1 cells, GSK3β also promotes nuclear translocation of PER2. Thus, these kinases may converge on PER2 in regulating nuclear translocation.

The timing of phosphorylation and oscillating protein–protein interactions shape the period length of circadian clock. PER proteins show similar circadian phosphorylation patterns, with peak phosphorylation levels near CT 21, when most of the PER is nuclear. Phosphorylated CLK is detectable in the nuclear fraction throughout the circadian cycle, with hypophosphorylated forms in the nucleus during the day. A similar pattern of phosphorylation is detected for BMAL1. At the time of negative transcriptional feedback, phosphorylated forms of mammalian clock proteins form complexes in the nucleus, but the significance of nuclear phosphorylated forms of clock proteins is unclear. CKIε is at least partly involved in regulating the nuclear stability of PER proteins and the transcriptional activity of BMAL1.

Protein–protein interactions can regulate receptiveness to PTMs that alter clock protein localization and state. PER appears essential to controlling the subcellular distribution and CKI-dependent phosphorylation of CRYs. CKI and CRYs do not initially bind directly. Rather, both bind to PER simultaneously to form a ternary complex in which CKI can phosphorylate CRY1 or 2. Additional PTMs may be contributed by other kinases. A recent report showed that MAPK directly interacts with and phosphorylates CRY1 and CRY2 *in vitro*, and suggested that MAPK-mediated phosphorylation reduces the repressor activity of CRY.

Regulation of Clock mRNA and Protein Expression by Light

The cell-autonomous SCN clock repeats each cycle in about 1 day. Over successive cycles, the circadian clock drifts away from the 24 h solar cycle on earth. When this desynchronization causes daytime light signals to impinge on the nighttime state of the SCN, the time base of the clock adjusted, or reset, realigning the internal state with the external environment. This process requires that the signaling pathways that transduce neurochemical signals of light from the retina to the SCN engage the molecular clockwork. Light signals in early and late night cause the delay and advance of clock phasing, respectively. In rats, *Per1* mRNA increases in the SCN at 60 min after the light pulse at either time. *Per2* mRNA induction can be observed after light exposure at early, but not late, night. Functionally, light-induced phase delays are attenuated by the co-injection of antisense oligodeoxynucleotide (αODN) to mRNA for *Per1* or *Per2*, whereas only *Per1* αODN blocks phase advance. This indicates that the expression of both these genes is necessary for phase delay of the clock mechanism, but only *Per1* is necessary for phase advance.

Nocturnal light exposure causes changes in PER levels in mouse SCN. PER1 and PER2 increase within 4–6 h after brief light pulse in the early night, when light signals delay clock phase, effectively extending the clock reckoning of daytime. However, during late night, only PER1 expression increases significantly. Light in late night signals an early morning, advancing the clock phase. PER1 peaks ~4 h after this light signal and also early in the next cycle, at 10 h post-stimulus, rather than the usual time, ~CT 12. This interval reflects the amplitude of the advance in clock phase. These data support the hypothesis that both PER1 and PER2 are important for phase delay, whereas only PER1 contributes to phase advances. However, questions remain as to how the light-induced increase in PER affects the negative transcriptional loop and what roles other clock proteins might play.

Light-stimulated changes in regional distributions of PER1 and PER2 within the SCN follow their respective mRNAs and depend on the circadian time of light pulse administration. After a phase-delaying light pulse in early night, the number of PER1-positive cells increases primarily in the ventrolateral core region, whereas PER2-positive cells show greatest increase in the shell. After a phase-advancing light pulse, PER1 expression increases in both the core and shell regions, without significant PER2 increase in either core or shell region. Thus, increased PER2 expression in the shell SCN region correlates with phase delay, whereas the induction of PER1 in the shell correlates with phase advance. Effects of light on other clock elements have not been established.

Summary

Circadian rhythms in mammals are orchestrated by a central clock in the suprachiasmatic nucleus (SCN). The clock emerges from cell-autonomous processes. Clock proteins cause the rhythmic expression of clock genes as well as output genes. Structural features and posttranslational modifications of clock proteins determine their intermolecular associations, subcellular localization, transcriptional activity, and stability. Some clock proteins positively and negatively regulate their own rhythmic expression via feedback on transcription. Patterns of clock gene expression within SCN cells and tissue are complex. The understanding of mammalian clock mechanisms critical to timekeeping is as yet incomplete.

Circadian Genes and the Sleep–Wake Cycle

A D Laposky and F W Turek, Northwestern University, Evanston, IL, USA

Introduction

There are two major physiological processes that interact to determine the need for sleep and to direct the temporal organization of sleep–wake states across the day and night. A homeostatic mechanism (process S) governs the propensity for sleep based on the amount of prior wakefulness (i.e., sleep–wake history); the longer an organism is awake, the more likely it will be to fall asleep and to increase sleep intensity. The circadian drive (process C) determines the timing of when sleep and wakefulness occur based on the coordination of an endogenous circadian clock system and entrainment to environmental cues, such as the light–dark cycle. The importance of homeostatic and circadian processes on sleep–wake organization has been demonstrated in organisms as diverse as humans, rodents and flies. Because the functions of the homeostatic and circadian processes are generally conserved, researchers have been able to take advantage of genetic animal models (e.g., mice and flies) to investigate the molecular mechanisms of sleep–wake regulation, as well as the genetic basis of human sleep–wake disorders. One of the interesting advances in this line of research has been the demonstration that circadian clock genes have unique roles in sleep regulation that go beyond just the timing of sleep. In this article, we focus on what is known about the involvement of mammalian circadian clock genes in the control of sleep amount, architecture, and homeostatic drive.

Systems-Level Studies: Suprachiasmatic Nucleus Lesions

The suprachiasmatic nucleus (SCN) consists of a small group of neurons situated just above the optic chiasm in the anterior hypothalamus. This structure represents the major circadian pacemaker in the brain, and its activity underlies the generation and/or coordination of virtually all behavioral and physiological rhythms of the body. It can be argued that the sleep–wake cycle is the master output rhythm of the SCN because most biological functions vary according to whether the organism is asleep or awake. Because of the important role of the SCN and the sleep–wake cycle in daily functioning, there has been an interest in understanding exactly how the SCN is involved in regulating sleep and wakefulness and what aspects of sleep (i.e., timing, quantity, and electroencephalogram (EEG) homeostatic drive) are under circadian control. The complexity of deciphering this role of the circadian system is that the propensity for sleep is also mediated by another factor that is oscillatory in nature – the sleep homeostatic process. Although the circadian and sleep homeostatic processes are essentially linked at the functional level, various experimental paradigms in humans and rodents have been developed to examine their independent roles. Early studies in rats used experimental SCN lesions to remove the influence of the central anatomical circadian pacemaker. These studies demonstrated that SCN lesions eliminated the diurnal sleep–wake rhythm but did not affect overall sleep–wake amount or the homeostatic response (i.e., EEG non-rapid eye movement (NREM) delta [0.5–4.0 Hz] power) to sleep deprivation. These results have contributed to the view that the SCN is involved only in regulating the placement of sleep across the light–dark or circadian cycle. The broader implication of this view is that the circadian system does not play an active role in generating sleep–wake states or sleep homeostatic drive and that there are no common mechanistic links between circadian and sleep–wake regulatory processes.

Following these initial studies in a single species, the laboratory rat, a few subsequent studies involving SCN lesions provided contrasting results to these earlier findings. The first demonstration that SCN lesions could affect sleep time was in the diurnal squirrel monkey, which had a loss of the sleep–wake rhythm but a large increase in NREM sleep time. This finding by Edgar and colleagues established a basis for the opponent-process model, which proposed that the SCN produced a wake-promoting signal across the active phase of the circadian cycle. This major drive for wakefulness could then initiate or contribute to the buildup of sleep homeostatic pressure, eventually leading to sleep initiation near the onset of the major rest period. Another important outcome of the opponent-process model is that it established a foundation for other interesting hypotheses about SCN function, such as that the SCN may also provide a sleep-promoting signal during the rest period that contributes to the dissipation of sleep drive and the cyclical increase in wake propensity. More recent experiments in rats and mice found that SCN lesions not only abolished the sleep–wake rhythm but also increased NREM sleep time, providing further support for the basic tenants of the opponent-process model. Another study in Siberian hamsters showed that following a 5 h phase shift, animals became

arrhythmic accompanied by a large increase in sleep time and an impaired homeostatic response to sleep deprivation. Certainly, it will be important in future studies to determine the extent to which these limited sets of data are replicable in different strains of mice and rats and are generalizable across different nocturnal and diurnal species. It will also be important to recognize that, in addition to the use of EEG NREM delta power as a measure of sleep homeostatic drive, sleep–wake amount and sleep architecture are other variables that are important components of the sleep–wake phenotype. Although the SCN lesion studies do not delineate a specific mechanistic link between circadian and sleep regulatory systems, they do provide important evidence that the circadian system can feed into and cause adjustments in sleep regulatory processes. These studies also established a foundation for interesting hypotheses to be tested regarding what these mechanisms could be, particularly at the genetic level.

Genetics-Level Studies: Mammalian Circadian Clock Genes

The ability of the SCN to entrain to the light–dark cycle and to generate endogenous rhythms in the absence of environmental cues is based on molecular events involving an integrated circuit of circadian clock genes that exists in individual neurons of the SCN. This group of core circadian genes forms a complex transcriptional–translation feedback loop within each cell, which cycles with a near 24 h period. The self-oscillating neurons in the SCN synchronize as a functional unit to create major output signals through both neural transmission and hormonal factors that drive a wide range of output behaviors and physiological processes. One of the most exciting recent discoveries in the circadian field is that the transcriptional–translational feedback loop of circadian clock genes also exists outside of the SCN, in other areas of the brain, as well as in various peripheral tissues (i.e., the lung, heart, muscle, liver, and pancreas). The discovery of circadian clock genes and the development of animal genetic models (see Table 1) have played a crucial role in understanding how the circadian system controls a wide range of output rhythms and have elucidated other potentially important roles of the circadian system that extend well beyond its role as a time keeper.

Clock, Bmal1, and *Npas2*

The first mammalian circadian clock gene was discovered in a forward mutagenesis program at North western University and was given the name *Clock (Circadian locomotor output cycles kaput)*. The *Clock* gene encodes a basic helix–loop–helix (bHLH)-period-arnt-single-minded (PAS) domain-containing transcription factor that is a component of the positive limb of the transcriptional–translational feedback loop of circadian genes. The protein products of *Clock* and another bHLH-PAS circadian gene, *Bmal1* (*Brain and muscle arnt-like 1*, also called *Mop3*) dimerize (CLOCK–BMAL1) to drive the transcription of negative-limb circadian genes, *cryptochrome* and *period*, which in turn feed back to inhibit CLOCK–BMAL1 activity. Mice that harbor a homozygous mutation in the *Clock* gene, the *Clock/Clock* genotype, entrain to a light–dark cycle with respect to locomotor activity, but have an altered circadian period of activity in constant darkness; initially they free-run with a notably long period (~28 h) and then become arrhythmic. Unexpectedly, when sleep–wake patterns were examined, our research group found that *Clock/Clock* mice exhibit a high amount of wake time (+1–2 h day^{-1} compared to wild-type mice) with a reciprocal decrease in NREM sleep time under both 12 : 12 light–dark and constant dark conditions. In the light–dark cycle, the increase in wake time occurs throughout the day, but is more pronounced during the light phase, the time of day when rodents normally have the most consolidated sleep. Furthermore, following short-term sleep deprivation, the homozygous *Clock* mutants recover less REM sleep time than wild-type mice. In combination, these data show that the increase in wake time is not simply a masking effect of the light–dark cycle or an indirect response to a change in circadian period but is a fundamental effect of the mutation. Most importantly, these data represent the first demonstration that an alteration in the function of a core circadian clock gene could have a direct impact on the amount of sleep produced and on the recovery response to sleep loss and opened the door to further inquiries into how circadian clock genes might influence the sleep–wake cycle at many levels.

Because of the remarkable sleep phenotype generated by *Clock* mutant mice, it was of interest to examine sleep in mice with a deletion of *Clock's* dimeric partner, *Bmal1*. Interestingly, we found that *Bmal1*$^{-/-}$ mice produce a high amount of sleep (+1.5 h day^{-1}) compared to their intact controls; a phenotype opposite the *Clock/Clock* mouse. The extra sleep in *Bmal1*$^{-/-}$ mice is achieved entirely during the 12 h dark phase, which is normally the major wake period for rodents. Despite high sleep time, *Bmal1*$^{-/-}$ animals exhibit a severely fragmented sleep pattern throughout the entire light–dark cycle with frequent arousals from sleep and less consolidated bouts of sleep and wakefulness. *Bmal1*$^{-/-}$ mice recover less sleep time in response to sleep

deprivation and show an attenuated rebound in NREM EEG delta (0.5–4.0 Hz) power, the prototypic measure of sleep homeostasis. Therefore, many components of sleep drive, including sleep time, sleep consolidation, and the compensatory response to sleep loss, are disrupted in *Bmal1*$^{-/-}$ animals. The sleep–wake rhythm is attenuated in *Bmal1*$^{-/-}$ mice across the light–dark cycle and is arrhythmic in constant darkness, but the sleep phenotype remains largely similar in both conditions. It is most interesting to note that although both *Clock* mutant and *Bmal1*$^{-/-}$ mice are arrhythmic in constant darkness, their basic sleep phenotypes – high-wake and high-sleep, respectively – are opposite. This pattern suggests that the changes in their sleep regulatory process are not simply the result of general circadian disruption but are due to a unique function of each of the circadian genes independent of the circadian timing system.

It may seem surprising that sleep regulation in *Clock/Clock* and *Bmal1*$^{-/-}$ mice is quite different, given that these genes are dimeric partners in their function as circadian transcription factors. One possible explanation for the difference in sleep patterns is that the *Clock* mutant mouse harbors a mutation leading to altered CLOCK protein function, whereas *Bmal1*$^{-/-}$ is a gene deletion model. Aside from this basic difference, it is plausible that *Clock* and *Bmal1* exert unique effects on other molecular pathways and multiple physiological systems (e.g., energy metabolism, activity levels, and endocrine function) that may feed back to modulate sleep–wake behavior. For example, a recent study by Turek and colleagues demonstrated that *Clock/Clock* mice develop increased adiposity and symptoms of the metabolic syndrome. *Bmal1*$^{-/-}$ mice may have altered glucose homeostasis and develop joint disease, which leads to abnormalities in locomotor activity. The *Bmal1* gene even plays a role in molecular pathways related to adipogenesis. It will be important to gain an understanding of the multiple molecular pathways in which *Clock* and *Bmal1*, as well as other circadian genes, are involved that may not be directly related to core circadian function. Because clock genes have been

identified in a variety of central and peripheral tissues, there is probably anatomical specificity to their activity at the physiological and molecular levels. Another important pursuit will be to identify the specific brain regions and/or peripheral tissues that are responsible for the effects of *Clock* and *Bmal1*, as well as other circadian genes, on sleep and wakefulness.

Npas2 (*neuronal PAS domain protein 2*) is a paralog of the mammalian *Clock* gene, dimerizes with *Bmal1* to encode a circadian clock transcription factor, and is sensitive to the redox state of the cell, indicating that it may represent a molecular link between energy homeostasis and circadian processes. In contrast to *Clock*, *Npas2* is not expressed in the SCN, but is present in other areas of the brain and shows expression in the cortex, basal ganglia, and limbic structures. The first sleep study in *Npas2*$^{-/-}$ mice provided evidence of an increase in locomotor activity and wake time, particularly during the middle of the dark period. Generally, mice demonstrate a consolidated period of wakefulness just after lights out that lasts for a number of hours. In the middle of the dark phase, mice achieve some sleep, often referred to as a napping period. *Npas2*$^{-/-}$ mice show a delay in the onset of napping, indicating that their nocturnal drive for wakefulness is stronger than animals with an intact *Npas2* gene. A second, more comprehensive study in *Npas2*$^{-/-}$ animals replicated the high-wake pattern and found additional differences in the knockout mice, including alterations in the power density of specific EEG frequency bands and attenuated recovery responses to acute sleep deprivation. The high-wake phenotype in *Npas2*$^{-/-}$ animals is in the same direction as *Clock/Clock* mutant mice, except that *Clock* mutants show a large amount of wakefulness in the light period, whereas extra wake in *Npas2*$^{-/-}$ mice is restricted to the dark phase. Because the anatomical distribution of NPAS2–BMAL1 is different than CLOCK–BMAL1, these data raise the interesting possibility that an SCN-independent role of circadian clock genes is involved in many aspects of sleep regulation. Significantly, a recent study in our laboratory showed that when the SCNs of *Clock/Clock* mice were lesioned, the mice still had more wake time than SCN-lesioned wild-type mice. These data provide evidence for the possibility that the role of *Clock* in mediating wakefulness is occurring in extra-SCN or peripheral sites.

Cryptochrome and *Period*

The CLOCK–BMAL1 and NPAS2–BMAL1 protein complexes drive the transcription of other clock genes, including two *cryptochrome* (*Cry1* and *2*) and three period (*Per1*, *2*, and *3*) genes, which are components of the negative-limb of the circadian transcriptional–translational feedback loop. The *Cry* genes belong to the family of blue-light photoreceptors and are located in retinal ganglion cells, in the SCN, and in various peripheral tissues. The protein products of *Cry1* and *2* form heteromultimeric complexes with PER1, 2, and 3, which translocate to the nucleus to influence the transcriptional properties of CLOCK–BMAL1 and NPAS2–BMAL1. The *Cry* and *Per* genes are thought to play an important role in the ability of the molecular circadian clock to respond to light and in mediating the phase relationship between behavioral rhythms and the light–dark cycle. When the activities of these genes are altered through either mutation or deletion, a variety of circadian abnormalities ensue, including altered entrainment to a light–dark cycle, changes in the free-running period of activity, or even complete loss of circadian rhythmicity. In addition to these varied roles in circadian regulation, a variety of interesting sleep–wake phenotypes have been reported in *Cry1,2*-deficient (*Cry1,2*$^{-/-}$) and *Per* mutant mice.

It is known that *Cry1,2*$^{-/-}$ mice have an attenuated sleep–wake rhythm under the light–dark cycle and have no circadian rhythm of sleep in constant darkness. In addition to the alterations in sleep–wake distribution, there are major changes in sleep time and architecture in these mice. *Cry1,2*$^{-/-}$ mice generate a large amount of NREM and rapid eye movement (REM) sleep time ($\sim$1.5 h more than the wild-type mice amount) throughout the dark phase of the diurnal cycle. In the light phase, NREM sleep is comparable between the genotypes, but REM sleep time is lower in *Cry1,2*$^{-/-}$ mice. Interestingly, *Cry1,2*$^{-/-}$ mice exhibit a notable increase in the duration of individual sleep bouts and have enhanced sleep intensity (i.e., NREM EEG delta power) throughout the light–dark cycle. These data indicate that under baseline conditions, the deletion of both *Cry* genes leads to an enhanced homeostatic drive for sleep. These same measures of increased sleep propensity occur when the mice are arrhythmic in constant darkness – this finding is important because locomotor activity in *Cry1,2*$^{-/-}$ mice is particularly sensitive to the masking effects of light. Therefore, the maintenance of high sleep time in constant darkness suggests that the extra sleep is not simply due to behavioral suppression by light. Following short-term sleep deprivation (i.e., 6 h during the first half of the light phase), *Cry1,2*$^{-/-}$ mice fail to achieve a robust compensatory or homeostatic response in NREM, REM, and NREM EEG delta power. One explanation for this surprisingly attenuated recovery could be that baseline levels of sleep drive were already high and the mice could not generate additional sleep or sleep

intensity, often referred to as a ceiling effect. However, *Clock/Clock* and *Npas2*$^{-/-}$ mice have lower amounts of baseline sleep time and also show smaller responses to sleep loss on various measures of sleep recovery, a pattern that cannot be explained by a ceiling effect. In combination, these results (also see the description of *Per* mutant mice next) indicate that clock genes may exert different effects on sleep under different physiological conditions (i.e., baseline vs. sleep deprivation). It is interesting to note that single *Cry1* and *Cry2* deletion models have been developed that show short and long free-running rhythms of locomotor activity, respectively. Sleep has not been recorded in these mice, and it will be interesting in future studies to determine whether these mice have unique sleep–wake patterns beyond the expected alterations in timing.

Another result in the *Cry1,2*$^{-/-}$ study is that *Per1* and *Per2* mRNA levels are increased in the cortex of sleep-deprived wild-type mice and return to baseline levels following a sleep recovery opportunity. *Per* transcript levels are also high in *Cry1,2*$^{-/-}$ mice under baseline conditions, suggesting that the *Per* gene may have a role in promoting sleep. Other studies have demonstrated that *Per* expression in the cortex is associated with wakefulness and arousal, independent of its expression pattern in the SCN. Two papers were published by separate research teams on sleep–wake patterns in *Per* mutant mice. In the first study, Kopp and colleagues found that PER1-deficient mice have increased wake time throughout the dark period and increased NREM sleep time at the light–dark transition period (i.e., dusk). *Per2* mutant mice exhibited increased wake time during the last 3 h of the light phase (i.e., dawn), consistent with their phase-advanced circadian phenotype (i.e., waking up too early), and had normal sleep–wake times throughout the dark phase. In neither group was the amount of 24 h baseline sleep or wake significantly different from wild-type levels, and no major changes in EEG power spectra were observed. In the second study, by Shiromani and colleagues, sleep in PER1-deficient and *Per2* mutant mice was examined with the addition of PER3-deficient and double *Per1/Per2* mutant mice. Based on the results from this group's genetic models, there was little effect on sleep due to PER1 or PER3 deficiency. On the other hand, *Per2* mutant mice had increased wake time at the end of the light phase, and this pattern was even more pronounced in *Per1/Per2* mutant mice. The altered phase angle of entrainment in *Per2* and *Per1,2* mutant mice is consistent with human studies that have shown an association between alleles in the *Per2* gene and advanced sleep-phase syndrome.

There are a number of changes in the response to sleep deprivation in *Per* mutant mice. In the Kopp study, 6 h of sleep deprivation occurred during the first half of the light phase. Both PER1-deficient and *Per2* mutant mice began to generate a positive rebound in NREM and REM sleep time sooner than wild-type mice, and *Per2* mice had the largest cumulative rebound in REM sleep time of the three groups. PER1-deficient and *Per2* mutant mice produced a significant homeostatic response (i.e., NREM EEG delta power) after sleep deprivation; however, the magnitude of this response was slightly less than wild-type levels in the first 2 h of recovery. Also, NREM delta power remained elevated for 1 h longer in *Per2* mutant mice compared to the other groups. In the Shiromani study, sleep deprivation was placed during the last 6 h of the light period and recovery sleep began at dark onset. At this time of day, *Per3* mutant, PER1-deficient, and *Per1/Per2* mutant mice exhibited longer-lasting recovery responses in EEG NREM delta power (i.e., sleep intensity) than wild-type mice. These results indicate that the rate at which sleep pressure is dissipated may be different among these genetic models. The amplitude (percentage of baseline) of this rebound response was particularly high in PER1-deficient and *Per1/Per2* mutant mice. Furthermore, although all mice produced a significant rebound in REM sleep time, only PER1-deficient and *Per2* mutant mice had elevated NREM sleep time following sleep deprivation. In summary, the results from these two experiments indicate that *Per* genes exert individual effects on the timing of sleep and are also involved in modulating many aspects of the compensatory response to sleep loss.

Summary

The combination of results outlined in this review points to a critical role of circadian clock genes in sleep–wake regulation that extends beyond a strict time-keeping function. It is intriguing that each of these genes appears to influence sleep (baseline patterns and/or compensatory responses to sleep deprivation) in a unique way. To date, a simple model does not explain the different effects of individual clock genes on sleep. For example, the opposite phenotype in *Clock/Clock* (i.e., high-wake) and *Bmal1*$^{-/-}$ (i.e., high-sleep) mice is surprising because the protein products of these genes normally function together in a dimeric capacity. Sleep time is increased in both *Bmal1*$^{-/-}$ and *Cry1,2*$^{-/-}$ mice; however, *Cry* mRNA levels are elevated in *Bmal1*$^{-/-}$ mice, and *Bmal1* expression is high in *Cry1,2*$^{-/-}$ mice, seemingly incompatible patterns with respect to their sleep–wake phenotypes. As another example, *Per1* and

Per2 transcript levels are often elevated during spontaneous or experimentally induced wakefulness and *Per1*, *Per2,* and *Per1,2* mutants show a tendency for high wake time; however, high-sleep *Cry1,2*$^{-/-}$ mice also have elevated *Per1* and *Per2* transcript levels. These types of comparisons reveal that the role of circadian genes in sleep regulation is complex and probably extends to mechanisms beyond the core circadian gene transcriptional–translational feedback loop. One of the difficulties in directly comparing sleep among the different genetic models is the variety of experimental paradigms that have been used to study sleep: various sleep deprivation protocols, different criteria for scoring/analyzing sleep parameters, different genetic backgrounds of the models, mutants versus knockouts, and so forth. Nonetheless, enough evidence has mounted for us to conclude that circadian genes do more than simply control the timing of sleep–wake states. Indeed, individual clock genes may influence sleep, in part, through their activity in circadian regulation, as well as through circadian-independent effects. Because clock genes exist in a wide variety of central and peripheral tissues, there may be an additional component to their role in sleep regulation – anatomical specificity. The exciting finding that *Clock/Clock* mice become obese and demonstrate symptoms of the metabolic syndrome provides a framework to investigate the multiple and common molecular pathways in which the *Clock* gene is involved and that may link sleep with other physiological processes, such as energy metabolism. It has also been demonstrated that a large number of transcripts in central and peripheral tissue show rhythmic expression, presumably due to direct or indirect interactions downstream of the core circadian machinery. For example, the deletion of genes for albumin D-binding protein (DBP), prokineticin-2 (PK2), and transforming growth factor (TGF)-α, all clock-responsive genes, results in alterations in sleep regulation in mice. Another important advance in the field of sleep research has been the convincing demonstration that flies exhibit sleep–wake patterns and that their sleep is under homeostatic regulation. Significantly, mutations to *Drosophila* circadian clock genes (e.g., *Clock*, *Cycle*, *Period*, and *Timeless*) lead to changes in baseline sleep–wake regulation and to some dramatic alterations in the response to sleep deprivation. Undoubtedly, the use of novel model organisms and the development of new genetic techniques will provide many opportunities to continue investigating the apparently ubiquitous roles that circadian clock genes serve in sleep–wake regulation, as well as in the overall health and well-being of the organism.

Organisms Exhibit Metabolic Rhythms: Daily and Annual Rhythms

Humans as well as animals exhibit daily rhythms in the sleep–wake cycle and in feeding and drinking behavior. In addition to these clearly visible behavioral rhythms, there are many physiological rhythms that serve to support behavioral rhythms; for example, several hormones and body temperature have a clear daily rhythm, as well as blood glucose and liver enzymes, which control glycogenesis and glycolysis. Diurnal metabolic rhythms are characterized by their dependence on the suprachiasmatic nucleus (SCN) and are independent of food intake; that is, some metabolic rhythms are expressed both during fasting and with a regular feeding schedule. Other metabolic parameters show fluctuations directly related to feeding events. For example, there is a rise in blood concentration of insulin after each meal. Some species exhibit annual fluctuations in metabolic functions, something that is especially observed in organisms that migrate, hibernate, or accumulate fat for winter. In these species, there are certain periods during the year in which they increase food storage, food ingestion, and fat storage.

The SCN Generates Metabolic Rhythms

The SCN is the master circadian clock, strongly entrained by the light–dark (LD) cycle. The daily changes in activity and sleep of the animal are mainly organized by the SCN and are synchronized to the daily change of the light to dark and vice versa via the light information that reaches the SCN through the optic nerve. There is experimental evidence that SCN lesions abolish the expression of daily rhythms involving glucose and corticosterone, body temperature, locomotor activity, and food intake. Because food intake is driven by the SCN, one might conclude that the other metabolic rhythms are derived from SCN-driven food intake rhythms. However, protocols that force animals into arrhythmic food intake and do not alter the SCN do not abolish glucose rhythmicity in the blood or the rhythmicity in liver enzymes. Such is the case with a protocol during which the animal eats every 4 h 6 times a day: under these conditions, the glucose rhythm in the blood is still maintained (Figure 1). In addition, when animals are fasting, the rise in plasma glucose still occurs in anticipation of the coming activity period. The mechanisms behind this daily peak in plasma glucose concentrations were examined by small bolus injections of glucose at different moments of the day. At the moment of the highest glucose concentrations in the blood, the lowest induced peak with injected glucose was also seen, indicating that at that moment not only the 'production' of glucose is the highest but also its 'uptake' (Figure 2). These observations indicate that the organization of the 'simple' glucose peak in the blood that precedes the activity is a complex event that requires an organization at different levels.

How Does the SCN Induce Rhythms in Metabolic Systems?

Hormonal and autonomic pathways are the two main pathways used by the SCN to transmit its rhythmicity to the body (Figure 3).

The Endocrine System

Since a high dose of corticosterone increases glucose output, it has been suggested that the daily corticosterone peak causes the peak in glucose concentrations at the end of the light period. However, in humans, the rise in glucose at the end of the light period is intact after cortisol action has been blocked. Also, no relationship is found between the blood levels of growth hormone (GH) and adrenalin over the 24 h of the day and the daily rhythm of plasma glucose. The 24 h rhythm in GH in rats, for example, is completely different from that in humans, that is, male rats do not display a clear circadian rhythm in GH concentrations, but a strong ultradian rhythm of 3 h. Although there is less and less evidence that links the circadian changes in corticosteroid levels in the blood to the production and release of glucose by the liver, corticosteroids are still assumed to play an important role in the circadian uptake of glucose by the cells of the body. There are several examples that show that glucocorticoids play an important role in preparing the animal for activity. For example, corticosteroids are increased when animals show food anticipatory activity. Moreover, when an animal shows two peaks

Figure 1 Basal glucose concentrations (values are percentages of the 24 h mean ± SEM) across the LD cycle, in intact rats (left panels; $n = 8$) and in SCN-lesioned rats (right panels; $n = 7$) under *ad libitum* feeding conditions (a, b), during fasting conditions (started at ZT = −12; c, d), and after having been subjected to a scheduled feeding regimen for at least 2 weeks (e, f). The scheduled feeding regimen consisted of a 10 to 12 min feeding opportunity provided every 4 h. Within 2 weeks, the animals learned to use each opportunity, that is, six every day, and consumed a meal of ±3.5 g at every occasion. The black areas indicate the dark period.

of activity in 24 h, two anticipatory peaks in corticosterone are also observed.

The exact mechanism by which the SCN controls plasma glucose concentrations is still being explored. The finding, however, of a simultaneous rise in blood glucose concentration and glucose uptake toward the activity period (Figure 2) suggests that glucose output to the general circulation must be so powerful that it compensates for increased glucose uptake. Of course, it makes perfect sense functionally to prepare an individual for upcoming activity: at the same time that glucose production is increased, the uptake of glucose increases as well. Moreover, it shows that the SCN is able to organize two completely different processes at the same time. The main source for glucose production is the liver. Hepatic glucose production can be stimulated by the sympathetic nervous system either indirectly, via adrenal hormones and glucagon, or directly, by sympathetic innervation of the liver. However, the evidence for the involvement of glucagon and adrenalin for the SCN-regulated anticipatory increase in plasma glucose concentrations toward the

Figure 2 Plasma glucose concentrations after injection of a glucose bolus at different times of the light/dark-cycle (a) and 24 h plasma glucose concentrations during *ad libitum* feeding (closed circles) or during a scheduled-feeding regimen (open circles) (b). Responses in (a) are expressed as the difference with their respective $t = 0$ values. The smaller responses at ZT11 and ZT14 indicate an increased and more rapid uptake of glucose at these times of the LD cycle. The comparable plasma glucose curves of *ad libitum*-fed and scheduled-feeding animals in (b) indicate that the daily rise in plasma glucose concentrations before the dark period is not caused by a day/night rhythm in food intake. In addition, a comparison of the daily plasma glucose curves in (b) with the glucose uptake data in (a) evidences that the daily rise in plasma glucose concentrations is not the consequence of a decrease in peripheral glucose uptake. The black bars in (a) and (b) indicate the dark period.

beginning of the activity period is very weak. There is no daily variation in plasma insulin or glucagon levels during a six-meals-a-day schedule; whereas insulin declines after fasting, glucose, in spite of the fast, still increases in anticipation of the activity period. Moreover, the diurnal increase in adrenalin was also shown to be more related to activity than to the anticipatory peak in glucose.

Interestingly, in addition to the 'spontaneous' circadian changes, also in situations of an acute glucose challenge, the SCN sets the response of the endocrine system and autonomic nervous system (ANS). For example, when confronted with a hypoglycemic event in the early activity period, the low glucose level results in enormous changes in corticosterone secretion, while the same hypoglycemic event in the early sleep period results in hardly any changes in corticosterone.

Recently, the role of the arcuate nucleus has been investigated more closely, especially with respect to the control of metabolism. The arcuate nucleus, which lacks a blood–brain barrier and can be seen as a circumventricular organ (CVO), has intense reciprocal connections with the SCN. It is proposed that the SCN may control the sensitivity of the arcuate for circulating metabolites in a daily manner by means of this interaction. Moreover, several studies have also implicated the arcuate nucleus in the control of seasonal metabolic functions. For example, in hamsters, an increase in VGF protein/mRNA content

Figure 3 Sagittal scheme of the rat brain illustrates the main pathways by which the SCN communicates its circadian message to the body. Via its connections with the PVN of the hypothalamus (PVN), three different output systems are affected: (1) the neuroendocrine neurons of the PVN responsible for the control of pituitary hormones, (2) parasympathetically projecting neurons in the PVN that specifically target the dorsal motor nucleus of the vagus nerve (DMV), and (3) sympathetically projecting neurons in the PVN that specifically target the spinal cord preganglionic neurons located in the intermediolateral column (IML). The neuronal message prepares and sets the sensitivity of the (endocrine) organs for the arrival of the (pituitary) hormones. In return, the neuronal and hormonal message of the organs will feed back to the CNS (including the SCN), as indicated by the three arrows directed toward the brain.

in the arcuate nucleus precedes the photoperiod-induced increase in food intake and body fat. VGF is a protein involved in the control of food intake and has a widespread distribution in the central nervous system (CNS), including the SCN. Interestingly, in the hamster, the region of the arcuate is an important target for melatonin. This hormone, whose nightly secretion is organized by the SCN, has important seasonal functions. Since the arcuate nucleus is also an important target for SCN neurons, the organization of annual metabolic rhythms can be seen to be tightly linked to daily and seasonal metabolic functions.

Autonomic Output

The output of the SCN to the preautonomic neurons in the hypothalamus (mainly paraventricular nucleus (PVN)) is responsible for sending the circadian signal directly to our organs by the autonomic nerves (Figure 3). The PVN has extensive projections to sympathetic and parasympathetic motor neurons in the spinal cord and in the brain stem, respectively. Early studies using electric stimulation of the hypothalamus combined with blocking the output of the ANS showed that the effects of electrical stimulation on glucose metabolism were mainly reached by the ANS. Interestingly, at that time, it was also shown that exposure to bright light resulted in an increase in sympathetic nerve activity to the adrenal gland, liver, and pancreas, and in a decrease in vagal nerve activity to the pancreas and the liver. This effect disappeared after SCN lesioning, suggesting that light via the retinal terminals in the SCN was able to reach the target organs by the ANS. Recent studies have shown that the dorsomedial hypothalamus (DMH)/PVN area is essential for transmitting the circadian signal to the liver, pancreas, and fat tissue via the ANS. Later anatomical studies showed that after retrograde transneuronal tracer injection in the liver, pancreas, and fat tissue, separate sympathetic and parasympathetic pathways could be made visible that originate in different cells of the SCN. Consequently, the SCN contains neurons that are either preautonomic to the parasympathetic system or preautonomic to the sympathetic system, which projects to the pancreas, liver, or visceral fat. These SCN neurons transmit their message to the PVN, from which separate parasympathetic and sympathetic pathways target

the respective autonomic motor neurons. Recent experiments have shown that the sympathetic innervation to the liver plays a major role in liberating glucose from the liver. Removing GABAergic blockade (γ-aminobutylic acid (GABA) from SCN terminals?) within the PVN by means of Bicucullin (a GABA-A antagonist) infusion showed that the resulting glucose peak was mainly induced via the sympathetic innervation of the liver and not by increases in corticosterone and glucagon.

The control by the SCN of glucose tolerance is more likely to be at the level of the muscle, where the major (insulin-mediated) glucose uptake occurs. The mechanisms by which the SCN affects glucose uptake are still not known.

Integration of Glucose Rhythms and Energy Balance

Interaction of the SCN with Hypothalamic Nuclei Involved in Energy Balance

Sensing energy stores The brain depends entirely on glucose as fuel for its energy, while other organs, such as the heart, kidney, and skeletal muscle, may also rely on free fatty acids (FFAs) or other metabolites. In addition, the brain can actively take up glucose via glucose transporters, independent of insulin, which assures that, when insulin levels are low (fasting), the brain acquires sufficient glucose preferentially, because other tissues are dependent on insulin for glucose uptake. Thus sufficient glucose is always available to the brain.

Of course, in order to be able to balance and direct energy fluxes, the brain needs a precise and clear view of the metabolic state of the body. Circulating humoral factors provide an average signal of the whole body status, while sensory information from specific body regions provides detailed information. Sensory information from tissues important for energy storage, such as the liver (short-term storage) and fat tissue (long-term storage), must be available; recent studies have shown that both liver and fat tissue do provide such sensory information to the brain. In addition, tissues that use up a great deal of energy, such as muscles (skeletal and heart) and kidney, also need to transmit their energy level (and requirements!) to the brain.

Consequently, the brain plays a crucial role in sensing circulating metabolites and hormones; the CVOs, which lack the blood–brain barrier, such as the ventromedial arcuate nucleus (vmARC), area postrema (AP), subfornical organ (SFO), and organum vasculosum of the lamina terminalis (OVLT), likely play an important role in this regard. At present, it seems likely that especially the AP and vmARC play a major role in metabolic sensing and signaling, while the OVLT and SFO functions are more adapted for maintaining the osmolarity and salt levels of the blood. Recently, reciprocal connections between the SCN and vmARC were described, indicating that not only is the SCN kept informed about circulating metabolites, but that it might also be able to gate this information at the vmARC, depending on the time of the day (Figure 4). This hypothalamic integration of peripheral metabolic information results in an immediate modulation of metabolism. For instance, fatty acids and insulin are sensed in the vmARC, which leads to a change in autonomic output, affecting endogenous glucose production by the liver, glycogen synthesis in muscle, and food intake. Also, leptin and glucose are sensed in the vmARC, and their increase leads to inhibition of food intake and activation of anabolic functions, such as promotion of glycogen synthesis and lipid storage.

Interaction with Other Hypothalamic Nuclei

For a better understanding of how the SCN affects metabolism, it is also necessary to have a view on how the different hypothalamic structures influence metabolism. Each hypothalamic structure has its own role and interacts and influences the other structures within the hypothalamus in a specific manner. Clearly, there are main food intake stimulatory centers such as the neuropeptide Y (NPY) and agouti-related peptide (AGRP)-containing neurons of the medial arcuate nucleus, while the food inhibitory centers (the pro-opiomelanocortin (POMC)-containing neurons) are in the lateral arcuate nucleus. In addition to these (according to the current views) main structures for controlling food intake, the ventromedial hypothalamus (VMH), the lateral hypothalamus, and the DMH are essential for integrating and transmitting visceral and hypothalamic information; the PVN seems to play a role mainly as integration and output center (hormonal and autonomic) of the hypothalamus. In addition to these structures that are directly involved in the control of food intake, there are also structures that are involved in related functions, which are also very important for metabolism, such as the medial preoptic area (MPO), which is essential for the control of thermoregulation. The importance of this interaction becomes clear when one evaluates the consequences of fasting for the physiological organization of the body. Fasting results in a diminishment in temperature, but only during the sleep period; it lowers the heart rate, during the day as well as at night; and it increases running wheel activity in rats in spite of the diminishing energy stores. At the same level, induced obesity in rats also affects the

Figure 4 Sagittal scheme of the rat brain to illustrate the main connections of the ventromedial arcuate nucleus (vmARC) within the CNS. Brain areas that have reciprocal connections with the vmARC are indicated in blue. Brain areas with a significant input to the vmARC (i.e., PVT, LSV, and Am) are indicated in orange. Red areas (i.e., IGL and SON) represent those brain areas that receive a significant output from the vmARC. Acb, nucleus accumbens; LSV, lateral septal nucleus ventral part; OVLT, organum vasculosum lamina terminalis; SFO, subfornical organ; LH, lateral hypothalamus; SCN, suprachiasmatic nucleus; SON, supraoptic nucleus; PVN, paraventricular nucleus; sPVN, sub paraventricular nucleus; Am, amygdaloid complex; DMH, dorsomedial hypothalamic nucleus; PVT, paraventricular nucleus of the thalamus; PMV, premammilary nuceus ventral part; IGL, intergeniculate leaflet; PAG, periaquaductal grey; NTS, nucleus tract solitarius, LC, locus coeruleus; AP, area postrema; PB, parabrachial nucleus.

organization of hypothalamic functions; it diminishes the amplitude of the circadian activity and decreases nighttime body temperature. On the other hand, infection also has a large impact on hypothalamic function; it increases corticosterone secretion, diminishes activity, increases temperature, and induces sleep. These observations emphasize the interactions between the different hypothalamic structures and how they affect the functioning of the biological clock. In order to understand these mechanisms, it is important to consider that, in addition to light information that reaches the SCN, mainly in the ventral part, also (metabolic) information from the circulation may reach the SCN via CVOs such as the arcuate nucleus. This site of integration in the SCN (i.e., light and metabolic data target the same area) may allow metabolic information to modify the activity of the SCN similar or contrary to the way light affects the SCN.

What is the Relevance of Metabolic Rhythms?

Metabolic rhythms allow adaptation to daily activities and to annual geographical fluctuations in temperature and food availability, thus allowing animals to adjust their energy balance according to the environment. And even more importantly, because of the regularity of these rhythms, they allow animals to anticipate and prepare for those environmental changes. Consequently, the coherence of endogenous metabolic oscillations with the external cycles of the environment is very important for health and homeostasis. When endogenous rhythms uncouple from the external cycles, individuals cannot exhibit the adequate response at the moment when it is needed and they develop health problems and disease. Such is the case in shift workers who work regularly during the normal sleeping period.

Anticipation of Changes in Energy Requirement

In order to maintain homeostasis, the body needs to anticipate changes in the environment. One of the clearest examples is the anticipation of seasonal changes. Here the SCN–pineal axis is essential for preparing the animal for the upcoming change in food supply, which forces profound changes in reproduction and metabolism. Day length influences the duration of melatonin secretion, and when the period of melatonin secretion is increased or decreased for some time, the reproductive axis, food intake, and fat

storage are simultaneously affected. A number of species (especially humans) are not (notably) influenced by the change in seasons, but in all mammals the biological clock, the SCN, has a special role, in that it takes care of anticipating change in metabolism prior to a period of activity. This anticipatory role of the SCN is characteristic of its involvement in the organization of the physiology in animals, and its influence on metabolism can be seen, for example, in the rise in glucose, corticosterone, and body temperature just before awaking (Figure 1). The appropriate organization of the metabolism is essential for the life of an organism: this may be the reason why, in addition to the circadian system, a number of other physiological systems and/or functions also influence metabolic functions, such as body temperature, fluid balance, the immune system, and reproduction. These functions are all organized within the hypothalamus, where the main tasks of the body are controlled and transmitted to the body by hormones and the autonomic nervous system. Clearly, the organization of metabolic functions takes place within this circuit of brain–body interaction, and a change anywhere in this circuit has repercussions for both brain and body. For example, the metabolic syndrome is a metabolic disease which is characterized by hyperlipidemia, visceral obesity, hypertension, or diabetes. Disturbed circadian rhythms are a prominent feature of the metabolic syndrome.

Metabolic Rhythms without the SCN; Food Entrainment

Under special conditions, when food is restricted to a short daily event, animals show metabolic adjustments that enable them to deal with such a restricted feeding schedule. Also, animals modify their behavioral patterns in order to be active and anticipate meal time. Animals show increased arousal, foraging, and locomotion 2–3 h before expected food access, a preparatory behavior known as 'food anticipatory activity.' This anticipatory behavior appears independent of the SCN-driven nocturnal activity characteristic of most rodents, which remains, although with decreased amplitude. In order to adjust to the feeding schedule, metabolic rhythms show phase shifts and exhibit peaks related to meal time; some of them, like the corticosterone rhythm, exhibit a peak during meal time anticipation, while the largest part of the SCN cellular activity and metabolism remains adjusted to the LD cycle. Metabolic rhythms persist independent of the SCN and continue to oscillate with a 24 h period, probably driven by food-entrained oscillators. This conclusion is based on the observation that food entrainment is also visible in SCN-lesioned animals, indicating that the SCN is not essential for food entrainment. Due to this latter fact, for approximately 30 years, there has been a search for a different biological clock, the food-entrained oscillator, which is thought to drive food-entrained rhythms when food access is uncoupled from the LD cycle. The functional and anatomical identity of this clock remains unknown to date. Recent studies have evidenced that under restricted feeding schedules, food becomes a powerful entraining signal for most of the peripheral organs in which diverse cellular functions exhibit food-entrained rhythms. In both peripheral organs and in brain structures, feeding schedules entrain daily oscillations of clock genes. Thus it has become clear that food, when restricted to a few hours a day, can override the signals of the LD cycle-driven clock and can uncouple the metabolic oscillations from the SCN. However, this does not imply that, under normal circumstances, the SCN is not involved in food entrainment, because in such conditions animals organize their meals according to their activity phase.

In order to approach phenomena of internal desynchronization resulting from jet lag, shift work, or nocturnal activities, it is important to keep in mind that food can exert a powerful influence as an entraining signal to the peripheral organs and metabolic processes. Such circadian disorders can be approached by tightly controlling the feeding schedules in order to shift metabolic rhythms to the expected phases. Also, it remains to be established whether disorganized feeding schedules can be linked to metabolic problems due to uncoupling of peripheral oscillators from the SCN.

The Metabolic Syndrome: A Brain Disease?

Ignoring the Signal of the Clock

The background of the mechanisms causing the metabolic syndrome is incompletely understood. In general, there is agreement that the cause for this outbreak of obesity must lie in the abundance of food in modern societies and the fact that evolution has shaped us for periods of scarcity rather than surplus. In addition, our evolutionary-shaped homeostatic systems have 'learned' to adapt to the everchanging LD cycle, in such a way that the body anticipates the upcoming sleep and activity periods. During the past century, life has changed dramatically in industrialized countries. Food has become abundant and snacking frequency has increased and shifted toward the end of the day, while at the same time the necessity for physical effort has become considerably reduced. Also, physical activity no longer necessarily coincides

Figure 5 Model of the metabolic syndrome caused by a central nervous deregulation. The disturbed output of the biological clock affects the selective balance of the autonomic nervous system (ANS) in different parts of the body. In the intra-abdominal compartment, the ANS is shifted in favor of the parasympathetic branch, resulting in high insulin secretion, growth of intra-abdominal fat tissue, and fatty liver. Contrarily, in the thorax and movement compartment, the sympathetic branch prevails, leading to high blood pressure and impaired glucose uptake by the muscle. In this model, the symptoms of the metabolic syndrome are result and not cause of the disease.

with the light period. We hypothesize that in such conditions the susceptible brain loses its feeling for internal and external rhythm. As a result, the environment sensed by the brain has become metabolically flattened and arrhythmic. Since the brain uses the ANS to implement the internal rhythmicity, we propose an unbalanced and arrhythmic ANS as a major cause of the metabolic syndrome.

The organization of the output of the SCN via the ANS forms the basis for this proposal. For a long time, fat tissue has been assumed to be targeted by hormones or to be innervated by the sympathetic nervous system only. Recently, it was demonstrated that parasympathetic input from the vagal motor nucleus to fat tissue clearly modulates insulin sensitivity and glucose and fat metabolism in fat tissue in an anabolic way. This allows the brain to stimulate either the burning of fat (sympathetic) or the accumulation of fat (parasympathetic). Moreover, we demonstrated that the brain has an astonishing capacity with respect to the specialization of neurons in the hypothalamus and SCN. For example, preautonomic neurons are present in the SCN and other hypothalamic areas that project either to the intra-abdominal or the subcutaneous body compartment. The significance of this is that the intra-abdominal organs, for example, visceral fat, liver, and pancreas, receive input from the same neurons (Figure 5). Since consuming a meal stimulates the parasympathetic output to the pancreas and results in insulin secretion, the consequence of this hard ANS wiring is that the same stimulus will also increase the insulin sensitivity of the liver and of the visceral fat. Since meals consumed in the evening are known to lead to enhanced insulin secretion, a more efficient uptake of glucose in visceral fat will accordingly result in easier accumulation of intra-abdominal fat. These facts, taken together, indicate that as a consequence of the changed lifestyle in industrialized countries, the metabolic syndrome is on the rise as well, not necessarily because too much food is consumed, but because food is eaten at the wrong time!

Introduction

A fundamental characteristic of life on the planet Earth is the 24 h cycle of changes that occur at the cellular, tissue, organ, and whole organism level, to match the period of the rotation of Earth on its axis. Throughout much of the second half of the twentieth century many investigators working on organisms as diverse as the fungus *Neurospora*, the fruit fly *Drosophila*, the hamster *Mesocricetus,* and humans (*Homo sapiens*) conclusively demonstrated that diurnal rhythms were not simply driven by the 24 h changes in the external physical environment, but instead arose from internal biological clocks. Because the endogenous period of these living daily clocks is rarely exactly 24 h, but nevertheless is always close to 24 h, the clocks are called 'circadian' (from the Latin, 'about a day'), and the rhythms that are measured (e.g., sleep–wake cycle, body temperature, feeding, pituitary hormone release) are referred to as circadian rhythms. The nonexact 24 h nature of the internal circadian clock necessitates that it somehow be synchronized to the precise 24 h solar day so as not to become desynchronized from the environmental day–night cycle, and for most organisms the daily light–dark (LD) cycle serves as the major entraining agent of the endogenous circadian clock. (Further details about how circadian clock systems are organized throughout the animal kingdom, and the remarkable progress that has been made in the past decade in unraveling the molecular machinery that underlies the generation of circadian rhythms, can be found elsewhere in this encyclopedia.)

The master circadian clock, located in the bilaterally paired hypothalamic suprachiasmatic nucleus (SCN) in mammals, regulates the timing of literally hundreds of physiological, metabolic, and behavioral parameters. Such timing is thought to be important for the health and well-being of the organism, both in terms of maintaining synchronization of the organism with the external environment (e.g., to search for food or sleep at appropriate time of day or night) and in terms of maintaining synchronization between the myriad of internal circadian rhythms. The SCN has often been referred to as being analogous to the conductor of a symphony. In the presence of the conductor, the individual components of the orchestra play in synchrony with one another. Without the conductor, the individual units will become out of synchrony, with the resulting cacophony of sound. Aging is known to lead to a disruption of the circadian organization of the organism at many levels; the following discussions focus on the mechanisms underlying age-related changes in the circadian clock system, and the possible consequences for the organism as it transitions from a highly synchronized to a less synchronized diurnal state with advancing age.

With advancing age there are changes in several components of the circadian timing system, and each may play a role in the age-related decline in efficacy of the system as a whole. While a decreased strength of input signals to the circadian system may explain some of the age-related decline in sensitivity to both photic and pharmacological stimuli, concurrent changes in the function of the central pacemaking mechanism may account for some changes in sensitivity. Changes in the central pacemaker may occur at the level of the intracellular loops of transcription and translation that have recently been elucidated. In addition, some of the decline in overt circadian rhythmicity may be due to changes in output signals from the circadian clock, or to deteriorating responsiveness of the body's aging effector systems to circadian signals. Thus, aging of the circadian clock system can occur at many levels: from the input to the clock, the clock itself, and its output signals, as well as the end processes affected by circadian signals (Figure 1).

Age-Related Changes in Inputs to the Circadian Clock

A remarkable feature of the mammalian circadian photoreceptive system is that the photoreceptors necessary for vision, the rods and the cones, are not necessary for light to entrain the circadian clock. It has been clearly established in rodents and primates that melanopsin-containing cells exist in the ganglion layer of the retina, and these ganglion cells appear to be the primary photoreceptors relaying light information from the retina to the SCN. While the anatomical and functional importance of these melanopsin-containing ganglion cells has only become apparent in the past few years, two features of the circadian organization of vertebrates/mammals that have been known for decades suggested that light input to the circadian clock was separate from the visual system. First, among the nonmammalian vertebrates, the circadian photoreceptors are not even in the eye, but instead are 'extraretinal' and lie deep in the brain. Second, in mammals, there is a special tract of nerves that projects directly

Figure 1 Schematic representation of the circadian clock system in its simplest form. An internal circadian clock must receive input from the external environment, which in the case of most mammals involves photic information from the light–dark environment that is detected by the eye. The internal clock in turn must then communicate temporal information to effector systems regulating such measurable output rhythms as the daily activity/rest cycle of rodents. Age-related changes in the circadian clock system could occur at any level along this pathway, both at the level of the central circadian clock in the suprachiasmatic nucleus and at the level of a multitude of molecular circadian clocks regulating expression of hundreds of clock-controlled genes in cells/tissues outside of the suprachiasmatic nucleus, through the central nervous system and periphery. Courtesy of Deanna Arble.

from the retina into the hypothalamic SCN, referred to as the retinohypothalamic tract (RHT). A second retinal input to the SCN involves an indirect route and goes through the thalamic intergeniculate leaflet. Both traits are separate from the inputs to the visual centers of the brain.

Studies in old rodents indicate that in advanced age (usually >18 months in rats, hamsters, and mice) the circadian photoreceptive system becomes less sensitive to light, based on biochemical, as well as behavioral, measurements. For example, in old rats, mice, and hamsters free-running in constant darkness (DD), the phase shifts which occur in the free-running circadian rhythm of activity in response to a single pulse of light (e.g., 1 h in duration) are less than in a young animal. Light induction of immediate-early genes in the SCN is also reduced in old mice and hamsters. Taken together, the studies of the light sensitivity of the circadian clock system of old rodents has led to the conclusion that in advanced age (1) the sensitivity of the photoreceptive system is decreased, (2) the transition of light information to the SCN is reduced, and/or (3) there is a change in the response at the cellular level of SCN neurons to photic inputs. The use of light therapy to aid in the entrainment of the sleep–wake cycle of elderly humans who are often exposed to very little natural light is partially based on the hypothesis that the photic sensitivity of the circadian system declines with advanced age.

While the light–dark cycle is the major entraining agent of the circadian clock in mammals, other stimuli, including social stimuli, food availability, and the timing of sleep and wake, can entrain and/or influence the temporal profile of rhythms regulated by the circadian clock. As with the response to light, the effects of these nonphotic stimuli on the circadian clock are attenuated in advanced age in rodents. Of particular interest is information reaching the SCN via serotonergic input from the midbrain raphe nuclei, since it appears that this input has a diminished effect on clock function with advanced age; an interesting age-related change in circadian input organization given the association between abnormal circadian rhythms and depression, and the prominent role played by 5-hydroxytryptamine (5-HT; serotonin)-related drugs in the treatment of depression.

Thus, the signaling strengths of both photic and nonphotic inputs into the SCN are diminished in advanced age. Since the proper functioning of input pathways to the central clock is necessary to synchronize the internal timekeeping mechanism with the external environment, age-related changes in the inputs could lead to an age-related pathophysiology of the circadian organization. In addition, as discussed in the next section, age-related changes in the central timing mechanisms can also occur with advanced age.

Age-Related Changes in the Master Central Circadian Clock

A common feature of age-related changes in different cellular, physiological, and behavioral circadian rhythms is a change (usually a decrease) in the amplitude of the rhythms. While a decrease in rhythm amplitude could be due to effects of age on downstream events, there is considerable evidence demonstrating that a decrease in the amplitude of the central core circadian clock is an important component of aging in the organization of the circadian system. This is directly observed in old rats and hamsters, in which the amplitude of the circadian rhythm of the firing rate of SCN neurons (the firing rate is higher during the day than in the night in both nocturnal and diurnal animals) is decreased with old age. This decrease does not appear to be due to an age-related

decrease in the number of SCN neurons, but instead has been attributed to a change in the ability of individual SCN cells to oscillate and/or to a decrease in the coupling strength between individual cells. The diurnal rhythm in glucose uptake within the SCN (also increased during the light period) is also attenuated in advanced age. *In vitro* studies have also found that while individual SCN neurons from young adult mice (2–4 months old) show robust circadian rhythms in spontaneous activity, with periods close to the period of behavioral rhythms in the intact animal, SCN neurons from 'middle-aged' mice (9–11 months old) show a decrease in the amplitude of impulse activity and more variability in the circadian waveform of activity.

A few laboratories have demonstrated that in rodents the expression of some of the core molecular circadian clock genes (e.g., *Clock*, *Bmal 1*, *Per*) is reduced in advanced age. In addition, a number of clock-controlled genes, as well as genes for which expression is induced by light (including core circadian clock genes), show reduced rhythms or induction by light in advanced age. An age-related decrease in gene expression in response to light is consistent with a decrease in the phase-shifting effects of light on measurable output rhythms, such as locomotor activity, with advanced age. Taken together, these data indicate that the age-related changes that are observed in multiple diverse rhythms in mammals may be due to changes within the SCN cells/tissues – changes that alter the ability of the SCN to generate rhythms and to respond appropriately to external entraining stimuli.

Age-Related Changes in Function of the Downstream Effector System

Of course, changes in the amplitude of many circadian rhythms could be due, in part, to age-related changes in the downstream (from SCN) elements for which diurnal timing is only one component of the overall function of the tissue/organ or behavior being measured. For example, a common characteristic observed almost universally in old rodents is a gradual decrease in the amount of locomotor activity (e.g., fewer wheel revolutions, or beam crossings in a cage), which could likely be due to a weakening of muscle strength. Similarly, aging reduces the circulating levels of many hormones, which could be due to diminished activity of the endocrine glands. Thus, when one observes a breakdown or changes in the circadian organization with advanced age, the underlying cause could be at the input, pacemaker, output signaling, and/or one of the many downstream components involved in the actual rhythm being measured.

A recent and far-reaching discovery about the circadian organization of higher organisms has important, but largely unaddressed, implications about the effects of aging on this organization. Just a few years ago it was generally believed that few cells/tissues outside of the SCN contained the machinery capable of generating a self-sustained molecular circadian rhythm in gene and protein synthesis. However, it is now recognized that most, if not all, of the tissues and cells of the body contain not only the core molecular circadian transcriptional and translational elements, but that many of these non-SCN central and peripheral tissues can sustain oscillations *in vitro* for a number of cycles. Furthermore, these cellular clocks, while under the upstream entrainment of the SCN molecular central clock, are regulating at the 'local' level the diurnal rhythms in expression of hundreds of clock-controlled genes. Since we know that aging has an impact on the input pathways to the SCN, as well as the central pacemaker cells in the SCN, it is almost certain that aging will have consequences for the inputs from the SCN to the downstream molecular circadian clocks, as well as on those downstream clocks. The functional consequences for age-related changes at multiple levels in the overall circadian organization await future research. However, the recent finding that aging may have differential effects on central and peripheral oscillators, as well as the resetting properties of these oscillators, raises the intriguing possibility that such age-related changes in timing at the tissue/organ level could contribute to diseases of the brain and periphery.

Attenuating or Reversing Age-Related Changes in Circadian Organization

As with other aging physiological systems, attempts have been made to find the 'fountain of youth' for aging circadian structures. Since the circadian clock becomes less responsive to the entraining effects of photic (as well as nonphotic) stimuli, early attempts to improve circadian rhythmicity involved increasing the strength of the entraining light–dark cycle by increasing light intensity. Modest success in increasing the amplitude of the sleep–wake or activity–rest cycle in rats and hamsters, particularly middle-aged animals (Figure 2), has lent support to the use of bright light therapy in the elderly at the beginning and/or end of the day in an attempt to enhance and increase the robustness of circadian rhythmicity.

It has been suggested that melatonin may be useful in treating a number of human circadian disorders, including age-related insomnia. The melatonin agonist S20242 significantly increases a measure of rhythm stability, the χ^2 value of the periodogram,

Figure 2 (a) Rhythm of wheel-running activity of male golden hamsters, one young (5 months old) and one old (17 months), showing how with advanced age the activity rhythm becomes less consolidated and more fragmented, with a decrease in total activity. (b) Activity rhythm of a 'middle-aged' male hamster (14 months) exposed to a light–dark cycle in which the light intensity was increased, at the indicated time, from 300 to 1500 lux. The increase in light intensity resulted in a more consolidated activity rhythm. Activity data for all three animals (ages 5, 17, and 14 months) are plotted over 48 h time intervals, and the animals were exposed to a 14:10 light–dark cycle, as indicated by the light and dark bars at the top of each record.

when administered to middle-aged and old rats. This treatment also increases the amplitude of the circadian rhythm of body temperature in middle-aged, but not old, rats. Daily feeding of a different melatonin agonist (S20098) to old hamsters restores their sensitivity to a dark pulse; when the treated food is removed, dark pulses once again fail to phase-shift the old hamsters. Together, these two findings suggest

that exogenous melatonin may be able to restore at least some of the 'youthful' properties to the circadian systems of old animals.

Can Circadian Dysfunction Affect Aging?

A final consideration reverses the question ('what are the effects of aging on the circadian organization?') that has been addressed throughout most of this article. Instead, now a different question is addressed: What are the effects of disrupted circadian rhythms on aging?

A salient characteristic of modern industrial societies is the fact that many jobs require individuals to work at times they would normally be asleep, and to sleep at times they would normally be awake. Such 'shift workers' are constantly changing the times when they are awake or asleep relative to the 24 h day. Thus there is repeated desynchronization or resynchronization between their internal 24 h clock with the external time of day. There is a good deal of epidemiological data to support the hypothesis that there are health consequences of circadian maladaptation and disrupted sleep–wake cycles in shift workers. Shift work has been associated with increased cardiovascular morbidity and mortality, as well as gastrointestinal and metabolic disorders. Surprisingly, there is little experimental evidence from animal models to support the hypothesis that the continuous disruption of normal temporal organization is in fact detrimental to the health of the organism. However, this may well be a classic case whereby the 'absence of evidence' does not mean the hypothesis is incorrect, but instead, is due to the fact that few studies have even addressed the question. While a few early studies indicated that exposure to non-24 h LD cycles, or repeated phase shifts of the external periodic environment to disturb normal circadian organization, decreased the life span of several invertebrate species, remarkably, few similar studies have addressed this question in mammals. In one study of cardiomyopathic hamsters, chronic reversal of the external LD cycle at weekly intervals resulted in a significant decrease in the survival time: the median life span was reduced by 11%. Thus, disrupting normal circadian rhythmicity in an animal susceptible to early mortality due to cardiac disease resulted in a further decrease in longevity. The deleterious effects of repeatedly phase shifting the LD cycle in cardiomyopathic hamsters may be related to reports of increased cardiovascular morbidity and mortality in humans engaged in shift work. Recent studies by Block and colleagues have demonstrated that repeated phase advances in the LD cycle can hasten the death of aged mice, but, interestingly, phase delays did not. Taken together, these findings suggest that experimental or voluntary disruption of the 24 h temporal homeostasis may have adverse effects on the health, well-being, and longevity of the organism.

Circadian Organization in Non-Mammalian Vertebrates

H Underwood, North Carolina State University, Raleigh, NC, USA

Introduction

Daily rhythms are a universal feature of eukaryotic organisms; daily oscillations occur at all levels of organization from the molecular to the whole animal. Significantly, most of these daily rhythms persist when the organism is isolated from cyclic environmental cues, showing that they are driven by an internal timekeeper – a circadian clock. When an organism is expressing its endogenous periodicity in constant conditions, it is said to be free-running. The daily light–dark (LD) cycle is the principal cue that synchronizes, or entrains, circadian clocks, although temperature cycles are effective entraining agents for poikilotherms as well. Entrainment of circadian rhythms by environmental cycles ensures that these rhythms occur at the right time of day. Circadian clocks allow organisms to predict, and prepare, for changes in the external environment; for example, a lizard can predict the coming of colder nighttime temperatures and seek shelter while surface temperatures are still conducive for activity or digestive enzyme levels can rise in anticipation of a meal. A popular hypothesis as to the origin of circadian rhythmicity proposes that rhythmicity originally evolved in response to the daily shower of ultraviolet radiation from the sun. Colored molecules are particularly prone to ultraviolet damage; consequently, organisms partitioned their biochemical activities so that light–sensitive reactions occurred during the dark phase of the daily light–dark cycle.

Conceptually, a basic circadian system must comprise at least one photic input pathway to convey entraining light information to the circadian clock, the circadian clock itself, and an output pathway coupling the clock to its overt rhythm. The expectation of early circadian biologists was that specific, presumably neural, sites within the animal played a significant role in generating circadian rhythmicity; that is, one (or several) circadian clocks controlled the myriad rhythms expressed throughout the body.

Much of the work on circadian systems in vertebrates, therefore, has focused on identifying the sites that generate circadian rhythmicity and their photic inputs. Within the last 35 years, remarkable strides have been made in identifying areas that play a major role within the circadian system of vertebrates. This journey has had its share of rewards and surprises as biologists have revealed the existence of multiple photic inputs, multiple circadian pacemakers, and the existence of cellular clocks spread throughout the organism.

Pineal Organ and Melatonin

The first organ that was shown to play a major role within the vertebrate circadian system was the pineal organ; it was demonstrated that removal of the pineal organ caused the activity rhythm of house sparrows to become arrhythmic in constant darkness (DD). Activity rhythms are frequently used by circadian biologists to monitor the behavior of the circadian clock because activity is easily measured, it can be monitored continuously, and it does not require that the animal be restrained or biopsied. Pineal organs are found in virtually all vertebrates, and they develop as evaginations of the roof of the diencephalons. The pineal organ is located on the surface of the brain in many vertebrates, making it an attractive site for investigation because it can be easily removed. Following the initial observation that pinealectomized house sparrows are rendered arrhythmic in constant conditions, investigators showed that pinealectomy had major effects on the activity rhythms of other non-mammalian vertebrates as well, including at least five species of fish, one species of amphibians, six species of lizards, and nine species of birds (Figure 1). Interestingly, pinealectomy did not always produce arrhythmicity; in some cases it caused a change in the period of the free-running rhythm or, more rarely, it caused the activity rhythm to split into two independently free-running circadian components. These three effects of pinealectomy – arrhythmicity, period changes, or splitting – could sometimes be observed between individuals of the same species. The most reasonable model to explain these diverse effects of pinealectomy posits that the pineal organ acts as a circadian pacemaker that controls the period and phase of subordinate oscillators. The subordinate oscillators are mutually coupled, and it is the inter- and intraspecific variations in the strength of coupling between the subordinate oscillators that accounts for the different effects of pinealectomy. If the coupling strength between the subordinate oscillators is strong, the removal of the pacemaker causes a change in the period of the coupled subordinate oscillators, whereas if coupling is weak, the subordinate oscillators do not remain coupled but will split apart and each subordinate clock will begin expressing its own endogenous periodicity.

Figure 1 Schema of activity patterns showing the effects of pinealectomy (P) in three classes of vertebrates: (a) birds; (b) lizards; (c) fish. Pinealectomy has one of three kinds of effects: splitting of the circadian activity rhythm into two circadian components (Texas spiny lizard and white sucker), arrhythmicity (house sparrow, green anole, and catfish), or a change in the period of the free-running rhythm (starling, western fence lizard, and burbot). From Underwood H, Wassmer GT, and Page TL (1997) Daily and seasonal rhythms. In: Dantzler WH (ed.) *Handbook of Comparative Physiology, Vol. 13: Comparative Physiology*, pp. 1653–1763. New York: Oxford University Press.

One experiment is particularly informative and bears directly on the question as to whether or not the pineal organ is indeed a pacemaker controlling the organism's entire circadian system. Zimmerman and Menaker transplanted pineal organs from donor birds entrained to light–dark cycles (in which light onsets occurred at either 09.00 or 23.00) into pinealectomized arrhythmic house sparrows in constant darkness (DD) (Figure 2). The recipients began showing a rhythm within a day or two of transplant, and, significantly, the rhythm began from the phase dictated by the donor's pineal, approximately 09.00 or 23.00. The sparrow's pineal, therefore, is indeed the site of a circadian pacemaker because an important property of a pacemaker – its phase – was transplanted along with the pineal.

Pineal organs have an interesting evolutionary history. The principal cell type in the mammalian pineal is a secretory cell, the pinealocyte, which is believed to have evolved from a photosensory cell. Indeed, the main cell type in the pineal organs of fish, amphibians, and reptiles is a cell that resembles in many aspects the cone photoreceptors of the lateral eyes; it is bipolar, it has a stack of photoreceptive discs (the

Figure 2 Evidence that the avian pineal is the site of a circadian pacemaker. The perching activity records of the two birds shown in the top records were entrained to light–dark cycles that were 14 h out of phase with one another. Subsequently, their pineal organs were removed and transplanted into two birds (middle records) that had become arrhythmic in constant darkness (DD) following pinealectomy. A free-running rhythm emerged in the transplanted birds (bottom records) and, significantly, the initial activity onsets occurred at the same time of day as the activity onsets in the donor birds. The pineal is the site of a circadian pacemaker because an important property of the pacemaker – its phase – can be transplanted along with the pineal. From Zimmerman NH and Menaker M (1979) The pineal gland: A pacemaker within the circadian system of the house sparrow. *Proceedings of the National Academy of Sciences of the United States of America* 76: 999–1003.

outer segment) containing the photopigments, it has an inner segment containing the nucleus, and it has a synaptic pedicle that makes contact with other neurons. However, in many cases this cell is more degenerate in appearance than a typical cone photoreceptor and, particularly in birds, the outer segment may be reduced to a simple whorl of membranes. A variety of studies have shown that the pineal organs of all the nonmammalian vertebrates are directly light-sensitive. The photosensory cell is also capable of considerable biosynthetic activity; in particular, this cell type can synthesize and secrete the hormone melatonin. Pineal melatonin is always synthesized rhythmically, with higher melatonin synthesis occurring during the night in both diurnal and nocturnal animals. Melatonin is not stored in the pineal, and this lipid-soluble hormone rapidly enters the blood, so blood melatonin levels increase at night as well.

The fact that pinealectomy had major effects on the circadian system immediately focused attention on a role for melatonin in the circadian system because the pineal is one of the few sites that produces melatonin and, in many species, the pineal is the sole source of blood-borne melatonin. To determine if melatonin could affect the circadian system, melatonin was exogenously administered to amphibians, lizards, and

birds using a variety of approaches, including implanting silastic capsules containing melatonin under the skin or injecting or infusing melatonin on a daily basis. Continuous exposure to pharmacological dosages of melatonin administered via silastic capsules caused period changes or arrhythmicity in a variety of birds (e.g., house sparrows, Java sparrows, house finches, Japanese quail, and pigeons) and lizards (Western fence lizard, Texas spiny lizard, ruin lizard, and green anoles). Daily administration of pharmacological doses of melatonin via injections, infusions, or drinking water entrained the activity rhythms of amphibians (Japanese newts), birds (starlings, Japanese quail, and pigeons), and lizards (Western fence lizard). Most convincingly, daily infusions of physiological levels of melatonin that accurately replaced endogenous levels in pinealectomized *Anolis* lizards and pigeons also entrained the activity or feeding rhythms. Taken together, these experiments support the hypothesis that there is a circadian pacemaker in the pineal organ that controls the period and phase of subordinate oscillators via the rhythmic synthesis and release of melatonin.

The pineal organs of a variety of nonmammalian vertebrates have been studied *in vitro*, primarily by measuring the synthesis and secretion of melatonin. In most cases, the pineal exhibited a light-entrainable rhythm of melatonin that persisted in constant conditions, proving that the rhythm is being driven by an intrapineal clock. The pineal pacemaker in comprised of multiple circadian clocks – individual pineal cells of chickens or *Anolis* lizards can exhibit a circadian rhythm of melatonin secretion and are directly light-entrainable *in vitro*. Therefore, the pineal pacemaker is a multioscillator system in which hundreds of individual light-entrainable pineal clocks mutually interact and produce a single coherent output in the form of the daily melatonin pulse.

Studies have shown that the amplitude and duration of the daily melatonin rhythm change in response to seasonal changes in day length in homeotherms and to seasonal changes in day length and temperature in poikilotherms. The pineal organ, therefore, acts as a photo- or photothermoendocrine transducer that converts environmental stimuli into an internal melatonin signal that accurately reflects the ambient environmental conditions. In turn, melatonin controls the phases of subordinate clocks so that the right internal events occur at the proper time of day.

Hypothalamic Clocks

Beginning in the 1970s, investigators used a variety of approaches including lesions of the suprachiasmatic nuclei (SCN) of the hypothalamus, *in vitro* recordings of electrical activity from SCN slices, and SCN transplantation to show that the SCN was the main circadian pacemaker in mammals. Studies in mammals also revealed that lighting information reaches the SCN via a monosynaptic retinohypothalamic tract (RHT) from the retina. Taking note of these experiments, investigators lesioned the suprachiasmatic area of nonmammalian vertebrates, including Japanese quail, Java sparrows, house sparrows, desert iguanas, and ruin lizard, to determine whether the suprachiasmatic area was playing a significant role in the circadian system of these vertebrates as well. As in mammals, these lesions abolished circadian rhythms of activity, rendering the animals arrhythmic in constant conditions. A significant complication in investigations into the role of the SCN, however, is the fact that the anatomy of the SCN in nonmammalian vertebrates is often more complicated that that in mammals.

We must be cautious in concluding that the nonmammalian SCN is the site of a major circadian pacemaker based solely on the effects of SCN lesions. Although the fact that ablation of a specific area renders an animal arrhythmic is compatible with the hypothesis that the site is the locus of a circadian pacemaker, it is not conclusive. It is conceivable, for example, that the pacemaker is located elsewhere and only its output pathway is disrupted by the lesion. Unfortunately, other studies such as *in vitro* studies of the SCN or SCN transplantation studies have yet to be performed in nonmammalian vertebrates. However, the fact that lesions of the suprachiasmatic area disrupt rhythmicity in nonmammalian vertebrates, and the abundant evidence in mammals that the SCN act as circadian pacemakers, strongly supports the hypothesis that the suprachiasmatic area of nonmammalian vertebrates is the site of the subordinate oscillators described previously. The pineal controls the SCN oscillators via the rhythmic secretion of melatonin. Supporting this hypothesis is the fact that melatonin receptors are found within the SCN.

In contrast to mammals, however, the central oscillators in many nonmammalian vertebrates do not maintain rhythmicity in the absence of periodic inputs, either from the daily LD cycle or from other pacemakers such as the pineal organ. For example, activity rhythms dampen into arrhythmicity over a period of days in most birds following pinealectomy. Arrhythmicity is also observed following pinealectomy in some (but not all) fish, amphibians, and lizards. Overall, these data suggest that the hypothalamic clocks often show less autonomously rhythmicity than the mammalian SCN, especially in birds. In these

species, periodic input, such as a daily melatonin pulse from the pineal, is required to maintain rhythmicity; the hypothalamic clocks either damp out or become desynchronized in the absence of this input.

This idea has been expanded to describe a mutual dependence between the pineal and the SCN in some birds. The neuroendocrine loop hypothesis proposes that neither the pineal nor the SCN is autonomously rhythmic in some avian species. Persistent rhythmicity in the pineal requires periodic sympathetic input from the SCN, whereas persistent rhythmicity in the SCN requires a daily pulse of melatonin from the pineal; consequently, neither the pineal nor the SCN is persistently rhythmic on its own.

As previously mentioned, some controversy surrounds the precise location within the nonmammalian hypothalamus of the homolog of the mammalian SCN. In birds, for example, neuroanatomical and neurochemical studies suggest that two anatomically distinct nuclei – the medial hypothalamic nucleus (MHN; also termed the periventricular preoptic nucleus) and the lateral hypothalamic retinorecipient nucleus (LHRN; also termed the visual SCN) – are possible homologs of the mammalian SCN. Lesioning the suprachiasmatic area of birds has been shown to disrupt rhythmicity, but these lesions probably damaged both nuclei. Recent advances in pacemaker localization, however, may clarify the precise location of hypothalamic pacemakers. A small suite of genes have been identified that code for essential components of the molecular clock in all animals from *Drosophila* to mammals. The heart of the molecular clock consists of a transcription–translation negative feedback loop in which cyclic gene transcription causes circadian variations in proteins that feedback and inhibit their own transcription. Because these clock genes have been cloned, it is now possible to determine their expression patterns in different tissues. In birds, the rhythmic expression of clock genes has been observed in the MHN, but not in the LHRN, of Japanese quail, Java sparrows, chickens, and pigeons, but the rhythmic expression of clock genes has been seen in both nuclei in house sparrows. The location of hypothalamic pacemakers in birds, therefore, may depend on species, being located in the MHN of some and in both the MHN and LHRN of others.

The Eyes as Photoreceptors

In mammals, lighting information is transmitted from the eyes to the SCN via a direct, monosynaptic neural pathway, the RHT. The only way light can entrain the mammalian circadian system is via the eyes. Surprisingly, however, early studies showed that entrainment by light–dark cycles can still occur in rodents in which the rod and cone photoreceptors were missing. Subsequent investigations revealed that a photopigment, melanopsin, found in a small subset (1–3%) of ganglion cells, could mediate entrainment in rodless and coneless rodents. These ganglion cells are intrinsically photosensitive, and they have a number of characteristics that are optimized for detecting the presence and intensity of light such as large receptive fields and a higher threshold for light detection than the classical photoreceptors. Significantly, the axons of these ganglion cells comprise the RHT. The melanopsin-containing ganglion cells, therefore, are fully capable of detecting LD information and transmitting this entrainment signal to the SCN. The threshold intensity of light that can entrain the activity rhythm of mice, however, is slightly higher in rodless and coneless animals than in animals with rods and cones, supporting the hypothesis that both the classical photosensory cells and the melanopsin-containing ganglion cells normally mediate entrainment.

Although the eyes play a role in transmitting LD information to the central circadian system of nonmammalian vertebrates, they are not the only photic inputs. As described previously, the pineal organ of nonmammalian vertebrates are directly photosensitive. However, fish, amphibians, lizards and birds in which both the eyes and the pineal organ have been removed are still entrainable by light, showing the existence of extraocular and extrapineal photoreceptors as well (termed extraretinal photoreceptors (ERRs)).

Along with the ERRs, the eyes of nonmammalian vertebrates are clearly involved in the perception of entraining the LD cycle because the light intensity threshold for entrainment is slightly higher in eyeless fish, lizards, and birds than it is in intact animals. Nonmammalian vertebrates possess a RHT, and it is undoubtedly via the RHT that lighting information is being transmitted to the hypothalamic clocks. The photopigment melanopsin is also found in the retinas of nonmammalian vertebrates and may be involved in mediating entrainment to LD cycles, as it does in mammals, although this has yet to be proven.

The Eyes as Circadian Pacemakers

Many events within the vertebrate eye show circadian rhythms, including the shedding of discs from photoreceptor outer segments, photomechanical movements of rods and cones, synaptic morphology, enzyme activities, and melatonin synthesis. Many ocular rhythms are driven by circadian clocks within the

eye; for example, rhythms of melatonin synthesis can persist in retinas held *in vitro*. Interestingly, the eyes of some nonmammalian vertebrates can also act as circadian pacemakers, controlling rhythms outside the eye. Such a role has been established in at least three lizard and two avian species. Removing the eyes of ruin lizards, Texas spiny lizards, and western fence lizards causes marked changes in the period of the free-running activity rhythm in DD, suggesting that the eyes may be the loci of circadian pacemakers that are significantly involved in controlling the period of central circadian clocks. In pigeons, the removal of the eyes abolishes rhythmicity in DD, but only if the pigeons have also been pinealectomized; eye removal alone, or pinealectomy alone, does not abolish rhythmicity, although it does affect the clarity of the activity and body temperature rhythms. Both the eyes and pineal in pigeons synthesize and secrete melatonin rhythmically, and infusions of physiological levels of melatonin that replace endogenous levels in pinealectomized plus blinded pigeons restore rhythmicity. In the pigeon, therefore, both the eyes and pineal are acting as pacemakers that control central oscillators (presumably in the SCN) via the rhythmic synthesis and secretion of melatonin. In the Japanese quail, the ocular pacemaker plays the predominant role because eye removal alone causes the quail to become arrhythmic in DD whereas pinealectomy has little effect. Additional experiments in quail have shown that the ocular pacemaker controls the central hypothalamic clocks both via a neural output and via rhythmic melatonin secretion.

The cells within the retina that contain the circadian pacemaker have not been definitively established, although the photosensory cells are likely sites because the rod/cone photoreceptors are known to possess circadian clocks and they also synthesize melatonin.

Extraretinal Photoreceptors

One of the most intriguing features of the circadian systems of nonmammalian vertebrates is the involvement of extraretinal photoreceptors; fish, amphibians, reptiles, and birds can be entrained by light–dark cycles after removal of their eyes and pineal systems. Blind lizards and birds can be entrained by light cycles in which the light is as dim as full moonlight (0.1 lux). These extraretinal photoreceptors are probably universally present in nonmammalian vertebrates because no cases have been found in which entrainment to a LD cycle failed after blinding, unless the light intensity was very dim.

An interesting question is: Why do animals that possess eyes also need to have extraretinal photoreceptors? We could argue that that primitive organisms possessed direct light sensitivity for entrainment before the development of the eye, but why has extraretinal photoreception persisted in nonmammalian vertebrates after the development of the eyes? A definitive answer to this question has not yet been made, but the fact that extraretinal photoreceptors are a universal feature of present-day nonmammalian vertebrates argues that there must be a significant selective advantage in maintaining them.

The extraretinal photoreceptors are located in the brain; blocking light penetration to the brain eliminates entrainment in blinded animals and localized illumination of the brain can cause entrainment. Extraretinal photoreceptors are presumably well-suited for irradiance detection (rather than a focused representation of the environment) because overlying tissues scatter light. The circadian system is also designed to integrate the total number of photons received and to do so over a long time span. It is not yet known exactly where these extraretinal photoreceptors are located in the brain or whether their nature or location varies between species or between classes of vertebrates. However, various opsins and other members of the phototransduction cascade have been identified in the hypothalamus (e.g., SCN and preoptic areas) and in the periventricular cerebrospinal fluid (CSF)-contacting neurons of the lateral septum of a variety of nonmammalian vertebrates. Most of the functional studies that have attempted to localize extraretinal photoreceptors have used the seasonal reproductive response to changes in day length (photoperiod) as a measure of photoreception, especially in birds, and these studies also implicate the infundibular zone of the hypothalamus and the lateral septum as photosensory sites. It has yet to be definitively established whether these putative photoreceptive areas mediate entrainment of the circadian clock. However, the fact that a major part of the circadian system resides in the hypothalamus supports the idea that the hypothalamus is a likely site for deep brain photoreceptors that mediate entrainment as well as seasonal photoperiodic responses.

Peripheral Oscillators

Until fairly recently, it was assumed that the SCN of mammals, or multiple interacting pacemaking sites (pineal, eyes, and SCN) of nonmammalian vertebrates were solely responsible for driving the myriad overt rhythms seen in individual vertebrates. This model, however, has undergone significant revision with the demonstration that (1) clock genes are expressed not only in neural pacemaker cells such as the SCN but also in a variety of other tissues and

Figure 3 Model of the circadian system of nonmammalian vertebrates. Circadian oscillators (OSC) reside centrally in the suprachiasmatic area of the hypothalamus and more peripherally in the pineal and eyes. The pineal is linked to the rest of the system via melatonin, whereas the eyes may be linked by melatonin or neurally, probably via the retinohypothalamic tract (RHT). Light can entrain oscillators in the pineal and eyes directly, it can entrain the central system via extraretinal receptors (Errs) in the brain, and it can entrain the central system via photoreceptors in the pineal and eyes. In some species, persistent rhythmicity in the pineal and suprachiasmatic nucleus (SCN) may depend on a mutual interaction between them.

(2) rhythmic gene expression can continue in cells, tissues, and organs cultured *in vitro*. In fact, it is likely that every vertebrate cell contains a competent molecular clock. Clocks located outside of the central nervous system have been termed peripheral oscillators.

The existence of peripheral oscillators raises interesting questions about the role of pacemakers located in the brain or eyes (the SCN of mammals or the SCN/pineal/eyes of nonmammalian vertebrates) within the entire circadian system. The crucial parameter that determines whether these pacemakers play a major role may be whether the peripheral oscillators are directly photosensitive. If a peripheral clock can be entrained directly by light, it may not require control by other pacemakers.

Clearly, in mammals the SCN must act as the master pacemaker that controls, via hormonal and/or neural links, the period and phase of peripheral oscillators because peripheral oscillators in mammals cannot be entrained directly by LD cycles; LD cycles entrain the SCN, which, in turn, controls peripheral clocks. However, studies of clock gene expression in zebra fish showed that a variety of organs, such as the kidney and heart, as well as individual cells, exhibit light-entrainable rhythms *in vitro*. In the zebra fish, therefore, the possibility exists that a master clock is not needed to control the period or phases of peripheral oscillators.

Peripheral clocks have also been identified in various tissues in other nonmammalian vertebrates such as birds, but there are no reports that these clocks are directly light-entrainable. More studies are needed to determine which nonmammalian vertebrates have light-entrainable peripheral clocks. Perhaps direct-light entrainment is confined to small fish that are relatively transparent to light.

Investigations into the circadian system of nonmammalian vertebrates over the last few decades showed that, in contrast to mammals, the circadian system is composed of several interacting pacemaker sites, although there are some significant differences between species in the relative roles that these sites play (Figure 3). Also, in contrast to mammals, light can entrain the circadian system via several routes.

Circadian Oscillations in the Suprachiasmatic Nucleus

W J Schwartz, University of Massachusetts Medical School, Worcester, MA, USA

The suprachiasmatic nucleus (SCN) in the anteroventral hypothalamus is a compact bilaterally paired nucleus straddling the midline, bordering the third ventricle, bounded anteroventrally by the optic chiasm (Figure 1). Best characterized in rodents, it is less than 1 mm long and consists of about 16 000 neurons that are tiny (<10 μm diameter) and very tightly packed. It is the site of an endogenous clock mechanism that governs daily behavioral, physiological, and endocrine rhythms. At the core of the clock is a self-sustaining, light-entrainable pacemaker that oscillates with a circadian (*circa*, about; *dian*, day) period when it is maintained in a constant environment free of external timing cues. Experimental destruction of the SCN by electrolytic lesions leads to a breakdown of the entrainment or generation of a wide range of circadian rhythms, without restoration of function even after prolonged postoperative survival. Transplants of fetal SCN tissue can reestablish overt behavioral rhythmicity in arrhythmic, SCN-lesioned recipients, and the rhythms restored by the transplants display properties that are characteristic of the circadian pacemakers of the donors rather than those of the hosts.

Circadian Rhythmicity of SCN Tissue *In Vivo* and *In Vitro*

In order to begin to understand the clock's mechanism, several assays have been employed as markers for the amplitude, phase, and period of the circadian pacemaker's oscillation. The use of multiple measures helps to distinguish those experimental manipulations that eliminate overt rhythms by actually arresting the pacemaker from those that uncouple a specific output from the still-oscillating pacemaker (loss of the clock's 'hands' rather than damage to its 'gears').

SCN metabolic activity was the first property of the nucleus reported to exhibit circadian rhythmicity. These experiments utilized an autoradiographic method for the *in vivo* determination of the rates of glucose utilization of individual structures within the brain by injecting animals with tracer amounts of 2-deoxy-D-[1–^{14}C]glucose. This assay is useful because regional brain functional activity is closely coupled to regional brain energy utilization, which is dependent on the continuous provision of glucose. SCN glucose utilization is high during the light phase (day) of a light–dark cycle and low during the dark phase (night) in both nocturnally and diurnally active animals. The rhythm persists when animals are maintained in constant darkness (subjective day and night), occurs in fetal animals *in utero*, and continues in acutely prepared SCN explants *in vitro*. A limitation of the deoxyglucose method is that injected animals must be killed in order to prepare brain sections for autoradiography; thus, the metabolic rhythm is not continuously recorded from individual subjects, each monitored longitudinally over several circadian cycles, but instead from groups of subjects sacrificed and sampled at different phases of a single circadian cycle. Methods that rely on such pooled groups, like the deoxyglucose method and those that measure mRNA or protein levels on brain sections, may lead to confusing results if rhythms among individual subjects are not synchronous. Apparent arrhythmicity of such a population might be due either to a loss of rhythmicity of each subject or to a desynchronization of rhythmicity between subjects if each of the individuals expresses a rhythm that differs in phase or period.

One rhythm that can be measured longitudinally in individuals is SCN electrical activity. *In vivo*, the overall firing rate of multiple neurons or the discriminated spikes from single neurons can be recorded using an extracellular electrode; discharge rates are low (around 1 Hz), double in frequency between day and night, and are high during the day or subjective day and low during the night or subjective night in both nocturnal and diurnal rodents. Circadian rhythms of single or multiple unit electrical activities have also been recorded from the SCN in hypothalamic slices *in vitro*. In general, these studies have been performed by sampling the spike activity of single units for short time intervals at different phases across the circadian cycle, pooling the data from a number of slices and phases, and then determining the phase of peak firing rate for the population of units as a whole. Workers using this method must make repeated electrode penetrations of the tissue, and they usually record from individual cells for a few minutes in slices kept for several hours, although there are reports of single neurons held for 14 h and single slices maintained for a few days. Although technically demanding, long-term (>24 h) multiple-unit recordings using single electrodes have also been accomplished in slices. Independent of method, the amplitude of the electrophysiological rhythm *in vitro*

Figure 1 Coronal Nissl-stained section through the rat forebrain, including the bilaterally paired SCN (arrow).

appears to be larger than *in vivo*, with a peak level about 4–5 times higher than baseline values, and without some of the high-frequency components observed *in vivo*. It is not yet understood how neuronal firing rate relates to the coding of efferent signals sent by the SCN to other brain regions.

Most recently, a restricted set of 'clock' genes has been identified and is believed to underlie the actual oscillatory mechanism of the circadian pacemaker; moreover, a significant percentage of the whole genome is modulated by the clock. Rhythms of neuroactive peptides synthesized in the SCN, usually measured in tissue punches and sections at the mRNA and protein levels, provide a valuable window on clock-controlled gene expression (transcription and protein translation and degradation). Within the SCN, mRNA and peptide levels of the neuropeptide transmitter arginine vasopressin (AVP) exhibit circadian rhythmicity, and nuclear run-on analysis has demonstrated that mRNA abundance is regulated by transcription; posttranscriptional mechanisms also contribute to the temporal pattern of SCN AVP expression. This peptide rhythm has been followed longitudinally in the cerebrospinal fluid (CSF) of individual animals and in the culture medium of individual explants. CSF levels are high during the subjective day and low during the subjective night in both nocturnal and diurnal animals, and the rhythm persists *in vitro* in hypothalamic slices and even dissociated cell cultures. The demonstration that two peptide rhythms (AVP and another SCN neuropeptide transmitter, vasoactive intestinal polypeptide (VIP)) can be serially and simultaneously measured *in vitro* is a powerful advantage of this approach.

Multiple Single-Cell Circadian Oscillators within the SCN

New technologies have enabled researchers to establish that SCN rhythmicity is a product of multiple individual cellular circadian oscillators that are coupled together in a tissue network. Fixed multielectrode arrays have provided a method that allows for the simultaneous monitoring of neuronal firing rates from individual dispersed cells in culture. Single cells dissociated from neonatal SCN and cultured at low density express circadian firing rhythms with widely varying phases, in part because different cells express independent circadian periods. This result shows that the SCN is a multioscillator system and suggests that individual SCN cells can act as competent circadian oscillators.

Several laboratories have now taken advantage of rhythmic 'clock' gene transcription to introduce reporter gene constructs for real-time monitoring of gene expression, and high-sensitivity cameras have made it possible to record the oscillation of such bioluminescent (e.g., luciferase) or fluorescent (e.g., enhanced green fluorescent protein (GFP)) reporters from individual cells. The kinetics of such reporters allow for monitoring changes in gene activity that are slower than approximately 1.5 h. GFP fluorescence is bright enough to be visualized in individual cells but requires repeated illumination with potentially damaging consequences. Bioluminescence from luciferase is dimmer but requires delivery of substrate (luciferin) to the region under study.

SCN slices made from neonatal transgenic mice carrying the promoter for the mouse *Period1* (*Per1*) gene linked to the gene for either GFP or luciferase show robust circadian rhythms in light emission. Notably, individual SCN cells in the slices show rather large phase differences in the peaks of their rhythms that persist over repeated cycles (i.e., the individual cellular periods are similar and stable) (**Figure 2**). The phase order does not appear to be a random property of the cellular network in the slice, because it is restored in *Per1::luciferase* slices after a protein synthesis inhibitor is applied to first stop and then reset the cellular oscillations to the same initial phase. These intercellular phase differences are not an artifact of transgenic preparations, because similar differences have been demonstrated by electrophysiological methods in wild-type rat SCN slices. Thus, the duration of high molecular and electrophysiological activities of individual SCN cells coupled together in a slice differs from the composite activities of the tissue as a whole (which generally lasts for most of the subjective day). The circadian waveform of synchronized SCN tissue activity is assembled from subpopulations or individual cells, each expressing

Figure 2 Circadian rhythms of bioluminescence from four individual SCN neurons within a cultured hypothalamic slice made from a neonatal transgenic mouse carrying a mouse *Per1* promoter-driven luciferase reporter. The signal intensity from each cell (in colors for this illustration) is integrated at 1 h intervals and plotted, with the trough time of total SCN tissue bioluminescence set to time = 0. narrower activity peaks sharing a similar period but differing in phase.

The functional significance of heterogeneous cellular phases is not known. It is possible that their distribution and clustering might be configured by afferent input. Perhaps heterogeneous cellular phases might play a role as part of the temporal programming of SCN outputs. Or, induced plasticity of phase differences might permit the encoding of a photoperiodic signal (see below).

Structural and Functional Heterogeneity of SCN Neurons

While the discussion thus far would seem to imply that the SCN contains a homogeneous population of equivalent neurons, it has been recognized since 1980 that this is not the case. Nissl and silver stains, Golgi impregnations, and electron microscopy of the rat SCN were the first techniques to reveal the presence of two predominant subdivisions: cells in the dorsomedial part of the nucleus are smaller and more tightly packed than those in the ventrolateral part. This dorsal/ventral distinction corresponds to regional differences in chemoarchitecture and the topography of afferent and efferent connections. Immunohistochemical identification of peptides in SCN cell bodies marks the dorsomedial (AVP) and ventrolateral (VIP) subdivisions (Figure 3); most SCN inputs (from the retina, raphe, and lateral geniculate) are segregated to the ventral part of the nucleus. The dorsomedial ('shell') and vetrolateral ('core') organization of the rat SCN has been extended to other species as well, but the comparative anatomy appears to be more complex. The golden hamster SCN, for example, also contains a defined retinorecipient caudocentral region; cells expressing the calcium-binding protein calbindin occupy this region but represent a minority of all the cells in the area.

Figure 3 Immunohistochemical AVP and VIP protein expression in a coronal section of the rat SCN, processed for double-label immunofluorescence and viewed using excitation wavelengths of 488 nm (green, for AVP) and 568 nm (red, for VIP). IIIV, third ventricle; OC, optic chiasm. Scale bar = 200 μm. Courtesy of Drs. Matthew Paul and Hoi Pang Low, University of Massachusetts Medical School.

Only a subset of all SCN cells are directly retinorecipient. Estimates of photoresponsiveness range from about one-fifth (by administering a light pulse and then analyzing the immunohistochemical expression of c-Fos, the protein product of a photoinducible gene) to about one-third (by electrophysiological techniques) of SCN cells in the ventral part of the nucleus. No more than about 20% of the cells in this subset can be attributed to any one identified peptidergic phenotype. Moreover, no peptidergic cell type uniformly produces photosensitive responses; for example, VIP neurons positioned ventrally and laterally appear to express photoinducible genes, whereas those located ventrally and medially do not.

That the dorsal and ventral SCN compartments might actually represent two dissociable regional

circadian oscillators was initially suggested by studies of rat SCN slices maintained as long-term organotypic cultures. Hypothalamic slices incubated for weeks (either embedded in plasma clots on coverslips in rotating roller tubes or adhered to filters in stationary cultures) lose at least 70% of their neurons and flatten to a few cell layers thick, but they survive, express immunoreactive AVP and VIP regionally as *in vivo*, and exhibit circadian rhythms of the release of both peptides into the medium. When such organotypic cultures are treated with antimitotics, the two peptide rhythms appear to free-run separately with different circadian periods, indicating that they represent a chemical manifestation of comparable, equipotent oscillators in both the dorsal and ventral SCN subdivisions. More recently, regional dorsal and ventral oscillators have been demonstrated in horizontally bisected coronal slices of SCN from transgenic mice carrying the *Per1*-driven luciferase reporter. In general, studies have suggested that gene expression appears to spread through the SCN like a wave, with dorsal cells peaking earlier in the day than ventral ones.

Regional dorsal and ventral oscillators can also be dissociated *in vivo* by perturbing the external lighting conditions. In the rat, an abrupt phase shift of the light–dark cycle results in a transient desynchronization between the two SCN subdivisions; ventrolateral gene expression and electrical activity shift rapidly, while dorsomedial expression and activity resynchronize only gradually over days to weeks. A stable, 'forced' desynchronization of gene expression between the two subdivisions has also been achieved by exposing rats to an artificially short 22 h light–dark (LD) cycle. In both of these situations, intercellular coupling between SCN subdivisions is lost but coupling within each subdivision is retained, suggesting that inter- and intradivisional synchronizing mechanisms may be different.

Notably, not all SCN cells are rhythmic. The calbindin-containing cells in the caudocentral region of the golden hamster SCN have been shown to be directly retinorecipient by tract-tracing and double-label electron microscopy, and c-*fos* and *Per* mRNA and protein levels are increased in calbindin cells after photic stimulation (as assayed on cut brain sections by *in situ* hybridization and immunohistochemistry). However, circadian rhythms of *Per* gene expression are not detectable in this region, and electrophysiological recordings of identified calbindin cells in hamster SCN slices have demonstrated an absence of endogenous rhythmicity. In rats, a similar regional separation of rhythmic and nonrhythmic (but photoinducible) gene expression has been found; and in electrophysiological studies *in vivo*, photically responsive neurons have been found which do not express the circadian rhythm of discharge rate that can be observed in photically insensitive cells.

Thus, SCN tissue is composed of cellular populations that are structurally, functionally, and spatially heterogeneous. The photoresponsiveness and endogenous rhythmicity of whole SCN tissue emerges through the coupling of individual cells, both rhythmic and nonrhythmic, within and across distinct regional compartments.

Coupling Mechanisms for Coordinating SCN Cellular Oscillators

Intercellular coupling is necessary in order to create an integrated tissue pacemaker that produces a coherent read-out to the rest of the organism. Coupling mechanisms enable photoresponsive cells to reset endogenously rhythmic cells and also synchronize the wide range of individual cellular periods to produce the averaged, genotype-specific circadian period characteristic of behavioral rhythmicity of whole animals. Elucidating SCN intercellular interactions will be critical to understanding circadian properties at the tissue level of organization; several attributes of the clock likely emerge at this level, for example, its regulation of complex behavioral patterns, adaptation to photoperiod, and remarkable day-to-day precision.

SCN cells are coupled together in such a way that environmental lighting can reorganize the tissue into multiple regional oscillating units (**Figure 4**). As described above, light–dark cycles that are either phase-shifted or artificially shortened unmask the presence of dual dorsal and ventral circadian oscillations. Perhaps the most dramatic example of functionally reconfigured SCN tissue is the phenomenon known as 'splitting' in golden hamsters maintained in constant light, in which an animal's single daily bout of locomotor activity dissociates into two components that each free-run with different periods until they become stably coupled 180° (about 12 h) apart. Splitting appears to be the consequence of a reorganized SCN with left and right halves oscillating in antiphase, as mRNAs characteristic of day and night are simultaneously expressed on opposite sides of the paired SCN. In rodents, another effect of exposure to constant light is locomotor arrhythmicity. SCN slices have been made from transgenic mice carrying the *Per1*-driven GFP reporter and rendered behaviorally arrhythmic by constant light; in such preparations, individual cells exhibit robust circadian rhythms of fluorescence but desynchronized in phase, resulting in arrhythmicity of the slice as a whole.

Figure 4 SCN *Per1* gene expression during hamster splitting in constant light (left) and rat forced desynchronization in an 11 h light–11 h dark cycle (right). Locomotor activity is plotted for individual representative animals in double actogram format, with activity over day n followed by day $n+1$ horizontally, succeeded by day $n+1$ and $n+2$ on the next line, and so on. *Per1* mRNA levels are assayed using a specific riboprobe and *in situ* hybridization on coronal brain sections. In splitting, the animal's single daily bout of activity dissociates into two split components that become stably coupled about 12 h apart, at which time *Per1* gene expression is markedly asymmetric; *in situ* hybridization signal is observed unilaterally on either the left or right side of the SCN. In forced desynchronization, two locomotor rhythms with different period lengths are expressed simultaneously, with one entrained to the external 22 h cycle and the other free-running with a period >24 h; at opposite phases for the two rhythms, *Per1* gene expression is restricted to either the ventrolateral or dorsomedial subdivisions. Stars represent times of animal sacrifice, scale bar represents 1 mm. Courtesy of Dr. Horacio O. de la Iglesia, University of Washington. Reprinted with permission from de la Iglesia HO, Cambras T, Schwartz WJ, and Díez-Noguera A (2004) Forced desychronization of dual circadian oscillators within the rat suprachiasmatic nucleus. *Current Biology* 14: 796–800.

Several candidate coupling mechanisms are currently under investigation. Much interest has focused on gamma-aminobutyric acid (GABA). Although still controversial, studies have suggested that GABA's actions on SCN neurons may be inhibitory or excitatory depending on circadian phase. Both effects appear to be mediated by a $GABA_A$ receptor, so the change from inhibition to excitation likely follows a rhythm of the GABA equilibrium potential, perhaps reflecting a circadian oscillation of intracellular chloride concentrations. A $GABA_A$ mechanism may be responsible for coupling oscillations between the ventral and dorsal SCN subdivisions.

A possible role for VIP has been inferred from analysis of 'knockout' mice deficient in the *VIP* or *Vipr2* genes, the latter encoding the $VPAC_2$ receptor. These mice exhibit disrupted behavioral, molecular, and electrophysiological rhythmicity, and long-term SCN neuronal recordings show that many cells are arrhythmic while others are rhythmic but with desynchronized periods. Importantly, these defects appear to be corrected by application of a $VPAC_2$ receptor agonist to $VIP^{-/-}$ cells. How VIP signaling might interact with the GABAergic system (and vice versa) is not known. Gastrin-releasing peptide is another SCN neuropeptide transmitter that possibly functions to synchronize photoresponsive and endogenous rhythmic SCN neurons.

Nonsynaptic mechanisms for intercellular coupling also appear to be involved, including gap junctions, which may couple neurons within subdivisions but not between them. Glial cells are likely to be an important part of any synchronizing mechanism, and intercellular Ca^{2+} waves can travel long distances across cultured SCN astrocytes.

The Search for Morning and Evening Circadian Clocks

A circadian clock mechanism is believed to underlie seasonal time measurement, with daylength (photoperiod) encoded by the circadian rhythm of melatonin production in the pineal gland. The alteration in the duration of the nocturnal melatonin signal, compressed during long summer days and decompressed during short winter days, appears to serve as an endogenous photoperiodic message. Melatonin rhythmicity is controlled by the SCN, and molecular and electrophysiological rhythms of SCN tissue display durations of high activity that expand and contract in concert with changes in the ambient photoperiod.

The photoperiodic clock has been modeled as a complex pacemaker consisting of two mutually coupled circadian oscillators. Variability in the phase relationship between these two oscillators could account for the ability to measure seasonal changes of daylength, with a morning oscillator (M) accelerated by light and synchronized to dawn, and an evening oscillator (E) decelerated by light and synchronized to dusk. Current hypotheses are that M and E might be assembled within SCN tissue from individual cellular oscillators or sets of 'clock' genes that assume different phase relationships as a function of changing photoperiod. Circadian oscillations that behave like M and E have been demonstrated in SCN slices made from the brains of golden hamsters; when the slices are cut in the horizontal (but not in the coronal) plane, the circadian rhythm of multiple-unit neuronal activity exhibits distinct morning and evening peaks. The morning peak follows projected dawn, while the evening peak occurs around projected dusk. The two peaks are differentially affected by changes in the antecedent photoperiod, and they are shifted independently in a phase-dependent manner after stimulation with glutamate. The anatomical basis for these putative M and E oscillators, and whether they might map to sets of dissociable regional SCN oscillators described above, is unknown. However, available data already indicate that left and right 'split' oscillators are not the substrate for M and E.

For the Future: From Intracellular Oscillations to Temporal Programs

While circadian oscillations in the SCN have been identified at multiple levels of biological organization, connecting these levels remains a pre-eminent challenge for researchers. It is not yet understood how cycles of intracellular regulatory molecules lead to rhythms of electrical activity, how individual cellular oscillators are entrained and synchronized within a heterogeneous tissue network, nor how multiple output pathways bring about the entrainment of extra-SCN oscillators elsewhere in the brain and body. The result is a remarkable daily timekeeping system that allows animals to both recognize local time and measure its passage.

Functional Properties of the Mammalian Circadian Clock in the Suprachiasmatic Nucleus

With the prevailing evidence for the endogenous rather than exogenous regulation of circadian or 24 h rhythms in multicellular organisms, identification of the internal biological clock(s) responsible for the generation of these oscillations became the primary focus of many investigations. Through functional studies determining whether the removal of neuroendocrine structures and destruction of nervous tissue alter the expression of overt rhythmicity, the circadian clock in mammals was eventually localized to the hypothalamic suprachiasmatic nucleus (SCN). Ablation of the SCN eliminates circadian rhythms in many behavioral, endocrine, and biochemical processes throughout the body. Transplantation studies have provided unequivocal evidence for SCN function in the central neural control of mammalian circadian rhythms. Experiments using donors and hosts with different circadian genotypes demonstrate that transplantation of fetal SCN tissue restores behavioral rhythmicity in SCN-lesioned hosts and that a specific circadian property, namely period, is conveyed by transplanted pacemaker cells, not the surviving SCN cells in the host, to the reestablished rhythms. SCN-independent clocks play a role, albeit limited, in the generation of circadian rhythms because rhythmic behavioral activity persists in SCN-lesioned rodents treated with methamphetamine or maintained on restricted feeding schedules. Neural substrates for these extra-SCN clocks are unknown, but recent studies implicated the dorsomedial hypothalamic nucleus (DMH) in the circadian regulation of food-anticipatory activity.

In addition to orchestrating circadian rhythms in other brain regions and peripheral systems, the SCN generates self-sustained oscillations in its cellular activities independent of external input. Rhythms in neuropeptide and neurotransmitter levels, cellular metabolism, and neuronal activity are indigenous to the SCN *in vivo* and persist for multiple cycles following the isolation of SCN cells *in vitro*. Circadian oscillations in gene expression are another fundamental property of SCN cells. Rhythmic expression profiles are especially prevalent in the SCN among genes that form the core of the circadian clock mechanism. The molecular clockworks consist of interlocked transcriptional/translational feedback loops in which the expression of core components, *Bmal1*, *Period1* (*Per1*), *Per2*, *Cryptochrome1* (*Cry1*), *Cry2*, and *Rev-erbα*, is rhythmically regulated through mutual interactions between their protein products.

Hierarchy and Cell-Autonomous Nature of Circadian Clocks in Mammals

The molecular dissection of the circadian timekeeping mechanism also brought about the discovery that clock properties are exhibited not only by the SCN but also by other tissues *in vivo* and fibroblast cell lines *in vitro*. The expression and rhythmic regulation of clock genes has been observed in many peripheral cells and tissues, ranging from the liver to endocrine tissues to the heart and skeletal muscles. Clock gene oscillations in peripheral tissues are comparable to those found in the SCN but phase delayed by 4–8 h. Similar to peripheral tissues, Rat-1 and NIH/3T3 fibroblasts exhibit induced oscillations of clock gene expression for several cycles in response to serum shock, forskolin, or corticosteroid treatment. The common molecular organization of the circadian clocks in the SCN, peripheral tissues, and fibroblast cell lines challenged existing dogma on SCN function in the mammalian circadian system by demonstrating that the SCN clock was one among many others throughout the body. These findings also raised many questions about the hierarchical organization of mammalian circadian clocks and functional implications of this canonical clock machinery in the SCN, peripheral tissues, and fibroblast cell lines: Is the SCN a master clock that regulates all or just some of these peripheral clocks? Beyond these molecular oscillations, what other properties are similar in SCN and peripheral clocks? Is clock gene rhythmicity sufficient for peripheral clocks to pace rhythms in downstream cells or tissues, and if not, what distinguishes the SCN from peripheral clocks? What SCN output signals are important in coordinating circadian oscillations in peripheral tissues?

Within the mammalian circadian hierarchy, the SCN appears to function as a master clock that coordinates rhythmicity in other brain regions and many, but not all, peripheral tissues (Figure 1). Consistent with this hierarchical organization, circadian oscillations of gene expression *in vitro* are more robust within the SCN than the peripheral tissues. Circadian rhythms of luciferase-reported *Per1* expression

Figure 1 Hierarchy of cell-autonomous clocks in the mammalian circadian system. Entraining light–dark cues are communicated from the retina directly to the master circadian clock located in the suprachiasmatic nucleus (SCN) via the retinohypothalamic tract (RHT). The SCN clock consists of numerous cell-autonomous clocks that, in turn, synchronize the circadian oscillations of clock cells in other brain regions and peripheral tissues such as the heart, lung, and liver. Signals responsible for the local coordination of circadian oscillations among individual clock cells may play a role in the distinctive functional properties of the SCN. SCN control of circadian clocks in other tissues and of behavioral rhythmicity is mediated by diffusible or humoral signals. Many of the signals necessary for SCN pacemaker function are unknown, but transforming growth factor (TGF)-α and prokineticin 2 (PK2) are SCN output signals involved in the circadian regulation of locomotor activity.

persist for many weeks in explant cultures of the SCN but damp after several cycles in cultured lung, liver, kidney, and skeletal muscle tissue. Further evidence for the hierarchical relationship between the SCN and peripheral clocks is based on *in vitro* studies using *Per2-Luc* knockin mice to demonstrate that lesions of the SCN disrupt the normal phase coordination of clock gene rhythmicity among explant cultures of different peripheral tissues. However, some peripheral tissues, such as the liver, are not slaves to the SCN clock but instead can function independently in response to nonphotic cues. Restricted feeding cycles entrain the liver rhythm in *Per1-Luc* expression without influencing the circadian phase of this oscillation in the SCN. The prevalence of this common timekeeping program throughout the body and its functionality even in the absence of the SCN indicate that peripheral clocks provide for the local organization of tissue- or cell-specific processes in time.

Similarities between the SCN and peripheral tissues extend beyond core molecular components to even the basic cellular organization of the circadian clockworks. In the SCN, circadian oscillations are not only an ensemble property of the entire nucleus but are also expressed by individual neurons. Like the composite SCN *in vivo* and in brain-slice preparations, many individual SCN neurons in dissociated cultures maintained on microelectrode arrays express independent oscillations in firing rate. The circadian phase and period of these SCN rhythms in firing rate differ widely among individual neurons despite the presence of synaptic connections. SCN cells in brain-slice preparations also exhibit ensemble rhythmicity in *Per-1*-driven green fluorescent protein (GFP) expression, and the waveform of this rhythm is derived from the multiphasic organization of autonomous oscillations in individual neurons. Recent findings suggest that peripheral tissues may contain cell-autonomous clocks similar to those found in the SCN. Individual NIH/3T3 fibroblasts exhibit circadian rhythms of gene expression that are largely synchronous following serum shock but are marked by broad phase differences in the absence of this treatment.

Functional Differences between Circadian Clocks in the Suprachiasmatic Nucleus, Peripheral Tissues, and Fibroblasts

Despite their apparent parallels at the molecular and cellular levels of organization, the SCN and peripheral

clocks are fundamentally different. The foremost distinction is that the SCN contains the only known clock cells that can be directly entrained by light. Photoentrainment signals from the retina are processed through the retinohypothalamic tract (RHT), which terminates in the SCN (Figure 1). Evidence for the essential role of this retinofugal pathway in circadian photoentrainment is based on the finding that rodent activity rhythms persist but fail to entrain to light–dark cycles following localized transection of the RHT. In contrast, no data are currently available to unequivocally demonstrate that peripheral tissues in mammals also receive direct photic input. In the circadian hierarchy, the SCN clock thus provides a vital link between the external environment and the internal circadian timekeeping system. Further evidence for the preeminent role of the SCN as the gateway for the coordination of local processes with the light–dark environment is provided by the observation that clock gene rhythms are more rapidly entrained by light in the SCN than in peripheral tissues. Moreover, the 4–12 h phase delay of peripheral tissue oscillations relative to SCN rhythms is presumably indicative of the time required for entrainment signals to reach the periphery.

Distinctions between the SCN and peripheral clocks are especially evident in their functional properties. SCN cells function as pacemakers and confer rhythmicity to SCN-lesioned rodents *in vivo* and to other cells *in vitro*, whereas peripheral tissues and cultured fibroblasts do not. Incontrovertible evidence for the unique pacemaker properties of the SCN is founded on transplantation studies. Fetal SCN tissue and immortalized rat SCN cells (SCN2.2), but not other types of tissue (e.g., cerebellum or cerebral cortex) or fibroblasts, reinstate circadian behavioral rhythmicity when transplanted into arrhythmic SCN-lesioned hosts. Similar to transplantation studies, the development of a coculture model has been instrumental in distinguishing the circadian pacemaker properties of SCN cells from the oscillatory behavior of fibroblasts. In this model, SCN2.2 cells are cocultured on companion plates with NIH/3T3 fibroblasts on cell-impermeable inserts. Consistent with SCN function *in vivo*, SCN2.2 cells endogenously generate circadian oscillations of glucose utilization and clock gene expression and confer this metabolic and molecular rhythmicity to cocultured NIH/3T3 fibroblasts (Figure 2). Serum-shock treatment produces rhythms of clock gene expression, but not glucose metabolism, in these fibroblasts. Despite the induction of clock gene oscillations, serum-shocked NIH/3T3 fibroblasts lack circadian pacemaker properties and fail to confer even this molecular rhythmicity to cocultured cells.

Figure 2 Diagram illustrating the distinctive rhythm-generating and pacemaker properties of SCN2.2 cells in coculture studies: (a) SCN2.2–NIH/3T3 cocultures; (b) serum-shocked (SS) NIH/3T3–untreated NIH/3T3 cocultures. For each cell type the cocultures, the upper (solid) waveform represents the temporal pattern of metabolic activity (2-deoxyglucose uptake) and the lower (dashed) waveform denotes the profiles of clock gene expression (*Per1* and *Per2*). The thick arrows between culture types indicate the presence or absence of signals that coordinate oscillations in cocultured cells. SCN2.2 cells, but not serum-shocked NIH/3T3 fibroblasts, are capable of pacing the metabolic and clock gene rhythms in cocultures of untreated NIH/3T3 cells.

Why peripheral tissues and fibroblasts cannot function as circadian pacemakers is presently unclear. One possible explanation is that all molecular elements of the clock mechanism may not be present or functionally configured. Experiments examining the effects of antisense inhibition of *Clock* reveal important distinctions between SCN2.2 cells and serum-shocked fibroblasts in the regulation of molecular oscillations. Treatment of SCN2.2 cells with *Clock* antisense oligonucleotides disrupted the circadian rhythm of *Per2* expression within these cells and cocultures of untreated NIH/3T3 fibroblasts. However, the circadian oscillations of *Per2, Bmal1*, and *Cry1* expression in serum-shocked fibroblasts showed some alterations in rhythm amplitude but otherwise persisted during antisense inhibition of *Clock*. These differences in *Clock* interactions within the molecular feedback loop could account for distinctions in the circadian pacemaker properties of SCN cells and fibroblasts.

The Search for Critical Output Signals of the Suprachiasmatic Nucleus

An alternative explanation for the distinctive pacemaker function of the SCN is that specific output signals necessary for coordinating rhythmicity among individual clock cells within the SCN and in the periphery may not be expressed or circadian-regulated in other tissues or stimulated fibroblasts. SCN pacemaker regulation of circadian rhythms in downstream cells and tissues is thought to involve diffusible or humoral factors rather than neurotransmission via synaptic connections. Functional implications for diffusible factors in the SCN pacemaker regulation of circadian rhythms were first provided by the observation that transplantation of fetal hypothalamic tissue into the third, or even lateral, ventricle of SCN-lesioned rodents restores circadian rhythms with few, if any, neural connections between the graft and host brain. However, the role of humoral outputs in the circadian pacemaker function of the SCN is directly supported by transplantation experiments determining whether the recovery of circadian function occurs in SCN-lesioned animals when grafted cells are encapsulated so as to prevent the establishment of neural connections with the host brain. Despite their isolation in polymeric capsules that allow graft–host communication only via diffusion of humoral signals, transplants of SCN cells still promote the recovery of circadian behavioral rhythmicity with the donor period in SCN-lesioned hamsters. Coculture studies similarly demonstrate that the rhythmic release of some paracrine signal(s) by the SCN is responsible for its function in pacing circadian oscillations in downstream cells. SCN2.2 cells impose rhythms of metabolic activity and *Per* gene expression on cocultured NIH/3T3 fibroblasts, and these conferred oscillations are mediated by diffusible signals because the two cell types are separated in the coculture environment by a semipermeable membrane preventing physical contact (Figure 2). Furthermore, sustained rhythmicity in NIH/3T3 cells is dependent on continued exposure to this SCN2.2-communicated signal. Following their coculture and subsequent isolation from one another, SCN2.2 cells continue to express circadian rhythms of glucose utilization, whereas NIH/3T3 fibroblasts fail to exhibit self-sustained metabolic oscillations in the absence of SCN2.2-specific outputs. Therefore, identification of specific diffusible or humoral factors that coordinate rhythmicity among individual clock cells in the SCN and among circadian clocks in peripheral tissues is critical in determining which cellular processes are responsible for the distinctive function of the SCN as a circadian pacemaker.

Glucocorticoids were among the first signaling candidates implicated in the coordination of circadian oscillations within peripheral clocks. The SCN regulates the cyclical secretion of glucocorticoid hormones, and this signaling pathway is thought to mediate SCN control of peripheral clocks *in vivo* because adrenalectomy alters the light-induced phase resetting of circadian gene expression in the periphery. Glucocorticoid receptor agonists also induce clock gene oscillations in cultured fibroblasts. Transforming growth factor α (TGF-α) and prokineticin 2 (PK2) were subsequently identified as SCN output signals that play a role in its pacemaker function, at least with regard to the circadian regulation of locomotor activity *in vivo* (Figure 2). TGF-α is rhythmically expressed in the SCN, with peak mRNA levels occurring during the mid-subjective day, and chronic infusion of TGF-α into the third ventricle completely inhibits wheel-running activity and disrupts the circadian organization of the sleep–wake cycle. These effects of TGF-α are mediated through its primary receptor, the epidermal growth factor receptor (EGFR) because mice with a partial loss-of-function mutation for EGFR exhibit increased daytime activity and decreased inhibition of wheel-running activity in response to light during the subjective night. In a similar fashion, PK2 mRNA levels rhythmically fluctuate in the SCN with peak expression during the subjective day, and intraventricular injections of recombinant PK2 during the subjective night, when endogenous levels are low, inhibit nocturnal increases in rat locomotor activity. Significantly, the receptors for TGF-α and PK2 (EGFR and PKR2) are distributed in primary targets of SCN efferent pathways, including the subparaventricular zone and paraventricular nucleus. This observation suggests that TGF-α and PK2 are not involved in

the synchronization of individual cell-autonomous clocks within the SCN but, instead, are critical SCN outputs necessary for pacemaker coordination of downstream clocks in other brain regions controlling locomotor behavior. The neuropeptide vasoactive intestinal polypeptide (VIP) is another output signal that mediates SCN pacemaker function in the circadian regulation of locomotor behavior. Mice with a null mutation of the VIP receptor, $VPAC_2$, show weak or low-amplitude rhythms of wheel-running behavior in conjunction with the disruption of circadian oscillations in SCN expression of core clock genes. $VPAC_2$ receptors are more prevalent within the SCN than in primary targets of its efferent pathways. Coupled with evidence for the essential role of $VPAC_2$ receptor signaling in the generation of the circadian rhythm in SCN neuronal activity, the local distribution of these receptors suggests that VIP may be involved in regulating cell-to-cell communication in the SCN. Thus, $VPAC_2$ receptor signaling may coordinate rhythmicity among populations of cell-autonomous clocks so as to provide for the generation of high-amplitude circadian outputs necessary for SCN pacemaker function.

It is unlikely that glucocorticoid hormones, TGF-α, PK2, and VIP are solely responsible for SCN pacemaker function in coordinating the entire spectrum of circadian processes in downstream cells and tissues. Global analysis of gene expression profiles has provided a valuable screening tool for other output signals that may distinguish the SCN from peripheral and fibroblast clocks. Comparisons of microarray and bioinformatics data indicate that the overall extent of circadian gene expression in the SCN and peripheral tissues *in vivo*, as well as cultured SCN2.2 cells and fibroblasts, was similarly low, ranging from approximately 2% to 10%. However, specific genes with circadian profiles are highly disparate among different tissue and cell types. The canonical clock genes constitute the principal portion of the overlap in circadian gene expression between SCN cells and peripheral tissues or fibroblasts. Other rhythmic genes in common to different mammalian tissues predominantly function as nuclear factors involved in the regulation of DNA-binding and activation of transcription. This intriguing observation suggests that the cyclical regulation of nuclear factors may have important implications in linking the common clockworks to tissue-specific cellular and physiological pathways so as to provide local control over circadian timing. In addition, functional analyses indicate that various mammalian cells and tissues are similar with regard to the diversity of rhythmically expressed transcripts. Within the SCN *in vivo*, SCN2.2 cells, fibroblasts, and peripheral tissues such as the liver, heart, and kidney, transcripts with cyclical profiles control a wide range of biological processes. Yet circadian gene expression is typically more prevalent within certain functional categories, and there is some degree of tissue and cell specificity in this differential distribution of rhythmic genes. In SCN2.2 cells and the SCN *in vivo*, functionally annotated genes with circadian expression profiles are predominantly involved in the regulation of cellular communication, protein dynamics, and metabolic pathways mediating fatty acid recycling, steroid synthesis, glucose metabolism, and mitochondrial energy transduction. The prevalence of rhythmicity among genes mediating intercellular communication may have some significance with regard to SCN-specific signals necessary for the endogenous generation of self-sustained oscillations, local synchronization of clock cell populations, or pacemaker coordination of circadian oscillations in other tissues and cells.

Among rhythmic genes in intercellular communication pathways, inducible nitric oxide synthase (*iNos* or *Nos2*), an isozyme involved in nitric oxide (NO) production, is noteworthy as a circadian signal that is unique to the SCN. The role of *Nos2* in the SCN and the regulation of circadian rhythms has not been examined, presumably because this isozyme is thought to be expressed by macrophages, not SCN cells, and because functional studies suggest that the other isoforms of nitric oxide synthase in the central nervous system are not necessary for the generation or entrainment of circadian rhythms. The activity rhythms of mutant mice lacking neuronal *Nos* (*nNos* or *Nos3*) and endothelial *Nos* (*eNos* or *Nos1*) show no distinct abnormalities with regard to their free-running patterns, entrainment to light–dark cycles, and phase-shifting responses to light. Initial evidence for *Nos2* involvement in the endogenous oscillatory and pacemaker properties of the SCN is derived from the recent observation that antisense inhibition of NOS2 expression abolishes the metabolic rhythmicity of both cell types in cocultures containing antisense-treated SCN2.2 cells and untreated NIH/3T3 fibroblasts. Moreover, *Nos2* function in SCN regulation of circadian rhythms is compatible with the effects of a general NOS inhibitor on rhythmic glucose uptake in SCN2.2–NIH/3T3 cocultures. Similar to *Nos2* antisense treatment, N^G-nitro-L-arginine methyl ester (L-NAME), a reversible inhibitor of all three isoforms of NOS, disrupts the circadian pattern of glucose utilization in SCN2.2 cells. Following treatment, glucose uptake fluctuated rhythmically in both L-NAME-treated SCN2.2 cells and untreated NIH/3T3 fibroblasts, but the peak-to-peak interval for this rhythmicity was increased from 24 to 32 h in both cell types. It is unclear how L-NAME and *Nos2* antisense treatment specifically produce this loss of

rhythmicity in SCN2.2 cultures. One possibility is that the treatment-induced inhibition of NOS2 may disrupt the clock mechanism by altering the biological effects of NO signaling through the intracellular second-messenger cyclic guanosine monophosphate (cGMP) and/or on posttranslational modification of cellular proteins. Another potential explanation for the abolition of metabolic rhythmicity in SCN2.2 cells is that L-NAME and *Nos2* antisense treatment may inhibit NO function as a diffusible messenger in the intercellular coupling or local synchronization of clock cell populations. As coupling strength among a multitude of autonomous clocks decreases from the population mean, changes in rhythm amplitude or period length are expected to occur and eventually result in the loss of rhythmicity from the ensemble. Thus, the disruption of metabolic rhythms in SCN2.2 cultures may reflect treatment-mediated loss of temporal synchrony among populations of clock cells. By affecting the generation of high-amplitude circadian output signals, this desynchrony between clock cells could also account for the effects of *Nos2* antisense treatment on the pacemaker function of SCN2.2 cells in regulating oscillations in cocultured fibroblasts. Together with evidence for the role of NO in resetting the SCN clock, these findings suggest that *Nos2* function in the production of this diffusible messenger may be essential for the endogenous rhythm-generating and pacemaker properties of the SCN.

Future Developments

The localization of cell-autonomous circadian clocks in the SCN, other brain regions, and peripheral tissues throughout the body has yielded a new understanding of the mammalian circadian hierarchy. It is not yet clear whether the canonical clock machinery in peripheral tissues is directly linked to the circadian regulation of any physiological processes. However, this discovery has kindled the search for SCN output signals responsible for the coordination of circadian oscillations in peripheral clocks. Although some candidates for SCN pacemaking signals have been identified, determining their role in the local coupling between individual clock cells and the coordination of circadian oscillations in peripheral clocks remains a major challenge.

Circadian Regulation in Invertebrates

T L Page, Vanderbilt University, Nashville, TN, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In the invertebrates, circadian clocks control a variety of behavioral, physiological, and developmental processes; and the study of the anatomical and physiological organization of circadian systems of invertebrates has a long and productive history. By far, most of the work has been carried out on arthropods (especially insects), though there have been seminal contributions from the opisthobranch mollusks. Much less is known about other invertebrates, though it is clear that most major groups exhibit circadian rhythms.

Although there are differences in detail, the studies suggest that the general outlines of circadian organization in the invertebrates parallel that in the vertebrates. In invertebrates the circadian system is composed of a population of oscillators that are located both within and outside of the nervous system. Appropriate phase relationships between the circadian system and the external environment are maintained by entrainment to environmental cycles. The most important cycle in the physical environment is the daily light cycle and the transduction of light is (with a few interesting exceptions) carried out largely by extraretinal, nonvisual photoreceptors with a contribution from photoreceptors in the retina. Internal temporal organization (phase relationships among the various oscillators and the rhythms they control) is maintained either by coupling between oscillating components or simply by the subjugation of individual oscillators to direct entrainment by environmental stimuli.

Localization of Circadian Oscillators

Studies on pacemaker localization in invertebrates initially focused on the nervous system. In mollusks, oscillators have been found to exist in both the eye and the central nervous system. The ocular oscillators have been particularly important as model systems for the study of the cellular mechanisms of circadian rhythms. In the arthropods, the brain has consistently been found to be important for generation of circadian timing signals for rhythms in behavior. However, it is clear that circadian oscillations that control physiologically relevant processes frequently arise in structures outside the central nervous system as well.

Pacemakers in the Molluscan Retina

The eyes of several marine opisthobranch mollusks have been shown to exhibit circadian rhythms of spontaneous nerve impulse activity when removed from the animal and maintained in artificial seawater. The rhythm in the isolated eye was first discovered in *Aplysia californica*. Subsequently, similar rhythms were documented in other species of mollusk, including *Navanax inermis*, *Bulla gouldiana*, and *Bursatella leachi plei*. The rhythms are expressed in the frequency of optic nerve large-amplitude, compound action potentials that arise from a population of electrically coupled cells in the eye. The impulses are spontaneously generated and occur even when the eye is maintained in complete darkness. In all species, peak impulse activity occurs during the animal's subjective day, and is likely due to the circadian modulation of potassium conductance. Efforts to further localize the pacemaking cells in the eye through localized lesions have been made in *Bulla* and *Aplysia*, and in both species the results indicate that the rhythm is generated by cells at the base of the eye. This proposition was confirmed in experiments showing periodic changes in membrane conductance in single, isolated cells.

There has also been an effort to assess the functional role of the ocular pacemaker in controlling behavioral rhythms in the mollusks. In both *Aplysia* and *Bulla*, removal of the eyes usually, but not invariably, resulted in disruption of the circadian rhythm in locomotor activity, suggesting these structures may participate as the driving oscillator for the rhythm. These results, combined with the persistence of locomotor rhythmicity in some eyeless animals, indicate that an additional oscillatory structure outside the eyes may play an important role in the temporal organization of behavior. In this context it is notable that in *Aplysia*, the animal's ability to form long-term memories exhibits a circadian rhythm that is not affected by eye removal, indicating that, for this rhythm, both the clock and the photoreceptor for its entrainment are located outside the eyes.

The effects of eye removal on locomotor activity have also been investigated in two pulmonate gastropod species, the terrestrial slug *Limax maximus* and the freshwater snail *Helisoma trivolvis*. Unlike the opisthobranch mollusks, there is no evidence in either of these species that the eye contains a pacemaker, and eye removal appeared to have no significant effect on the ability of animals to generate a circadian rhythm in activity. It seems likely that the pacemaker

for the activity rhythms in these mollusks is located in the brain, though that has yet to be demonstrated.

Pacemakers in the Arthropod Brain

Arthropods exhibit circadian rhythmicity in a variety of behaviors and physiological processes. Three of these – locomotor activity, eclosion, and retinal sensitivity to light – have been investigated extensively and there are several instances in which circadian pacemakers that regulate these rhythms have been localized to the brain (supraesophageal ganglion). In a classic early study on the moths *Hyalophora cecropia* and *Antheraea pernyi,* it was shown that a circadian pacemaker that controls the timing of eclosion (a behavioral sequence that allows the adult moth to emerge from its pupal case after metamorphosis) is located in the brain. The time of day when eclosion occurs is different for the two species. *Hyalophora cecropia* emerges shortly after dawn while *A. pernyi* emerges just before dusk. Removal of the brain did not prevent eclosion, but did disrupt its timing. However, if the brain was reimplanted in the abdomen, normal rhythmicity was restored in both entrained and free-running conditions. The most compelling evidence was provided by experiments in which brains removed from one species were transplanted to the abdomen of the other. Moths that had received these 'switched brain' transplants exhibited normal species-specific eclosion behavior, but the phase of the rhythm was characteristic of the donor and not the host. *Antheraea pernyi* which had received *H. cecropia* brains emerged just after lights-on, while *H. cecropia* that had received *A. pernyi* brains emerged near lights-off. The demonstration that the transplanted brains restored rhythmicity and determined the phase of the rhythm leaves little doubt that circadian pacemaker that regulates the timing of the eclosion rhythm is located in the brains of these moths.

Early studies on cockroaches focused attention on the optic neuropils of the insect brain. The three optic neuropils (from distal to proximal, these are the lamina, medulla, and lobula) form the optic lobe, which is morphologically quite distinct in the cockroach. It was shown that surgical ablation of the cockroach optic lobes or their neural isolation from the midbrain by section of the optic tracts disrupted the locomotor activity rhythm. Although severing the optic tracts invariably disrupted rhythmicity, the rhythm consistently reappeared after several weeks as a consequence of regeneration of the neural connections between the optic lobes and the midbrain. These results led to experiments in which the optic lobes were transplanted between individuals with different free-running periods. Animals that received transplanted optic lobes recovered rhythmicity, and the preoperative period of the donor and the postoperative period of the host were strongly correlated. Thus transplantation of the optic lobes from one animal to another, from which the optic lobes had been removed, both restored the rhythm of locomotor activity and, critically, imposed the period of the donor animal's rhythm on the rhythm of the host. Other experiments have also shown that the optic lobes control the phase of the free-running locomotor activity rhythm and that the tissue could generate a free-running circadian oscillation in multiunit impulse activity when isolated *in vitro*. Studies on crickets and beetles have also indicated pacemakers that are located in the optic lobes. In cockroaches and crickets, the region within the optic lobe that contains the circadian pacemaker for the locomotor activity rhythm was more precisely localized with the use of small lesions. The results suggested that the cells responsible for generating the circadian signal have their somata and/or processes in the ventral half of the optic lobe, between the medulla and the lobula.

The cellular identification of pacemakers in the insect brain came rapidly on the heels of two seminal discoveries. The first was the identification of the sequence of the 'clock gene' *period* and its protein product (Per) in fruit flies. The identification of the gene made it possible to utilize both *in situ* hybridization and immunocytochemistry to identify putative cellular oscillators and to carry out genetic manipulations to evaluate the functional roles of the cells. The second discovery was the finding that antibodies to a crustacean peptide hormone, pigment-dispersing hormone (PDH), specifically stained cockroach optic lobe cells that had a location and projections that made them ideal candidates as the cockroach circadian pacemaker.

In the cockroach, a population of approximately 16 cells in a region that is located at the ventral margin of the medulla was found to be immunopositive for PDH. Subsequently, both lesion and transplantation experiments provided strong evidence that these cells are both necessary and sufficient for driving the circadian rhythm of locomotor activity, suggesting that these cells generate the pacemaking oscillation and that pigment-dispersing factor (PDF; the insect version of crustacean PDH) may be a significant circadian signaling molecule.

In the fruit fly, *Drosophila melanogaster,* several lines of evidence have implicated a small population of neurons, called the lateral neurons, in the regulation of locomotor activity and eclosion rhythms. These neurons are located near the medulla neuropil and express *per* as well as the other clock genes *timeless* and *doubletime*. Genetic manipulations

have shown that these neurons and their rhythmic expression of *per* are essential to rhythmicity. In addition, it is notable that a subset of the lateral neurons produces PDF, and mutations in the *pdf* gene or manipulations of its expression cause major disruptions of the circadian rhythms of locomotor activity, reinforcing the suggestion from the cockroach data that PDF may be a critical signaling molecule in the insect circadian system.

The localization of circadian pacemakers that regulate behavioral rhythms raised the question of whether other rhythms are controlled by the same clocks. A common feature of arthropod visual systems is that the sensitivity of the eye to light exhibits a circadian variation which is reflected in a daily change in the amplitude of the electroretinogram (ERG) recorded in response to a standard light pulse. Depending on the species, several mechanisms may contribute to producing the sensitivity change; however, it does appear, invariably, to be associated with structural changes, including daily migration of screening pigments which surround the rhabdomeres of the ommatidia. In the cricket *Gryllus bimaculatus*, the beetle *Anthia sexguttata*, and the cockroach *Leucophaea maderae*, the pacemaker regulating the ERG amplitude rhythm has been localized to the optic lobe and appears to be the same pacemaker that controls locomotor activity rhythms.

Efforts at localization of circadian pacemakers that regulate retinal sensitivity have also been made in two chelicerate arthropods, the horseshoe crab *Limulus polyphemus* and the scorpion *Androctonus australis*. In both cases the pacemaker that drives the circadian rhythm in ERG amplitude is located in the brain and communicates with the eye via efferent neural projections to the retina (discussed in more detail later).

Lesion studies have also been carried out on decapod crustaceans in an effort to localize pacemakers that regulate both locomotor activity and ERG amplitude rhythms. Much of the work has been on freshwater crayfish, and the results suggest that normal rhythmicity requires both the optic lobes and the cerebral lobes (supraesophageal ganglion), since lesions to either of these structures disrupt, but do not completely abolish, rhythmicity. ERG rhythms persist *in vitro* in preparations that contain only the photoreceptors and the first optic neuropil (lamina ganglionaris), showing that these structures must have the ability to generate a circadian oscillation.

Circadian Pacemakers outside the Nervous System

Although the focus of efforts to find circadian oscillators has been on pacemakers in the nervous system that regulate behavior, there are well-documented cases, all in insects, of circadian pacemakers that reside outside the brain and retina. In the cockroach, studies on circadian deposition of cuticle indicated that this rhythm is driven by a pacemaking system that is independent of the brain. In both *L. maderae* and *Blaberus craniifer*, the new cuticle of the newly molted adult is secreted rhythmically in layers. The rhythm persists in constant conditions with a circadian period that is temperature compensated. Further, in *Blaberus*, the rhythm in cuticle deposition persists in pieces of leg tissue cultured *in vitro*. The results raise the possibility that the epidermal cells that secrete the cuticular material may be autonomously rhythmic.

Several studies have shown that the complex of testis and seminal ducts in moths contains a circadian pacemaker. In the flour moth *Anagasta kueniella*, the release of the sperm from the testis exhibits a daily rhythm that persists in constant darkness in the isolated abdomen. A similar rhythm of release of mature sperm from the testis into the seminal ducts was found in the gypsy moth, *Lymantria dispar*. In this species the rhythm persisted, and could be phase shifted by light, *in vitro* in isolated complexes of seminal ducts and testis. Thus this tissue contains a circadian pacemaker and photoreceptor for entrainment.

In the moth *Samia cynthia*, preparation for pupation and metamorphosis involves a series of morphological and behavioral changes, including an excretion of the contents of the gut which occurs shortly after a cessation in feeding. This 'gut purge' is regulated by the circadian system. Timing of the gut purge appears to be controlled by a circadian clock in the prothoracic gland (PG), an endocrine organ which is responsible for the secretion of the insect steroid hormone ecdysone. A small peak of ecdysteroid occurs in the hemolymph just prior to gut purge. The circadian timing of the ecdysteroid peak persists in decapitated larvae, showing that a brain-centered clock is not necessary. Other studies involving the transplantation of the PGs followed by their local illumination indicated that the glands contain a photosensitive circadian clock that can regulate the timed release of ecdysone. Additional work in the bug *Rhodnius prolixus* and the moth *Galleria mellonella* also provided evidence that insect prothoracic glands contain a photosensitive pacemaker that regulates synthesis of ecdysteroids.

The fact that circadian pacemaking activity is widespread among tissues of the body was particularly clearly demonstrated in experiments on *D. melanogaster* in which the coding sequence of a reporter gene was coupled to the promoter of the clock gene, *period*, allowing tissues in culture to be assessed for the presence of circadian oscillations in transcription. Molecular oscillations were found to be widespread

and to exist even in peripheral cells and tissues where there had never been a hint of endogenous rhythmicity, such as in wings, antennae, proboscises, and legs. The molecular rhythm in the antennae was subsequently shown to drive a circadian rhythm of response in the olfactory receptors of the antennae.

Multioscillator Organization of the Pacemaking System

The data showing that the circadian system in the individual is composed of several oscillators located both within and outside the nervous system raise the question of how temporal order is maintained among the population of oscillators and the circadian rhythms they control. One potential mechanism to ensure appropriate phasing is to have the oscillators directly communicate with one another via internal 'coupling pathways' that allow for hierarchical or mutual entrainment. A second strategy is to give all oscillators direct access to environmental cyclic signals that could entrain the individual pacemakers. The available evidence suggests that both mechanisms are utilized.

The bulk of the information available is on bilaterally paired oscillators, for which the data indicate significant differences among species. In the cockroach, the optic lobe pacemakers are strongly coupled to one another via direct neural connections between the optic lobes, connections probably made by PDH immunopositive cells. In contrast, in the beetle, *Blaps gigas*, the ERG amplitude rhythms from the two eyes of an individual beetle were found to free-run with different periods in constant darkness; and it was shown that the phase and period of the rhythm from one eye could be controlled by local illumination of that eye without any consistent effect on the rhythm from the other eye. The results indicated that each eye was controlled by its own pacemaker, and that the two pacemakers were independent or only weakly coupled. A similar conclusion came from studies on the regulation of locomotor activity by the optic lobe pacemakers in two species of crickets, *Teleogryllus commodus* and *G. bimaculatus*. Thus it appears that within the insect families there are significant species differences in the strength of coupling between bilaterally distributed oscillators, and some appear to rely largely on entrainment by the environmental light cycle to maintain an appropriate phase relationship. Similar species differences have been observed in mollusks. In *Aplysia* maintained in constant darkness, the two ocular pacemakers spontaneously desynchronize and appear to be independent of one another. In contrast, in *Bulla*, the eyes remain closely in phase, suggesting that the pacemakers are coupled. The apparent difference in coupling between the two species was confirmed in studies on the eyes and brain isolated *in vitro*. Following treatments to one eye that induced a phase difference of several hours between the ocular pacemakers, in *Bulla* the eyes tended to come back into phase at a rate of about 1 to 1.5 h day^{-1}, while in *Aplysia* phase separations were maintained. Thus in one case coupling between oscillators is adequate to maintain phase relationships while in the other entrainment by environmental light cycles is crucial.

There is little information available on the coupling relationships between central and peripheral oscillators or among peripheral oscillators. In *D. melanogaster*, data suggest that the central brain pacemaker that regulates circadian rhythms in locomotor activity is neither sufficient nor necessary for a peripheral rhythm in olfactory sensitivity in the antennae. This rhythm is driven by oscillations that are generated in the antennae. In contrast, recent results suggest there is an interaction between pacemakers in the lateral neurons of the brain and in the prothoracic glands that together regulate the circadian rhythm in eclosion.

In cases in which coupling appears to be absent, temporal order among oscillators is likely to be maintained by entrainment to the external environment. In *Drosophila*, for example, peripheral oscillators appear to have access to information about the environmental light cycle through dedicated and distributed photoreceptors (see later).

Localization of Photoreceptors and Mechanisms of Entrainment

Circadian clocks are set to local time by entrainment to daily cycles in the immediate physical environment. While a variety of potential cycles could be utilized, a universal feature of circadian oscillators is that they can be entrained by environmental light cycles, and therefore the circadian system must have access to information from photoreceptors.

Extraretinal Photoreceptors

A striking feature of invertebrate circadian organization is that invertebrate species rarely rely exclusively on photoreceptors of the visual system for entrainment, and with few exceptions, removal of the eyes of mollusks, crustaceans, or insects has little effect on the ability of the circadian oscillators to be entrained by light. This indicates that extraretinal receptors are dominant in detecting light for entrainment in invertebrates.

In view of the wide tissue distribution of circadian oscillators in invertebrates, the question of anatomical localization of the relevant photoreceptors for entrainment is particularly interesting. Data thus far

suggest that the wide distribution of oscillators may also be reflected in a wide distribution of photoreceptors for entrainment. In the fruit fly, for example, it has been shown that the molecular clocks in the brain, legs, antennae, gut, and excretory system can be directly entrained by light *in vitro*, suggesting that the cells that generate the circadian oscillations also contain the molecular machinery necessary for their entrainment. Data from various species of moths paint a similar picture. They suggest that the eclosion rhythm is entrained by a photoreceptor located in the brain; the pacemaker in moth testis can be entrained by light *in vitro*, indicating some cells in the testis–seminal duct complex must be photosensitive, and the photoreceptor for entrainment of the pacemaker in the prothoracic glands appears to be in the gland itself.

Studies on mollusks further reinforce the idea that circadian pacemaker cells may also contain the molecular machinery for photic entrainment. *Aplysia* and *Bulla* eyes isolated *in vitro* can be phase shifted by light, demonstrating that ocular photoreceptors are sufficient for entrainment of the ocular pacemaker. Efforts to identify the specific cells within the molluscan eye that are responsible for entrainment have suggested that the pacemaker cells are the site for phototransduction.

Participation of Retinal Photoreceptors in Entrainment

Although 'organized' photoreceptive structures are frequently bypassed in entrainment in insects, there are at least two insects, the cockroach and the cricket, in which the compound eyes are the exclusive photoreceptors for entrainment. In the cockroaches and crickets, section of the optic nerves between the eyes and the optic lobe, or painting over the compound eyes, eliminated entrainment of the locomotor activity rhythm to light cycles.

In a variety of invertebrate species, even when extraretinal photoreception is sufficient for entrainment, there is evidence that the eyes participate. For example, in *D. melanogaster*, although the eyes are not required, they appear to contribute to the entrainment of behavioral rhythms such as locomotor activity and eclosion. In chelicerate arthropods, both retinal and extraretinal photoreceptors may be involved in the entrainment of ERG amplitude rhythms that are driven by pacemakers in the brain. In *L. polyphemus*, for example, the ERG amplitude rhythm of the lateral eyes can be phase shifted via either retinal photoreceptors in the ventral, median, and lateral eyes or extraretinal photoreceptors in the telson.

In summary, extraretinal photoreception is prevalent, and although retinal photoreceptors may serve as alternate sources of photic information for the circadian system, they are generally not required. With few exceptions (cockroaches, crickets) the results are consistent with the notion that cells that contain the molecular mechanisms for generating circadian oscillations also contain the phototransduction machinery for their entrainment. These observations raise at least two questions of interest. The first concerns the general reliance on extraretinal photoreception for entrainment. It seems likely to be significant that extraretinal pathways are quite prevalent, even in species that have well-developed visual systems, and this raises the possibility that the photoreceptors involved in entrainment may possess unique properties relative to photoreceptors that participate in more 'classical' visual processes. Alternatively, the widespread distribution of extraretinal pathways may simply be a reflection of the hypothetical participation of a photopigment in the early evolution of the molecular machinery of biological clocks. Here the suggestion is that natural selection has maintained the close relationship between phototransduction and the generation of circadian oscillations, as a mechanism for maintaining temporal order among various oscillators and as an alternative to the development of novel coupling pathways and mechanisms between oscillators within the individual.

Cellular Mechanisms of Entrainment by Light

There has been substantial progress in understanding the cellular and molecular mechanisms by which light regulates the phase of the circadian oscillator in the mollusk eye. In *Bulla*, the data suggest that light is absorbed by an opsin-based photopigment. By an unknown mechanism the absorption of photons leads to a depolarization of the putative pacemaker neurons, the basal retinal neurons. The depolarization is both necessary and sufficient for phase shifting the oscillator. Reduction in extracellular calcium concentration or application of the calcium channel blocker nickel chloride blocked the phase shift caused by depolarization, indicating that a voltage-dependent transmembrane calcium flux is a step in the phase-shifting pathway; however, the role of the increase in intracellular calcium is uncertain. In *Aplysia*, an opsin-based pigment is also a likely candidate for photon absorption, and the entrainment pathway involves depolarization. As in *Bulla*, a calcium flux may also be an important element, though the exact role of calcium is uncertain. There is also evidence that protein synthesis is involved in phase shifting by light in *Aplysia*, since protein synthesis inhibition can block light-induced advance phase shifts.

In *Drosophila*, one photopigment that has been shown to participate in entrainment is cryptochrome, and disruptions of the gene coding for this

flavin-containing protein, which has been localized to cells that generate circadian oscillations, cause major disruptions in entrainment. Precisely how cryptochrome is coupled to the molecular machinery of the clock within the cell has not been delineated in detail, but it appears to be different between the central brain clock, where cryptochrome is involved in phototransduction for entrainment but is not required for expression of the rhythm, and the peripheral clocks, where it appears to be part of the molecular clockworks.

Identification of Output Pathways

In addition to discovering the organization of the pacemaking system, another important issue is how circadian oscillators impose periodicity on the various physiological and behavioral processes they control. At this time, there has been no complete description of a pathway for the biochemical and physiological steps that are involved in the representation and transmission of circadian information for the regulation of specific overt rhythms; there has, however, been significant progress in the identification of potential signaling molecules. Two examples will serve to illustrate.

Rhythms in Insect Development

A large number of studies suggest that secretion of a variety of insect hormones, including ecdysone, prothoracicotropic hormone (PTTH), and eclosion hormone, is under the control of the circadian system during development. These hormones are involved in the regulation of various developmental events, including ecdysis – the process by which the insect sheds its exoskeleton. The hormonal control of adult ecdysis (eclosion) has been particularly well studied. Although it appears that there are significant differences in detail among different species, it seems to be consistent that at least two physiologically and anatomically separable circadian oscillators are involved in regulating the timed release of these hormones – one located in the brain and a second located in the prothoracic glands. The clock in the brain appears to interact with the clock in the prothoracic glands to regulate the timing of ecdysis.

Rhythms in Retinal Sensitivity to Light

A particularly nice demonstration of a neural link in circadian regulation comes from studies on the efferent regulation of retinal sensitivity in the horseshoe crab *L. polyphemus*. In *Limulus*, a circadian pacemaker in the brain drives synchronous activity in efferent fibers that project to the lateral, ventral, and median eyes, all of which show a circadian rhythm in sensitivity to light. These efferents drive a variety of functional and structural changes in the eye that alter its sensitivity to light. While it is likely that multiple transmitters are involved, one signaling cascade is known to involve the release of the biogenic amine octopamine. Octopamine in turn stimulates a rise in cAMP, which activates cAMP-dependent protein kinase. The activated kinase mediates several of the known efferent effects on the eye.

In summary, the efforts to identify mechanisms by which circadian clocks regulate the effectors under their control indicate that the pacemakers are able to exploit the full range of signaling mechanisms, from direct neural transmission, to neuromodulatory signals, to circulating hormones.

Circadian Rhythm Models

P D Smolen and J H Byrne, University of Texas Medical School at Houston, Houston, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Many organisms, including animals, plants, and cyanobacteria, undergo 24 h rhythms in physiology and behavior, and these rhythms persist in constant dark conditions. Therefore, self-sustaining internal oscillators with periods of approximately 24 h must have evolved in these organisms. The operation of complex biological systems, such as these circadian oscillators, is generally too complex to understand by intuition. Mathematical models are therefore essential to provide a picture of how the system components work together to determine the dynamics and the response to changes in the organism or the environment. Models are also useful to suggest further experiments, to test whether the system responds in ways that the model predicts, or to verify/disprove hypothetical regulatory mechanisms that are predicted to explain specific system behaviors.

Before experiments characterized the molecular mechanisms of these oscillators, attempts were made to describe their dynamics using phenomenological oscillator models from physics. Such relatively simple models are still important. For example, the Van der Pol equations, originally developed to describe oscillating electrical circuits, have proven useful to model light-induced entrainment and phase-shifting of circadian oscillations in humans and cyanobacteria.

Early Models Illustrated Essential Roles of Negative Feedback and Posttranslational Modifications

Data establishing the molecular nature of the internal circadian oscillators have been obtained for many organisms. Mutations have been found that alter or abolish circadian oscillations in mammals, fruit flies (*Drosophila*), fungi (*Neurospora*), and plants. In all these organisms, circadian oscillations in the rate of transcription of genes and in the levels of gene protein and mRNA products have been characterized. Circadian rhythms of protein phosphorylation and degradation have also been observed. Therefore, the internal oscillators are believed to rely on periodic feedback regulation of gene transcription by gene product proteins, as well as periodic posttranslational modifications. Modeling has proven very useful to characterize more specific schemes of molecular interactions and to suggest experimental tests. Since the 1990s, numerous investigators have developed models that have enhanced the understanding of the ways in which feedback regulation and posttranslational modification are organized to sustain oscillations that are robust to changes in the organism's internal or external environment, and that are entrained by light or temperature cycles.

Sustained oscillations in reaction rates and concentrations can be exhibited by biochemical systems with nonlinear kinetics that operate away from equilibrium due to ongoing energy input (e.g., ATP hydrolysis). Most commonly, to drive oscillations, a particular type of kinetic nonlinearity is required – a negative feedback loop. In a negative feedback loop of chemical reactions, the product of the last reaction inhibits the first reaction. A model proposed by Goodwin in 1965 was the first to simulate circadian oscillations due to negative feedback in which a protein repressed its own gene. This venerable model is still proving useful, for example, to simulate aspects of *Neurospora* oscillations.

Drosophila was the first organism for which a negative feedback loop was found essential for circadian oscillations. Experiments established that the period protein (PER) inhibits the transcription of its own gene (*per*). Early modeling by Goldbeter determined that a negative feedback loop in which PER underwent several posttranslational modifications prior to repressing *per* transcription could sustain circadian oscillations in PER levels and formation. Both a critical number of sequential reactions in the loop (at least six or seven) and a significant, sigmoidal nonlinearity in the repression of *per* by PER (e.g., a Hill function of PER with an exponent of 3 or 4) appear necessary to sustain large-amplitude oscillations. Subsequent experiments have confirmed the necessity of this negative feedback loop. PER is multiply phosphorylated, and specific phosphorylations appear to gate PER nuclear entry. PER nuclear entry may also require the TIM protein, and *tim* mutations block rhythmicity. Nuclear PER interacts with a transcriptional activator protein, CLK, and inhibits CLK's binding to DNA. In this way, PER rhythmically inhibits the transcription of not only *per* but also numerous other genes that are activated by CLK, thereby driving numerous physiological/behavioral aspects of rhythmicity. Transcriptional repression by PER persists for several hours, during which PER is progressively phosphorylated. This process is an important factor in setting the long (~24 h) oscillation period. When PER is maximally phosphorylated, it degrades rather abruptly,

and CLK-dependent transcriptional activation of *per* and other genes then resumes, beginning the next cycle. Figure 1 illustrates this negative feedback loop and simulated PER circadian oscillations.

Experiments have identified analogous negative feedback loops that underlie circadian rhythms in mammals (rhythmic repression of transcription by PER and cryptochrome (CRY) proteins) and in *Neurospora* (rhythmic repression of transcription by FRQ protein) as well as in the flowering plant *Arabidopsis*. Models based on negative feedback have simulated molecular oscillations in these organisms. Indeed, it appears that a generic mechanism of rhythmicity based on a negative feedback loop of transcriptional repression is very widespread. Note, however, that some observations indicate rhythmicity can persist in the absence of these loops, perhaps suggesting that multiple mechanisms of rhythm generation exist. For example, in cyanobacteria, circadian oscillations in the phosphorylation of proteins necessary for circadian rhythms (KaiA–C) persist in the absence of transcription.

Figure 1 (a) Schematic of the negative feedback loop which appears to be central to circadian rhythm generation in *Drosophila*. Transcription of *per* is activated by the CLK transcription factor. *Per* mRNA is translated, and PER protein then undergoes multiple phosphorylations. Data suggest some phosphorylation must precede PER's nuclear entry. Nuclear PER represses *per* expression by interfering with CLK, closing the negative feedback loop. Subsequently, PER is further phosphorylated over succeeding hours. Fully phosphorylated PER is then rapidly degraded. PER degradation releases *per* repression, allowing a new cycle to begin. When repression is relieved, *per* expression is again induced. (b) Oscillations of *per* mRNA and protein simulated by using the original model of the negative feedback loop from Goldbeter A (1995) A model for circadian oscillations in the *Drosophila* period protein (PER). *Proceedings of the Royal Society of London, Series B* 261: 319–324.

The models with negative feedback loops also rely on nonlinear repression of transcription to sustain large-amplitude oscillations (e.g., sigmoidal Hill functions of FRQ, CRY, or PER levels). However, experiments have failed to demonstrate cooperative binding of these proteins to regulatory regions of their target genes. Therefore, a mechanism for the hypothesized nonlinear repression has not been found. However, a model of circadian rhythm generation in *Drosophila* by Smolen et al. suggests that multiple sequential chromatin modifications that accompany binding of PER or CLK to DNA could account for nonlinear repression. In mammals, binding of CLK and/or PER is known to be accompanied by such rhythmic chromatin modifications (multiple histone acetylation/methylation events).

Recent Models Consider Additional Positive Feedback and Simulate the Effects of Mutations

Experiments have revealed additional molecular interactions that modulate the negative feedback interactions discussed previously. In *Drosophila*, the transcriptional activator CLK indirectly represses its own gene. In mammals, an analogous activator, denoted BMAL1, indirectly represses its own gene. In both organisms, a positive feedback loop is also present. This loop is organized as follows for mammals and *Drosophila* (*Drosophila* in parentheses). First, *bmal1* (*clk*) gene expression increases levels of BMAL1 (CLK) protein. Second, the increased BMAL1 (CLK) activates *cry* and *per* expression. Third, the expressed CRY and PER inhibits the action of BMAL1 (CLK). Finally, this inhibition of BMAL1 (CLK) de-represses *bmal1* (*clk*), increasing *bmal* (*clk*) expression and thereby closing the positive feedback loop. A detail of the mammalian loop is that BMAL1 inhibition reduces expression of the REV-ERBα transcriptional repressor, and this is the way in which *bmal1* expression is de-repressed. In *Neurospora*, a similar positive feedback loop involves FRQ and the activator WCC. Figure 2 illustrates the mammalian positive and negative feedback loops.

Recent models have examined plausible effects of these positive feedback loops. The existence of both positive and negative loops has been suggested to increase the robustness (stability) of the oscillation period and/or amplitude given biochemical parameter

Figure 2 Schematic of the feedback loops that appear to underlie mammalian circadian rhythm generation. *Per* and *cry* expression is induced by the *bmal1* and *clk* gene products. In the first negative feedback loop, PER and CRY proteins repress expression of their own genes via blocking of transcriptional activation by BMAL1/CLK. In a second negative feedback loop, BMAL and CLK proteins indirectly repress their own genes by inducing *rev-erbα*. The REV-ERBα protein is a repressor. In the positive feedback loop, expression of *bmal1* and/or *clk* leads to induction of *per* and *cry*, which inhibits induction of *rev–erbα* repressor by BMAL1/CLK. *Bmal1* expression is therefore de-repressed and can increase further, closing the positive feedback loop. For clarity, proteins are omitted from the figure and multiple *per* and *cry* isoforms are not distinguished.

variations, such as would occur between individuals in a species. However, others have suggested that positive feedback may not increase robustness. Rather, it may primarily drive oscillations in the expression of 'output' circadian genes that are not part of the core oscillatory mechanism but act to govern physiological and behavioral rhythms. Indeed, data suggest that in *Drosophila*, the level of CLK remains relatively constant.

Another perspective on robustness of oscillations has been obtained from studies that examined a range of simplified model network motifs that simulate oscillations of gene expression. These investigations attempted to determine what type of networks exhibit the greatest stability of oscillation period and/or amplitude to parameter changes. In some of these studies, multiplicity of feedback loops was found to increase oscillation robustness.

Since the 1970s, numerous mutations have been found to alter or abolish circadian rhythms. Arrhythmia can be induced by mutation of *Drosophila per* or *clk*, mammalian *clk*, or *frq* in *Neurospora*. Less drastic mutations of these genes, which preserve partial function, can result in lengthened or shortened free-running circadian oscillations (i.e., in constant darkness the period differs from 24 h). Any viable model of circadian rhythm generation should at least qualitatively simulate the effects of such mutations. For mammals, gene duplication has led to several *per* genes that differ slightly in their importance for rhythmicity (*per1–3*). Two other mammalian transcriptional repressors, CRY1 and CRY2, are also core circadian proteins that function similarly to the PERs.

Complex models attempt to capture most of the currently known complexity of the mammalian oscillator (posttranslational modifications and the roles of additional core circadian genes) and therefore consist of as many as 73 differential equations. However, these models only represent regulation of approximately five core genes, and it is likely that additional genes help drive or shape circadian behavioral oscillations. Although there may be value in increasing the complexity of models to incorporate additional genes, it is clearly also necessary to develop 'reduced' models with fewer variables that capture one or a few of the critical mechanisms underlying rhythm generation and modulation, such as feedback loops, or entrainment by light stimuli. For *Drosophila*, the original model with a single negative feedback loop (Figure 1) remains useful. One- or two-variable reduced models with a time delay have also been developed that represent circadian transcriptional feedback in *Drosophila* and in *Neurospora*, as well as effects of light stimuli. However, a weakness of such models is that introducing explicit time delays generally and strongly promotes oscillations, without representing kinetic details of biochemical reactions.

An alternative approach to model reduction begins with a complex model containing many differential equations and projects the dynamics onto a two- or three-dimensional manifold. For example, the 73-variable model of the mammalian oscillator noted previously has been reduced to a two-variable model that retains most of the qualitative dynamics and is much easier to analyze.

Models Have Increased the Understanding of Entrainment and Phase-Shifting by Light Cycles, Light Pulses, and Temperature Changes

Circadian oscillators generically respond to light. Day–night cycles entrain these oscillators. That is, if the constant darkness oscillation period is within a few hours of the light–dark cycle length, then the oscillator will adjust its period to match the light–dark cycle. It is also generically observed that during a background of constant darkness, brief light pulses will shift the phase of the free-running oscillation. A phase–response curve (PRC) is commonly used to present the light pulse data. In plotting this curve, the abscissa represents the time in the free-running cycle at which the pulse is applied, and the ordinate represents the phase shift caused by the pulse. For a variety of organisms, the PRC has comparably sized regions of both positive and negative phase shifts and tends to have a rather abrupt transition from negative to positive phase shifts. Such a curve is a 'type 1' PRC.

For very strong stimuli, type 0 PRCs are occasionally observed. With these PRCs, phases after stimuli cluster near some fixed value and are thus independent of the phase before stimulus.

The biochemical effects of light on core circadian oscillator genes have been examined. In *Drosophila*, light indirectly enhances degradation of the PER protein (via enhanced TIM degradation, which in turn destabilizes PER). In mammals, light enhances expression of *per* genes, and in *Neurospora* light induces *frq* expression. Models of the mammalian and *Drosophila* oscillators have incorporated these effects and have succeeded in simulating light entrainment of oscillations as well as experimental type 1 PRCs. However, given the same model parameter values, these models have usually not succeeded in simulating type 0 PRCs. Figure 3 illustrates simulated light entrainment of *Drosophila* circadian oscillations and a simulated PRC.

Simulations of PRCs and entrainment can help in understanding human circadian rhythm sleep disorders. Advanced and delayed sleep phase syndromes have been identified, and simulations suggest that mutations decreasing or increasing phosphorylation of PER protein could phase-shift the rhythm and account for these syndromes. Experiments have indeed implicated *per* mutations. In other patients, the phase of sleep does not entrain to night and day but, rather, continuously varies. Analogously, in models, modest changes in PER degradation or in other kinetic parameters can alter oscillation period so that entrainment to a 24 h light–dark cycle is no longer possible.

Circadian models incorporating light responses have been seen, for some parameter ranges, to exhibit multiple dynamic behaviors, including coexistence of a steady state and an oscillating solution (hard excitation) or coexistence of two oscillating solutions (birhythmicity). With coexistence, the initial conditions (initial values of the dependent variables) determine which model behavior is observed. For hard excitation, modeling predicts that an appropriate perturbation (e.g., a light pulse of appropriate intensity) could switch the behavior from the oscillating solution to the steady state or vice versa. Indeed, in constant darkness, a single light pulse has been observed to abolish rhythmic oscillations, and oscillations can be restored by a second pulse. This observation is an example of a behavior that can only be understood or predicted with the help of a mathematical model. For certain parameter ranges in some models, chaotic behavior occurs (i.e., seemingly random variable trajectories without periodic behavior). However, chaotic dynamics have not been confirmed experimentally.

In many organisms, circadian rhythms are observed to be temperature compensated. That is, if the environmental temperature is varied within a limited but substantial range (typically 10–15 °C above or below normal), the period of the free-running rhythm in constant darkness is observed to remain almost constant, and near 24 h. Temperature compensation is surprising because the rates of all biochemical reactions increase with temperature, typically by a factor of approximately two for a temperature increase of 10–15 °C. Models have attempted to simulate

Figure 3 (a) Simulated circadian oscillations of *Drosophila* PER and CLK entrained to a short 22 h light–dark cycle. Note the accelerated degradation of PER at light onset ($t = 11$ h). (b) A simulated *Drosophila* PRC. Constant darkness circadian oscillations were phase-shifted by a brief light pulse, simulated as a 3 h enhancement of the rate of PER degradation. To generate the curve, light pulses were applied at various times during the circadian oscillation. (c) Simulated stochastic oscillations of PER and CLK suggest that relatively reproducible oscillations, with little variation in period, can be sustained when copy numbers of core clock proteins are on the order of 100. (a, b) model used from Smolen P, Hardin PE, Lo BS, Baxter DA, and Byrne JH (2004) Simulation of *Drosophila* circadian oscillations, mutations, and light responses by a model with VRI, PDP-1, and CLK. *Biophysical Journal* 86: 2786–2802. temperature compensation. To date, the only explanation supported by modeling relies on simultaneous acceleration of opposing reactions. For example, sequential phosphorylations of PER protein must be completed during a circadian cycle in *Drosophila* or mammals. At each phosphorylation site, there are opposing phosphorylation and dephosphorylation reactions. If, at each site, the rates of the opposing reactions are increased by similar amounts, then simulations have illustrated that the time required for progression through the sequence of phosphorylations can remain almost constant. This sequence of PER phosphorylations, in turn, appears to be an important determinant of oscillation period length, and as a result, oscillation period does not change appreciably upon a temperature increase.

The above explanation of temperature compensation does rely on 'fine-tuning' of kinetic parameters in the opposing reactions. However, it appears plausible that molecular evolution could lead to such fine-tuning if maintaining a circadian rhythm of proper period in different seasonal temperatures is evolutionarily advantageous to an organism. Indeed, a rhythm of proper period is important for the organism's fitness to ensure that active behaviors (food seeking) and rest/sleep occur at the correct phases of the day–night cycle.

Despite temperature compensation, temperature cycles are observed to entrain circadian rhythms, and temperature pulses can phase-shift rhythms. Models in which temperature affects the rates of opposing reactions can show these effects as well, but the phenomena have not been studied in detail.

Models Illustrate Sensitivity of Rhythms to Stochastic Molecular Noise and Suggest Mechanisms to Enhance Noise Resistance

Models of biochemical systems can be extended to include random variability in the times of individual macromolecular synthesis and degradation events. Observations indicate that the timing of transcription of individual mRNAs is indeed quite random. Also, for some macromolecules, such as specific mRNAs or transcription factors, average molecule numbers per cell can be modest ($\sim$100). In this case, variability in the times of single-molecule synthesis or degradation will lead to significant stochastic fluctuations in macromolecule numbers. These fluctuations can considerably alter the dynamics of biochemical pathways.

It is difficult to determine absolute copy numbers of proteins or mRNAs in neurons, and for circadian gene products, these data are generally not available. Therefore, models including molecule number fluctuations have focused on qualitative predictions of the minimal average copy numbers needed to sustain oscillations of reproducible period and amplitude. Simulations predict that a few hundred copies of PER and other key proteins should be present on average, and average numbers of mRNAs can be somewhat less. Figure 3(c) illustrates *Drosophila* model simulations that sustain reproducible molecular oscillations when the average copy number of key proteins is on the order of 100.

Several theoretical studies have identified mechanisms capable of increasing resistance to either stochastic and environmental fluctuations or noise in genetic oscillators. One conclusion is that positive feedback can enhance noise resistance by generating oscillator dynamics that are characterized by abrupt and large transitions states of high and low gene expression. A related conclusion is that noise resistance is increased in oscillators for which the limit cycle is strongly attracting (i.e., for which perturbations away from the normal periodic time course decay very quickly).

Models Examine the Efficacy of Proposed Mechanisms of Intracellular Synchronization

In the brains of mammals and in *Drosophila*, specific small groups of neurons are responsible for generating the circadian rhythm. This central oscillator, in turn, entrains peripheral oscillators localized in other organs (e.g., the mammalian liver). Two types of synchronization are required in this scheme. Rhythm-generating neurons must synchronize with each other, and the central oscillator must synchronize (entrain) the peripheral oscillators.

In mammals, rhythmogenic neurons are located within the suprachiasmatic nucleus (SCN). Synchronization of these rhythmogenic neurons (and of analogous *Drosophila* neurons) appears to rely on coordinated release of a diffusible neurotransmitter, such as GABA or vasoactive intestinal polypeptide. Electrical coupling of neurons by gap junctions may also play a role. Diffusible neurotransmitters and electrical coupling modulate neuronal electrical activity, and data indicate that variations in electrical activity and Ca^{2+} influx regulate *per* expression. These data therefore suggest a mechanism for rhythm synchronization within the central oscillator. Synchronization of central and peripheral oscillators relies on pulsatile secretion of hormones, such as gonadotropin-releasing hormone, from neurons within or coupled to the SCN.

Models have simulated synchronization of SCN neurons by diffusible neurotransmitters. A plausible

model should also make experimental predictions. One prediction is that efficient synchronization may be achieved even if the average neurotransmitter concentration would dampen individual oscillating neurons. In this case, due to the global neurotransmitter oscillation in the SCN, cells are effectively synchronized. As experimental characterization of SCN neurotransmitter release and possible gap junction coupling proceeds, model refinement will be important to help understand which synchronization mechanisms are most important and to predict how drugs or other environmental changes could alter synchrony.

Directions for Research

Experimental data characterizing the mechanisms of circadian oscillations continue to accumulate rapidly. As a result, no published model of circadian rhythms in mammals, *Drosophila*, or other organisms represents all the known details of rhythm generation. Revision of current models will be necessary as new data become available. However, it is likely that core mechanistic elements represented in current models will remain essential, such as negative feedback loops based on rhythmic repression of clock genes such as *per*, cycle lengths set largely by the time required for multiple phosphorylations of proteins regulating transcription, and relatively simple representations of the known responses to light and temperature.

Conclusion

Models of circadian rhythm generation have helped to determine that circadian oscillators in organisms including animals, fungi, and some prokaryotes share a common element of a negative feedback loop. Due to this loop, core circadian genes are rhythmically repressed by some of their protein products. The 24 h oscillation period is largely required for multiple posttranslational modifications of these core gene products, which are then degraded, allowing the next cycle of transcription. In some organisms, positive feedback loops modulate oscillation phase and amplitude. Multiple feedback loops may increase oscillation robustness to stochastic fluctuations and to mutations. Whether oscillations can be sustained by mechanisms other than transcriptional feedback is still being studied. Models have also helped in understanding some human sleep disorders, predicting mutations in *per* as one causative factor.

Negative feedback loops in which proteins act (directly or indirectly) to repress the transcription of their own genes appear to be a common motif for sustaining biologically important oscillations. Some examples are the cyclical development of somites of the vertebrate embryo, driven by a genetic oscillator in the mesoderm; the oscillatory response of p53 tumor suppressor expression to DNA damage; and oscillations in nuclear levels of the transcription factor NF-κB. Artificial gene circuits with oscillating expression are also being developed and might prove useful for gene therapies that seek to normalize pulsatile release of hormones or other proteins. Models similar to those discussed for circadian rhythms are being applied to characterize these diverse oscillations and predict their responses to environmental and pharmaceutical stimuli in healthy and diseased states.

Circadian Rhythms in Sleepiness, Alertness, and Performance

J D Minkel and D F Dinges, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Circadian rhythms (i.e., biological processes that repeat about every 24 h) reflect the incorporation of Earth's daily rotation into living systems. Internal circadian clocks are found in all eukaryotic and even some prokaryotic organisms indicating that natural selection has highly favored circadian rhythms from the beginnings of life for virtually all species.

The suprachiasmatic nucleus (SCN) in the hypothalamus serves as the brain's master clock, in humans and many other animals as well. Neurons in the SCN fire in a 24 h cycle that is driven by a transcriptional–translational feedback loop. Loss of the SCN abolishes the circadian rhythms of a range of behaviors and physiological processes, including sleep, if the animals are not given other external timing cues. Under normal circumstances, the SCN is reset on a daily basis by light inputs from the retina during the day and by melatonin secretion from the pineal gland at night.

The SCN temporally organizes physiological and behavioral tendencies, but the circadian rhythms it promotes are not fixed. This plasticity is believed to reflect adaptation to dynamic demands of the environment such as seasonal changes in daylight. Humans in industrialized societies, however, routinely push the limits of the adaptive capacity of circadian rhythms. Social demands and opportunities (e.g., night shift work, travel across time zones) often lead to abnormal sleep and wake times that are out of phase with biological requirements. The circadian clock has been shaped by natural selection to regulate physiological processes to occur at optimal times relative to each other or relative to the external environment. With the introduction of artificial lighting and 24 h services, however, many humans are awake when their biological clocks are telling them it is time to sleep and trying to sleep when the circadian clock is sending signals throughout the brain that it is time to be awake. The combination of restricting sleep and attaining it at biologically misaligned times is problematic. Approximately 6 million people in the US alone work during the biological night without adapting their internal physiology to these conditions.

In this article, we review what is currently known about circadian modulation of neurobehavioral and affective systems in humans.

Identifying the Circadian Rhythm in Sleep and Wakefulness

Subjective Measures of Fatigue and Alertness

Circadian rhythmicity in neurobehavioral variables has been successfully identified using a wide array of subjective measures of alertness and fatigue. Visual analog scales, Likert-type rating scales, the Karolinska sleepiness scale, the activation–deactivation adjective check list, and the profile of mood states have all demonstrated sensitivity to circadian fluctuations in sleepiness and mood.

Subjective measures may be particularly vulnerable to numerous confounding influences, however. Masking (i.e., the effects of noncircadian factors on the measurement of circadian rhythmicity) frequently prevents underlying circadian signals from being separated from noise. The context in which such measurements are taken (regardless of whether the setting is experimental or environmental) is a major source of masking effects. Demand characteristics, levels of motivation or boredom, distractions, stress, food intake, posture, background noise, ambient temperature, lighting conditions, and pharmacological factors (e.g., caffeine use) are some of the influences that have been identified to mask underlying circadian rhythmicity in subjective measures. These same variables can also create the false appearance of a circadian rhythm, especially in uncontrolled studies where daily schedules may be influenced by sociocultural factors as much as underlying biology.

Circadian rhythms in mood states and sleepiness can be masked by physical, mental, and social activity as well, even in highly controlled experiments. For example, subjects have reported feeling less alert after being challenged to perform. Thus, if not properly controlled, the drop in subjective alertness due to performance effort can mask circadian effects. Similarly, social interactions with staff and/or other subjects in a study can influence subjective variables. In experimental studies, this potential confound can be reduced through careful training of staff and attention to interpersonal interactions among study participants. However, experiments that fail to control social variables risk contaminating true endogenous circadian variance in self-report measures of alertness and fatigue.

These outcomes can also be masked by prior sleep–wake schedules. Sleep and sleep loss have large effects on alertness and performance that can interact with and alter subtler circadian fluctuations. Despite their sensitivity to masking factors, however, subjective scales have been used to index circadian rhythmicity by repeated administration across the day under carefully controlled conditions.

Cognitive Performance

Objective performance measures also demonstrate circadian rhythmicity and are generally less susceptible to masking influences than subjective reports of mood and sleepiness. Tasks that assess psychomotor and/or cognitive speed are particularly sensitive to circadian fluctuations in arousal and somewhat more resistant to masking effects than many other measures. For example, performance on the well-validated Psychomotor Vigilance Test, which shows almost no learning curve and little variance within and between healthy subjects who are fully rested, has been demonstrated to vary with other markers of circadian phase such as melatonin and core body temperature (see Figure 1).

Circadian variation has also been demonstrated in a wide range of cognitive tests including search-and-detection tasks, simple sorting, logical reasoning, memory access, and even school performance and meter-reading accuracy. A number of studies have concluded that different tasks and task parameters may yield different peak phases of circadian rhythmicity, but under strictly controlled laboratory conditions, most of these intertask differences disappear. Thus, it can generally be stated that circadian rhythms of cognitive and psychomotor performance covary. Furthermore, these rhythms are synchronized with physiological markers of circadian phase, such as body temperature.

Electroencephalographic and Ocular Measures

The circadian rhythm in task performance and subjective states reflects functional changes in the brain. Neural activity, as measured by evoked potentials or event-related potentials (ERPs), has been used to measure alertness. ERPs are relatively subtle signals that must be measured over many consecutive stimulus probes in order to separate them from background electroencephalographic (EEG) noise. Therefore, ERPs are usually recorded during repetitive tasks, such as reaction time tasks and search-and-detection tasks. Circadian rhythms in the changes to amplitude and location of ERP waves have been identified and interpreted to reflect fluctuations in alertness. Measurement of EEG during wakefulness has demonstrated circadian rhythmicity, especially in theta and alpha frequencies. The amounts of theta and alpha activity in the resting EEG are associated with levels of alertness.

Figure 1 The mean (SEM) circadian minimum (nadir) in body temperature occurred approximately 4 h before the maximum of lapses of attention (note downward deflection on the upper graph indicates worse performance).

Sleep latency measured by EEG and electrooculographic (EOG) activity has been found to exhibit marked circadian variation. Since sleep latency is an indication of propensity of the brain to fall asleep, the circadian system is actively regulating sleepiness and sleep–wake cycles. In addition to shifts toward lower EEG frequencies at night, there is a circadian-mediated increase in slow eyelid closure and slow rolling movements, both of which herald the onset of sleep. Finally, autonomic tone has also been shown to covary with sleep pressure as measured by pupillometry (pupils dilate with sympathetic activation).

Midafternoon Dip

In addition to circadian fluctuations in performance that are tightly linked to physiological markers of phase, some individuals appear to demonstrate a short-term dip in performance in the afternoon (sometimes called the midafternoon dip, siesta, or postprandial dip). This dip has been observed in both field and laboratory studies, but is not consistently demonstrated, suggesting that it may be a relatively weak variable.

The best evidence for the existence of such a midafternoon dip comes from studies of sleep propensity and on the timing of daytime naps. There is much less evidence that the midafternoon dip has deleterious effects on performance measures, which makes the phenomenon's relationship to the biological clock somewhat unclear. Although field studies have reported a decline in performance at this time of day the uncontrolled nature of such experiments prevents strong conclusions about the underlying biology of the phenomenon. As mentioned earlier, external variables can produce the illusion of circadian rhythmicity as well as mask it.

Problems in Detecting Circadian Rhythmicity in Performance

Practice Effects and Other Artifacts

Although repeated administration of the same task is important for identifying circadian fluctuations in performance, increasing familiarity with a task also produces a practice effect (i.e., improved performance with practice on a given task). Practice effects can be difficult to distinguish from the circadian rhythm, but the problem can be circumvented by testing subjects in different orders across times of day, thus balancing out improvements in performance due to learning. This solution assumes however that the practice effect and circadian rhythm are merely additive influences on performance that have the same relationship in every subject. For most tasks, neither assumption can be made with certainty. A better way to deal with the practice effect is simply to train subjects to their full capacity (i.e., until performance levels reach an asymptote) on tasks before attempting to assess circadian rhythms. When possible, the best way to deal with this problem is to use a measure that has no practice effects like simple psychomotor vigilance tasks.

In addition to the practice effect, many of the same variables that serve to mask circadian rhythmicity in subjective estimates of fatigue and alertness can also conceal, accentuate, or otherwise distort such rhythmicity on objective performance measures. The effects of masking can vary from changes in the shape of the circadian curve to fully obscuring the circadian influence. It is therefore difficult to extract meaningful information about the mathematical characteristics of the circadian phase without an understanding of the masking effects that influence the variables under investigation.

Not only is performance affected by learning, aptitude, and other masking factors, but also by neurocognitive processes and strategies that can be conscious or unconscious. For example, subvocalization (a strategy that can improve performance on certain tasks) has been reported to fluctuate with a circadian rhythmicity. Similarly, compensatory effort in the face of drowsiness can maintain objective performance at steady levels despite underlying circadian fluctuations. Finally, neuroimaging studies have begun to demonstrate that a given task can be accomplished using multiple neural pathways. Sleep-deprived subjects have been shown to compensate for their performance impairment by increasing activation in the parietal lobes. Such compensatory plasticity in neural function illustrates that the effects of sleepiness and arousal are not always expressed through differences in performance. For all of these reasons, successful demonstration of circadian rhythmicity in performance measures requires that tasks be structured in ways that minimize or eliminate masking effects.

Interindividual and Intraindividual Variability

A large body of literature supports relatively stable interindividual differences in many parameters related to the human circadian system. An important exception however is the period of the human circadian pacemaker. Although published reports spanning several decades asserted that the period could range from 13 h to 65 h, highly controlled data demonstrated that the period is very close to 24 h with little variation between or within subjects. The free running

period of the human pacemaker is also not heavily influenced by age in healthy subjects. The large variance reported in less-controlled studies therefore probably represents individual differences in the sensitivity of the circadian system's response to masking factors such as physical activity, knowledge of time of day, and exposure to artificial light.

In contrast to the human circadian period, individual differences in circadian amplitude, phase, and mean performance level have been demonstrated. Differences in phase are particularly important because they determine differences in circadian variables relative to time of day. For example, personal preference in timing of work hours is related to individual differences in circadian phase.

The tendency for people to prefer to be active and alert earlier or later (often referred to as 'morningness' or 'eveningness,' respectively) is probably the most substantial source of interindividual variation in circadian rhythmicity. Individuals who prefer different times of day differ endogenously in the circadian phase of their biological clocks. Objective performance measures and physiological variables (e.g., core body temperature) support the morningness/eveningness distinction. This traitlike difference in performance may be seen as a phenotypic aspect of circadian rhythmicity in humans.

Intraindividual differences in circadian rhythms refer to changes within one individual over time, such as differences in morning alertness during the summer compared to the winter. The circadian trough is associated with increased intraindividual variability in performance, reflecting increased wake-state instability similar to what is seen with extended wakefulness. Age is also a source of interindividual variability in the circadian rhythm of alertness and performance, but no consistent relevance of sex has been found.

Circadian Rhythmicity and Sleep–Wake Cycles

Sleep Deprivation

Unmasking the circadian rhythm has been a priority in sleep research for many years. An important method in this domain has been the constant routine procedure (also called the unmasking procedure) which involves keeping subjects awake with a fixed posture in a constant laboratory environment for at least 24 h. By maintaining such a static environment, many of the potential confounding factors (changes in lighting and noise, social interaction, cognitive fatigue, etc.) are eliminated or minimized. Relatively subtle circadian fluctuations can then be readily separated from background noise.

Sleep deprivation, however, can still exert a masking influence on neurobehavioral variables because sleep loss adversely affects performance. Performance may be pushed to extremes by a single night of sleep loss, making circadian fluctuations impossible to detect. This is precisely what happens to sleep latency in the widely used multiple sleep latency test (MSLT). Subjects with extremely high homeostatic sleep pressure fall asleep as quickly as possible regardless of their circadian phase. Nevertheless, when sleep pressure is not extremely elevated and the constant routine procedure is used, both circadian and homeostatic influences on performance can be seen.

Sleep–Wake Regulation

The interaction of circadian and homeostatic influences on performance and alertness has prompted efforts to mathematically model the regulatory processes involved. Current theory and mathematical models posit that the homeostatic process represents the drive for sleep which increases linearly during wakefulness and decreases with sleep. When the 'homeostat' reaches a certain threshold, sleep is triggered; when it is sufficiently dissipated, wakefulness is initiated. The circadian process represents daily oscillatory modulation of these threshold levels, but may have an additional role in promoting wakefulness even in the absence of sleep.

These two processes not only determine the timing of sleep and wakefulness, but also interact to determine waking neurobehavioral performance during sustained wakefulness. Sleep-deprivation experiments clearly show that the circadian process continues to influence performance even as the homeostat increases beyond what would normally initiate sleep.

Forced Desynchrony

Like the constant routine procedure, forced desynchrony is an experimental paradigm that unmasks circadian rhythmicity. In this procedure, study participants stay in an isolated laboratory in which the times for sleep and waking are scheduled to deviate from the normal day. Although humans can entrain to days that are not exactly 24 h, artificial days that are extremely short (e.g., 20 h) or very long (e.g., 28 h) are outside the adaptive capacity of the biological clock. When such a routine is kept for several days, the sleep–wake schedule cannot entrain to endogenous circadian rhythms. Studies using this method have clearly demonstrated that both circadian and homeostatic processes influence sleepiness, performance, and mood. The interaction of the two processes is oppositional during natural waking periods such that

a relatively stable level of alertness and performance can be maintained throughout the day.

Ultraradian Days

The 'ultradian' day (meaning 'very short day') paradigm was designed to sample waking behavior across the circadian cycle without significantly curtailing the total amount of sleep allowed. Studies using this method allow subjects relatively brief periods of sleep and wakefulness (e.g., 30 min of sleep followed by 60 min of wakefulness). Thus, ultraradian schedules maintain the normal ratio of sleep to wakefulness (i.e., 1:2). In one such experiment using 7 min of sleep to 13 min of wakefulness, a clear circadian rhythm emerged for the response time on a choice reaction time task. A movement time component was also recorded. This study showed that even in conditions of extremely short artificial days both circadian and homeostatic influences still interact to determine performance.

Circadian Disorders

The laboratory is not the only place one finds people divorcing their sleep–wake pattern from the tendencies of the biological clocks. Recent labor statistics estimate that about 6 million members of the American workforce engage in work at night. While emergency services have been offered 24 h a day for many years, nonessential services are increasingly being offered throughout the night as well. As expected from the research reviewed above, those who work at the circadian phase for sleep show an increased prevalence of sleep disturbance and related medical and psychiatric conditions relative to those who work during the day.

Field studies have estimated that at best, it takes at least 1 week before the biological clock adjusts to shift work. Complicating the problem is the circadian system's sensitivity to both light and dark. Although in a controlled environment the human circadian system can be shifted a full 12 h over a number of days, in natural settings sunlight will disrupt the reentrainment process. Many shift workers therefore never fully adjust physiologically to their schedules. Melatonin has been investigated as a means of facilitating phase shifts, but its ability to shift circadian phase in the presence of natural light has been found to be fairly weak.

Jetlag is also a common chronobiological problem in modern society. At any given time, approximately 500 000 people are traveling in planes, many of whom will cross many time zones. Most individuals experience unpleasant symptoms for several days after arriving at a destination in a new time zone. Because humans have only very recently achieved high-speed transportation, our circadian systems have not been shaped by evolution to entrain quickly to shifted light–dark cycles. As a result, people experience daytime sleepiness, fatigue, impaired alertness, and difficulty initiating and maintaining sleep for several days after crossing time zones.

Accident Risk

Circadian lows in alertness and performance increase the risk of human-error-related accidents. Motor vehicle accidents caused by drivers falling asleep at

Figure 2 Frequency histogram of time of occurrence during the day of crashes in which the driver was judged to be asleep but not intoxicated. Data for years 1990–92, inclusive. Reprinted from Pack AM, Rodgman E, Cucchiara A, Dinges DF, and Schwab CW (1995) Characteristics of crashes attributed to the driver having fallen asleep. *Accident, Analysis and Prevention* 27: 769–775, with permission from Elsevier.

the wheel show a circadian rhythm quite similar to laboratory-based findings (see **Figure 2**). Fall-asleep accidents increase throughout the night as sustained attention decreases. Such accidents peak around 8:00 a.m., when vigilant performance is at its lowest, then begin to fall as the circadian system increases alertness and arousal.

Conclusion

Despite the difficulties inherent in identifying circadian influences on performance at various levels of alertness, a large body of research employing diverse methodology has clearly dissociated the effects of oscillating circadian rhythms from homeostatic influences on performance and mood. While controlling for factors that mask circadian rhythms is important for scientific and theoretical purposes, it is important to remember that these factors are also an integral part of the regulation of neurobehavioral functions that allow for adaptation to rhythmic changes in the environment.

Understanding circadian rhythmicity in performance and affective processes is important for understanding circadian disorders (such as shift-work- and jet-lag-induced sleep problems) and for correctly anticipating performance lapses and fatigue-related impairments (e.g., drowsy driving). When sleep is chronically restricted, both homeostatic and circadian influences must be understood in order to correctly predict levels of performance impairment that result from the interaction of these two systems.

Circadian Organization in Humans

Many aspects of human physiology and behavior are dominated by 24 h rhythms that have a major impact on our health and well-being. For example, sleep–wake cycles, alertness and performance patterns, core body temperature rhythms, and the production of hormones such as melatonin and cortisol are all regulated by an endogenous near-24 h oscillator in the suprachiasmatic nuclei (SCN) of the anterior hypothalamus. The cells in these nuclei spontaneously generate rhythms with a period close to, but not exactly, 24 h, and in order for the circadian pacemaker to ensure that physiology and behavior are appropriately timed to anticipate events in the outside world, environmental time cues must be able to reset this internal clock. The major environmental time cue that resets these rhythms in mammals is the 24 h light–dark cycle generated by the earth's axial rotation. Light information is captured exclusively by the eyes using specialized retinal photoreceptors and transduced directly to the SCN via a dedicated neural pathway, the retinohypothalamic tract (RHT). Each day the light–dark cycle resets the internal clock, which in turn synchronizes the physiology and behavior controlled by the clock.

The major biochemical correlate of the light–dark cycle is provided by the pineal melatonin rhythm. Under normal light–dark conditions, melatonin is produced only during the night and provides an internal representation of the environmental photoperiod, specifically night length. The synthesis and timing of melatonin production requires an afferent signal from the SCN which projects to the pineal gland via the paraventricular nucleus and the superior cervical ganglion. Ablation of this pathway, as occurs in some people due to spinal damage at the upper cervical level, completely abolishes melatonin production, although other circadian rhythms not requiring this projection, such as the cortisol, temperature, and sleep–wake rhythms, persist. Light exposure during the night also inhibits melatonin production acutely and provides an indirect assessment of light input to the SCN via the RHT. Given the close temporal relationship between the SCN and melatonin production, the melatonin rhythm is often used as a marker of circadian phase and the melatonin suppression response as a proxy for RHT–SCN integrity and sensitivity.

The time taken to complete one cycle of a circadian rhythm is defined as the period (τ). A fixed point within a single cycle is termed the phase (ϕ) and is usually measured from the peak (maximum) or trough (minimum) of the rhythm. The circadian period is therefore defined as the duration between one phase and the next. The amplitude of a rhythm is defined as half of the maximum to minimum oscillation of the rhythm.

Circadian Photoreception in Humans

The Effect of Visual Impairment on Circadian Rhythms

The impact of different types of visual impairment on the circadian system has been used as an indirect method to assess the role of light on circadian rhythms and to determine the photoreceptor systems mediating such responses to light. First, these studies have shown that eyes are required for circadian photoreception: individuals without eyes, either through bilateral enucleation or as a result of developmental disorders, are unable to entrain their circadian pacemaker to the 24 h light–dark cycle. Similarly, the majority of totally blind individuals who retain their eyes but cannot consciously perceive light also exhibit circadian rhythms that are not entrained to the 24 h light–dark cycle. As a result of light information failing to reach the SCN to synchronize the clock and its outputs, the pacemaker reverts to its endogenous non-24 h period. Consequently, the timing of physiology and behavior that is controlled by the circadian system, such as the sleep–wake cycle, alertness and performance patterns, the core body temperature rhythm, and melatonin and cortisol production, becomes desynchronized from the 24 h day (Figure 1). These non-24 h rhythms are remarkably stable, ranging from 23.7 to 25.1 h across individuals, and can persist for decades. The resultant clinical disorder is termed 'non-24 h sleep–wake disorder' and is characterized by episodes of good sleep, followed by episodes of poor nighttime sleep and excessive daytime nappitng, followed by good sleep and so on, as the non-24 h circadian pacemaker cycles in and out of phase with the 24 h social day (Figure 1).

Disorders of the visual system do not always attenuate the circadian effects of light, however, demonstrating a functional separation of the visual and circadian photoreception systems. The majority of legally blind individuals who retain some degree of light perception, even with very little usable vision in some cases, have normally entrained circadian rhythms. Primary loss of the central or peripheral visual fields is also not

Figure 1 Circadian rhythms of sleep and melatonin in two visually impaired subjects. (a, b) subjects completed daily sleep and nap diaries for 4 or 5 weeks and their sleep times (solid squares) are double-plotted according to time of day (abscissa) and study day (ordinate). Subjects also collected sequential 4 to 8 hourly urine samples for 48 h per week, and the peak time of urinary 6-sulfatoxymelatonin (aMT6s) production each week (open circles) is plotted. (c, d) the weekly rhythms of urinary aMT6s production (solid circles) that correspond to the peak times shown and the gray bars represent the normal range of peak production for aMT6s (01.00–07.00 h). Panels (a) and (c) show data from a visually impaired female aged 35 years with a visual acuity to detect 'hand movements only' (subject 21). Both the sleep–wake cycle and aMT6s rhythm remain entrained to 24 h (a) with normal night-time production of melatonin (c) and such rhythms would be typical of most normally sighted subjects. Note that her visual impairment, while severely disrupting the visual system, does not affect the circadian photoreception system, illustrating the functional separation of the visual and circadian photoreceptor systems. The subject in panels (b) and (d) is a 66-year-old totally blind man with one eye and no conscious light perception (subject 20). He exhibits a sleep–wake cycle and melatonin rhythm that are not entrained to 24 h (b). The aMT6s rhythm exhibits a non-24 h period ($\tau = 24.68$ h) which clearly delays from week to week and is not entrained to the night (d). Closer observation of the sleep patterns shows a cyclic sleep disorder in this subject in which sleep occurs normally at night with no day time naps when the endogenous aMT6s rhythm coincides with the night but becomes very disturbed at night and is accompanied by many daytime naps when the aMT6s rhythm does not occur at night. The timing of the naps follows the timing of the aMT6s rhythm, which represents the internal 'biological' night and the time when the circadian system promotes sleep. The subject tries to remain on a normal social day, this is, sleeping at night and remaining awake in the day, but cannot sleep well when the circadian system in not entrained to the light–dark cycle. This example of non-24 h sleep–wake disorder is typical of most totally blind subjects and highlights the disturbance caused by a failure of light–dark information to reach the hypothalamic circadian pacemaker on our ability to sleep and wake on a 24 h pattern. Adapted from Lockley SW (1997) *Sleep, Melatonin and Other Circadian Rhythms in the Blind*. PhD thesis, University of Surrey, Guildford, UK.

associated with circadian rhythm disorders, suggesting that the circadian photoreceptor system is less sensitive to the spatial distribution and intensity of light than vision. Color blindness, a more specific lesion of the three-cone photopic visual system, also does not attenuate circadian responses to light, as measured by acute suppression of pineal melatonin. Finally, and most definitively, it has been demonstrated that some totally blind people retain normal circadian phase shifting and melatonin suppression responses to light even in the absence of any normal visual response, as assessed by conscious ability to detect light, visually evoked potentials, or electroretinogram (Figure 2). These individuals exhibit normally entrained 24 h rhythms under real-world conditions and do not report sleep disorders. The effects of light in these subjects are mediated exclusively via the eyes because when their eyes are covered, the effects of light are inhibited. Thus, circadian photoreception can be maintained in humans in the absence of a functional visual system, as has also been shown in transgenic and developmental rodent models.

Figure 2 Circadian photoreception in a totally blind subject. (a, c) Subjects completed daily sleep and nap diaries for approximately 11 or 12 weeks and their sleep times (solid lines) are double plotted according to convention in Figure 1. Subjects also had their circadian phase measured at regular intervals from either core body temperature minimum (a, circles) or plasma melatonin onset (c, triangles). (b, d) The results of a melatonin suppression test during which the subjects' eyes were exposed to bright white light (6000–13 700 lux) for 90–100 min during plasma melatonin production. Panels (a) and (b) show the sleep–wake pattern and melatonin suppression response for a 70-year-old blind man with congenital glaucoma. He retained both eyes but reported no conscious light perception. Electroretinogram (ERG) and visually evoked potential (VEP) responses were not detectable. As shown in (a), the subject's circadian system was not entrained to the light–dark cycle and the core body temperature rhythm exhibited a non-24 h period. Consistent with the lack of entrainment by light, light exposure did not have any effect on the melatonin rhythm, confirming that the retina–SCN–pineal pathway was not functional in this patient. Panels (c) and (d) show the sleep–wake pattern and melatonin suppression results for a 21-year-old woman with Leber's congenital amaurosis, a type of retinal dystrophy. The ERG was undetectable, but an abnormal VEP was recorded. As shown in (c), the sleep–wake cycle was normal with stable entrainment to 24 h. The melatonin suppression response was clearly positive, with an immediate suppression of melatonin at lights on (open bars) which ceased once the bright lights were turned off. Despite the subject's lack of conscious light perception, light was still able to stimulate the retina–SCN–pineal pathway; covering the eyes prevented the response. The normal sleep–wake cycle, coupled with the positive melatonin suppression test, indicated that light was able to entrain the circadian system of this totally blind women. Note that a similar sleep–wake pattern accompanied by a negative melatonin suppression test would indicate that (1) the subject was entrained to 24 h by nonphotic time cues or (2) the subject's endogenous circadian period was exactly 24 h. Reproduced from Czeisler CA, Shanahan TL, Klerman EK, et al. (1995) Suppression of melatonin secretion in some blind patients by exposure to bright light. *New England Journal of Medicine* 332: 6–11.

Spectral Sensitivity of Circadian Photoreception

Assessment of the spectral sensitivity of circadian responses has been used as an indirect method to determine the photoreceptor system mediating these effects of light. Using classical photobiology techniques, action spectra have been generated to describe the spectral sensitivity of the melatonin suppression response. These action spectra predict a peak sensitivity in the short-wavelength (blue) range (λ_{max} ~460 nm) that does not match the action spectra for human scotopic (rod) or photopic color (cone) vision or the absorption spectra for the individual red, green, or blue cones (Figure 3). Although full action spectra are not available for circadian phase shifting, comparisons of equal photon density exposures of monochromatic 460 and 555 nm light have shown that the circadian system is also more sensitive to short-wavelength 460 nm light, confirming that the three-cone photopic photoreceptor system (which has a peak sensitivity at 555 nm) is not the primary photoreceptor system mediating the resetting effects of light (Figure 4). These findings are consistent with the concept of a non-rod, non-cone photoreceptor system in the eye. In fact, studies in rodents and primates detailed elsewhere in this encyclopedia have discovered a novel opsin in the eye, melanopsin, which is also present in the human eye. Melanopsin is contained in intrinsically photosensitive retinal ganglion cells which project to the SCN, and these cells have a peak spectral sensitivity in the short-wavelength range (~480 nm), making melanopsin a prime candidate for mediating the circadian effects of light.

Extraocular Circadian Photoreception

Photoreceptors external to the eye that detect light for circadian rhythms are common in nonmammalian vertebrates, such as the pineal gland in birds and the parietal eye and pineal gland in reptiles. There is no evidence, however, for the presence of extraocular circadian photoreceptors in adult mammals despite multiple investigations. The concept of extraocular light sensitivity for circadian response in humans, specifically via exposure to the popliteal region, was widely disseminated following a study published in the late 1990s. These preliminary findings, however, have not stood up to rigorous reevaluation and, coupled with the lack of entrainment observed in enucleated blind subjects as described previously, the current consensus is that human circadian photoreception is mediated exclusively via the eyes.

Figure 3 Spectral sensitivity of the light-induced melatonin suppression response. Two action spectra are shown from separate experiments examining the spectral (color) sensitivity of light-induced melatonin suppression. The relative melatonin suppression response is plotted against the wavelength of light exposure. The suppression data were generated from many hundreds of experiments in which subjects were exposed to either 90 min ($n = 72$) (a) or 30 min ($n = 22$) (b) of monochromatic visible light (range, 420–600 nm) of varying intensities during the night after administration of a pupil dilator. Each point in the action spectra represents the half-saturation constant of the dose–response function of one wavelength, normalized to the maximum response. The solid curve in (a) shows the best-fit template for a vitamin A_1 retinaldehyde photopigment and predicts a maximal spectral absorbance (λ_{max}) of 464 nm (range, 446–477). Similar analysis of the data in (b) also predicts a peak sensitivity in the short-wavelength (blue) part of the spectrum with $\lambda_{max} = 459$ nm (range, 457–462). Panel (b) also shows the absorbance spectra for scotopic (rod) vision (solid line) and photopic three-cone color vision (dotted line) and demonstrates that the spectral sensitivity of the melatonin suppression response is blue-shifted relative to conventional visual systems. (2001) Action spectrum for melatonin regulation in humans: Evidence for a novel circadian photoreceptor. *Journal of Neuroscience* 21(16): 6405–6412. (b) Thapan K, Arendt J, and Skene DJ (2001) An action spectrum for melatonin suppression: Evidence for a novel non-rod, non-cone photoreceptor system in humans. *Journal of Physiology* 535(1): 261–267.

	460 nm	555 nm
Photons cm^{-2} s^{-1}	2.8×10^{13}	2.8×10^{13}
μW cm^{-2}	12.1	10.0
Photopic lux	5.0	68.1
Scotopic lux	116.6	68.7

Figure 4 Spectral sensitivity of the light-induced circadian phase shifting response. Two groups of young healthy subjects ($n = 8$ per group) were exposed to an equal photon density of 460 nm (blue) or 555 nm (green) monochromatic light for 6.5 h during the night following administration of a pupil dilator on a background of <2 lux. The phase shift of the circadian system was assessed using the endogenous melatonin rhythm, measured before and after the experimental light exposure using a constant routine procedure. Both light exposures caused a phase delay (negative sign) of the individuals' plasma (solid circles) or salivary (upside-down triangles) melatonin rhythm. On average, exposure to 460 nm light caused nearly twice the phase shifting response compared to exposure to an equal photon density of 555 nm light (mean ± SEM, -2.98 ± 0.50 vs. -1.67 ± 0.73 h, respectively). The relative photopic lux of the exposures, as would be measured using a standard lux meter, does not correspond to the biologic effects of light, indicating that the spectral sensitivity of the meters ($\lambda_{max} = 555$ nm) is not appropriate for quantifying light for circadian responses. The scotopic lux values, although appearing to correlate with the biological responses, are not applicable because the levels of light used saturate rod responses. Adapted from Lockley SW, Brainard GC, and Czeisler CA (2003) High sensitivity of the human circadian melatonin rhythm to resetting by short wavelength light. *Journal of Clinical Endocrinology and Metabolism* 88(9): 4502–4505.

Measuring Circadian Rhythms in Humans

Circadian Phase and Amplitude

In order to assess the effects of light on the human circadian pacemaker, an accurate measurement of circadian phase and amplitude is required. Common parameters used to assess circadian phase include melatonin and its metabolites or cortisol in plasma, saliva, or urine, and core body temperature. These parameters, however, are susceptible to direct environmental influences that alter their pattern and 'mask' the endogenous circadian component of their rhythms. For example, core body temperature can be directly increased by mild activity or exercise, eating, or taking a shower. Cortisol can be directly affected by stress and melatonin is acutely suppressed by light. A technique is therefore required that removes or minimizes these influences or, if this is not possible, distributes them evenly across all circadian phases so that any effect of the masking stimulus is effectively averaged out. The gold standard method used to achieve these conditions is the constant routine (CR) procedure, developed by Mills and colleagues in the 1970s and later refined by Czeisler. This method requires subjects to be assessed for at least 24 h (usually 30 h or more) in constant conditions; subjects remain awake during continuous semirecumbent bed rest in constant dim light (<15 lux or lower) with no activity and regular (e.g., hourly) identical meals and fluids. Using these techniques, it has been possible to make a systematic review of how the circadian system is affected by a range of properties of light as outlined later.

Circadian Period

Measurement of circadian period requires a longer assessment than can be achieved during a CR procedure. Although a CR can sometimes last two or, rarely, three circadian cycles (48–72 h), the small number of cycles is insufficient to assess circadian period accurately. A range of techniques have been used to measure period in the laboratory, but the forced desynchrony protocol, pioneered by Kleitman in the 1930s and later extended by Czeisler and colleagues, represents the most well-developed method for the accurate and reliable measurement of circadian period. The technique requires that subjects live on a scheduled day length (called a T cycle) that is outside the range of entrainment of the circadian pacemaker; that is, a T cycle so different from 24 h that the circadian pacemaker cannot entrain to it and consequently reverts to its intrinsic period. Examples of forced desynchrony T cycles include 20 min, 90 min, 11 h, 20 h, 28 h, 30 h, and 42.85 h, although the very short T cycles cannot be sustained for more than a few days. Under these conditions, the circadian pacemaker of healthy adults exhibits an average period of ~24.2 h with a range from 23.5 to 24.7 h. Similar non-24 h periods have been observed in subjects living in near-darkness during cave experiments or under dim light in the laboratory.

Resetting the Human Circadian Pacemaker with Light

Circadian Entrainment

In order for the circadian pacemaker to remain entrained to environmental time, a daily phase shift is required that opposes the daily 'drift' in phase as determined by the endogenous period of the pacemaker. For example, if the endogenous period of an individual is 24.5 h, then a phase shift of 0.5 h per day is required to maintain entrainment. As this shift requires a shortening of the period, causing the circadian cycle to be completed in a shorter time, the direction of shift is termed an advance shift. If the period (τ) = 23.8 h, then a phase delay shift of 0.2 h per day is required, lengthening the period and delaying the time taken to complete one circadian cycle. Depending on the circadian phase of exposure, light can both phase advance and phase delay the clock; the magnitude of the phase shift depends on the intensity and number of exposures. The direction and magnitude of phase shifts induced by a stimulus are defined by a phase response curve (PRC), and the PRCs for light are reviewed in detail later. Although light is the most potent environmental stimulus in humans, other nonphotic stimuli, such as scheduled exercise, sleep, food intake, and some drugs (e.g., melatonin), can shift the timing of the clock to a lesser extent and have their own PRCs. In some cases, these nonphotic stimuli are strong enough to entrain the circadian pacemaker, as observed in the minority of totally blind people who are not sensitive to light but remain synchronized with the 24 h day.

As the strength of the light stimulus determines the maximum shift per day that can be achieved, it also determines the 'day' length to which the circadian pacemaker can be entrained – also termed the limits or range of entrainment. Under a dim light–dark cycle (<8 lux), the circadian pacemaker can remain entrained to a 24 h day but the light is not bright enough to achieve the daily phase shift required to entrain to a 23.5 or 24.6 h 'day.' If the intensity of the light during the day is increased, then the limits of entrainment expand. Model predictions suggest that entrainment could occur to day lengths ranging from 22 to 27 h depending on the endogenous circadian period and the intensity of the light.

A practical example of the consequences of the limits of entrainment can be observed in US submariners, who are routinely scheduled to an 18 h 'day.' The combination of the short day length and the relatively dim lighting conditions on board prevents entrainment to the imposed schedule, causing the circadian clock to run at its endogenous non-24 h period, on average ~24.3 h. The resultant desychronization between the circadian system and the sleep–wake schedule is likely to cause decrements in alertness and performance when the submariners are on duty at an inappropriate circadian phase and increase the risk of a fatigue-related accident. Similar problems occur in night-shift workers who also often work during their biological night and have an increased risk of accidents and injuries during this time, as reviewed elsewhere in this encyclopedia.

Properties of Light and Circadian Resetting

The circadian photoreception system is not designed to detect light with the same degree of sensitivity as the visual system but, rather, represents a relatively insensitive irradiance detector. This irradiance detection system predates vision in evolutionary terms and both the anatomical location of the photoreceptors, distributed sparsely in a network across the eye, and the properties of the system, particularly the ability to integrate light information over a long duration of time, reflect this specific role.

The circadian resetting effects of light are determined by a range of factors, including the timing, intensity, duration, pattern, wavelength and history of exposure. These factors have largely been studied separately in order to confirm their individual contribution to the resetting effects of light, although their interactions are beginning to be examined. In real-world conditions, of course, many of these factors will apply simultaneously to the net phase resetting effects of light.

Timing One of the primary factors determining the phase resetting effects of light is the timing of the light exposure. Light can either phase advance or phase delay the circadian system depending on the timing of exposure. Under normal conditions, light exposure in the late day/early night causes a phase delay of the pacemaker, whereas light exposure in the late night/early day will phase advance the clock. The relationship between the timing of a stimulus and the direction and magnitude of the resultant shift is described in a PRC (Figure 5). Two types of light PRCs have been described across many organisms, including humans – a low-amplitude PRC with maximum shifts of several hours and a high-amplitude PRC with maximal shifts of 12 h. Winfree classified these PRCs as type 1 (weak) and type 0 (strong), respectively, according to the shape of their resetting contours (phase transition curves) (Figure 5). In order to achieve type 0 resetting, the light must be of appropriate strength and duration (e.g., 10 000 lux for 5 h) and be timed at a critical phase (approximately equivalent to the phase

Figure 5 Type 1 and type 0 phase response curves to light. (a, c) Smoothed phase response curve (PRC) following exposure to a single stimulus (a) or three stimuli over consecutive days (c) on a background of <15 lux. The magnitude and direction of the phase shifts are plotted against the initial phase of the stimulus. The magnitude of the shift is expressed in degrees (± SEM); if one circadian cycle is 360°, then a shift of 90° represents one-fourth of the circadian cycle, equivalent to a 6-h phase shift under normally entrained conditions (0.25 × 24 h). Advance shifts are positive on the ordinate and delay shifts are negative. Phase shifts and the timing of the light exposure were assessed from the timing of the core body temperature minimum (0°) under constant routine conditions before and after light exposure. (a) Following a single exposure to bright light (7000–12 000 lux for 5.24 ± 0.22 h; range, 4.0–6.2), a low-amplitude PRC is observed, with maximum delay shifts of −71° and advance shifts of +21°. The asymmetry is caused by the 'drift' between the pre- and postexposure constant routines due to endogenous circadian period which on average causes a net delay ($\tau = 24.2$ h). (c) Following exposure to three light exposures (7000–12 000 lux for 5 h each), the resultant PRC has a much larger amplitude, with maximum advance and delay phase shift of +180° and −180° (equivalent to +12 and −12 h), respectively. These large phase shifts only occur at a particularly sensitive phase, close to the core body temperature minimum (0°). (b, d) Smoothed phase transition curves (PTC) for the corresponding PRC data, with the final circadian phase of the stimulus plotted against the initial phase of the stimulus. The slope of the resultant plot indicates whether the phase resetting response is type 1 (slope ∼1; b) or type 0 (slope ∼0; d). Reproduced from Jewett ME, Kronauer RE, and Czeisler CA (1994) Phase-amplitude resetting of the human circadian pacemaker via bright light: A further analysis. *Journal of Biological Rhythms* 9(3–4): 295–314.

of the core body temperature minimum) such that the amplitude of the circadian oscillation is suppressed. Once the oscillation is suppressed, a phase shift of up to 12 h can be achieved with similar multiple light exposures over the next 2 or 3 days. An analogy for this type of response would be to consider the amplitude of the oscillation with respect to the earth's rotation at the Poles. When the amplitude is nearly zero (i.e., very close to the Pole), a short step in one direction could achieve an immediate phase shift of up to 12 h. When on the equator, however, the amplitude of the earth's rotation with respect to the Poles is very large, and only small phase and amplitude shifts can be achieved by stepping in any particular direction. These weak shifts are analogous to type 1 resetting in which shifts of only a few hours are achieved in response to a single light exposure (Figure 5). In practice, most phase shifts experienced by humans are type 1 shifts since very specialized conditions are required to achieve type 0 resetting.

In animal studies, some species have been shown to be insensitive to light during the middle of the subjective day, creating a so-called 'dead zone' in the PRC. Human PRCs lack a dead zone, as shown in Figure 5, illustrating that the circadian pacemaker is sensitive to the resetting effects of light at all times of day, although the sensitivity to light is lowest in the middle of the day.

The PRC provides an essential tool in calculating when to time light therapy for treatment of circadian rhythm sleep disorders or in anticipating the effects of altered light–dark exposure experienced during transmeridian travel or during shift work.

Intensity The intensity of light is a vital property when considering the resetting strength of the light exposure. There is a nonlinear relationship between the intensity of light and its circadian phase resetting effects such that exposure to relatively dim indoor room light (~100 lux) for 6.5 h at night can stimulate 50% of the maximum effect of an equal-duration exposure with 10- to 100-fold greater illuminance (Figure 6). Thus, the human circadian pacemaker is exquisitely sensitive to light, and light levels commonly experienced from artificial indoor illumination are able to induce considerable resetting effects on the clock.

Duration and pattern The duration of light exposure interacts nonlinearly with the magnitude of suppression such that shorter exposures induce greater effects than would be predicted by a simple linear relationship. When continuous exposures are compared to intermittent patterns, a nonlinear interaction is also observed. Compared to a single continuous 6.5 h bright light exposure (~10 000 lux) at night, an intermittent exposure pattern consisting of six 15 min bright light pulses separated by 60 min of very dim light (<1 lux) caused ~80% of the phase shifting response (3.0 vs. 2.3 h delay, respectively) despite representing only 23% of the total duration (Figure 7). Similar results are observed for multiple exposures. The ability of the circadian system to integrate light information over time presents potential advantages when developing light therapy programs because most of the potential benefit can be realized without requiring prolonged continuous exposure.

Wavelength As outlined previously, the spectral sensitivity of the circadian system is blue-shifted relative to the photopic and scotopic visual systems, indicating the presence of a novel non-rod, non-cone photoreceptor system (Figure 3). Equal photon density comparisons of 460 and 555 nm monochromatic light exposure at night show that 460 nm light is twice as effective at phase delaying the clock (Figure 4). Morning exposure to polychromatic blue light has also been shown to be at least equally as effective at

Figure 6 Illuminance–response curves for circadian phase resetting and melatonin suppression. Twenty-three young healthy subjects were exposed to white light (4100 K) for 6.5 h during the night. Each subject was exposed to a different intensity of light, ranging from 3 to 9100 lux (squares) on a background of <10 lux. The phase delay shift in the plasma melatonin rhythm was calculated from the difference in phase from the pre- and postexposure constant routines. Melatonin suppression was calculated from the difference in the area under the curve for the 4 h prior to peak melatonin level on the first constant routine and the corresponding 4 h during the light exposure. The resultant dose–response curves were fitted with a four-parameter logistic model using a nonlinear least squares analysis (solid line) and the 95% confidence intervals are shown (dotted lines). The model for the phase delay response predicts an inflection point of the curve (i.e., the half-saturation constant) at 119 lux and saturation of the response at ~550 lux (a). Similar results were obtained for melatonin suppression, with half-maximal response at 106 lux and saturation at a slightly lower illuminance of ~200 lux (b). These data show that relatively dim light exposure, equivalent to that experienced indoors, is capable of shifting the circadian pacemaker and inducing neuroendocrine responses. Reproduced from Zeitzer JM, Dijk D-J, Kronauer RE, Brown EN, and Czeisler CA (2000) Sensitivity of the human circadian pacemaker to nocturnal light: Melatonin phase resetting and suppression. *Journal of Physiology* 526(3): 695–702.

Figure 7 Effect of intermittent light exposure on circadian phase resetting. Twenty young healthy subjects were exposed to white light (4100 K) for 6.5 h during the night. (a) Subjects were randomly assigned to received continuous exposure to bright light (BL; ~9500 lux, $n = 6$), intermittent exposure to bright light (IBL; 6 × 15 min exposures to ~9500 lux each separated by 1 h, $n = 7$), or continuous very dim light (VDL; <1 lux in the angle of gaze, $n = 7$). (b) The phase delay shift was calculated as described for **Figure 6** (solid circles). Despite representing only 23% of the total light exposure duration, intermittent bright light caused ~70% of the phase shift compared to continuous bright light exposure. Reproduced from Gronfier C, Wright KP Jr., Kronauer RE, Jewett ME, and Czeisler CA (2004) Efficacy of a single sequence of intermittent bright light pulses for delaying circadian phase in humans. *American Journal of Physiology Endocrinology and Metabolism* 287: E174–E181.

phase advancing the circadian system as exposure to a 185-fold higher photon density of cool white light.

As a consequence of the finding that the spectral sensitivity of the circadian photoreception system is blue-shifted relative to the three-cone photopic system, a revision of the units used to measure illuminance is required. Currently, lux (1 lux = 1 lumen m^{-2}) is the unit of measurement for illuminance and estimates the amount of light stimulating the visual system. As the three-cone photopic visual system has a peak sensitivity (λ_{max}) of 555 nm, the lux measurements also assume the same spectral sensitivity and therefore so do most commercially available light meters. When measuring the amount of light stimulating a circadian response to light, however, this assumption is incorrect because the peak sensitivity of circadian photoreception is ~460–480 nm. Lux values are therefore inaccurate when quantifying the absolute amount of light stimulating the circadian photoreception system (**Figure 4**), although if the light source remains constant, lux can quantify relative changes in light amount (**Figure 6**). The development of appropriate units and light sensors adapted for circadian photoreception is currently ongoing.

Photic history The effect of a light stimulus on the circadian system is not simply dependent on the intensity of light but also on the relative change in intensity. The circadian photoreception system exhibits adaptation to prior light exposure in determining the response to a current stimulus. As shown in **Figure 8**, under laboratory conditions subjects kept in dim light (<2 lux) for 15 h prior to exposure to 200 lux for 6.5 h showed significantly greater melatonin suppression compared to when they were exposed to 200 lux for 15 h prior to the experimental 6.5 h exposure.

Figure 8 Effect of prior light exposure on the light-induced melatonin suppression response. Eight young healthy subjects were studied in a within-subjects design. (a) Subjects completed three 40 h constant routines (CR), each separated by three baseline days (16 h wake: 8 h sleep in darkness). On the first CR, all subjects were exposed to continuous dim light (<2 lux) after three baselines days at 200 lux. On the second and third CRs, subjects were randomized to receive a 6.5 h exposure to 200 lux (suns) after three baseline days of <2 lux or 200 lux, respectively. (b) The individual plasma melatonin profiles during each 40 h CR are shown for each condition (A–C). Melatonin suppression was significantly greater when 200 lux exposure was preceded by exposure to <2 lux (mean ± SEM, 85.7 ± 6.5%; B) compared to prior exposure to 200 lux (71.2 ± 7.1%; C). Reproduced from Smith KA, Schoen MW, and Czeisler CA (2004) Adaptation of human pineal melatonin suppression by recent photic history. *Journal of Clinical Endocrinology and Metabolism* 89(7): 3610–3614.

Furthermore, subjects routinely exposed to more bright light during the day for 1 week have a reduced melatonin suppression response than following exposure to dimmer light, and it has been suggested that people who routinely work outdoors are less sensitive to the melatonin-suppressing effects of light than those who routinely work indoors. At a cellular level, the melanopsin-containing intrinsically photosensitive retinal ganglion cells also demonstrate an adaptation process which may also be wavelength as well as intensity specific. Further work is required to define the time course of this adaptation response, although these initial studies suggest that the circadian photoreception system is able to integrate light information over hours if not days.

Other Neuroendocrine and Neurobehavioral Effects of Light

In addition to resetting the phase of the circadian pacemaker, light also stimulates other neuroendocrine and neurobehavioral responses. One major response, the inhibitory effects of light on pineal melatonin synthesis, has already been discussed. In addition, light exposure directly stimulates cortisol production in the morning, improves subjective ratings of alertness, improves psychomotor reaction time and lapses of attention, changes the frequency of electroencephalogram (EEG) brain waves that specifically indicate a more alert state, increases heart rate, alters thermoregulatory processes, and induces pupillary constriction. Light exposure has also been shown to stimulate circadian clock gene expression, specifically the expression of PER2 in buccal cells. These effects of light have been collectively termed 'nonvisual' or 'non-image forming' responses and are sometimes grouped under the term 'circadian photoreception' because much of the behavioral and neuroanatomical work that first identified these effects was focused on studies of circadian phase resetting.

Some of the properties of light outlined previously that affect phase shifting responses have also been demonstrated for other effects of light. For example, the acute arousing effects of light at night on alertness, performance, and EEG power are dose dependent

Figure 9 Illuminance–response curves for the acute alerting effects of light. In addition to phase shifting and melatonin suppression (Figure 6), the acute dose-dependent alerting effects of light were also examined in the same subjects. Before, during, and after the 6.5 h light exposure, subjects completed the nine-point Karolinska Sleepiness Scale (1 = very alert, 9 = very sleepy) every 30 min and had continuous electroencephalogram (EEG) and electooculogram (EOG) recordings. The summed alertness ratings during the entire light exposure are shown on the left; the number of 30 s EOG epochs containing at least one slow-rolling eye movement, an objective indicator of fatigue, are shown in the middle; and the percentage EEG power in the theta–alpha frequency range (5–9 Hz) during the last 90 min of light exposure are shown on the right. Open circles represent subjects with >50% suppression of melatonin during the light exposure, and closed circles identify those with <50% melatonin suppression. The logistic regression model fit to the individual data points is also shown for each parameter. Both the subjective and the objective markers of sleepiness exhibit a clear dose-dependent response to light, with increasing intensity causing a reduction in sleepiness, the number of slow eye movements, and theta–alpha EEG power. These reductions in sleepiness were also correlated with the degree of melatonin suppression, although the mechanism of how light induces alertness is not yet known. Reproduced from Cajochen C, Zeitzer JM, Czeisler CA, and Dijk D-J (2000) Dose–response relationship for light intensity and ocular and electroencephalographic correlates of human alertness. *Behavioural Brain Research* 115: 75–83.

(Figure 9) and wavelength dependent (Figure 10). One mechanism by which light could exert its alerting effect is via the suppression of melatonin, the timing of which closely parallels the endogenous rhythm in subjective sleepiness and, when taken exogenously, increases sleepiness. Nighttime light exposure both suppresses melatonin and induces a simultaneous increase in alertness. Furthermore, studies measuring light-induced changes in EEG correlates of arousal have shown that blue light (460 nm) is more effective than green light (555 nm) in activating high-alpha frequencies (9.5–10.5 Hz) which closely parallel the circadian rhythm of melatonin production. Notably, however, light exposure during the day still improves alertness and performance when melatonin is undetectable, suggesting that at least during the biological day, alertness is not mediated via suppression of melatonin. Further separation of day and night responses is also observed in other effects of light; for example, heart rate and temperature are elevated by white light exposure during the night but not the day. These data suggest that it may be possible that multiple light responses have differing spectral sensitivities to light, theoretically mediated through differences in the relative contributions of the short-wavelength sensitive melanopsin-driven system and the longer-wavelength sensitive photopic and scotopic visual photoreceptor systems.

Circadian Rhythm Disorders and Light

Shift work The most common circadian rhythm disorder is shift work sleep disorder, experienced by many of the estimated 15 million shift workers in the United States. Shift workers experience sleep problems, fatigue, poor performance and memory, and gastrointestinal problems and have increased long-term risk of cardiovascular disease, diabetes, and some types of cancer. The underlying source of these problems is the desychronization between the shift work schedule and the light–dark cycle. As illustrated in totally blind subjects, circadian desynchronization is caused by a failure of the internal circadian pacemaker to remain entrained with the environmental light–dark cycle. Shift workers' schedules (and therefore light–dark cycle) often change so rapidly that the circadian system cannot adapt, resulting in wake (work) and sleep occurring at an inappropriate circadian phase. Consequently, sleep duration and quality are reduced,

Figure 10 Spectral sensitivity of the acute alerting effects of light. Sixteen subjects were studied to test the spectral sensitivity of the photic phase resetting response (**Figure 4**) and the acute alerting effects of light. Subjects completed the nine-point Karolinska Sleepiness Scale (1 = very alert, 9 = very sleepy) and an auditory psychomotor vigilance test every 60 min before, during, and after exposure to 6.5 h of either 460 or 555 nm monochromatic light (open rectangles) in addition to continuous EEG recordings. A pupil dilator was administered 15 min prior to experimental light exposure. Subjects exposed to 460 nm (blue) light reported significantly lower sleepiness (a), exhibited a shorter auditory reaction time (b), and had fewer lapses (responses >500 ms) (c) compared to subjects exposed to an equal photon density of 555 nm (green) light. Note the rapid deterioration of alertness and performance after cessation of light exposure. The 460 nm light also caused a preferential elevation of high-alpha activity (9.5–10.5 Hz) in the EEG compared to 555 nm light (data not shown), which has been shown previously to correlate highly with subjective sleepiness ratings. Reproduced from Lockley SW, Evans EE, Scheer FAJL, et al. (2006) Short-wavelength sensitivity for the direct effects of light on alertness, vigilance, and the waking electroencephalogram in humans. *Sleep* 29(2): 161–168.

alertness is reduced, performance is impaired, and the risk of on-the-job accidents and injuries increases. Meals are also taken at inappropriate circadian phases, causing postprandial levels of insulin, glucose, and fats to rise, potentially increasing the risk of heart disease and diabetes.

The problems associated with circadian desynchronization due to shift work can be alleviated once the circadian system has fully adapted to the new schedule. A general 'rule of thumb' is that the circadian system takes 1 day to shift by approximately 1 h under uncontrolled conditions; thus, adapting to a 12 h shift from day shift to night shift will require approximately 12 days. This is possible in fixed night or day shifts that persist for several weeks at a time. Unfortunately, if the shift duration lasts only 2 weeks, the shift is changed again only 1 or 2 days after adaptation has been achieved, and desychronization is reestablished. Most shift systems change every few days or are interrupted by days off (when workers tend not to maintain the same schedule as during work days), making it virtually impossible for the circadian system to adapt. A different approach is to have a rotating shift system that is so rapid (e.g., only 1 day on each shift) that it does not induce major shifts in circadian phase. This system, however, requires workers to be on shift at night in a fully unadapted state and therefore on duty during the biological night when the risk of accidents is highest. More detailed information on shift work disorder in humans is provided elsewhere in this encyclopedia.

Jet lag Another common circadian rhythm disorder is jet lag, which is essentially the same problem as experienced by shift workers except that the desynchronization between the circadian system and the environment is caused by the rapid change in light–dark cycle following transmeridian travel. As with shift work, the circadian system cannot adapt to the immediate change in light–dark schedule and the symptoms (insomnia, fatigue, impaired cognition, and gastrointestinal problems) persist until the circadian system has adapted to the new time zone, which will take up to 12 days, depending on the number of time zones crossed. Unlike shift work, however, most episodes of jet lag are isolated, and the magnitude and direction of the phase shift required to adapt are generally predictable. It is possible, therefore, to design light–dark exposure schedules to facilitate circadian adaptation and reduce the number of days required to reentrain to the new time zone. Such schedules require consideration of the PRC for light in order to time light and dark exposure appropriately. Often, travelers will be told to 'get on the new time zone as soon as possible' in order to adapt more quickly and reduce their jet lag symptoms. Although in principle this advice is valid, working through several example itineraries with respect to the PRC illustrates that this approach is oversimplistic and requires a more sophisticated consideration of the timing of light. The following example illustrates how such advice could be counterproductive and demonstrates the general principles in designing jet lag adaptation schedules.

Consider a flight from New York to London leaving at 07.00 h. The flight lasts 7 h and arrives in London at 19.00 h local time, given the 5 h difference in time zones. In order to adapt to UK time, travelers from the United States need to advance their circadian system; eastward travel always requires a phase advance, whereas westward adaptation requires a phase delay. According to the PRC, light exposure at 19.00 h will cause a phase delay, opposite to that required. When the traveler arrives in London, however, minimal circadian adaptation has yet taken place and therefore he or she remains entrained to US time (i.e., 14.00 h). Consultation of the PRC for 14.00 h shows that light at this time and for the next 4 h will cause a phase advance. In fact, light exposure during the entire duration of the flight is also at the correct time to cause a phase advance. The advice to the traveler is therefore to expose him- or herself to as much light as possible for the entire flight and for the first 4 h in London, retiring to bed at 23.00 h and thereby avoiding the phase delaying effects of light that would begin at this phase (**Figure 11**).

Now consider the same flight but this time leaving New York at 19.00 h and arriving in London at 07.00 h. Again, a 5 h phase advance is required to adapt to the new time. Most people would follow the same plan as the daytime flight and expose themselves to light upon landing in London. Closer inspection of the PRC, however, reveals that this plan will in fact prevent adaptation to London time and likely shift their circadian system in the opposite direction than that required, sending their circadian systems toward Hawaii. When landing in London at 07.00 h, the circadian system is still synchronized to US time (i.e., 02.00 h). Light exposure at this time causes a particularly robust phase delay, the opposite direction to that required. It is therefore necessary to avoid light at this time and for the next 4 h until the PRC predicts that light will cause a phase advance (06.00 h) (**Figure 11**). The advice to the traveler in this case is to avoid light during the entire flight and for the first 4 h in London (by sleeping, using an eye mask, or wearing dark sunglasses) and then expose him- or herself to as much light as possible after this time (**Figure 11**). Any schedule can be assessed in this

Figure 11 Application of circadian principles in reducing the symptoms of jet lag. Two example flights from New York to London are shown relative to the phase response curve (PRC) for light. Times are shown for both New York and London time zones (5 h apart). The point on the PRC when the change from phase delay to phase advance shifts occurs is shown by a dashed line (06.00 h, New York time). (a) A 7 h flight leaving New York at 07.00 h and arriving in London at 19.00 h local time. Light exposure during the flight and for the first 4 h in London (yellow rectangle) will cause a phase advance shift required for adaptation following an eastward flight. Light exposure after that time should be kept minimal in order to prevent the delay shift which would coincide with 23.00 h London time (18.00 h New York time). (b) Now consider the same flight but leaving New York at 19.00 h and arriving in London at 07.00 h local time. Light exposure during the flight and for the first 4 h in London would cause a phase delay shift, the opposite to that required, and therefore light exposure should be minimal at these times (gray rectangle). After 11.00 h London time, light exposure will cause a phase advance and therefore should be maximized. Adapted from Rajaratnam SMW and Arendt J (2001) Health in a 24 h society. *Lancet* 358: 999–1005.

way, and by judicious use of light exposure (natural light, even on a cloudy day, is very effective and indoor room light is also sufficient if natural light is not accessible) and light avoidance (dark sunglasses will suffice if the eyes cannot be closed), adaptation to the new time zone can be significantly enhanced.

Advanced and delayed sleep phase syndrome Advanced sleep phase syndrome (ASPS) and delayed sleep phase syndrome (DSPS) are circadian rhythm disorders which cause sleep to occur routinely at a particularly early or particularly late time, respectively, relative to normal sleep. These disorders are described in detail elsewhere in this encyclopedia. Treatment of these syndromes requires that the sleep–wake cycle be phase shifted in the appropriate direction. Again, the PRC for light provides the guide to timing; evening light therapy would cause the required phase delay to correct ASPS and morning light therapy would phase advance the circadian system in DSPS. Without knowledge of the PRC, however, light therapy could be timed at the wrong circadian phase, exacerbating the disorder. The exact timing of the light can be determined from a reliable marker of circadian phase which, in an outpatient setting, can be derived simply from salivary or urinary rhythms of cortisol or melatonin and its major metabolite (6-sulfatoxymelatonin).

Unusual environmental photoperiods Some specialized environments present unusual challenges to the circadian system. As outlined previously, submariners scheduled to work an 18 h 'day' in relatively dim light conditions are unable to maintain circadian entrainment to their light–dark cycle and revert to their endogenous circadian period. Similar observations have been made during the Antarctic winter, when only artificial light is available. Interestingly, circadian rhythms can remain entrained at bases where strict schedules are maintained, whereas at bases where researchers are free to keep their own schedules, their circadian rhythms 'free run' on a non-24 h day, highlighting the importance of nonphotic time cues when living under conditions of low light.

Space travel exposes astronauts to challenging light–dark schedules that are the result of both natural and man-made conditions. In the space shuttle, a very high-amplitude, 90 min light–dark cycle is observed as the shuttle orbits the earth. General light levels, however, are remarkably low, averaging

Figure 12 Light exposure and sleep–wake schedules experienced by space shuttle crew. Light levels were measured during the STS-90 shuttle mission using a portable light meter stationed in the habitable quarters of the space shuttle – that is, the flight deck, windowless mid-deck, and the space lab. The time course of illuminance over a representative 48-h episode (a, left) and the corresponding relative frequency distribution of illuminances during wakefulness (thick solid line) and sleep (thin solid line) (a, right) are shown for all three areas. The mid-deck and space lab, where crew members spend most of their time, have stable light–dark patterns with a period of ~23.67 h, although the absolute intensity of light is relatively dim (maximum of 93 and 171 lux, respectively). The flight deck, however, has a much different light–dark pattern. Although the ~23.67-h pattern is apparent, superimposed is an extremely high-intensity light pulse, reaching a maximum of 80 000 lux, caused by the orbital dawn that occurs approximately every 90 min as the shuttle orbits the Earth. This pulse is even observed when the shades are drawn during scheduled sleep. (b) An activity–rest pattern measured using wrist actigraphy from one shuttle crew member before, during, and after the STS-90 mission. Activity levels are shown per minute, with low activity indicating sleep times (except during launch and landing, when monitors were not worn). The 23.67-h schedule imposed on the crew members in order for the shuttle to take off and land on schedule is clearly seen, with sleep start and end times getting progressively earlier day to day. Sleep start time, however, is clearly more variable than wake time, and the duration of sleep obtained varies from night to night. Upon landing, an abrupt 4-h phase delay shift in sleep times is also observed. The low-amplitude light–dark cycles in the mid-deck and space lab and the variable exposures in the flight deck (a), coupled with the requirement to remain on a non-24 h schedule (b), are likely to induce desynchrony between the sleep–wake cycle and the circadian system and expose crew members to the inherent risks caused by the sleeping and waking at an inappropriate circadian phase. Reproduced from Dijk D-J, Neri DF, Wyatt JK, et al. (2001) Sleep, performance, circadian rhythms, and light–dark cycles during two space shuttle flights. *American Journal of Physiology Regulatory, Integrative and Comparative Physiology* 281: R1647–R1664.

10–100 lux in the mid-deck and space lab, respectively, where astronauts spend most of the time (Figure 12(a)). Superimposed on these ambient light levels is a <24 h schedule that is required in order to ensure that the shuttle takes off and lands at the correct times (Figure 12(b)). Although precise measures of circadian phase have not been conducted in space, it is likely that these unusual light–dark cycles cause desynchronization of the circadian system from the astronauts' sleep–wake cycle, impairing sleep and causing fatigue in an extremely dangerous environment. In fact, sleep disorders are highly prevalent in astronauts and hypnotics are the most often used medications in space, suggesting that circadian desynchrony may indeed have a significant negative impact on sleep and alertness. Other space missions are also likely to introduce problems related to circadian entrainment; for example, manned missions to Mars will require both astronauts and Earth-based ground crew to be entrained to a day length of 24.65 h to match that on Mars in order to maintain optimal performance. The proposed missions to set up a lunar base camp also present significant problems because artificially generated light and darkness will be required to allow those living on a lunar base to remain entrained to a 24 h day.

Aging Most adults notice a change in their circadian rhythms as they age such that they choose to sleep and wake at both an earlier time and an earlier circadian time than they did when they were younger. Adolescents tend to sleep and wake at a later circadian phase than younger children and adults. These changes are due in large part to age-related changes in how the circadian system controls sleep–wake timing and are detailed elsewhere in this encyclopedia.

Aging is also associated with a change in light–dark input to the circadian pacemaker which may contribute to the phase advance of sleep experienced by older adults. As the lens in the eye ages, its pigmentation yellows due to a change in the composition of lens proteins resulting in a reduction in the transmission of short-wavelength light that is most effective at resetting the circadian pacemaker (Figure 13).

Figure 13 Ocular lens transmission as a function of age. The transmission spectra for postmortem lenses to visible and UV light show a clear age-dependent change. Lenses of older subjects (60–69 years old, $n = 40$) fail to transmit a high proportion of the short-wavelength visible light (400–550 nm) that maximally stimulates the circadian photoreception system compared to the lenses of young adults (20–29 years old, $n = 36$). Newborn lenses ($n = 5$) transmit a higher proportion of all visible and some UV wavelengths. Reproduced from Brainard GC, Rollag MD, and Hanifin JP (1997) Photic regulation of melatonin in humans: Ocular and neural signal transduction. *Journal of Biological Rhythms* 12(6): 537–546.

Psychiatric disorders Circadian rhythm and sleep–wake problems are associated with a range of psychiatric disorders, some of which are related to alterations in light–dark exposure. The most well-characterized light-related disorder is seasonal affective disorder (SAD) or 'winter depression.' This syndrome is characterized by the onset of a depressive episode coincident with the onset of fall/winter and specifically the change in night length during this season. An effective treatment for SAD is ocular light therapy, which aims to ameliorate the lack of light that is thought to initiate the depressive episode. The exact mechanism underlying light therapy is unknown, although light exposure in the morning may be more effective than at other times of day, suggesting that a phase delay of the circadian system may contribute to its onset in some cases. Although clinicians generally prescribe daily bright white light therapy (2500–10 000 lux) for 30–60 min, few systematic studies have been conducted to examine the effect of light intensity, duration, and pattern on clinical outcomes. Given the nonlinear relationship between these properties and the circadian phase resetting effects of light, it may be possible to induce similar therapeutic benefits using dimmer and/or intermittent light exposure, which may improve patient compliance. Similarly, selecting the most potent wavelengths of light may also reduce the intensity or duration of therapy required. Studies have shown that short-wavelength (blue) light exposure for 45 min per day can be an effective therapy for SAD, and further investigations are ongoing.

Another sleep–wake rhythm disorder related to light exposure is observed in patients with Alzheimer's disease (AD). These patients have a highly disturbed rest–activity cycle, with greater activity at night and reduced activity in the day compared to similar-aged patients without AD. These symptoms are most often the ones that prompt institutionalization of AD patients, although this may lead to further exacerbation of rest–activity disorders because robust light–dark

Figure 14 Effect of changes in ambient light exposure on rest–activity patterns in Alzheimer's disease. Patients with Alzheimer's disease ($n = 16$), multi-infarct dementia ($n = 3$), dementia associated with alcoholism ($n = 2$), and normal pressure hydrocephalus ($n = 1$) were studied in a nursing home environment for ~10 weeks each. After a 2-week baseline, bright lights were installed in the ceiling (during the night so that patients would not see the fitting) and remained for 4 weeks, when they were removed again for 4 weeks (baseline 2). Patients' rest–activity and light–dark exposure was assessed using wrist actigraphy during the baseline, during the last 2 weeks of light therapy, and during the last 2 weeks of normal light (baseline 2). During baseline 1, average light levels (± SEM) in the living rooms were 436 ± 90 lux (range, 93–1417). Under the brighter light conditions, light levels increased to 1136 ± 89 lux (range, 790–2190) and returned to 372 ± 65 lux (range, 110–1106). Raw activity data of a patient with Alzheimer's disease are shown on the left for 5 days before (top), during (middle), and after (bottom) light treatment. The right panels show double plots of the average 24 h activity level (solid line) +1 SD (dashed line). On average, the variability of the rest–activity rhythm was reduced and its stability improved during the light exposure compared to the pooled pre- and postbaseline levels. These effects were not observed in patients with severe visual impairment. Reproduced from Van Someren EJW, Kessler A, Mirmiran M, and Swaab DF (1997) Indirect bright light improves circadian rest–activity rhythm disturbances in demented patients. *Biological Psychiatry* 41: 955–963.

cycles are not generally available to those living in nursing homes. Examination of the circadian rhythms of cortisol and melatonin in these patients does not reveal gross abnormalities in phase or arrhythmic patterns that might be expected to be associated with such disturbed rest–activity cycles, suggesting that the rest–activity disorders may be caused by an attenuation of the output of the circadian pacemaker to other efferent targets. Restoration of robust light–dark cycles, however, has a dramatic effect on rest–activity patterns and results in more consolidated bouts of both sleep and wake in institutionalized patients (Figure 14), although the mechanism is unknown. Ongoing research suggests that such light therapy may even improve mortality and morbidity in patients with AD. Investigations of the mechanism underlying the therapeutic benefits and optimization of light therapy (intensity, duration, wavelength, and pattern) are ongoing.

Other psychiatric disorders may also be related to changes in light exposure or sensitivity to light or may respond to light therapy (e.g., unipolar and bipolar depression, schizophrenia, and Parkinson's disease), but further work is required to substantiate these relationships. The association between circadian rhythms and psychiatric disorders is outlined in further detail elsewhere in this encyclopedia.

Circadian Systems: Evolution

T L Page, Vanderbilt University, Nashville, TN, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Circadian rhythms are daily oscillations in physiology, metabolism, or behavior that persist in organisms that have been isolated from periodic fluctuations in the environment. The rhythms are thought to have arisen from selection pressure for organisms to organize activities in time as well as in space, and thus to reflect the evolution of an internal timekeeping system – the circadian clock. The fact that circadian rhythms have been described in every major group of eukaryotic organisms, coupled with their discovery in the prokaryotic cyanobacteria, suggests that the origin of circadian clocks occurred very early in evolutionary history, and the molecular data indicate that circadian clocks may have arisen multiple times. While a discussion of the evolution of circadian clocks can be approached from a variety of perspectives, the focus here is on the circadian systems of the metazoa and how the components of the system above the cellular level have been organized through evolutionary history to provide for the temporal organization of the individual.

Fundamental Properties

There are three universal features ('clock-like' properties) of circadian rhythms that provide clues to their adaptive significance and thus to selective pressures that have shaped the evolution of the circadian systems that drive them. First, these rhythms are under the control of regulatory systems that are based on endogenous, self-sustaining oscillators (or pacemakers) whose periods approximate those of the naturally occurring 24-h environmental cycles. The self-sustaining property of the oscillator gives the organism a means to anticipate, rather than simply react to, periodic environmental change. Second, a universal feature of circadian rhythms is that the period of the oscillation is at most only slightly affected by changes in the constant level of ambient temperature. The 'temperature compensation' of period is a functional prerequisite for the underlying oscillator's function in time measurement, since a clock whose motion is temperature sensitive is not particularly useful. Finally, the phase and period of the rhythms are subject to entrainment by a limited number of environmental cycles that are referred to as 'zeitgebers' (literally, time-givers). Zeitgebers are what 'set the clocks to local time' and thus maintain an appropriate phase relationship of the circadian system with the external world. Environmental light cycles are universally effective in the entrainment of circadian rhythms, and while other stimuli such as temperature, sound, or food availability may be effective in some species, it is clear that light intensity, as the most reliable and 'noise-free' environmental cycle, is the dominant zeitgeber. A final generalization can be proposed that is pertinent to the current discussion. Circadian oscillations are generated within individual cells and while intercellular interactions may influence the phase and period of the oscillation, they are not necessary for its generation. This conclusion is based not only on the fact that single-celled organisms exhibit circadian rhythms that possess all of the general properties just described, but also on recent demonstrations that individual cells isolated from multicellular organisms can express circadian rhythms in cell culture.

Function

Circadian systems have two conceptually different functional roles in the temporal organization of the individual. The first is to restrict to a particular time of day aspects of physiology, behavior, and metabolism that are best undertaken at a specific phase of the environmental cycle. A second major function of circadian oscillations is to provide a temporal framework for timing various activities relative to each other. Thus the system provides for an internal 'temporal program' that is an important adjunct to temporal order with respect to the external environment. In both cases, a key factor is the control of phase relationships – both among various rhythms and with respect to the cycles of the immediate external environment.

For this reason, one emerging view is that an important element of selection in the evolution of circadian systems has been the development of entrainment mechanisms that are appropriate to the environmental niche occupied by the individual. Similarly, because multicellular organisms are composed of multiple circadian oscillators (see later), it is plausible to suggest there is strong selection for mechanisms to ensure coordination of phase relationships among oscillators – that is, all oscillators within the individual ultimately must have access to a common phase (time) reference. Conceptually, this could occur either by providing all oscillators with direct access to environmental cycles or by developing coupling mechanisms to allow internal communication between oscillating elements. The discussion that follows is largely based on the proposition that the requirement of mechanisms

to ensure proper phase control (development of a reliable time reference) is a major selective force that provides a framework for interpretation of phylogenetic differences in the circadian organization of major groups of animals.

Physiological Organization and Evolution

Figure 1 illustrates the basic components of a circadian system. The model consists of four essential elements – a pacemaker or oscillator that generates the primary timing signal, photoreceptors for entrainment, and two coupling pathways, one that mediates the flow of entrainment information from the photoreceptor to the pacemaker and another that couples the pacemaker to the effector mechanisms that it controls. A first step in the effort to understand the evolutionary history of the organization of circadian systems in animals is to define the physiological and anatomical organization through the identification of cells or tissues that generate the circadian oscillations, elucidation of the signals by which the oscillations control relevant rhythms, and delineation of the pathways by which the oscillators receive environmental information for entrainment. One can then exploit these data to discuss the evolution of the circadian system in the context of a comparative phylogenetic approach. Here the focal questions are: (1) What do circadian systems of various groups have in common and how are they substantively different? (2) Based on similarities and differences, combined with the natural history and evolutionary relationships among the groups, can one devise a plausible hypothesis about the relevant selective pressures, evolutionary history, and adaptive significance of central features of circadian organization? Addressing the first question would appear to be relatively straightforward, since the answer can be based on hard data derived from physiological and anatomical study of extant organisms. The immediate difficulty here, though, is that our knowledge of the physiological and anatomical organization of circadian systems is both incomplete and rapidly changing – as a result, much of the discussion that follows is as much about the recent evolution of our understanding of how circadian systems are organized as it is about the evolution of circadian organization in natural populations. Attempts to answer the second question are even more difficult and involve much in the way of conjecture, supposition, and frank speculation. This is because much of the relevant information (such as the specifics of the photic environments of ecological niches inhabited by extinct organisms) is lost to history and thus involves a substantial amount of guesswork (hopefully informed).

Figure 1 Functionally defined model showing the four major components of the circadian system that drive the circadian rhythm. Environmental light is detected by an entrainment pathway that consists of a photoreceptor and a coupling mechanism. The cycle of light and dark synchronizes a self-sustaining oscillator (pacemaker). The output of the pacemaker regulates the timing of various processes (e.g., locomotor activity) via a second coupling pathway.

Photoreceptors for Entrainment

One especially striking feature of circadian organization is that animals almost never rely exclusively on photoreceptors in the retina for entrainment. With a few notable exceptions (discussed later), removal of the eyes of mollusks, crustaceans, insects, fish, amphibians, reptiles, and birds typically has little effect on the ability of the circadian system to be entrained by light. The results indicate that extraretinal receptors are dominant in detecting light for entrainment in all major groups that have been studied, with the exception of mammals. In mammals, there are no known exceptions to the generalization that they rely exclusively on retinal photoreceptors for entrainment, and this raises the interesting evolutionary question of why mammals have lost all photoreception outside of the retina, or, alternatively, why extraretinal photoreceptors have been retained in all other groups.

Extraretinal photoreceptors that function in entrainment in nonmammalian vertebrates may be widely distributed in the individual. The pineal complex (pineal gland and parietal eye), which is photoreceptive in all vertebrates except mammals, is known to contribute to entrainment. In addition, evidence shows that 'deep brain photoreceptors' (which have been localized to several brain regions) are also involved. Further, as discussed later, recent evidence from zebra fish indicates that photoreceptors for entrainment may be very widespread and reside in several, perhaps even most, tissues.

Interestingly, even when the photoreceptors mediating entrainment are located in the retina, results suggest at least a subset of them represent a subpopulation of cells that are not involved in forming vision. For example, studies in mammals suggest that entrainment is mediated by a unique population of retinal ganglion cells. These cells contain a novel photopigment (melanopsin), are photosensitive, and project directly to a circadian clock in the suprachiasmatic nucleus (SCN) of the hypothalamus. The separation of photoreceptors for image formation (vision)

and for entrainment may be explained by the fact that the two functions have rather different requirements, a suggestion supported by observation that the photoreceptors for entrainment and those for vision have distinctly different physiological properties. For example, photoreceptive retinal ganglion cells involved in entrainment in mammals integrate light information over relatively long timescales, respond only weakly, if at all, to brief stimuli, and show little adaptation.

Localization of Circadian Oscillators

The notion of localization of circadian pacemakers encompasses two separate questions. The first is what cells or tissues are able to generate circadian oscillations, and the second is what roles do those tissues play in driving overt rhythms in physiology, metabolism, and behavior. While it has been known for many decades from studies on protists and fungi that single eukaryotic cells had the capacity to generate circadian oscillations, until recently it had generally been argued that the number of cells or tissues that could function as circadian oscillators in multicellular organisms was limited. The arguments were generally supported by two kinds of observations.

First, in a variety of organisms, vertebrate and invertebrate, lesion and transplantation studies indicated that identifiable neural or endocrine structures (such as the optic lobes of cockroaches, the pineal gland of sparrows, and the SCN of mammals) were responsible for the control of multiple rhythms, suggesting that they were 'master oscillators' whose distributed output determined the temporal organization of the individual. Second, efforts to demonstrate that cells from a wide variety of tissues could generate circadian oscillations *in vitro* met with only limited success, and those successes most frequently involved tissues that were thought to function as 'the clock' in one organism or another. For example, in vertebrates, early studies on pacemaker localization generally proceeded on the assumption that since entrainment by light was a universal feature of circadian clocks, pacemakers would likely be found in close association with known photoreceptive structures. This assumption led to the discovery that three structures that are found in all vertebrate groups, from cyclostomes to mammals – the retina, the pineal gland (which is photoreceptive in all nonmammalian vertebrates), and the suprachiasmatic nuclei of the hypothalamus (which receive direct input from the retina via the retino-hypothalamic tract or from 'deep brain photoreceptors') – played significant roles in vertebrate circadian organization. Precisely what role these structures played varied significantly among species and the variation, at best, only roughly followed phylogenetic lines. However, in one species or another, each of these structures appeared to be essential for expression of overt circadian rhythms, and these structures were also the ones widely shown to generate circadian oscillations *in vitro*.

The notion of a centralized, master oscillator seemed to be particularly true of the most studied group, the mammals. It was known from very early studies that hypothalamic lesions could abolish circadian rhythms in behavior in mammals. This fact, combined with the discovery of a direct connection between the retinas of the eyes and the SCN of the hypothalamus, led to a cottage industry of examining the effects of SCN lesions on various overt rhythms. It was rather quickly shown that lesions to the SCN abolished rhythms in wheel running activity, drinking, plasma corticosterone levels, pineal *N*-acetyltransferase, pineal melatonin, growth hormone secretion, luteinizing hormone secretion, body temperature, and sleep/wake cycles. With one exception (the 'food anticipatory activity' rhythm), there were no convincing reports of rhythms that persisted after complete destruction of the SCN and retained properties that compelled acceptance of the notion that a functionally relevant circadian clock resided outside the SCN. In addition, the disruption of circadian rhythmicity following SCN lesions seemed universal within the mammalian species studied, which ranged from rats to primates, and transplantation and tissue culture studies showed unequivocally that the SCN could generate circadian oscillations that controlled locomotor activity rhythms. These results suggested that mammals were endowed with a restricted and well-defined, centralized locus for the circadian pacemaker. That view was first challenged with the successful demonstration of rhythms in melatonin release from the hamster retina *in vitro*, which showed quite definitively that the retina, in addition to the SCN, contained a perfectly respectable circadian pacemaker.

A more revolutionary change in the landscape came in the past decade, following on the heels of the discovery and characterization of several 'clock genes.' Clock genes are genes that appear to be essential for the generation of circadian oscillations within cells and whose transcription is, in most cases, rhythmic. Interestingly, clock genes appear to be well conserved across phylogenies that range from fruit flies to mammals, indicating strong evolutionary conservation in the molecular mechanism of the clock. By coupling the coding sequences of reporter genes to promoters of clock genes, it was possible to examine tissues in culture rapidly and reliably for the presence of circadian oscillations in transcription in fruit flies, rats, and mice. The results were quite remarkable. Molecular oscillations were found to be pervasive

and widespread in these multicellular organisms, and to exist in peripheral cells and tissues where there had never been a hint of endogenous rhythmicity. In flies, it was shown that isolated wings, antennae, proboscis, and legs were capable of circadian oscillation in culture. In rats and mice, the tissues included (in addition to the SCN) skeletal muscle, liver, lung, fibroblasts, and pineal. Multiple, widely distributed oscillators were also demonstrated in zebra fish, where rhythmic activity in gene transcription has been observed in a variety of isolated tissues. This included not only the 'classical' vertebrate circadian pacemakers – the brain, pineal, and retina – but also the heart, spleen, and kidney. In insects, the generality of the results from fruit flies is buttressed by studies in other insect species that have shown persistent, circadian oscillations in physiology or metabolism *in vitro* in tissues that include endocrine tissue (prothoracic glands), testis, and cuticle. These results, spanning a phylogenetically broad spectrum, lead directly to the conclusion that many, perhaps most, cells in organisms have retained the ability to generate circadian oscillations throughout the evolutionary history of circadian systems.

The data are clear in establishing the fact that animal circadian systems are composed of many cellular oscillators; we presume (with, as yet, little substantiating data) that these oscillators control physiologically relevant rhythms in the cells or tissues in which they reside. This raises the question of what mechanisms have arisen with the evolution of multicellular organization to ensure that correct phase relationships are maintained among the various oscillators and the rhythms they control. One potential mechanism to ensure appropriate phasing is to have the oscillators directly communicate with one another via internal 'coupling pathways' that allow for hierarchical or mutual entrainment. A second strategy is to give all oscillators access to environmental signals that could directly entrain the individual pacemakers. The available evidence suggests that natural selection has capitalized on both options with the dominant strategy in any particular species being correlated with the behavioral ecology of the individual.

Phase Control and the Evolution of Circadian Systems

A perhaps even more surprising discovery in the studies on *in vitro* molecular rhythms in fruit flies and zebra fish was that the circadian oscillations in gene expression in the various tissues could be entrained by light in culture. Thus it appeared that all peripheral oscillators in these two phylogenetically distant organisms also had dedicated photoreceptors. Available data, though limited, suggest that the ability of pacemaker tissues to directly detect light for entrainment extends to all other major groups with the exception of mammals. With one exception (returned to later), in every case in which a tissue has been shown to oscillate *in vitro*, the rhythms were also entrainable by light *in vitro*. In contrast, the ability to detect light for entrainment appeared to be completely absent in any mammalian tissue except the retina. In mammals, the results suggested that coordination of the newly discovered peripheral molecular oscillators with the environment relied on signals distributed from the circadian clock in the SCN, which was, in turn, entrained by photoreceptors in the retina. The data lead to the suggestion that a presumed ancient tie between photoreception and the molecular oscillator was conserved in the evolution of organization of the circadian systems in all major groups of organisms except mammals.

These results suggest that the answer to the question of how temporal organization is maintained is different between the mammals and other major groups. In the invertebrates and nonmammalian vertebrates, the direct coupling to the photic environment could ensure that all of the clocks are appropriately phased, and, therefore (at least initially), there is no reason to presume that internal coupling is critical to the temporal order of the system. In contrast, in mammals, the results indicate that photoreception for entrainment is restricted to the retinas of the eyes and that (with the exception of retinal rhythms) it is necessary for the phase information to be passed from the retina through the SCN. The entrained oscillation in the SCN then distributes timing information directly to effectors or to peripheral oscillators, and internal entrainment pathways assume a newly prominent role in temporal organization. As a specific example of the shift to SCN dominance, one can point to the observation that regulation of the circadian rhythm in pineal melatonin, an important rhythmic signal molecule in the integration and coupling of circadian oscillators in vertebrates, has shifted in mammals from a photosensitive oscillator in the pineal, common to all nonmammalian vertebrates, to regulation in mammals by the SCN (via the sympathetic innervation of the pineal) with the complete loss of pineal photoreception.

This hypothesis results in the two distinct models illustrated in Figure 2. In one case, the common time reference for all rhythms is the external light cycle, while in the other, phase coordination is directly under the control of an internal master clock, and internal coupling pathways for entrainment between oscillators are the critical factor in maintaining internal phase relationships.

Figure 2 Two models of circadian organization. In the upper model, pacemaking activity arises from a population of distributed oscillators, each with direct access to environmental light information for entrainment, that serve as pacemakers for various rhythms. In the lower model, a centralized pacemaker that is entrained by light either directly drives rhythms in the periphery or regulates the phases of peripheral oscillators that in turn control overt rhythm expression. In this model, the central pacemaker functions as a 'master clock' and serves as the primary source of phase information for maintaining internal temporal organization, while in the upper model, internal temporal organization is dependent on entrainment to the environmental light cycle.

The complete loss of extraretinal photoreception, perhaps driven by the centralization of phase control, appears to be a major step in the evolution of circadian organization and raises the question of why this transition specifically occurred with the mammals. One plausible scenario that has been forwarded derives from the argument that one of the central reasons for the great success of mammals when they initially diverged from their reptilian ancestors approximately 200 Ma was their invasion of the virtually unoccupied nocturnal temporal niche – a time of day when mammals could be active and avoid the dominant, day-active reptilian predators. A switch from a diurnal to nocturnal life style that included hiding in dark burrows during the day would significantly alter the photic environment for entrainment. The nocturnal mammals might only be exposed to the dim light available at transitions in early morning or late evening, or on some days might miss the light signal entirely. For example, laboratory results on flying squirrels given access to a completely dark nest box suggest that these strongly nocturnal animals may only emerge in the light once every several days, and even then only at times near twilight.

Two features of mammalian circadian organization may have arisen as a consequence of the selective pressure of this altered photic environment. First, a strictly nocturnal existence could provide the selective pressures necessary to shift to a more centralized pacemaking system. An internal 'master oscillator' would provide the common phasing signal for maintenance of temporal order among the various peripheral oscillations, shifting the primary source of time information for maintaining internal phase relationships from the now less reliable perception of the daily light cycle to an endogenous clock. Thus even in the absence of a regular exposure to a stable environmental entraining signal, the continued maintenance of appropriate internal phase relationships would be ensured. Second, this shift to a centralized pacemaking system could have led to the centralization of photoreceptor function for entrainment. The restriction of the photoreception to the retina would be advantageous since the photoreceptors are more

directly exposed to light relative to extraretinal photoreceptors buried in tissues of the body. The loss of the extraretinal receptors would obviate any possibility of distributed photoreceptors sending to elements of the circadian system conflicting signals that might result from differential exposure in dim light.

If the arguments presented here are correct, one might look to other organisms with a nocturnal heritage for a similar reorganization of their circadian systems. One group of insects for which we have extensive behavioral, physiological, and anatomical data and that appear both to be strictly nocturnal and to spend daytime in dark hideouts – buried in leaf litter, inside or under decaying logs, or nestled under the bark of trees and thus isolated from the view of light – are the cockroaches (Dictyoptera). Interestingly, cockroaches share several key features of circadian organization with mammals. One remarkable similarity is that all available evidence indicates that photoreception for entrainment in cockroaches, like in mammals, is strictly limited to the retina and there is no evidence for the involvement of extraretinal photoreceptors in entrainment. The retinal photoreceptors entrain a pacemaker that is located in the optic lobes of the brain (adjacent to the eyes). Further, like the mammalian SCN pacemaker, lesions of the optic lobe pacemaker in cockroaches cause rapid loss of most rhythms, including the rhythms in locomotor activity, sensitivity in the photoreceptors of the compound eye, electrical activity in the cervical connectives, and sensitivity of olfactory receptors in the antennae to odor. These results lead to the suggestion that the central pacemakers of both mammals and cockroaches are critical to sustained rhythmicity in nearly all overtly expressed rhythms.

In contrast, in other (day-active) insect models, such as *Drosophila melanogaster*, the available data are more consistent with the view that peripheral oscillations can independently drive sustained, directly entrainable rhythms. For example, in the fruit fly, the data indicate that the central brain pacemaker that regulates circadian rhythms in locomotor activity is neither sufficient nor necessary for the peripheral rhythm in olfactory sensitivity in the antennae. This rhythm is driven by oscillations that are generated and entrained in the antennae. In addition, like mammals, the entrainment information received by the retinal photoreceptors in cockroaches appears to be funneled through the central pacemaker for distribution. In this context, it is notable that a peripheral oscillation in cuticle deposition in cockroach, like the peripheral molecular oscillations in mammals, cannot be entrained by light *in vitro*. The emerging picture is that the two fundamental properties of circadian organization – generation of pacemaking signals for rhythm phase setting and photoreception for entrainment by environmental light cycles – are more centralized in mammals and cockroaches, and the hypothesis posed here is that this centralization traces to the selective pressure of a nocturnal existence.

If a nocturnal existence provides a strong selection pressure for centralization of pacemaker and photoreceptor function, one might also look to moths, another insect group for which we have substantial information on the physiology of the circadian system and which are largely nocturnally active. Based on the physiology, moths appear to have a distributed circadian system with distributed extraretinal photoreceptors much like that of day-active fruit flies, rather than the centralized pacemaker/photoreceptor system of night-active cockroaches. However, rather than escaping light by spending the day in dark burrows, moths often rest in the open during the day, relying on cryptic coloration to protect them from predation. Thus, one could plausibly assume that the peripheral oscillators and their dedicated extraretinal receptors are exposed to, and are readily entrained by, the solar cycle.

There are two other interesting examples where differences in circadian organization between closely related organisms may be traced to differences in temporal behavioral niche. One comes from the nocturnally active, primitive vertebrates, the cyclostomes. In one group of cyclostomes, the lampreys, extraretinal photoreceptors are adequate for entrainment of the activity rhythm. In contrast, in the other group, the hagfish, retinal photoreceptors are required, and the photoreceptive pineal found in other nonmammalian vertebrates is absent. It has been suggested that this difference is related to the fact that lampreys, as parasites on diurnal teleost fish, must be exposed to the light cycle despite a nocturnal activity pattern. In contrast, the hagfish are benthic marine organisms that spend their time feeding inside carcasses of dead fish at depths that are typically over 10 m. Thus it is likely that they are frequently isolated from the daily light cycle.

A second example of a potentially informative dichotomy between closely related species comes from the marine opisthobranch mollusks, *Aplysia californica* and *Bulla gouldiana*. Here the data support the proposition that selection for internal coupling to maintain temporal order between oscillators is related to a nocturnal lifestyle. In both species, circadian oscillators that can be entrained by light *in vitro* reside in cells of the retinas of the two eyes. In *Aplysia*, which are diurnally active and thus can rely on the environmental light cycle as a reliable time reference,

there appear to be no interactions between the ocular pacemakers. When *Aplysia* are placed in constant darkness, isolated from entrainment by the environmental light cycles, the two oscillators rapidly become desynchronized. In contrast, *Bulla* are nocturnally active and bury in mudflats during the day. In *Bulla*, the oscillators of the two eyes are coupled so that even in constant darkness the eyes remain in phase.

Caveats

It is a virtual certainty that the suggestion that evolution has opted for two distinct modes of circadian organization (Figure 2) is an oversimplification and there is good reason to be skeptical that the story is complete. The central arguments are only strongly buttressed by the dichotomies in physiology and behavior represented in the vertebrates by zebra fish and rodents and in the invertebrates by fruit flies and cockroaches and are supported by incomplete data on the physiological organization of the circadian system in other groups. One major omission here is any discussion of the role of internal coupling between oscillators in organisms with distributed circadian systems. A second is the narrow focus on the role of the light cycle in entrainment without recognition of the potential of other environmental factors to drive evolutionary processes in circadian organization. Finally, the hypothesis relies heavily on conjecture about the evolutionary history and natural history of the behavior and photic environment of organisms. Nevertheless, the hypothesis provides a conceptual framework that should be heuristically useful in further investigation on the evolution of circadian organization in the metazoa.

Summary

The view forwarded here is that the photic environment of the organism, largely determined by behavioral strategies, provides a strong selective pressure for dictating the evolution of organization of circadian systems. Most organisms do not escape exposure to daily light cycles, and thus the solar cycle can function as a precise and reliable source of phase information for the myriad of circadian oscillators within the individual. Temporal order can be maintained with a distributed system of oscillators, each with its own photoreceptor, through subjection to entrainment by light. However, for those organisms that have adopted a lifestyle that involves both nocturnal activity and escape from daylight exposure, the external light cycle is a less reliable, less precise source of phase information. As a consequence, it is advantageous to rely more heavily on a centralized, internal clock and on internal coupling for dictating temporal order to the periphery and, concomitantly, to restrict the photoreceptive input to the centralized pacemaker.

Introduction

Regulation of body fluid homeostasis is complex and critical for survival. It is essential that the body maintain a stable balance whereby there are no net changes in blood volume and osmolality (concentration of dissolved solute) over time. In order to achieve such a balance, complex integration of multiple physiological systems (including behavioral, physiological, and hormonal responses) must take place in a seamless, continuous manner. Although perhaps intuitive, it is important to state at the outset that in order to control such an integrated system regulating blood volume and osmolality, the first essential step is detection of the changes in the interior milieu such that appropriate types and magnitude of responses can be initiated when necessary. This article outlines the roles of the circumventricular organs within the brain in the maintenance of body fluid and mineral balance, with a specific emphasis on the vital roles played by the sensory circumventricular organs (CVOs) in sensing perturbations in these systems and initiating appropriate physiological responses.

The Blood–Brain Barrier

Although the brain is highly vascularized, the tight junctions between vascular endothelial cells which form the blood–brain barrier (BBB) limit free access (by diffusion) of large and ionized solutes from the blood into the neuronal parenchyma. This situation provides protection for neurons from circulating toxins and large shifts in plasma constituents (e.g., Na^+ and glucose), but the BBB also prevents direct monitoring of these variables. Likewise, molecules such as neuropeptides, neurotransmitters, and peptide hormones are prevented from moving from the brain to the circulation, and thus the homeostatic responses that are dependent on such secretion would be severely compromised in the absence of a physiological bridge through the BBB.

Features of CVOs

In most tissue throughout the body, the microvessels are inherently leaky; that is, the movement of solute from the plasma into the surrounding tissue is fairly unrestricted. This is achieved by numerous fenestrations (pores) within the endothelial cells, a lack of tight junctions between endothelial cells, and numerous plasmalemmal vesicles within endothelial cells. Within the brain, however, the BBB is established in cerebral microvessels by tight junctions between endothelial cells and a lack of fenestrations or vesicles. In addition, astrocytic end feet surround the microvessels, probably providing structural and trophic support. Most solute molecules are unable to cross the BBB, and therefore most areas of the brain are not exposed to changes in the composition of these substances in the plasma. Substances can cross the BBB by one of three mechanisms. Small molecules such as oxygen, and lipophilic molecules such as ethanol and steroids, can diffuse across the BBB. The rate of diffusion is proportional to the size and partition coefficient of the molecules. Alternatively, some molecules such as glucose, and some hormones such as leptin and insulin, may be transported across the BBB by specific saturable transporters, the molecular identity and physiological relevance of which have yet to be completely defined. Lastly, the CVOs are physiological 'windows' that contain fenestrated capillaries, through which molecules may pass freely from the circulation into the central nervous system (CNS) (or vice versa). The CVOs play either sensory (permitting molecules in the circulation access to CNS tissue) or secretory (permitting molecules in the CNS access to the circulation) roles. There are three sensory CVOs – the subfornical organ (SFO), the organum vasculosum of the lamina terminalis (OVLT), and the area postrema (AP) – and five secretory CVOs – the median eminence (ME), the neurohypophysis (NH), the intermediate lobe of the adenohypophysis, the subcommissural organ (SCO), and the pineal gland.

Sensory CVOs

The sensory CVOs are primarily composed of neuronal cell bodies, glia, and epithelial cells. They are highly vascularized compared to other areas of the brain, and they exhibit large spaces surrounding the microvasculature (Virchow–Robin spaces). These specializations allow for increased contact between the cells of the CVO and the blood-borne substances. Importantly, they contain a wide variety of receptors to peripheral signals, including regulatory hormones (angiotensin II (Ang II), vasopressin, atrial natriuretic peptide, amylin, and estradiol) and ions (Ca^{2+} and Na^{2+}). In addition, the sensory CVOs have extensive efferent connections with all of the important autonomic control centers in the medulla and hypothalamus.

Subfornical Organ

The SFO is a protrusion of cells on the midline of the wall of the third ventricle, on the dorsal aspect of the lamina terminalis. The SFO sends monosynaptic and polysynaptic connections to the paraventricular nucleus (PVN) and the supraoptic nucleus (SON) of the hypothalamus. Some of these projections are known to excite vasopressin- and oxytocin-producing magnocellular neurons of the PNV and SON. Other projections connect to parvocellular neurons of the PVN that project to the median eminence, medulla, and spinal cord. Minor efferent targets include zona incerta, raphe nuclei, bed nucleus of the stria terminalis, lateral preoptic area, lateral hypothalamus, and arcuate nucleus of the hypothalamus. Afferent neural connections to the SFO come from many of the same areas that receive efferent connections. However, such neural inputs are not extensive, which implies that the majority of sensory input controlling the excitability of SFO neurons is derived from signaling molecules in the systemic circulation.

Organum Vasculosum of the Lamina Terminalis

The OVLT is a midline structure on the anteroventral aspect of the third cerebral ventricle, ventral to the medial preoptic nucleus and dorsal to the optic chiasm. The densest efferent projections from the OVLT are monosynaptic and polysynaptic connections to the magnocellular neurons of the PVN and SON. Additional minor projections target CRH neurons of the PVN, the stria medullaris, and basal ganglia. The strongest afferent connections are received from medial preoptic nucleus, SFO and nucleus tractus solitarius (NTS), whereas minor connections include ventromedial nucleus, arcuate nucleus, and anterior, posterior, and dorsal hypothalamus.

Area Postrema

In rodents and lagomorphs, the AP is a midline structure protruding into the fourth ventricle on the dorsal surface of the medulla, immediately adjacent to the NTS. In most other mammals, the AP is a bilateral structure projecting into the fourth ventricle on either side of the obex. The AP sends dense efferent connections to many of the important autonomic control centers in the hindbrain, including the NTS and lateral parabrachial nucleus (l-PBN). There are also minor connections to the dorsal motor nucleus of the vagus (DMV), nucleus ambiguus, and dorsal tegmental nuclei. The AP receives afferent information from the NTS and l-PBN as well as the PVN and vagus nerve. Importantly, the vagus nerve also provides afferent input to the AP, thus providing sensory information from the viscera and positioning the AP as a unique medullary multimodal sensory integration area.

Properties and Sensory Abilities of CVO Neurons

Much work has described the electrophysiological properties of sensory CVO neurons, with SFO and AP neurons receiving the majority of the attention. In all three sensory CVOs, many neurons fire spontaneous action potentials (firing frequencies usually less than 1 Hz *in vivo*), whereas a subpopulation is typically quiescent. SFO and AP neurons exhibit compact dendritic trees and exhibit high input resistances ($>1\,G\Omega$), observations which are consistent with a prominent role of these cells in detecting humoral inputs as opposed to receiving synaptic input. Voltage-gated ionic currents in SFO and AP neurons are beginning to be thoroughly investigated, a task made easier in recent years with the identification of specific antagonists for genetically identified ion channels. Sensory CVO neurons possess a variety of ion channels that confer electrical excitability, including voltage-gated Na^+ (transient and persistent), Ca^{2+}, K^+ (delayed and transient) currents, and hyperpolarization-activated cation currents (I_h). Of specific interest in sensory CVO neurons, however, are nonspecific cation currents (NSCCs); activation of this type of conductance by circulating regulatory hormones such as Ang II, orexin, and ghrelin, as well as by changes in essential circulating ions such as Ca^{2+}, is often an endpoint leading to changes in membrane potential and thus firing rates. Interestingly, some of these signaling molecules control excitability by modulation of multiple ionic conductances, as illustrated by the actions of Ang II, which modulates transient voltage-gated K^+ currents and Ca^{2+} currents in CVO neurons in addition to its activation of an NSCC. A comprehensive description of all examples of ionic currents that are modulated by hormones and factors related to fluid balance is beyond the scope of this article. However, sensory CVO neurons express a number of receptors for hormones and factors that are directly and indirectly related to fluid balance, including receptors for adrenomedullin, Ang II, amylin, aldosterone, atrial natriuretic peptides, calcium, calcitonin, endothelin, estrogen, ghrelin, glucagon like peptide (GLP)-1, interleukin-1β, orexin, prokineticin 2, relaxin, vasopressin, and vasoactive intestinal peptide. Activation of these receptors by their ligand has in many cases been shown to modulate voltage-gated ion currents (and thus patterns of activity) in sensory CVO neurons.

This modulation of activity represents the mechanism by which information is transduced from the circulation to neural code in the CNS.

Angiotensin II Sensing

The identification in the 1970s of the SFO as the primary CNS site at which circulating Ang II acted to cause drinking first focused attention on the SFO and on the integrative roles of the three 'sensory' CVOs more generally. The initial observations were followed by studies demonstrating dense aggregations of AT_1 receptors in SFO, OVLT, and AP and (by single unit recordings) subpopulations of Ang II-sensitive neurons in all three CVOs. Studies using patch clamp techniques have identified potassium, calcium, and nonselective cationic conductances as potential channels modulated by Ang II, which thus may be responsible for inferring Ang II sensitivity of these neurons.

Sodium Sensation

The SFO and OVLT can detect changes in the concentration of sodium in the extracellular fluid independent of the osmolality. A logical potential signal is the Na^+ ion, whereby high levels of Na^+ can act in the brain as an inhibitory signal for sodium appetite. The identity of the necessary sodium receptor was elucidated in 2000 when tissue distribution of a poorly understood voltage-gated Na^+ channel (called Na_x) was closely examined, revealing a prominent expression in SFO, OVLT, ME, and NH. This restriction of Na_x to areas lacking a BBB implied a possible involvement with regulation of water/salt balance. Electrophysiological studies revealed that the sensor is a Na^+-gated Na^+ channel. Experiments revealed that Na^+ sensitivity was lost in SFO cells of Na_x knockout mice and these mice did not stop ingesting salt when dehydrated. These behavioral defects could be rescued with viral-mediated gene transfer (replacement) of the Na_x channel. Although early work suggested that the Na_x channel was expressed in neurons of the CVOs, subsequent studies have suggested that, at least in mice, Na_x expression is restricted to perineuronal processes of astrocytes in the CVOs, for the first time suggesting that the glial cell is likely to be a very active partner in the mechanisms through which the CVOs detect at least some extracellular signals. How the signals are then transduced from the glia to the neurons has yet to be elucidated.

Osmosensitivity

In addition to Na^+ concentration, the SFO and OVLT can detect changes in the osmolality of plasma. Many SFO and OVLT cells increase or decrease action potential firing rates with increasing and decreasing osmolality, respectively. Current evidence suggests that the osmosensor might be an ion channel (or heteromultimer of channels) of the transient receptor potential (TRP) family, the activation of which results in the NSCCs that have been recorded. These channels are thought to be mechanically gated, such that they open and close in response to changes in pressure on the cell membrane associated with osmotically driven fluid movement. Thus, physical stress on the membranes associated with changing extracellular osmolality modulates activity of these channels, resulting in changes in membrane conductances and changes in action potential frequency. Changes in extracellular osmolality outside the BBB may be transduced to brain centers protected by the BBB.

Calcium Sensation

Calcium is an essential factor in many biological processes, and its concentration in both the extracellular and the intracellular compartments must be maintained within strict limits. For example, calcium entry is required for synaptic release of neurotransmitters and induction of some forms of synaptic plasticity, and changes in $[Ca^{2+}]_i$ may lead to activation of intracellular kinases. Increases or decreases in $[Ca^{2+}]_{ext}$ lead to decreases or increases, respectively, in parathyroid hormone (PTH) release. PTH is a negative feedback hormone released from the parathyroid gland that stimulates Ca^{2+} retention by the kidney, uptake from the gut, and release from bone. The Ca^{2+} sensing receptor (CaR) responsible for detecting $[Ca^{2+}]_{ext}$ has been identified and located in the parathyroid gland, kidney, bone, intestine, and selected sites within the brain. Although the function(s) in brain has not been firmly established, CaR is highly expressed in both neurons and oligodendrocytes of SFO and AP. Activation of this receptor has been shown to increase the excitability of SFO neurons through the modulation of specific ionic conductances (NSCC and I_h). Such observations suggest that SFO may play important roles in the physiological regulation of $[Ca^{2+}]_{ext}$, presumably as a consequence of the ability of these neurons to regulate appropriate autonomic outputs through connections with hypothalamic and medullary autonomic control centers.

Secretory CVOs

The two secretory CVOs that play essential roles in the regulation of fluid and mineral balance are the ME and NH. They represent the 'exit portals' through which neuroendocrine cells of the hypothalamus can secrete their hormones into the systemic circulation for delivery to effector tissues located throughout the body.

Vasopressin and oxytocin are secreted primarily from the NH, which is primarily viewed as a secretory structure composed of axon terminals, glial support cells, and the vasculature supplying and draining the region. There is also limited release of the neurohypophysial peptides from the ME, which is the primary site for other hypophysial hormones of varying importance in the regulation of fluid and mineral balance. These include corticotropin releasing harmone (CRH) (controlling the adrenocortical axis), thyrotropin releasing harmone (TRH) (the thyroid axis), dopamine (prolactin secretion), gonadotropin releasing harmone (GnRH) (reproductive axis), and growth harmone releasing harmone (GHRH)/somatostatin (growth). There likely are important roles for local and circulating factors in regulation at the axon terminal of the processes in the NH and ME through which hypophysial hormones are released.

Roles of CVOs in Osmotic/Mineral Challenges

Water in the body is maintained within two compartments, the extracellular and the intracellular. NaCl is the most important solute, and its concentration in the extracellular compartment primarily determines the distribution of water. Perfusion of the tissues within the body (supplying oxygen and removing metabolites via the circulation) critically depends on the maintenance of fluid balance. Loss of water through evaporation from the skin and lungs, and through excretion in urine and/or feces, usually results in loss from both intracellular and extracellular compartments, whereas vomiting, diarrhea, and hemorrhage result initially in water loss from only the extracellular compartment. The latter conditions also result in significant solute loss. Complex compensatory responses minimize further losses through the skin and urine while modulating cardiovascular tone and output to ensure adequate tissue perfusion. However, these responses do not restore lost water and NaCl. Detection of the fluid/salt imbalance ultimately must lead to activation of neural circuits invoking motivational states of thirst and salt appetite such that lost constituents can be replenished and normal parameters restored. The sensory CVOs have been shown to play essential roles in this process, detecting the perturbations and initiating the integrated physiological response that includes fluid intake, fluid retention, and fluid redistribution until normal balance is restored.

CVOs in the Regulation of Thirst by Intracellular Dehydration

More than 50 years ago, Verney conducted experiments in which he demonstrated release of vasopressin from the posterior pituitary in dogs that had received infusions of hypertonic solutions of NaCl and sucrose into the cerebral arteries. However, a similar infusion of hypertonic urea failed to stimulate vasopressin release. These observations led him to propose that the hypertonic stimulus produced with NaCl or sucrose caused a movement of water out of the cells in the brain, thus activating CNS osmoreceptors and stimulating vasopressin release. He proposed that urea, which rapidly diffuses across cell membranes and does not cause osmotic water movement, did not stimulate the osmoreceptors. Later studies also reported that NaCl and sucrose infusions also caused antidiuresis and drinking, whereas urea was ineffective, again implying that cellular dehydration was an essential prerequisite for the initiation of these responses. Whereas early studies suggested that OVLT lesions blocked drinking and vasopressin secretion in response to hypertonic saline infusion, more recent work has suggested partial roles for both SFO and OVLT in mediating these responses. These studies have also clearly demonstrated that double lesions destroying both SFO and OVLT in the same animal do abolish drinking and vasopressin secretion in response to hypertonic NaCl.

CVOs in the Regulation of Thirst by Hypovolemia

Hypovolemia activates the renin–angiotensin system, resulting in increased circulating concentrations of the hormone Ang II. Ang II has multiple coordinated and convergent actions to regulate water and salt balance. These include direct actions on vascular smooth muscle cells causing arteriolar vasoconstriction, which elevates systemic vascular resistance and therefore increases the systemic blood pressure. Ang II also acts directly on the kidney to stimulate Na^+ reabsorption in the early proximal tubule, and it acts in the adrenal cortex to stimulate release of the mineralocorticoid aldosterone, which in turn causes Na^+ and water reabsorption by the kidney.

Actions of Ang II on CVOs to regulate thirst are direct and indirect. In 1969, Ang II was shown to stimulate thirst, and in 1978 the SFO was identified as the primary CNS site at which circulating Ang II acted to induce such responses (although central administration of Ang II appeared to elicit similar effects through actions at the OVLT). Later studies demonstrated Ang II binding and receptors in the sensory CVOs. Remarkably, Ang II is also found in the brain, where it is apparently used as a neurotransmitter (neuropeptide) in a number of pathways involved with fluid balance. Ang II also activates SFO and OVLT neurons, which send efferent projections to SON and PVN neurosecretory cells, thus stimulating release of vasopressin, oxytocin, and CRH into the circulation through the

posterior pituitary and median eminence (secretory circumventricular organs). These actions have the net effect of reestablishing normal fluid volume.

AP neurons also have the ability to sense changes in circulating Ang II, as well as vasopressin. In addition, they receive direct neural information from the cardiac and arterial baroreceptors. Through efferents to the NTS, DMV, nucleus ambiguus, and l-PBN, AP neurons influence baroreflex sensitivity, heart rate, and sympathetic output, which are essential to an integrated response to hypovolemia.

CVOs in the Regulation of Salt Appetite

Hypovolemia also activates salt appetite (to restore lost solute), albeit on a slower timescale than thirst. Ang II and aldosterone play roles in inducing salt appetite during hypovolemia, perhaps acting synergistically. The possible mechanism of the synergism is quite elegant: aldosterone may act via a nuclear receptor to increase expression of the AT_1 subtype of receptor protein in the SFO, leading to a potentiated response of SFO neurons to Ang II and thus increased salt appetite. Available data also suggest an inhibitory role of AP in salt appetite because AP lesions enhance NaCl solution intake.

CVOs and the Gustatory Aspects of Salt Appetite

The sensory CVOs are thought to play a role in salt appetite associated with gustation. Salt appetite caused by sodium depletion can be sated (temporarily) by the presence of Na^+ on the tongue. Normally this taste elicits an aversive reaction, accompanied by elevated activity of chorda tympani fibers projecting to NTS. However, sodium-deprived rats exhibit decreased responses to NaCl, presumably associated with an inhibition of the aversive reaction. Lesions of the NTS and PBN block the arousal of the salt appetite, indicating the vital role of these areas in the motivation. AP has dense reciprocal connections with NTS and PBN, whereas SFO and OVLT also project to NTS, and it has thus been suggested that modulation of the sensory CVOs by Ang II or other signals may modulate gustatory sensory pathways in the brain stem.

CVOs as Controllers of Integrated Autonomic Function

The previous discussion implies that in addition to their unique position at the blood–brain interface, the sensory CVOs combine broad-ranging sensory abilities with the capability to exert control (through their efferent projections to autonomic control centers) over diverse yet interrelated physiological systems that collectively comprise the integrated control of body fluid balance. The large number of CVO neurons influenced by multiple circulating signals (25–65%) implies that single neurons likely have multiple sensory abilities. Significant proportions of neurons in the three sensory CVOs are also sensitive to circulating signals controlling immune function, energy homeostasis, and reproduction. It is not clear whether single CVO neurons sense multiple signals related to such diverse physiological systems; for example, are amylin- and glucose-sensitive AP neurons also sensitive to Ang II and/or vasopressin? Nonetheless, a picture has begun to emerge of CVO neurons sensing multiple signals and thus potentially controlling in an integrated manner broad physiological outputs. In other words, the 'sensory CVOs' should be considered in a broader context than simply as structures involved in the regulation of body fluid balance.

Circumventricular Organs in Neuroendocrine Control

Introduction

Certain specialized brain structures have as their major distinguishing feature a dense vascularization which usually lacks the structural components that comprise the blood–brain barrier. In most of the white and gray matter of the central nervous system, capillary endothelial cells form an obstruction that restricts access of many blood-borne ions and molecules to brain parenchyma. In addition, glial cells tightly wrap the outer surface of these vessels to retard access to surrounding neurons. In contrast to typical brain tissue, most of these organs have fenestrated capillaries, and the surrounding glia are relaxed to form large perivascular spaces to allow ready exchange between the blood and interstitial fluid.

Neuroanatomic reports throughout the 1910s and 1920s frequently noted the absence of a blood–brain barrier in several discrete brain locations. After the systemic administration of vital dyes, staining was absent from most of the brain except for several small regions located in areas around the cerebral ventricles and in certain midline structures lying in the subarachnoid space. By the mid-1950s, the body of anatomic findings describing this collection of regions lacking a blood–brain barrier led Hofer to apply the title circumventricular organs (CVOs) to categorize these structures.

The number of CVOs described in amphibians, reptiles, birds, and mammals varies across vertebrate classes and species. For example, in birds, one author has identified 17 CVOs. The general consensus is that mammals have 7–9 CVOs. The areas often referred to as mammalian CVOs are presented in Figure 1. Those most consistently agreed on are the subfornical organ (SFO), organum vasculosum of the lamina terminalis (OVLT), the median eminence (ME), the neural lobe (NL), the pineal gland (PI), and the area postrema (AP). Many, but not all, authors include the intermediate lobe (IL) and the choroid plexus (CP). Although the subcommissural organ (SCO) is usually listed as a CVO, many qualify this structure as unique from the others because it lacks fenestrated capillaries and thereby has an intact blood–brain barrier.

Although there is a 'defect' in the blood–brain barrier associated with most CVOs, they still have properties that retard access from their parenchyma to other brain tissues and the cerebrospinal fluid (CSF). In essence, barrier properties are displaced to the periphery of the organs, and materials gaining access to CVOs do not readily diffuse from the organ into adjacent brain structures. In the region where CVOs and 'normal' brain parenchyma interface, the outward spread from the CVO is impeded. The structural feature giving rise to this limitation of diffusion appears to be a dense array of glia. In addition, tight junctions between the ependymal cells covering the surface facing the ventricles also limit the transfer of agents from CSF to the organ and vice versa. Hence under normal physiologic conditions, CVOs should not be viewed as portals of entry for bulk dissemination of blood-borne agents to the brain or CSF. Rather, CVOs appear as restricted regions allowing for limited localized exchange between blood and brain.

Functional Roles for CVOs

CVOs have been proposed to have a role in many homeostatic and nonhomeostatic functions. Some of these include the maintenance of body fluid balance, blood pressure, temperature, respiration, energy balance, mediation of immune and host-defense responses, pain modulation, protection against toxic substances (e.g., emesis and conditioned taste), biological rhythms, reproduction, parental behavior, lactation, growth, sleep, arousal, and attention. Although some investigators have argued for a global, coordinated action among several or all CVOs for a specific function, others believe it is more likely that each CVO has a unique role and that at most, only small subsets of organs are functionally linked.

CVOs are strategic loci that couple the transfer of information among the CSF, blood, and brain. The possible types of information exchange between these three compartments are summarized in Table 1. The experimental evidence supporting each of these eight classes of interaction varies from substantial to minimal. Evidence for Class I exchanges (e.g., secretion of vasopressin) is the best established, with Classes II and III somewhat less established. Even less functional evidence is currently available for the remaining types of CVO, CSF, and brain interactions.

The function of CVOs for which there is the most general and longest agreement is the role in neurosecretion. The early discoveries of endocrine functions of the NL, ME, PI, and pituitary IL have firmly established this role for these CVOs. A well-described secretory role for the CP and the SCO

Figure 1 A medial sagittal representation of the human brain depicting nine circumventricular organs (CVOs). The organs have been classified according to their putative primary functions.

Table 1 Classes of hypothesized interactions of circumventricular organs (CVOs) and mode of mediation

Class	*Signal source, target*	*Mode of information transfer*
I	CVO, blood	Humoral
II	Blood, CVO	Humoral
III	CVO, brain parenchyma	Neural
IV	Brain proper, CVO	Neural
V	CVO, CSF[a]	Humoral
VI	CSF, CVO	Humoral
VII	CVO, brain proper	Humoral
VIII	Brain proper, CVO	Humoral

also exists. It is recognized that the CP is the primary source of CSF. The SCO secretes a mucoidlike thread, Reissner's fiber, into the cerebral aqueduct. However, the functional significance, if any, of Reissner's fiber is unknown.

For the remaining three CVOs, the SFO, OVLT, and AP, only a small amount of evidence suggests that they also may secrete materials into either blood or CSF. However, recent research has been more successful in implicating these particular CVOs as targets for blood-borne factors such as hormones or humoral agents (i.e., specific ions or nonspecific osmols). In essence, the SFO, OVLT, and AP constitute a set of sensory CVOs.

The SFO, OVLT, and AP have been especially implicated in the control of body fluid and cardiovascular homeostasis. Findings made in the late 1960s provided evidence that angiotensin II (ANG II) acts on the AP to reduce the gain of baroreceptor-mediated cardiovascular reflexes. These findings were followed by studies implicating the SFO in the control of angiotensin-induced water intake (thirst), vasopressin release, sodium chloride ingestion (salt appetite), and cardiovascular responses. Stimulation and ablation studies of the periventricular region that includes the OVLT indicate that this CVO houses a critical set of the body's osmoreceptors or sodium receptors that influence thirst, vasopressin release, salt appetite, and arterial blood pressure.

Biochemical Properties and Anatomic Connections

Biochemical and immunocytochemical studies have identified many hormonal and neurotransmitter-like factors in CVOs. The CVOs that are primarily neurosecretory contain neurohormones (e.g., vasopressin, adrenocorticotrophic hormone, and melatonin)

that, depending on the specific hormone and CVO, are either synthesized *in situ* or transported to release sites. Sensory CVOs also contain an extensive number of hormonal and neurotransmitter-like factors, including many neuropeptides and biogenic amines. Although some substances may be concentrated in CVOs as a result of extraction from blood or CSF, it is likely that many are transported via axons into the CVOs from other brain regions or that they are synthesized locally; several synthetic enzymes have also been localized in sensory CVOs.

Support for the concept that sensory CVOs are targets for extracellular agents is demonstrated by high concentrations of ligand-binding sites, immunocytochemically identified receptor proteins, and messenger RNAs for the receptors of a number of putative neurotransmitters and hormones. Some of the binding sites or receptors identified in the SFO, OVLT, and AP include those for a number of peptides (e.g., ANG II, atrial natriuretic peptide, calcitonin, endothelin, cholecystokinin, insulin, somatostatin, substance P, vasopressin, various opioids, neuropeptide Y, and vasoactive intestinal peptide), biogenic amines (e.g., catecholamines and serotonin), amino acids (e.g., γ-aminobutyric acid and glycine), and several steroids (e.g., aldosterone, estrogen, glucocorticoids, and progesterone). Evidence from both *in vivo* and *in vitro* electrophysiologic studies indicates that many of the substances with receptor or binding sites in sensory CVOs evoke voltage-related responses in cells within these organs.

Neurons with cell bodies located in brain parenchyma and axons that project and terminate in the NL, ME, IL, or PI are common paths for the release of neurohormones either into the general circulation (e.g., NL or PI) or into specific portal systems (e.g., ME to anterior pituitary). The somata of many of the cells that project into secretory CVOs are points of convergence for multiple types of neural inputs. These inputs typically arise from diverse brain regions, including hypothalamic nuclei, other limbic structures, and brain stem regions. It is also notable that among the CVOs with known neuroendocrine function, the control of melatonin synthesis and secretion in the PI is exerted by sympathetic innervation arising from the superior cervical ganglia.

Recent progress applying refined neuronal track-tracing methods has provided substantial insight into the relationship of sensory CVOs with the rest of the nervous system. The AP, SFO, and OVLT all have a rich distribution of efferents. Notably, many of the targets receiving projections from sensory CVOs are

Figure 2 Sensory circumventricular organs (CVOs) associated with the lamina terminalis and descending projections to forebrain regions involved in autonomic, neuroendocrine, and behavioral control of body fluid and cardiovascular homeostasis. OVLT, organum vasculosum of the lamina terminalis. Adapted from Johnson AK and Gross PM (1993) Sensory circumventricular organs and brain homeostatic pathways. *FASEB Journal* 7: 678–686.

brain nuclei that receive input from visceral afferent nerves and from other brain regions implicated in homeostatic processes such as the maintenance of body fluid and energy balance. In essence, sensory CVOs project into an extensive visceral neural network that has been referred to as the visceral neuraxis. This neural network processes (integrates) input related to the control of homeostatic response systems. Outputs from this network control behavioral, autonomic, and neuroendocrine responses to perturbations in homeostatic states.

An example of the relationship between sensory and neurosecretory CVOs and with other effector systems is provided by the relationship of the outflow of the two forebrain sensory CVOs (i.e., SFO and OVLT), along with their related neural circuitry in the lamina terminalis. The SFO and OVLT, along with the adjacent median preoptic nucleus, which is inside the blood–brain barrier, project to several structures implicated in the control of fluid balance and blood pressure. A model for the influence of the outputs from the lamina terminalis is presented in Figure 2. Substantial evidence indicates that in several species, the SFO is sensitive to circulating angiotensin and that the OVLT contains osmoreceptors. Descending pathways from these two CVOs and from the median preoptic nucleus project to multiple regions, influencing physiologic and behavioral mechanisms that maintain cardiovascular and body fluid homeostasis. Among these 'descending' projections are those that terminate in the region of cell bodies of (1) parvocellular paraventricular nucleus (PVN) neurons, which in turn project to the ME and to more-caudal structures involved in the control of sympathetic outflow; (2) magnocellular neurons of the PVN and supraoptic nuclei, which in turn project to the NL and release vasopressin (antidiuretic hormone) and oxytocin; and (3) regions (e.g., periformical hypothalamic region, central nucleus of the amygdala, and bed nucleus of the stria terminalis) implicated in the control of water and sodium intake. Extracellular signals such as ANG II or increased osmolarity reach the SFO- or the OVLT-activating pathways that alter activity of higher-order neurons controlling the secretion of hydration-related hormones, behaviors, and sympathetic outflow. It is interesting to note that a close relationship between the SFO/OVLT and neurosecretory neurons provides a short loop reflex for controlling hormone release. Although the relationship between sensory and secretory CVOs is best illustrated by the mechanisms that maintain body fluid homeostasis, it is likely that future research will fully implicate CVOs in a multitude of critical regulatory processes involved in health and disease.

Discovery of CL1

CL1 was originally purified as α-latrotoxin binding protein in the absence of Ca^{2+} in efforts to elucidate the mechanisms of α-latrotoxin actions. α-Latrotoxin is a member of latrotoxins that are isolated from the venom of the black widow spider, *Lactrodectus*. Latrotoxins have been used to study the molecular mechanisms of neurotransmitter exocytosis in vertebrates, insects, and crustaceans. α-Latrotoxin is by far the most studied toxin since it is the only one that stimulates neurosecretion from neurons and neuroendocrine cells of vertebrates. α-Latrotoxin has been cloned and sequenced together with three other latrotoxins – α- and γ-latroinsectotoxins and α-latrocrustaceanotoxin. Similar to other latrotoxins, α-latrotoxin is a large protein composed of four domains: a cleaved signal peptide (domain I), a conserved N-terminal domain with three invariant cysteine residues among all the latrotoxins (domain II), a domain composed of 22 ankyrin-like repeats (domain III), and a C-terminal domain (domain IV) that is cleaved during venom maturation. Mature α-latrotoxins are composed of domains II and III, with the molecular weight of 130 kDa (Figure 1).

α-Latrotoxin has a complex mode of action: it stimulates neurotransmitter release from neurons in the presence or absence of extracellular Ca^{2+}, and it also stimulates neurotransmitter release from neuroendocrine cells, but only in the presence of Ca^{2+}. Even in Ca^{2+}-dependent transmitter release, the mechanisms of α-latrotoxin-stimulated exocytosis may differ between neurons and neuroendocrine cells. The Ca^{2+}-independent stimulatory action of α-latrotoxin in neurons has attracted attention because the elucidation of the underlying mechanism will likely lead to the discovery of novel triggering mechanisms of neurotransmitter release.

Regardless of the complex mode of action, α-latrotoxin stimulates exocytosis only after binding to neuronal cell surface receptors. The first receptor to be discovered was neurexin 1α, a neuronal protein with a single transmembrane domain. However, neurexin 1α binds to α-latrotoxin only in the presence of Ca^{2+}. Since α-latrotoxin also acts in the absence of Ca^{2+}, this clearly indicated the presence of another Ca^{2+}-independent toxin receptor. Such a protein was later discovered by two independent research groups and separately termed CIRL1 (Ca^{2+}-independent receptor for latrotoxin 1) and latrophilin 1. As a result, the term CL1, which incorporates both of these names, has been used to represent the protein.

Structure of CLs

CL1, which was purified from the brain by affinity purification with α-latrotoxin column, was originally estimated by SDS-PAGE analysis to be 120 kDa in size. However, cDNA cloning of CL1 revealed the actual size of this protein to be greater than 160 kDa. After careful analysis, it has become clear that CL1 goes through proteolytic processing into two subunits: an N-terminal 120 kDa subunit (p120) and a C-terminal 85 kDa subunit (p85) (Figure 2). The 120 kDa protein purified by α-latrotoxin column is the p120 subunit of CL1.

Immediately after cloning of CL1, two isoforms of CL1 were cloned and termed CL2 and CL3. Although CL2 and CL3 are highly homologous, only CL1 binds tightly to α-latroxin. CL2 may bind weakly to α-latrotoxin, whereas CL3 has no affinity to the toxin. As G-protein-linked receptors, CLs are unusually large (Figure 2). The central part of CLs is occupied by seven transmembrane regions (TMRs) and their connecting loops. The TMRs of CLs are homologous to TMRs of other serpentine receptors, particularly those of the secretin family of peptide hormone receptors. On the N-terminal extracellular side, the TMRs are preceded by at least six domains: (1) a signal peptide; (2) a short cysteine-rich sequence (~90 residues) distantly related to lectins; (3) a longer domain (~290 residues) that is homologous to olfactomedins and the glaucoma gene myocilin; (4) a serine- and threonine-rich linker sequence that may be glycosylated; (5) a long domain (~280 amino acids) that exhibits homology only to BAI1, -2, and -3, which are large serpentine receptors of unknown function characterized as potential inhibitors of brain angiogenesis; and (6) a short (~50 residues) cysteine-rich domain that is located immediately N-terminal of the first TMR and represents a novel type of widely distributed extracellular protein module. The precise site of proteolytic cleavage is identified within this cysteine-rich domain, and this domain is called the G-protein-coupled receptor proteolytic site (GPS) domain (Figure 2).

CLs belong to the group of large N-terminal family B seven-transmembrane (LNB 7TM) receptors, which is composed of at least 33 members, as identified by bioinformatics. All 33 proteins contain the GPS domain, and at least three LNB 7TM receptors, including CL1, appear to be cleaved within this site.

Figure 1 Schematic representation of α-latrotoxin. Composition of α-latrotoxin precursor of four domains: I, signal peptide (SP); II, conserved N-terminal domain. Locations of the only three cysteine residues that are conserved in all latrotoxins are indicated by the letter 'C'; III, central region, composed of 22 ankyrin-like repeats; IV, C-terminal region. α-Latrotoxin is processed by endoproteolytic cleavage after the last ankyrin repeat (open arrowhead). Thus, mature α-latrotoxin is composed of two domains (domains II and III).

Figure 2 Domain structure of CLs. SP, N-terminal signal peptide; lectin, a lectin-like domain; olfactomedin/myocilin, a domain homologous to olfactomedins and myocilin; BAI1, -2, and -3 homology, a domain homologous to BAI1, -2, and -3; GPS, a cysteine-rich domain that contains a cleaving site. CL1 is cleaved within the GPS domain into two subunits – an N-terminal subunit (p120) and a C-terminal subunit (p85). These two subunits remain associated by noncovalent interactions after cleavage. The C-terminal subunit is a seven transmembrane protein coupled with G-protein.

This observation suggests that the rest of the proteins in the family could also be cleaved at this specific site. Cleavage occurs in the endoplasmic reticulum within the cell, with the N-terminal subunit (p120) remaining associated with the seven transmembrane C-terminal subunit (p85) (Figure 2). The nature and specificity of the cleavage enzymes remain unknown. The biological significance of the cleavage also remains to be fully understood. The mutagenesis in the GPS domain of CL1 that blocks proteolytic cleavage also blocks CL1 trafficking to the cell surface, which indicates that cleavage is critical for delivery of CL1 to the cell surface.

CL1 Is a Major α-Latrotoxin Receptor

The critical role for CL1 in α-latrotoxin action was demonstrated through the phenotypic analysis of CL1 knockout mice. Ca^{2+}-independent binding of α-latrotoxin to brain membranes is impaired in CL1 knockout mice by approximately 75% and Ca^{2+}-dependent binding (approximately two times higher than Ca^{2+}-independent binding) is decreased in CL1 knockout mice by approximately 50%. The binding of α-latrotoxin to the brain membrane is two times greater in the presence of Ca^{2+} than that in the absence of Ca^{2+} since α-latrotoxin can also bind neurexin in the presence of Ca^{2+}. In neurexin 1α knockout mice, Ca^{2+}-dependent binding of α-latrotoxin to brain membranes is decreased by approximately 50%, whereas Ca^{2+}-independent binding of the toxin is not affected, supporting the biochemical finding that binding between neurexin 1α and α-latrotoxin occurs only in the presence of Ca^{2+}.

Synaptosomes lacking CL1 exhibited the same decrease in α-latrotoxin-stimulated glutamate release in the presence and absence of Ca^{2+} (approximately 75%). In contrast, synaptosomes lacking neurexin 1α exhibited only a small decrease in α-latrotoxin-triggered release in the absence of Ca^{2+} (approximately 20%) but a major decrease in the presence of Ca^{2+} (approximately 75%). These findings suggest that CL1 and neurexin 1α account for the majority of α-latrotoxin receptors in the brain and any remaining receptor activity could be accounted for by other CL and neurexin isoforms. They also suggest that CL1 and neurexin 1α act additively in binding α-latrotoxin but not in triggering release. Together, these two receptors act autonomously in binding of α-latrotoxin but cooperatively in transducing the stimulation of neurotransmitter release by α-latrotoxin. However, the underlying mechanisms of the cooperativity between CL1 and neurexin 1α remain to be fully understood.

Role for CL1 in α-Latrotoxin-Stimulated Neurotransmitter Release in the Presence of Extracellular Ca^{2+}

In normal physiological circumstances, 1 or 2 mM of Ca^{2+} is present in the extracellular environment and the binding of α-latrotoxin to neuronal cells is largely mediated by its binding to both CL1 and neurexin 1α. How does α-latrotoxin stimulate neurotransmitter release after binding to CL1 and/or neurexin 1α? The mechanisms underlying α-latrotoxin-induced, extracellular Ca^{2+}-dependent neurotransmitter release in neuroendocrine cells are well established. The key observation is that overexpression of CL1 or neurexin 1α in neuroendocrine cells facilitates α-latrotoxin-induced, extracellular Ca^{2+}-dependent neurotransmitter release that does not rely on intracellular domains of CL1 or neurexin 1α. Based on this finding, it is believed that the α-latrotoxin cell surface receptor is important for recruiting the toxin to the site of action but is not involved in the exocytotic signal, which is transmitted by the toxin. The toxin has long been known to form Ca^{2+}-permeable pores in the plasma membrane of cells sensitive to it. By expressing exogenous toxin receptors (CL1 or neurexin 1α) in cells that are normally insensitive to α-latrotoxin (COS-7, HEK293, or BHK), the toxin easily induced pores. Furthermore, signaling-deficient (intracellularly truncated) mutants of the receptors also facilitated pore formation that correlated with toxin binding irrespective of the receptor structure. Thus, pore formation is the major mechanism by which α-latrotoxin triggers Ca^{2+}-dependent neurotransmitter release in neuroendocrine cells and does not rely on signal transduction by receptors.

How is the hydrophilic α-latrotoxin able to insert itself into the membrane? The three-dimensional structure of α-latrotoxin has been determined and toxin tetramers inserted into the membranes of liposomes have been directly visualized by cryo-electron microscopy. The most relevant feature of the tetramer is the central channel surrounded by toxin monomers; at the lower end, this pear-shaped channel is 25 Å in diameter, and it then widens to 36 Å to be constricted to 10 Å at the top. Thus, the inserted α-latrotoxin tetramer would permeabilize the membrane to all substances that can pass through the central channel, such as small molecules and hydrated cations. Detailed structure–function analysis has been conducted using recombinant α-latrotoxins. It was found that the last two ankyrin-like repeats are not required for binding to neurexin 1α or CL1 but essential for pore formation. This mutant largely lost the ability to stimulate exocytosis from neuroendocrine cells, which supports the fact that pore formation plays a critical role in Ca^{2+}-dependent exocytosis from neuroendocrine cells.

Pore formation may not be the only mechanism underlying α-latrotoxin-stimulated exocytosis from neurons in the presence of extracellular Ca^{2+}. Since CL1 is a G-protein-coupled receptor, it has been hypothesized that the activation of G-protein pathway also contributes to neurotransmitter release. Biochemical analysis suggests that CL1 is linked to $G\alpha_{q/11}$, and the downstream effector of $G\alpha_{q/11}$, phospholipase C (PLC), stimulates extracellular Ca^{2+}-dependent hydrolysis of phosphoinositides. Activated PLC increases the cytosolic concentration of IP_3, which in turn induces release of Ca^{2+} from intracellular stores. This rise in cytosolic Ca^{2+} may increase the probability of neurotransmitter release and, consequently, the rate of spontaneous exocytosis and the amplitude of evoked release. Thus, activation of CL1 leads to extracellular Ca^{2+}-dependent mobilization of intracellular Ca^{2+} and mobilization of Ca^{2+} appears to play a potential role in neurotransmitter release stimulated by α-latrotoxin receptor signaling. The contribution of this receptor signaling pathway to the stimulation of neurotransmitter release is evident from the analysis of a unique α-latrotoxin mutant called $\alpha\text{-LTx}^{N4C}$. This mutant has four extra amino acids that were inserted between domain II and domain III, and it does not seem to form the Ca^{2+}-dependent ionophore, but it stimulates extracellular Ca^{2+}-dependent hydrolysis of phosphoinositides as well as extracellular Ca^{2+}-dependent neurotransmitter release. More important, this mutant can stimulate glutamate release from CA3 neurons in the presence of extracellular Ca^{2+}. Thus, activation of this receptor signaling pathway appears to contribute to the stimulation of neurotransmitter release from neurons in the presence of extracellular Ca^{2+}. In contrast, this mutant is ineffective in stimulating exocytosis from neuroendocrine cells, which supports the belief that the influx of extracellular Ca^{2+} is essential for α-latrotoxin-stimulated exocytosis from neuroendocrine cells. Therefore, this suggests that mechanisms underlying extracellular Ca^{2+}-dependent exocytosis may differ between neuroendocrine cells and neurons.

Role for CL1 in α-Latrotoxin-Stimulated Neurotransmitter Release in the Absence of Extracellular Ca^{2+}

Even in the absence of extracellular Ca^{2+}, α-latrotoxin can stimulate massive neurotransmitter release from neurons. Based on the analysis of CL1 knockout mice, CL1 is the major (~75%) surface receptor for α-latrotoxin, but it remains a mystery how α-latrotoxin

can stimulate Ca^{2+}-independent exocytosis after binding CL1. Unlike wild-type α-latrotoxin, removal of extracellular Ca^{2+} by EGTA abolishes the stimulatory action of α-LTx^{N4C}. Thus, activation of CL1 receptor signaling itself does not explain the stimulation of Ca^{2+}-independent neurotransmitter release by α-latrotoxin. Also, the previously mentioned CL1 signaling pathway ($G\alpha_{q/11}$, PLC) requires the presence of extracellular Ca^{2+} and will not be activated otherwise. It has been hypothesized that secretion triggered by α-latrotoxin in the absence of Ca^{2+} may be attributable to its membrane penetration and/or pore formation. This is further substantiated by the requirement of Mg^{2+} for α-latrotoxin-stimulated release in Ca^{2+}-free conditions, which corresponds to the fact that Mg^{2+} facilitates toxin tetramerization and pore formation. However, it is unclear whether secretion in the absence of extracellular Ca^{2+} can be induced by the pore-mediated influx/efflux of cations or membrane depolarization. The tetrameric wild-type toxin inserted into the neuronal plasma membrane could potentially interact directly with some components of the intracellular transmitter release apparatus, defining a novel hypothetical mechanism proposed recently.

CLs Are Conserved Proteins: Lessons from *Caenorhabditis elegans*

The presence of CL orthologs is reported in *C. elegans* (*lat-1* and *lat-2*) and *Drosophila* (RE25258p/CG8639-PA), which indicates the function of CLs to be conserved evolutionally. Interestingly, null mutation of *lat-1* or RNA interference-mediated knockdown of *lat-1* in *C. elegans* results in a prolonged pharyngeal pump duration and constipation phenotype. Extended pharyngeal pump duration and constipation phenotype are often observed in *C. elegans* mutants with defective neurotransmission, although the defect observed in *lat-1* mutations is not as marked. Furthermore, *lat-1* knockdown worm is more resistant than wild-type worms to lavamisole and imipramine, blockers of acetylcholine receptors, indicating a decrease in the release of acetylcholine. *Lat-1* appears to be expressed in subsets on neurons rather than muscles. These results suggest that *lat-1* may be involved in aspects of neurotransmitter release and that there may be endogenous ligands which exist to activate *lat-1* and/or *lat-2*.

Interestingly, black widow spider venom, from which α-latrotoxin is purified, is toxic to *C. elegans* but purified α-latrotoxin is not. This suggests that venom from the black widow spider contains toxins other than α-latrotoxin. In addition, knockdown of *lat-1*, but not *lat-2* or neurexin 1 homolog, confers resistance to the venom. These results suggest that *lat-1* functions as the receptor for latrotoxin-like proteins in the venom. Furthermore, it has been discovered that emodepside, which belongs to a new class of drugs, the cyclo-octadepsipeptides, binds to nematode *lat-1*. Emodepside causes paralysis in nematodes, including in the pharynx, and facilitates destaining of vesicles stained with FM4-64 in the pharynx, which suggests that emodepside facilitates neurotransmitter release. More important, the pharynxes of *lat-1* mutants are resistant to emodepside, indicating that *lat-1* functions as a receptor for emodepside.

How does emodepside trigger neurotransmitter release after binding to *lat-1*? Unlike α-latrotoxin, emodepside does not have pore-formation abilities. This suggests that it induces exocytosis through the activation of *lat-1*. Similar to CL1, *lat-1* is a G-protein-coupled receptor. In addition, reduction or loss-of-function mutations in Gq, PLC-*β*, and *unc13* in the worm confers resistance to emodepside, suggesting that these pathways are critical for the actions of emodepdide. As discussed previously, the Gq and PLC pathway is activated by mammalian CL1. Thus, *lat-1* and CL1 appear to activate a similar signaling pathway leading to neurotransmitter release. Unc13 is a key priming molecule essential for synaptic vesicle-mediated release of neurotransmitter. Thus, activation of *lat-1* may activate Unc13 and prime neurotransmitter release. Unc13 is also a well-conserved protein and three mammalian homologs (Munc13-1, -2, and -3) are essential for priming of neurotransmitter release in mammalian neurons. When both Munc13-1 and -2 are knocked out, the effects of α-latrotoxin are severely reduced. Thus, α-latrotoxin-dependent exocytosis may involve Munc13 activation via CL1 signaling pathways. However, Munc13s are required for neurotransmitter release stimulated not only by α-latrotoxin but also by other stimulation such as Ca^{2+} influx following depolarization. Thus, the results of Munc13 knockouts do not necessarily demonstrate that α-latrotoxin directly utilizes the Munc13 pathways to trigger neurotransmitter release.

Biological Functions of CLs

CL1 and CL3 are highly enriched in the mammalian brain, whereas CL2 is expressed ubiquitously. This suggests that although the primary function of CLs is in the brain, they function ubiquitously. The conservation of CL1 in lower organisms strongly suggests that CLs are involved in critical physiological functions. Based on the phenotype of *lat-1* in *C. elegans*,

CLs are likely involved in the stimulation of neurotransmitter release. CL1 knockout mice do not show phenotypes, but this lack of phenotype is probably due to the presence of closely related isoforms, CL2 and CL3.

Since CL1 is the major receptor for α-latrotoxin and α-latrotoxin induces neurotransmitter release after binding to presynaptic receptors, CL1 is believed to be localized at the presynapse. To identify the physiological function of CL1, efforts have been made to identify the CL1-interacting proteins by yeast two-hybrid screens using a large intracellular sequence of CL1 as bait. Two groups identified the Shank family of proteins as CL1-interacting proteins, and this interaction was further confirmed by coimmunoprecipitation experiments. This is surprising because the Shank family of proteins is enriched at the postsynapse. The interactions with the Shank family of proteins suggest that CL1 is also expressed at the postsynaptic side, although the role for CL1 at the postsynapse is enigmatic.

The structure of CLs suggests that they are involved in cell-to-cell interaction processes coupled with signal transduction. At least 33 proteins, including CL1, -2, and -3, belong to the LNB 7TM family of proteins. Surprisingly, binding proteins or ligands have been identified for very few of the LNB 7TM proteins. CD97, a member of the LNB 7TM proteins and a homolog to CLs in the GPS and TMR domains, is one of these few examples that has been found to bind CD55. This interaction is mediated by the N-terminal epidermal growth factor-like domain of CD97, which does not exist in CLs. The study to elucidate the physiological significance of this interaction is under way. The extracellular domains of CL1 contain lectin-like and olfatomedin/myocillin-like domains that are considered to be cell adhesion motifs. Identification of the physiological ligand for CL1 will facilitate better understanding of the function of CL1, but no ligand has been identified so far. Further work including identification of ligands is clearly required to elucidate the physiological functions of CLs.

Clathrin and Clathrin-Adaptors

R M Twyman, University of York, York, UK

© 2009 Published by Elsevier Ltd.

Introduction

Cells are able to internalize molecules that are outside the plasma membrane by engulfing them in vesicles and drawing those vesicles into the cell interior, a process known as endocytosis. There are several different endocytic pathways, but clathrin-mediated endocytosis is the best understood at the molecular level. This pathway, which is often used for the internalization and recycling of membrane-spanning receptors, involves the formation of special patches of membrane called pits, which are defined by the presence of the cytosolic protein clathrin. Because clathrin is used to internalize many different receptor molecules but does not have affinity for all of them, the formation of a clathrin-coated pit requires the sequential action of numerous factors, beginning with clathrin adaptors whose function is to associate clathrin with particular cargo molecules and recruit accessory factors that help the clathrin to form a polymeric matrix on the inner membrane surface. The polymerization of clathrin is responsible for membrane buckling which allows the vesicle to form. After vesicle scission, the clathrin and adaptor molecules dissociate, leaving them free to contribute to further coated pits and vesicles.

Clathrin

Clathrin is the structural protein which accumulates at the sites that form clathrin-coated pits. The native clathrin molecule is a hexamer comprising three identical copies of a 180 kDa heavy chain and three copies of a 30–40 kDa light chain to form a three-legged structure known as a triskelion. The heavy chain is invariant and contains recognition motifs for clathrin adaptors. In contrast, there are several light-chain isoforms in mammals, resulting from the presence of two genes, the primary transcripts of which can be spliced in different ways. The light chain regulates clathrin self-assembly into polyhedral lattices and is capable of doing so both *in vivo* to form pits and vesicles and *in vitro* to form empty cages that are structurally very similar to clathrin-coated pits. Clathrin has no affinity for membrane lipids or for any known class of transmembrane receptor. Therefore, clathrin assembly at the site of receptor molecules targeted for endocytosis is completely dependent on adaptors and accessory proteins.

Clathrin Adaptors

Clathrin adaptors are required to recruit clathrin to the membrane and assemble clathrin-coated pits at the sites of appropriate cargo molecules. They achieve this through their ability to recognize and bind multiple components of the endocytic pathway simultaneously, including the plasma membrane, clathrin, the cargo targeted for internalization, and various accessory proteins. Two major classes of adaptor are recognized – classic adaptors, which are multimeric, and alternative adaptors known as CLASPs (clathrin-associated sorting proteins), which are either single polypeptides or, occasionally, homodimers.

Classic adaptors are tetrameric with a molecular mass of approximately 300 kDa. The general architecture is $X\beta\mu\sigma$, where X is a variable subunit responsible for membrane binding and the recruitment of accessory proteins, and the $\beta\mu\sigma$ subunits are more structurally conserved. In the well-characterized activator protein (AP)2 adaptor, for example, X is the α subunit and the other three subunits are designated $\beta2$, $\mu2$, and $\sigma2$ (Figure 1). The larger subunits (α and $\beta2$) each comprise an N-terminal trunk domain and a C-terminal appendage joined to the trunk by a flexible hinge region. The α subunit binds to membrane lipids (specifically PtdIns$_{(4,5)}$P$_2$) and to accessory proteins such as epsin-1. The $\beta2$ subunit binds to cargo dileucine motifs, recognizes clathrin via its hinge domain, and recognizes additional accessory proteins via its appendage domain. The $\mu2$ subunit is cargo specific and is absolutely required for cargo recognition, but it also interacts with membrane lipids and with accessory proteins such as stonin-1. The $\sigma2$ subunit is thought to have a purely structural role, facilitating interactions between the other subunits.

A number of different CLASPs have been identified, most of which function as single polypeptides. CLASPs have multiple domains that recognize lipids, the peptide signals in the cytoplasmic tails of their cargo, clathrin, accessory proteins, and in some cases the classic adaptors such as AP2. This modular design allows the adaptors to interact simultaneously with multiple components of the endocytic pathway in a highly synchronized manner. Well-characterized CLASPs include Golgi-associated γ-ear-containing ADP-ribosylation-factor-binding (GGA) proteins, which function in concert with the AP1 classic adaptor

epsin, AP180/clathrin assembly lymphoid myeloid leukemia protein (CALM), and β-arrestin.

Initiation of Endocytic Complex Assembly by Clathrin Adaptors

It is thought that lipid–adaptor interactions initiate the process of clathrin-coated pit formation, followed by interactions with cargo, accessory proteins, and finally clathrin itself. Lipid binding by the α and $\mu 2$ subunits of AP2 (Figure 2) and by epsin is particularly well characterized, and specific domains responsible for interaction with PtdIns$_{(4,5)}$P$_2$ have been identified on many of the alternative adaptor proteins.

In AP2, the N-terminal core domain of the α subunit contains a series of basic side chains, including two clusters of lysine residues which cooperate with lysine residues found at the C-terminus of the $\mu 2$ subunit to bind the phosphate groups of PtdIns$_{(4,5)}$P$_2$. Several different lipid-binding domains have been identified in the CLASP-adaptor proteins, including the epsin NH2-terminal homology (ENTH) domain in epsin, the AP180 N-terminal homology (ANTH) domain in AP180/CALM and the phosphotyrosine-binding (PTB) domain in autosomal-recessive hypercholesterolemia (ARH) and Numb (Figure 3). Unlike the strategy used by AP2, the ENTH domain of epsin binds to both the phosphate head group and the glycerol backbone of PtdIns$_{(4,5)}$P$_2$, which is achieved through a conformational change during binding. Four α-helices in the ENTH domain form a basic pocket to secure the head group, but binding results in a conformation change that forms an additional, amphipathic helix. The hydrophobic face of this helix aligns with the hydrophobic portion of the lipid, whereas the hydrophilic face cooperates to hold the head group in the basic pocket, thus anchoring epsin into the membrane. The ANTH domain of AP180/CALM is also understood in detail. This domain comprises nine α-helices, two of which contact the head group of PtdIns$_{(4,5)}$P$_2$ via three lysine residues and one histidine.

Cargo binding is achieved through the recognition of various peptide motifs and/or specific forms of posttranslational modification on the cytosolic portion of the cargo molecule. It is unclear whether lipid binding or cargo binding occurs first, but it is known that the stability of cargo binding is enhanced by simultaneous interaction with the membrane. For example, the recruitment of AP2 to the plasma membrane may occur through sequential interactions, first between the α subunit and PtdIns$_{(4,5)}$P$_2$, then between the $\mu 2$ subunit and both PtdIns$_{(4,5)}$P$_2$ and cargo carrying the peptide motif Y-X-X-Hy (where Y is tyrosine, X is any amino acid, and Hy is any hydrophobic amino acid), and then between the $\beta 2$ subunit and dileucine motifs on the cargo ([DE]xxxL[LI]). Similarly, studies in yeast suggest that epsin binds to PtdIns$_{(4,5)}$P$_2$ via its ENTH domain and simultaneously to ubiquitylated proteins via two ubiquitin-interacting motifs (UIMs). The removal of either UIM reduces, but does not abolish, the ability of epsin to interact with the membrane, indicating some sort of cooperative-binding behavior.

Once the adaptor has been recruited to the membrane, the scene is set for the recruitment of clathrin

itself. Many studies have confirmed the necessity of adaptor proteins for clathrin localization, and indeed colocalization experiments have shown unambiguously that yeast cells lacking clathrin adaptors fail to generate localized clathrin pits. Clathrin recruitment requires adaptors already bound to the plasma membrane. The presence of lipid- and clathrin-binding motifs in these adaptors allows the adaptors to interact simultaneously with the plasma membrane and clathrin. In the case of AP2, recruitment is achieved by way of the clathrin box – a short motif in the hinge region of the β2 subunit with the sequence LLNLD, which interacts with the β-propeller formed by WD40 repeats at the N-terminal domain of the clathrin heavy chain. There is also evidence for a second clathrin-binding motif in β2 which acts cooperatively with the LLNLD motif. Two distinct classes of clathrin-binding domain have been identified in CLASPs: a type I box with the sequence L-Hy-X-Hy-[DE] (where Hy is any bulky hydrophobic amino acid residue, X is any amino acid, and the negatively charged residue (D or E) can also be represented by the C-terminal carboxyl group) and a type II box with the sequence L-Hy-D-L-L (a shortened version comprising the last three residues is present in AP180). These also interact with the N-terminal domain of the clathrin heavy chain and promote clathrin polymerization with the same efficiency.

The process of cargo recognition, membrane association, and clathrin recruitment would not proceed (or would not proceed with such efficiency) but for the presence of numerous accessory proteins that provide a structural architecture that facilitates the interactions between adaptors and other endocytic components. Many of the clathrin adaptors interact with the same repertoire of accessory proteins, one example being epidermal growth factor receptor pathway substrate (Eps)15, which has been shown to bind AP2, epsin, AP180, Numb, Stonin-2, and membrane cargo proteins. Experiments have shown that Eps15 and other accessory proteins can accelerate the formation of clathrin cages *in vitro*, indicating a similar stimulatory role *in vivo*. Interestingly, Eps15 also interacts with downstream components of the endocytic pathway that are not discussed in this article, such as dynamin. This suggests that Eps15 needs to adopt a position within the forming endocytic structure that will allow it to interact transiently with adaptor proteins that are part of the clathrin-coated bud as well as with endocytic proteins that act later, which are found only at the narrowing bud neck.

Roles of Clathrin and Clathrin Adaptors during Vesicle Formation

During the formation of clathrin-coated vesicles, the plasma membrane encounters increasing degrees of deformation. The regulated assembly of clathrin coats and adaptor complexes at the plasma membrane initiates the membrane's curving to form a vesicle. The driving force seems to come from the combined action of clathrin coats and adaptors recruited to the plasma membrane, providing the mechanical support and energy necessary to deform the membrane.

Biophysical and structural studies demonstrate that clathrin coats assemble with the same degree of curvature as coated vesicles. It has been proposed that localized clathrin-coat assembly can promote membrane deformation because of the intrinsic curvature of the clathrin coat. The constraint of the curved coat on the lipid bilayer might provide some of the force necessary to destabilize and pull the membrane inward. However, a recent thermodynamic model proposes that, instead of driving the curvature of the membrane, clathrin provides not the force but the mechanical support required to maintain an already curved membrane in that state. This thermodynamic model includes parameters that account for clathrin triskelion rigidity, intrinsic triskelion curvature, and free-energy changes resulting from interactions between triskelions. Integrating all these parameters predicts the size distribution of clathrin baskets or coats *in vitro*

and reveals that polymerized clathrin triskelion rigidity is not sufficient to surpass the bending resistance of the lipid bilayer. Thus, to bend the membrane to form a vesicle, other mechanical forces must cooperate with clathrin-coat formation to overcome membrane-bending resistance. In agreement with this idea, the same study demonstrates that the binding of adaptor proteins to the coat stabilizes the interaction between the triskelion subunits and increases their intrinsic curvature and rigidity.

Two models have been proposed to explain how adaptors promote membrane deformation. The first model proposes that endocytic adaptors with amphipathic helices promote the deformation of the plasma membrane by the physical penetration of the amphipathic helix into one leaflet of the membrane, whereas the second one suggests that adaptor proteins also facilitate membrane deformation by clustering at specific areas through interactions with PtdIns$_{(4,5)}$P$_2$ head groups, reaching concentrations high enough to provoke local destabilization and prompting membrane deformation.

Epsin seems to use the mechanism proposed by the amphipathic helix model. The simultaneous recruitment of epsin and polymerization of clathrin coats helps stabilize the deformed membrane. By contrast, the role of the AP180 ANTH domain in membrane deformation is less clear because the domain lacks an amphipathic helix to insert into the membrane. However, although no deformation of the membrane is observed on ANTH-domain binding, AP180 promotes the formation of uniformly sized clathrin-coated vesicles, resulting in a more homogeneous population than vesicles assembled by epsin alone, which might be essential for the regulation of the size of synaptic vesicles. It has been proposed that AP180 might control the size of the clathrin coat, which might be significant for processes dependent on vesicle size, such as synaptic vesicle formation. Thus, adaptors such as AP180 that do not intrinsically deform the membrane might act as proposed in the second model, in which protein clustering leads to membrane deformation. Perhaps both models are correct, and adaptors such as AP180 cooperate with membrane-deforming proteins such as epsin to stabilize the curved state of the membrane. The coordination of these two types of adaptors might guarantee the successful internalization of an endocytic vesicle with a minimal energy cost.

The membrane curvature and membrane bending that are needed at late stages of endocytosis might be mediated by yet another class of endocytic proteins that contain bin-amphiphysin-rvs (BAR) or F-BAR domains. These lipid-binding domains can either bind membranes with a preexisting curvature or assist in membrane bending through the insertion of an amphipathic helix into the hydrophobic layer.

Regulation of Clathrin Adaptors: Interactions and Functions

It is clear that clathrin adaptors play the most significant role in the formation of clathrin-coated pits and vesicles, which suggests they are the prime target for upstream regulation. There is evidence that posttranslational modification is used to regulate the activity and potential interactions of these proteins, allowing them to be controlled by upstream signaling pathways.

One of the most abundant forms of regulatory modification in eukaryotic cells is the phosphorylation of tyrosine, serine, and threonine residues. A relevant example is the phosphorylation of AP2 subunit $\mu 2$ by protein kinase AP2-associated kinase (AAK1). The phosphorylation of a single threonine residue within the lipid-binding domain of subunit $\mu 2$ has a profound effect on its ability to interact with PtdIns$_{(4,5)}$P$_2$ head groups, increasing its affinity over 100-fold. The additional negative charge introduced by phosphorylation is thought to cause a conformation change that alters the relative spacing of the cargo-binding and lipid-binding domains, allowing both sites to bind their respective ligands simultaneously, and leading to a stable complex at the membrane. Other adaptor proteins are negatively regulated by phosphorylation. For example, epsin phosphorylation prevents endocytosis, presumably because the additional negatively charged residue interferes with crucial interactions with the endocytic machinery.

As already stated, the ubiquitylation of cargo molecules can be important for the initiation of vesicle formation by epsin, but an additional complication is that such adaptors can also undergo ubiquitylation at a site distinct from their ubiquitin-binding domain (UBD). *In vitro*, it has been shown that the presence of a single ubiquitin moiety on epsin inhibits its ability to bind to accessory proteins and ubiquitinylated cargo, therefore reducing the efficiency of vesicle formation. It is possible that the ubiquitin moiety interacts with the UBD on the same protein and that this intramolecular binding outcompetes such interactions with other molecules, whereas the UBD on the nonubiquitinylated form of the protein is more likely to partake in intermolecular interactions.

Summary

Clathrin and clathrin adaptors are key molecules in the process of clathrin-mediated endocytosis, which is used for the specific uptake of large extracellular molecules

such as proteins, membrane-localized receptors, and ion channels. Clathrin has no affinity for the plasma membrane or any receptor molecules located therein, so the onus for initiating the formation of clathrin-coated pits lies firmly with the clathrin adaptors, multidomain proteins which simultaneously bind to membrane lipids, specific cargo proteins, clathrin itself, and other endocytosis accessory proteins to recruit all the endocytic machinery into a complex and initiate the process of clathrin polymerization which underlies vesicle formation. Many of the specific domains involved in the assembly of such complexes have been identified and functionally characterized. It is clear that the regulation of endocytosis is mediated in part by the posttranslational modification of clathrin adaptors, a process which directly influences their ability to interact with other components of the endocytic machinery.

Clock Gene Regulation of Endocrine Function

F W Turek, Northwestern University, Evanston, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

A major characteristic of the endocrine system is its high degree of temporal organization. Two of the most prominent temporal variations are those in the circadian range (i.e., about a day, 24 h) and in the ultradian range (e.g., 1–2 h). In addition, some secretory oscillations are also in the 5–20 min range, while others can occur over many days (e.g., estrous and menstrual cycling hormones) or over many months (e.g., seasonal rhythms in reproduction and metabolism). This article focuses on the circadian regulation of the endocrine system with an emphasis on the role of circadian clock genes in this regulation.

Circadian Control of the Endocrine System

It is now recognized that hormones in all the endocrine systems show 24 h fluctuations. For example, the hormones produced by the pituitary gland (e.g., adrenocorticotropic hormone or growth hormone) are synthesized and released to greater or lesser extents on a regular basis throughout the 24 h day. Similarly, hormones involved in energy regulation, such as leptin, insulin, and ghrelin, also show 24 h fluctuations in the bloodstream. These diurnal rhythms are regulated by an internal circadian clock that is entrained by daily environmental cues in the physical environment, primarily the 24 h light–dark cycle imposed on the earth due to the rotation on its axis.

The circadian control of endocrine fluctuations can be direct or indirect. That is, the master circadian clock located in the suprachiasmatic nucleus (SCN) of the hypothalamus in mammals can directly regulate the 24 h pattern of synthesis and release of a particular hormone. This is the case, for example, for the pineal hormone, melatonin, whose release into the bloodstream occurs during the nighttime in mammals and is under direct neural control via a multisynaptic input from the SCN to the pineal gland. Alternatively, the SCN may indirectly control components of, or even the entire, rhythmic 24 h pattern of the circulating levels of a given hormone by regulating a 24 h rhythm in behavior, which in turn may play a major role in the timing of a particular hormonal rhythm. For example, some hormones may be influenced in part by the sleep–wake state of the animal (e.g., growth hormone), or the 24 h rhythm in food intake (e.g., insulin), behavioral rhythms that for most animals are under the tight control of the circadian clock in the SCN. Whether direct or indirect, the SCN control of the 24 h rhythms in endocrine function ensures that the internal endocrine milieu maintains synchrony both within the organism and between the organism and the daily changes in the external physical environment.

Circadian Clock Genes and the Endocrine System

Remarkable progress was made in the last few years of the twentieth century in unraveling the genetic basis of the core molecular transcriptional/translational feedback loop that underlies the generation of circadian rhythms in mammals. While the discovery of the circadian clock genes, and the proteins that are encoded by these genes, has provided great insight into how all living organisms can actually keep track of time on a 24 h basis, their discovery had an interesting side effect. Once the clock genes were discovered and their expression patterns could be followed, a surprising finding was made: these genes were expressed not only in the central master circadian clock, the SCN, but also in most, if not all, the tissues of the body, both in the central nervous system (CNS) and in the periphery. Furthermore, these circadian clock genes were not just expressed in these non-SCN cells, but were also expressed on a circadian basis. Most surprisingly, when tissues were cultured *in vitro*, many (e.g., lung, muscle, liver, pancreas, and ovary) were found to be capable of expressing 24 h rhythms in a dish. In other words, circadian clocks were everywhere, and they were not just keeping time everywhere for themselves, but were actually regulating the timing of the expression of hundreds, if not thousands, of so-called clock-controlled genes (CCGs).

The finding of circadian clock genes in many endocrine tissues, including the pancreas, liver, fat, pituitary, ovary, testis, and adrenal gland, and their temporal regulation of the timing of hundreds of downstream CCGs, has profound implications for endocrine physiology and pathophysiology. The ubiquitous nature of the circadian molecular machinery in endocrine tissues raises the possibility that mistiming at the tissue or organ level could lead to dysfunction of that endocrine tissue/organ at a local level. Just as the molecular circadian clock in the SCN regulates all the endocrine, metabolic, and behavioral circadian rhythms in the whole organism, that same molecular circadian clock machinery is in turn regulating the internal timing within specific cells, tissues,

and organs at a local level. Any disruption of this circadian timing, at the organismal or local level, could in turn lead to dysfunction globally or within a particular endocrine system. Indeed, recent data from mice carrying a mutation of one of the canonical circadian clock genes, named *Clock*, demonstrate how a disruption of circadian clock gene function can have far-ranging effects on diverse endocrine tissues. The *Clock* gene was the first mammalian circadian gene to be identified, and its protein product is known to dimerize with another circadian gene, *Bmal* (also known as MOP3). Together these proteins act as a transcription factor to stimulate the production of two other sets of circadian genes, the period (*Per*) and chrytochrome (*Cry*) genes. The PER and CRY protein products are on the negative feedback loop of the molecular clock as they dimerize to inhibit the transcription of the *Clock* and *Bmal* genes. A mutation of the *Clock* gene leads to an extremely long circadian period (27–28 h) in homozygous *Clock* mutant animals maintained in constant darkness (DD), before leading to a state of arrhythmicity in many animals, that is, no expression of a circadian rhythm in DD. The *Clock* mutation also alters the expression of other circadian genes, particular the *Per* genes, as well as CCGs.

Given the important role played by the circadian clock in regulating rhythmicity in the endocrine system, one might expect that a mutation leading to an alteration in circadian rhythmicity at the molecular level would have important consequences for endocrine function. Indeed, the *Clock* mutant animals are obese, particularly on a high-fat diet, relative to littermate controls, and they show many symptoms in common with the metabolic syndrome in humans. In addition, leptin levels are elevated and hypothalamic peptides involved in energy regulation (e.g., orexin and cocaine-amphetamine-regulated transcript (CART)) show reduced levels of expression. Female *Clock* mutant mice show alterations in the timing of the luteinizing hormone (LH) surge and have irregularities in pregnancy and in the timing of birth, suggesting that the *Clock* mutation causes changes in function across a broad range of endocrine systems.

Circadian Clock Genes and Endocrine Pathophysiology

As noted previously, diurnal rhythmicity is observed in essentially all endocrine systems. For many of these systems, alterations in timing, changes in amplitude, and even the total absence of rhythmicity have been associated with a variety of endocrine, metabolic, and psychiatric disorders. For example, hypercortisolism and alterations in the low point in the cortisol rhythm have been associated with severe depression, while growth hormone levels are markedly suppressed in obese subjects. Aging itself is known to decrease the amplitude of many hormonal rhythms. However, the role that differences or changes in circadian clock gene function *per se* may play in changes in endocrine physiology remains unknown.

Soon after circadian clock genes were discovered in mice, the successful search for human orthologs of genes such as *Clock* and *Per* occurred. Much like the drunk man who looks for his lost keys under the lamppost at night because that is where there is light, initial inquiries as to whether different clock gene alleles were linked to specific circadian phenotypes have focused on looking for genetic linkage of clock gene alleles with two relatively well-characterized unusual circadian phenotypes, delayed sleep phase syndrome (DSPS) and advanced sleep phase syndrome (ASPS). In both DSPS and ASPS, the desired onset of sleep occurs unusually late or early, respectively, independent of environmental factors. Due to the difficulty in being able to accurately monitor endocrine rhythms, as opposed to an easily observable behavioral rhythm such as the sleep–wake cycle, we have much less information about 'circadian disorders' that may exist in endocrine systems that could be due to inherent differences in circadian clock genes. However, the recent demonstration that night eating syndrome (NES), in which a large percentage of daily caloric intake occurs in the evening and during the night, is most likely not a sleep disorder but instead is a disorder of time keeping, has led to the suggestion that NES may just be the tip of the iceberg: a temporal disorder we can easily see or observe that is internal in nature. In contrast, many other metabolic and endocrine temporal disorders that are due to altered circadian clock gene function may go unnoticed, since they are not readily observable and no one is looking for them.

There are two common situations in which humans 'voluntarily' desynchronize their circadian clock from the local light–dark cycle as well as other day–night environmental cues. One condition, commonly referred to as jet lag, occurs when humans move rapidly across time zones. The other occurs when humans work (or play) at a time they normally would be asleep and attempt to sleep when they normally would be awake: the phenomenon of shift work. Both conditions are associated with a variety of physical and performance deficits, as well as changes in metabolic and endocrine function. Intriguingly, some individuals are better able to cope with jet lag and shift work than others. Indeed, the *Diagnostic and Statistical Manual for Mental Disorders* (DSM-IV)

recently classified those individuals who are severely affected by shift work as having shift-work sleep disorder, to distinguish them from the majority of shift workers who, while being affected by circadian disruption and lack of sufficient sleep, are nevertheless able to cope with the shift-work schedule. Such differences between individuals may depend upon differences in circadian clock genes, clearly an area for future research.

Central Nervous System Organization of Mammalian Circadian Rhythms

The Clock Is Universal

The molecular architecture of the biological clock is universal in diverse organisms, including cyanobacteria, plants, flies, birds, and mammals. Clock genes are expressed in nearly all cells and give rise to cellular circadian rhythms. In mammals, pacemaker neurons in the suprachiasmatic nuclei (SCN) preside over peripheral tissue clocks and maintain temporal synchrony of internal systems to match the external 24 h light–dark (LD) cycle caused by the daily rotation of Earth. The length of the circadian period is a critical, genetically programmed metric of the endogenous clock (circadian comes from *circa diem*, about a day). Period length is also species-dependent; for instance, mice show a shorter and humans exhibit a longer internal period length than 24 h in constant darkness. However, all terrestrial species are entrained to the same external period when exposed to an LD cycle of 24 h.

Light: Zeitgeber and Photoreception

Light is the predominant Zeitgeber signal (time giver) that entrains the biological clock of the SCN. The SCN, in turn, maintains temporal synchrony between internal periodic cycles and the external environment that is thought to enhance overall organismal function and survival. For example, the daily peak in the secretion of glucocorticoid promotes cardiovascular tone during the transition from sleep to wakefulness, and a rise in growth hormone during the rest phase may contribute to metabolic homeostasis, for instance, by promoting hepatic gluconeogenesis.

A major advance in understanding how the SCN receives photic input came from the discovery of the melanopsin photoreceptor pathway by Provencio and colleagues in 2000. In mammals, retinal photoreceptors, which comprise rods, cones, and ganglion cells, receive both visual (sight) and nonvisual (light) information. The nonvisual response, called circadian photoreception, plays an important role in the light entrainment of the circadian system. The discovery of melanopsin, a novel opsin, opened a new window on the detailed mechanism of circadian photoreception. A subset of retinal ganglion cells was subsequently shown to express melanopsin, and genetic ablation of melanopsin reduced the locomotor activity response to light. Melanopsin-containing ganglion cells receive input from the rod–cone system and send neural projections to multiple central nervous system (CNS) regions, including the hypothalamus and thalamus. Retinal photoreceptors project to the SCN via the retinohypothalamic tract (RHT). Recent studies also suggest that melanopsin-containing neurons may also project to broad regions of neocortex and thereby provide direct light input into regions involved in alertness, attention, and arousal independently of the RHT input into the SCN.

Suprachiasmatic Nucleus: Integration of Metabolic and Circadian Signals

Overview In mammals, the SCN comprises a pair of nuclei that undergo 24 h periodic waves of depolarization that are initiated within the dorsal cell mass and followed by depolarization of the ventral cells. SCN lesioning experiments performed in the 1970s showed that the SCN is crucial for 24 h rhythms of locomotor activity, feeding, drinking, and sleep. Conclusive evidence that the SCN contains a master pacemaker came from experiments in the 1990s showing that transplantation of SCN from tau (short-period) mutant hamsters into SCN-lesioned wild-type hamsters resulted in a period length matching that of the donor SCN. However, SCN transplantation into SCN-ablated animals fails to restore 24 h rhythms of glucocorticoid and melatonin, suggesting that direct neural projections are necessary for the full activity of the SCN. Recent studies have also identified several molecules that may play a role in SCN outputs, including transforming growth factor (TGF-)α, prokineticin 2 (PK2), and arginine vasopressin (AVP). Both TGF-α and PK2 are highly expressed in the SCN during the subjective night and reduce locomotor activity when injected into the third cerebroventricle. Interestingly, the receptor for PK2 (PKR2) is widely expressed in CNS regions, including the dorsomedial hypothalamic nucleus (DMH) and lateral hypothalamic area (LHA), areas that are important for activity, feeding, and sleep regulation. Thus, both hard-wired neural networks and secreted signals are involved in the generation of neuroendocrine and behavioral rhythms.

Suprachiasmatic nucleus neural circuits Neural projections of the SCN are quite restricted, largely confined to areas in the hypothalamus and midline thalamus (Figure 1). The vast majority of projections

Figure 1 Neuroanatomy of pathways linking circadian and energy centers. Photic information received by retinal ganglion cells is transmitted to the CNS through the RHT, which terminates in retino-recipient cells in the SCN, the master pacemaker cell group. SCN cells then transduce photic information into neural or chemical signals which oscillate with a period of 24 h. The major targets of SCN projections are localized within two cell clusters of the medial hypothalamus, the subparaventricular zone (SPZ) and dorsomedial hypothalamus (DMH). The SPZ in turn innervates the medial preoptic area (MPOA) which plays an important role in both thermoregulation and reproductive function. The DMH projects to wide variety of nuclei involved in energy homeostasis (LHA), sleep (LHA and VLPO), and stress response (PVN). ARC, arcuate nucleus; CNS, central nervous system; DMH, dorsomedial hypothalamus; LHA, lateral hypothalamic area; MPOA, medial preoptic area; PVN, paraventricular nucleus; RHT, retinohypothalamic tract; SCN, suprachiasmatic nucleus; SPZ, subparaventricular zone; VLPO, ventrolateral preoptic nucleus.

from the SCN synapse on cells within the subdomain of two hypothalamic nuclei, localized to the subparaventricular zone (SPZ) and DMH. Axons from SPZ and DMH cell bodies, in turn, project to multiple CNS nuclei important in the regulation of behavior and endocrine function. A current model has proposed that the SPZ constitutes an intermediate relay station that amplifies and distributes signals from the SCN to other regions of brain. Indeed, lesioning studies have supported the hypothesis that the SPZ contributes to the regulation of daily rhythms of sleep, locomotor activity, and body temperature. In addition, DMH projections innervate the ventrolateral preoptic nucleus (VLPO) and LHA, two areas critical in sleep–wake regulation and energy balance. The DMH also projects to the paraventricular nucleus of the hypothalamus (PVN), which plays an important role in the hypothalamic–pituitary–adrenal axis stress response and autonomic tone. Because the DMH receives input from perikarya of the arcuate nucleus (ARC), it is conceivable that both DMH and SPZ may integrate energy and circadian systems.

In addition to preformed neural networks, recent studies indicate that intercellular communication is subject to highly dynamic changes involving synaptogenesis. Such synaptic changes may play an important role in generating daily rhythms of feeding behavior and in coordinating these processes with the 24 h sleep–wake cycles. For example, cells in the hypothalamus that express neuropeptide Y (NPY), agouti-related peptide (AGRP), cocaine- and amphetamine-related transcript (CART), and proopiomelanocortin (POMC) undergo marked changes in synaptic plasticity following an overnight fast and in response to leptin. Horvath and coworkers proposed that orexigenic (i.e., NYP/AGRP) neurons and anorexigenic (i.e., POMC/CART) neurons are reciprocally dominated by either inhibitory or stimulatory inputs that vary across the LD cycle.

Thus, it is also conceivable that daily synaptic rearrangement may impact the diurnal rhythms of neuropeptide gene expression, providing an additional link between circadian and metabolic homeostasis.

Neuroendocrine signals influence the suprachiasmatic nucleus clock Several lines of evidence indicate that the SCN also integrates metabolic signals from both CNS and peripheral tissues. First, neural projections into the SCN originate in several nuclei important in sleep and energy balance such as the raphe and hypothalamus. Second, SCN neurons express receptors for key hormones important in energy balance, including those for leptin. Third, leptin affects the phase of SCN oscillations. Fourth, many genes shown to oscillate in the SCN are involved in intermediary metabolism and energy balance. Thus, the SCN itself may play an important role in integrating environmental and metabolic information.

The Molecular Clock in Neural and Peripheral Metabolic Cells

The Discovery of Mammalian Clock Genes

The discovery of the molecular underpinnings of the circadian system has been a triumph of forward genetics (phenotype to gene) and recently provided further clues concerning interconnections between the circadian and metabolic systems. The molecular clock within the cell was first identified in the fruit fly *Drosophila melanogaster* and in the fungus *Neurospora*. Specifically, chemical mutagens were used to introduce mutations into the genomes of the fly and fungus, and circadian phenotypes were analyzed so researchers could then map and positionally clone the responsible genes. This mutagenesis approach led to the identification of the first clock mutations, *Period* (*Per*) and *Frequency*, in the 1980s. A similar mutagenesis approach was applied to the search for the clock genes in mammals in the early 1990s, resulting in the discovery in 1994 of the first mammalian clock gene, *Clock* (*circadian locomotor output cycles kaput*). The protein encoded by the *Clock* gene belongs to the superfamily of the basic helix–loop–helix (bHLH)-PAS (*Period-Arnt-Single-minded*) transcription factors that are conserved from flies to mammals. Recognition that bHLH-PAS domain proteins function as heterodimers provided the rationale for a two-hybrid screen that identified BMAL1 (or MOP3) as the major partner of CLOCK. CLOCK and BMAL1 heterodimerize in the cytoplasm and translocate to the nucleus to activate transcription from target genes containing an E-box enhancer element (Figure 2).

In addition to these transcriptional activators, the search for mammalian orthologs of the *Drosophila Per* gene led to the discovery of the mammalian *Per* genes (*Per1*, *Per2*, and *Per3*), paralogous members of the PAS protein family. The CLOCK–BMAL1 heterodimer was subsequently shown to activate *Per* gene expression through binding to the M34 E-box element in the *Per* promoter. PER proteins and cryptochromes (CRY1 and CRY2), members of the vitamin B_2-based blue-light photoreceptor/photolyase family, form a heteromultimeric complex that translocates to the nucleus to inhibit binding activity of the CLOCK–BMAL1 heterodimer. Thus, transcriptional activators and repressors form a feedback loop that generates 24 h cycles of gene transcription.

Metabolic Transcription Factors Participate in the Circadian Oscillator

Following the discovery of CLOCK, BMAL1, PER, and CRY proteins, subsequent analyses have revealed that several metabolic transcription factors also participate in generating circadian rhythms. The best characterized of these are REV-ERBα and the retinoic acid receptor-related orphan receptor α (RORα). REV-ERBα inhibits and RORα stimulates the transcription of the *Bmal1* gene by activating ROR elements (RORE) in the *Bmal1* promoter. A peak of *Rev-erbα* transcription occurs early to mid-circadian day and is antiphasic to the *Bmal1* peak, whereas *Rorα* does not oscillate. Hence, the circadian oscillation of *Bmal1* transcription is mediated by the reciprocal activities of REV-ERBα and RORα. In addition, transcription of the *Rev-erbα* and *Rorα* genes is also induced by CLOCK–BMAL1. Interestingly, both *Rev-erbα* and *Rorα* gene transcription increase during adipogenesis. Although interactions among REV-ERBα, RORα, and BMAL1 have been established, how these proteins might coordinate metabolic and circadian processes remains uncertain.

In addition to control at the transcriptional level, posttranslational modification also plays an important role in clock function. For example, several kinases, including casein kinase I epsilon (CKIε) (in mice) and CKII (in flies) have been shown to participate in the regulation of PER phosphorylation. Phosphorylation of PER is thought to trigger the translocation of the PER protein into the nucleus, where it then inhibits the CLOCK–BMAL1 heterodimer. In addition, glycogen synthase kinase 3 (GSK3), a central molecule in carbohydrate metabolism, has been shown to phosphorylate and stabilize REV-ERBα. Together, mounting evidence indicates that transcriptional and posttranslational modification of clock genes involves

Figure 2 Overlapping gene network regulating the circadian and metabolic systems. The prevailing model illustrating the core autoregulatory feedback loop of the clock consists of transcriptional activators, CLOCK and BMAL1, and repressors, PER and CRY. The CLOCK–BMAL1 heterodimer activates the transcription of *Per* and *Cry* through the E-box enhancer element in their promoters. The PER and CRY proteins multimerize and translocate into the nucleus to inhibit the transcriptional activity of the CLOCK–BMAL1 heterodimer, resulting in reduced expression of the *Per* and *Cry* genes. Several metabolic transcriptional factors that have been shown to interact with clock genes are also illustrated. Particularly important transcription factors regulating both circadian and metabolic systems are REV-ERBα and RORα, which are both induced during adipogenesis. Transcription of these metabolic genes is also activated by CLOCK–BMAL1 through binding to the E-box element in their promoters. REV-ERBα and RORα reciprocally regulate *Bmal1* transcription through the RORE motif in the *Bmal1* promoter; interestingly, REV-ERBα inhibits and RORα stimulates *Bmal1* transcription. PPARα, a nuclear hormone receptor which regulates lipid catabolism, has also been shown to interact with BMAL1. Transcription of *Pparα* is activated by the CLOCK–BMAL1 heterodimer. Conversely, PPARα activates *Bmal1* expression through the PPRE in the *Bmal1* promoter. DBP is illustrated because it is among the best-characterized transcriptional outputs of the core clock pathway in liver cells that is directly linked to both sterol and glucose metabolism.

molecules previously known to mediate glucose and lipid metabolism, suggesting extensive molecular links between the circadian and metabolic pathways.

Clock Genes in Extra-Suprachiasmatic Nucleus Neurons and Peripheral Tissues

A remarkable series of studies by Schibler and colleagues first showed that circadian clock genes are expressed cell-autonomously in peripheral tissues (fibroblasts) and can be reentrained to a 24 h period by serum shock alone. Subsequent *in vivo* studies in transgenic and knockin mice expressing the bioluminescent reporter luciferase as a fusion to the PER protein established the ubiquity of peripheral clock gene expression. Studies using these and other models also showed that clock genes are expressed and function in extra-SCN regions of brain, including the ARC. Collectively, these findings have led to the prevailing model that places the SCN at the top of a neural hierarchy that maintains synchrony between the external environment and multiple behavioral and physiological processes (Figure 3).

Food Entrainment of the Clock

Studies of the anatomy and molecular machinery of the clock also opened a window on the co-regulation of feeding and circadian rhythmicity. In particular, the vexing question of how food and feeding affect the clock has continued to stimulate intensive investigation. A food-entrainable oscillator (FEO) is thought to reside outside of the SCN because SCN-lesioned animals still display an anticipatory burst of activity when food is presented during the subjective night. Yet the anatomic and molecular basis for this

Figure 3 Model of the organization of circadian and metabolic systems. The molecular clock machinery in the suprachiasmatic nucleus (SCN) encodes the master neural pacemaker that is entrained to the daily light–dark cycle. The SCN in turn generates neural and endocrine circadian rhythms and synchronizes the clock machinery in peripheral tissues, as well as in extra-SCN neurons. Processes ranging from glucose and lipid metabolism in liver and adipose tissue to glucocorticoid secretion from the adrenal gland have been shown to be entrained to the SCN; however, each tissue also expresses the full repertoire of clock genes, and in each cell type the outputs of the clock network probably exert distinct physiological effects.

behavioral adaptation to food is still an area of active research. Saper and colleagues reported that DMH-ablated animals show dampened food anticipatory activity (FAA), suggesting that the DMH might contain the FEO. Further focus on the DMH also came from Yanagisawa and colleagues, who showed robust *Per2* oscillation within this location, suggesting a role for the DMH cell cluster in food entrainment. Interestingly, *Per2* mutant mice fail to respond to food entrainment. In contrast, *Clock* mutant mice have persistent FAA, perhaps suggesting differential effects of CLOCK versus PER2 on food-related activity. It is possible that the CLOCK paralog, neuronal PAS domain protein 2 (NPAS2), may compensate for CLOCK and preserve food entrainment in the *Clock* mutant mouse. Additional studies using both genetic models and anatomic approaches promise to increase our understanding of the nature, mechanism, and function of food-entrainable behavior.

Circadian, Sleep, and Metabolic Disorders in Humans

The aforementioned research on the molecular clock and neural clock circuits has also provided an important framework for emerging studies investigating the links between sleep, circadian disruption, diabetes mellitus, and obesity. Here we provide a brief overview of this line of research, highlighting findings that may offer insight into the pathophysiology of metabolic disorders.

Epidemiology of Sleep and Metabolic Disorders

The first series of studies to hint at connections between sleep and obesity came from observational reports on the association between sleep time and body mass index (BMI). Indeed, reduced sleep is a common behavioral perturbation associated with industrialization, the spread of artificial light, increased shift work, and jet lag. Recent studies also showed a correlation between sleep loss and the development of metabolic disorders. Although the precise molecular mechanisms remain unknown, a striking and consistent finding has been the connection between shift work and a propensity for metabolic syndrome in human subjects. In particular, shift work is associated with increased risk of impaired glucose tolerance, hyperinsulinemia, elevated leptin levels, hypertension, and dyslipidemia, all hallmarks of metabolic syndrome. This epidemiological evidence raises the question of whether circadian misalignment may be an etiological factor in abnormalities of glucose and lipid metabolism.

Clinical studies also uncovered a connection among circadian behavioral alterations, sleep, and obesity. One intriguing example is the night-eating syndrome, characterized by the constellation of fragmented sleep

with night-time binge eating. Although the cause of night-eating syndrome remains poorly understood, clinical studies in patients with the disorder have consistently revealed abnormalities in the circadian phase of food intake, often accompanied by obesity. Advanced sleep-phase syndrome (ASPS) is another human circadian disorder that gives rise to changes in sleep. Recently, a missense mutation in the human *Per2* gene was identified in subjects with ASPS. Interestingly, in the delayed sleep-phase syndrome (DSPS), subjects fall asleep and awake at a later time each day. DSPS has been associated with polymorphisms that may alter PER3 phosphorylation. Although still an uncharted area, the discovery of the molecular bases for both ASPS and DSPS now provides a new opportunity for researchers to examine the relationship between circadian gene disorders and metabolism in man.

Narcolepsy and Energy Balance

An additional intriguing link between sleep and energy regulation has emerged from studies of canine narcolepsy and the orexin system in the laboratories of Mignot, Yanagisawa, and Sutcliffe. Orexin is a neuropeptide produced by cells within the LHA and posterior hypothalamus that was originally identified by cDNA cloning of transcripts enriched in this region. The function of orexin was initially thought to involve the regulation of feeding behavior. Surprisingly, positional cloning revealed that mutations in the receptor for orexin give rise to canine narcolepsy. These findings raise the intriguing possibility that orexin may link the regulation of ingestive behavior with control of the sleep–wake state. In support of this hypothesis, Mignot showed that orexin levels in the cerebrospinal fluid of human narcoleptic subjects correlate with BMI. Genetic and pharmacological studies in experimental models have also provided evidence for a role of orexin in alertness, food intake, and energy expenditure. Furthermore, recent neural tracing studies uncovered projections from SCN neurons to orexin-producing cell bodies. Thus, a convergence of clinical, genetic, molecular, and pharmacological analyses points toward a key role for orexin in the neural integration of appetite, body weight, and sleep.

Molecular Interconnection between the Circadian and Metabolic Systems

Role of Cellular Redox State and Chromatin Remodeling in Clock Gene Transcription

Advances from several laboratories have also begun to identify nodal points through which molecular networks involved in both metabolism and circadian rhythms may communicate. Emerging research on nicotinamide adenine dinucleotide cofactors represents an important area of progress. One compelling hypothesis stems from the observations of McKnight and colleagues that demonstrated a link between cellular redox and the transcriptional activity of both the CLOCK–BMAL1 and NPAS2–BMAL1 heterodimers. Specifically, the reduced forms of the nicotinamide adenine dinucleotide cofactors (NAD(H) and NADP(H)) enhance DNA-binding of CLOCK–BMAL1 and NPAS2–BMAL1. Because the ratio of oxidized-to-reduced NAD and NADP cofactors is related to levels of glycolysis and pentose metabolism, these cofactors may act as sensors that couple circadian and metabolic processes.

Another intriguing candidate pathway linking circadian and metabolic processes has emerged from innovative work on chromatin remodeling. Specifically, recent findings suggest that CLOCK possesses histone acetyltransferase (HAT) activity and that chromatin remodeling is important in sustaining oscillations of gene transcription. Because NAD also plays a pivotal role in transcriptional silencing by histone deacetylases, chromatin remodeling may constitute an additional mechanism for metabolic and circadian communication. Together, these observations highlight a potential broad role for NAD cofactor oxidation and chromatin remodeling in the interconnection between behavioral and metabolic outputs of the clock.

Insight from Experimental Genetic Models into Links between Circadian and Metabolic Systems

In the past few years, genetic models in mice have begun to uncover an important role of clock genes in glucose and lipid metabolism *in vivo*. The findings that animals harboring a mutation in the *Clock* gene are hyperphagic and obese first demonstrated that clock genes are necessary for the maintenance of energy balance. As already reviewed, BMAL1 has also been shown to directly affect nuclear hormone receptors important in lipid catabolism and lipogenesis. However, important questions remain concerning whether the genetic disruption of clock genes alters metabolic regulation through direct effects or through mechanisms secondary to the (circadian) behavioral changes in these model animals. Interestingly, within the brain, RNA expression is affected by both circadian time and by the behavioral state of the animal (i.e., sleep and wakefulness). In addition, metabolic genes involved in hepatic lipid metabolism display broad circadian-dependent patterns of expression, and the expression of hepatic RNAs can be shifted by scheduled feeding. In the mediobasal

hypothalami of *Clock* mutant mice, an area outside of the SCN, extensive changes occur in the expression of both core clock genes and genes encoding neuropeptides that regulate organismal energy balance. Thus, an exciting area of investigation involves the elucidation of the role of clock gene expression within extra-SCN neural circuits. Finally, a fascinating yet unanswered question is whether perturbation of metabolic signaling pathways might cause reciprocal changes in clock gene expression.

Future Questions

Studies of the link between circadian and metabolic processes offer an exciting opportunity for us to delve into molecular mechanisms controlling both behavior and energy balance. Significantly, the discovery of clock genes has established the details of the molecular control of circadian rhythms that were previously invisible. Many investigators are now poised to merge analyses at the physiological, molecular, and genetic levels to further dissect the molecular and neural bases for disorders of timing, sleep, diabetes mellitus, and obesity.

Cochlear Development

The Structure of the Cochlea

The inner ears lie deep in the temporal bones on either side of the hindbrain (Figure 1). In the mammalian inner ear, the ventral portion of the inner ear forms the spiraling cochlea. Everything about the cochlea and the structures within it varies longitudinally from its wide basal turn to its narrow apical turn. Chamber dimensions, epithelial width and thickness, cell numbers, cell dimensions, and innervation patterns all vary systematically along the axis that correlates with frequency selectivity from high frequency (located at the base) to low (located at the apex). For example, the basilar membrane is narrower and stiffer at the base compared to the apex. The cochlea is somewhat analogous to a bicycle wheel comprised of an inner tube surrounded by a tire; only both tube and tire are filled with fluid rather than air, and the structure is spiral rather than truly circular. The 'tire' rests upon the spiral ganglion (the rim of wheel). The axons of the ganglion neurons radiate inward (the spokes of the wheel), gather together (at the hub) to project to the brain as the auditory nerve. The innertube is called scala media and it is filled with a fluid of unusual ionic composition called endolymph. Endolymph is high in potassium and low in sodium. In cross section, scala media looks triangular (Figure 1). One side of the triangle is formed by Reissner's membrane, a thin two-layered epithelial sheet. It is flanked on one side by scala media and on the other side by another fluid-filled chamber, scala vestibuli. The fluid within scala vestibuli is the perilymph. It is typical of normal extracellular fluid, being high in sodium and low in potassium. When viewed in cross section, the basilar membrane forms a suspension bridge across the posterior side of the triangle. This tough elastic matrix supports the organ of Corti, which is a thin, ribbon-shaped tissue that contains mechanosensory hair cells. The apical surfaces of the hair cells are each adorned with a stereociliary bundle that faces scala media. Both the basilar membrane and its passenger, the organ of Corti, are displaced by fluid pressure changes in the cochlea. The opposite side of the basilar membrane contains fibroblasts and blood vessels, and it faces a perilymph-filled chamber called scala tympani. The third side of the triangle is plastered up against the outer wall of the cochlea: it contains a complex tissue called the stria vascularis which is notable for its essential role in endolymph secretion.

The Embryonic Origins of the Cochlea

The epithelial cells lining scala media all share a common embryonic origin in the ectoderm of the otic placode. This includes the hair cell mechanoreceptors, their supporting cells, the apical layer of the stria vascularis, the innermost layer of Reissner's membrane, and the other nonsensory epithelial cells that connect these structures. Together this epithelial sheet tightly seals and ionically isolates the endolymphic fluid by means of junctional connections. The neurons of the auditory (spiral) ganglion also derive from the otic placode, having migrated away from the otic ectoderm very early in embryogenesis. Nearly all of the other soft tissue components housed within the cochlea are of mesenchymal origin, with the exception of neural-crest derivatives that will become melanocytes of the stria vascularis and glial cells of the auditory nerve and ganglion. The entire membranous labyrinth is surrounded by the otic capsule which begins as cartilage but is gradually replaced by bone; both the cartilage and the bone are of mesenchymal origin. The development of both the perilymph chambers and the otic capsule are strongly influenced by factors released from the placode-derived epithelial core, which arises earlier in embryogenesis. Because considerably more is known about the molecular basis of scala media development as compared to the structures around it, these otic-placode-derived cells will be the focus of this article.

Otic Induction

The otic placode is a thickened ectodermal patch located adjacent to the dorsolateral hindbrain and above the branchial arches. Over the course of 1–2 days in the mouse, the otic placode dips into the mesenchyme, forming a cup. The rim of the otic cup constricts, eventually pinching off from the overlying ectoderm to release the otic vesicle into the tissue below. The otic vesicle then begins an extended process of growth and shape changes, called morphogenesis (Figure 2). Not only does it give rise to the cochlea and the neurons of the auditory (spiral) ganglion, but it also forms inner ear vestibular structures including the utricle, the saccule, the semicircular canals, and the vestibular ganglion.

Figure 1 Gross anatomy and histology of the developing cochlea. (Top) The fluid compartment of the mouse inner ear was filled with opaque paint solution at embryonic day 16 and photographed *in situ*. The brain was removed to provide better contrast, and the image was photographically reversed. (Bottom) Histological section through a newborn mouse cochlea immunolabeled for integrin alpha6 (dark brown). This labels axons of the auditory nerve and a subset of epithelial cells lining scala media. Cross sections through the spiraling cochlea are numbered 1–5 from the basal to the apical ends. At this age, the apical turn is less well developed than more basal turns, due to the basal-to-apical gradient of differentiation. Throughout the cochlea, the greater epithelial ridge cells located next to the organ of Corti have not yet undergone programmed cell death, so the epithelium is thicker than in the mature cochlea. Histological artifacts have caused a collapse of Reissner's membrane onto the organ of Corti in some of the cochlear turns. BM, basilar membrane; GER, greater epithelial ridge; RM, Reissner's membrane. (Top) Photograph courtesy of John Brigande (Oregon Health Sciences University). (Bottom) Image generously provided by Donna Whitlon (Northwestern University).

In mammals, the otic placode arises at the level of rhombomeres 5 and 6 and depends upon hindbrain-derived signals for its induction. The endoderm and mesenchyme located beneath the otic placode are also essential for otic induction. Fibroblast growth factors (Fgfs) arising from all three of these tissues convert general preplacode ectoderm to a pre-otic fate. The pre-otic state can be recognized by the expression of the transcription factor, Pax2. Pax2-expressing cells are dispersed within and beyond the otic field, and gradually many of these cells gather together to form the otic placode. The otic state is stabilized by exposure to Wnt ligands. In mice, these essential otic-inducing factors arise sequentially from several different tissue sources. Fgf8 is released from the endoderm, causing the subotic mesenchyme to secrete

Figure 2 Origin and morphogenesis of the embryonic mouse cochlea. The otic placode originates adjacent to rhombomeres 5 and 6 and deepens to form the otic cup. The hindbrain and notochord generate sources of Wnts and Sonic hedgehog (Shh) that give the inner ear dorsal–ventral polarity. The ventral floor of the otic cup is a neurosensory domain which generates both neuroblasts (yellow) that colonize the statoacoustic ganglion and sensory primordia (pink). The stages of cochlear morphogenesis are shown schematically for the medial half of the otocyst which is portrayed as though it was sectioned in half along the parasagittal plane. cd, cochlear duct; ed, endolymphatic duct; ac, anterior crista; nc, notochord; oC, organ of Corti; pc, posterior crista; r, rhombomere; sag, statoacoustic ganglion; sg, spiral ganglion; sm, saccular macula; um, utricular macula; vg, vestibular ganglion. Staging of the mouse ear is based on the work of Morsli H, Choo D, Ryan A, Johnson R, and Wu DK (1998) Development of the mouse inner ear and origin of its sensory organs. *Journal of Neuroscience* 18: 3327–3335.

Fgf10. Fgf10 then signals to the hindbrain, directing it to secrete both Fgf3 and Wnts. In mice, otic induction is thought to require a combination of mesenchymal Fgf10, neural Fgf3, and neural Wnts, all acting directly on the placodal ectoderm. A direct role for Fgf8 on otic placode is more difficult to ascertain since it is expressed by a number of embryonic tissues, including the otic placode itself.

Axial Polarity and Patterning of the Cochlea

Otic vesicle formation occurs somewhat late relative to the appearance of other embryonic structures, such as the neural tube and the notochord. As a result, the otic ectoderm is poised to use signals arising from these surrounding structures not only for its induction, but also for subsequent patterning. Otic patterning begins at the otic cup stage and is evidenced by asymmetries in gene expression.

The neurogenic portion of the otocyst is located on its ventral–anterior floor (Figure 2). It can be recognized in the mouse by expresson of neurogenin-1 (Ngn1), a gene required for specification of neuroblasts of the otic placode as well as several other neurogenic placodes in the head. Neuroblasts leave the Ngn1 domain from its anterior pole, delaminate from the epithelium into the underlying mesoderm, and migrate medially to colonize both the auditory and vestibular ganglia.

The cochlear duct elongates from the ventral otocyst. The dorsal–ventral (D–V) axis of the duct will come to represent the basal–apical axis of the cochlea. The major tissue types lining the cochlear duct (the organ of Corti, Reissner's membrane, and the stria vascularis) appear to originate from specific positions along its circumference. The primordia for each tissue may be marked by the expression of different combinations of genes as early as E11.5 as discussed below, although this needs to be confirmed by fate mapping. Nonetheless, it is likely that the establishment of anterior–posterior (A–P) and medial–lateral (M–L) axial polarity at the otocyst stage will be related to the specification of cochlear tissue types. Furthermore, D–V axial polarity could underlie the appearance of molecular and structural gradients that mediate frequency selectivity along the basal–apical axis of the mature cochlea.

The regulation of otocyst D–V polarity is best understood in molecular terms. Signals are secreted from the hindbrain and possibly the notochord to influence D–V polarity. Mouse mutants and experimental manipulations of chicken embryos both reveal that Wnts can dorsalize the otocyst while sonic hedgehog (Shh) can ventralize otocyst. Since the cochlea arises ventrally, it has a special need for Shh (Figure 2). The stage of fixation of an otic axis is defined as the earliest time when rotation of the otic vesicle with respect to its surroundings no longer regulates to form an ear of normal orientation.

These experiments have been done in chickens, where there is an elongated cochlear duct that does not spiral. Results show that a cochlea often projects ventrally from a D–V reversed otocyst, indicating that the D–V axis was not fixed at the time of rotation and can be respecified by the surrounding environment if the manipulation is performed before cochlear morphogenesis begins.

There is good evidence that M–L polarity is also under the influence of the hindbrain. Mutations that reduce hindbrain Fgf3 levels are associated with severely underdeveloped otic vesicles. Fgf3 is high in rhombomeres 5 and 6 located adjacent to the otocyst. Retinoic acid, which is enriched in the hindbrain, is also essential for otic development, although it is difficult to distinguish its direct versus indirect effects on the otic ectoderm. For example, retinoic acid can influence rhombomere identity via its effects on Hox genes, and this could indirectly affect the ear by changing the levels of Fgf3 released from the hindbrain. More direct effects of hindbrain-derived retinoic acid are also possible, particularly since retinoic acid receptors are present in the otic ectoderm. Both changes in retinoid signaling and defects in hindbrain rhombomere identity can alter the normal M–L asymmetries in gene expression in the otocyst. Rotations of the otocyst that reverse the M–L axis in chickens generate cochlear ducts in their normal location, but generally the auditory sensory organ fails to differentiate.

The polarity of the third otic axis, anterior–posterior (A–P), is the least understood in terms of molecular signals. This axis is the first of the three to be fixed in the chicken otocyst. Surprisingly, though, the relevant signals do not appear to originate from the hindbrain, as evidenced by failure of hindbrain A–P rotations to reverse the A–P axis of the otocyst even when performed prior to the stage of fixation. Nonetheless, the environment does influence the direction of cochlear outgrowth, since even in A–P reversed ears where the cochlea originates from an abnormally anterior location, the sickle-shaped cochlear duct of the chicken assumes its normal arch in a ventral–medial direction. Presumably, these signals must arise from the mesenchyme surrounding the ventral otocyst.

In summary, signals from surrounding tissues influence otocyst polarity. The requirement for some of these signals, such as Shh, is maintained for an extended period to complete the task of ventralizing the part of the otocyst that generates the cochlea. There are no data yet regarding whether a ventral-to-dorsal gradient in the concentration of Shh protein may underlie the tonotopic organization of the organ of Corti that will later be arrayed along the same axis.

Morphogenesis of the Cochlea

The cochlear duct arises as a tubular outgrowth from the ventral otocyst. It is flattened somewhat along its medial–lateral dimension. As the duct elongates, it makes a sharp anterior turn to run nearly parallel to the A–P axis in mice. Then, the tip of the duct loops upward (dorsally), and laterally to generate the first coil (**Figure 2**). In the mouse, the cochlea stops elongating after 1.75 coils, while other mammals make 1.5–4 coils. The human cochlea coils 2.5 times. Virtually nothing is known about the cellular or molecular basis of cochlear coiling. However, there is some progress on the mechanism of cochlear elongation. At first glance, one might expect such directed outgrowth to be primarily based on cellular proliferation, and certainly this is important. Cell divisions continue throughout the period of duct elongation, at least in nonsensory regions.

In addition to control of cell numbers, it is also theoretically possible to regulate the overall dimensions of an epithelial tube such as the cochlear duct through oriented cell divisions, directed cell movements, and cell shape changes at the level of individual cells. Such mechanisms require that the cells sense the overall polarity of the epithelial sheet in which they reside and orient in response to it through a process known as planar cell polarity (PCP). Indeed, elongation of the cochlea shares a molecular PCP program in common with the elongation of the A–P axis of vertebrate body during gastrulation and neural tube closure. At the cellular level, the morphogenetic processes of gastrulation utilize a choreographed intercalation of cells called convergence-extension that serves to narrow and elongate an epithelial sheet. In zebra fish, oriented cell divisions, whereby the mitotic spindle is aligned with the elongating A–P axis, also drive axis elongation during gastrulation and are regulated by components of a Wnt–PCP pathway.

In the cochlea, data at the resolution of individual cells are lacking, but by analogy to the gastrula, the prediction is that cells will converge along a 'medial–lateral' axis running across the width of the duct and/or they will divide orthogonally to this along the apical–basal axis. Convergence-extension would serve both to narrow a strip of epithelium along the axis of directed cell movement and to lengthen it along the apical–basal dimension (**Figure 3**). Extension of the sensory primordium progresses for several days after the cells have stopped dividing and thus oriented cell divisions cannot explain its lengthening. However, this mechanism could be active in the flanking nonsensory regions, since they remain mitotically active during elongation.

Figure 3 Convergence-extension of the cochlear duct and lateral inhibition of hair cells. A schematic surface view of the development of a strip of the organ of Corti from epithelial cells on the medial side of the inner hair cell row to the first row of outer hair cells. Elongation of the cochlear sensory epithelium in the apical direction could result from directed medial–lateral convergence and intercalation of cells, leading to a longer and thinner shape as shown. Thinning of the cochlear epithelium in the third dimension, within the plane of the paper, involves radial intercalation (not shown) that could also squeeze the cells in the apical dimension; this thinning begins at E14.5, when the duct has already completed approximately one full turn. The polarized localization of hypothetical PCP proteins, shown in blue and red, could provide the cells with directional cues both for medial–lateral convergence underlying cochlear elongation and for polarizing the hair bundle. This may explain why both processes are defective in PCP mutants. Differentiated hair cells are always separated from each other by supporting cells, and this mosaic arrangement probably involves a lateral inhibitory mechanism mediated by Notch signaling. Both the kinocilium and the localized expression of PCP proteins will disappear with maturation of the bundle (see **Figure 5**). IHC, inner hair cell; OHC, outer hair cell.

A second organized cell movement, that of radial intercalation, has been proposed to underlie elongation of the sensory epithelium. During cochlear outgrowth, the sensory primordium reduces from a thickness of several cells to only two cells on average. The cells are presumed to be squeezed apically as a result of these cell rearrangements.

Evidently apical elongation of the cochlea is not simply a question of growth in the direction of least resistance because only apically directed elongation is observed when a section of embryonic mouse cochlea is isolated in culture, even though both ends should be free to elongate under these conditions.

Several mutant strains of mice show shorter and wider cochlear ducts that are found together with defects in neural tube closure. Examples include Dishevelled 1 and 2 double-knockout mice (Dvl DKO) and looptail mutant mice (defective in the Ltap gene). These genes are active in the PCP pathway. In PCP mutants, cochlear outgrowth is stunted even though radial thinning progresses on schedule, leaving medial–lateral intercalation and oriented cell divisions as potential mechanisms that are affected by the mutations.

Some proteins in the PCP pathway have been shown to be asymmetrically organized in individual cochlear cells along the axis of convergence as would be expected if they are endowing the cells with directional sensitivity. However, it is unclear if the timing of this asymmetry is early enough to account for polarized extension of the cochlear duct. Asymmetry in protein localization is usually not detected until E18.5 in the mouse organ of Corti, at which point the cochlea has already completed 1.75 turns. By this age, PCP mutant mice already have shorter and wider cochlear ducts. Interestingly, the direction of medial–lateral cell intercalation is also the primary axis of polarity for hair cell bundles. The same PCP genes that regulate cochlear elongation also affect hair bundle orientation, as discussed later.

What initiates cochlear duct outgrowth? The process fails entirely in knockout mice that lack Eya1,

Six1, Gata3, and Tbx1, genes that are expressed very early in the otic ectoderm and, in the case of Tbx1 and Six1, also in periotic mesenchyme. In Tbx1 and Gata3 mutants, early axial polarity and initial regional specification appear unaffected because generation of the endolymphatic duct, cochleovestibular ganglion, and some sensory specification is observed. Instead, it is the morphogenetic process that fails. In Tbx1 nulls, this may be because the normal boundaries between gene expression compartments break down. In Gata3 nulls, the otocyst separates into dorsal (endolymphatic) and ventral (neurosensory) halves, apparently in response to disruptions in dorsal–ventral gene expression and cell adhesion molecules. The ganglion cells delaminate but fail to express Fgf10 and there is progressive loss of the spiral ganglion. In Eya1 and Six1 nulls, the otocyst itself fails to progress beyond the cystic stage, the otic ganglion is missing, and there is increased cell death. The expansion of dorsal genes into the ventral otocyst in Six1 nulls may explain the failure to develop ventral structures such as the cochlea and the ganglion, although there is also extensive cell death in the early otocyst. Six1 expression depends upon Eya1.

Cases where the cochlear duct is present but abnormal suggest perturbations at later stages. Defects in cochlear length or coiling occur in knockouts of several transcription factors that are expressed in the otic ectoderm, including Pax2, Ngn1, Otx1, Otx2, and a weak allele of Eya1 (Eya1-bor). Of these, Pax2 has the most severe phenotype. It is probable that these genes act cell autonomously in the normal animal. A frameshift mutation in Pax2 underlies a syndromic form of human deafness, coloboma syndrome. Even when the cochlear duct is severely misshapen, considerable specification of different cell and tissue types can occur. For example, neuroblasts, sensory cells, and adjacent nonsensory cell types arise in the Pax2 null mouse but then show later defects in survival (neuroblasts) or spatial patterning. Pax2 requires Shh to maintain its expression in the developing cochlear duct. In contrast to Pax2, the shortened cochlea in Brn4 nulls is probably an indirect effect since this transcription factor is normally expressed in the periotic mesenchyme at the time of duct outgrowth.

Specification of Tissue Types

The major tissues of the cochlear duct derived from the otocyst are the organ of Corti, the stria vascularis, and Reissner's membrane. Figure 4 shows schematically the origins and some gene expression patterns that precede specification of the cochlear tissues. Cochlear prosensory tissues and the greater epithelial ridge cells (which degenerate during the first postnatal week) appear to originate from the medial wall of the duct that expresses lunatic fringe (Lfng) and Pax2 at E10.5. One day later, Lfng and Pax2 expression domains separate, with Lfng shrinking to a small domain that may represent either a sensory-competent state, or perhaps it is the earliest marker of the primordium of the organ of Corti. The cells opposite to this, on the posterior–lateral wall, express Pax2 at E10.5–E11.5 and will eventually become the stria vascularis. In the mature cochlea, the sensory and strial tissues are separated by nonsensory cells, including Hensen's cells and Claudius' cells; they originate from progenitors of the posterior–medial cochlear duct that co-express Bmp4, Pax2, and Lfng at E10.5, with persistent expression of Bmp4 on E15.5. Reissner's membrane originates from the anterior–lateral quadrant of the E10.5–E11.5 cochlear duct, marked by Otx2 expression. The anatomical position of cochlear duct tissues relative to the body axis is significantly altered by the spiraling of the cochlea. So while the organ of Corti is presumed to arise from the Lfng domain on the anterior–medial wall of the ventral otocyst on E11.5, it is eventually located along the posterior wall of the triangular scala media compartment.

Specification of Sensory Cells

Sensory specification of the organ of Corti is an extended process. The transcription factor, Sox2, plays a fundamental role in prosensory specification. A strong mutant allele of this gene, called light coat and circling (Lcc), fails to form any recognizable sensory domain in the cochlea. Sox2 expression is present as early as E9.5 in the mouse. Fgf10 is also expressed at early stages in prosensory domains. Mutants or treatments that block Fgf signaling can significantly reduce the number and arrangement of sensory cells in the organ of Corti.

Cells of the sensory primordium are the first in the cochlear duct to leave the cell cycle. Molecular regulation of cell cycle withdrawal is correlated with expression of the cell-cycle inhibitor, p27kip1. In the absence of this gene, organ of Corti progenitors exit the cell cycle at a later stage than normal, with the result that supernumerary differentiated sensory cells are formed.

Molecules of the Notch signaling system are also expressed within and around the prosensory domain and are essential for its development. The receptor, Notch1, is broadly expressed in the ventral otocyst while several different Notch ligands (Deltas and Jaggeds) are expressed at various time points. Perturbations in the Notch signaling pathway can alter the number of sensory cells in different and seemingly

Figure 4 Gene expression domains in the otocyst may correspond to a fate map of cochlear tissue types found in the mature cochlea. The images represent approximate horizontal cross sections through the ventral otocyst (E10.5–E11.5) or the mid-base of the cochlea (E13.5–postnatal). The successive changes in the gene expression domains of the epithelial cells of the cochlear duct are shown. Note that Bmp4 expression is also present at E10.5 and E11.5 in the posterior vesicle but is not shown due to its partial overlap with other genes at these stages. The initial appearance of a zone of nonproliferation reveals the location of the sensory primordium at E13.5, which can be visualized by the absence of DNA synthesis by BrdU (bromo-deoxyuridine) labeling. The thick black line denotes the location of junctional complexes that serve to isolate the endolymphatic fluid. The figure is primarily based on data presented by Burton Q, Cole LK, Mulheisen M, Chang W, and Wu, DK (2004) The role of Pax2 in mouse inner ear development. *Developmental Biology* 272: 161–175; and Chen P, Johnson JE, Zoghbi HY, and Segil N (2002) The role of Math 1 in inner ear development: Uncoupling the establishment of the sensory primordium from hair cell fate determination. *Development* 120: 2495–2505.

paradoxical ways. When this signaling pathway is ectopically activated prior to sensory specification, extra sensory patches are formed in the chicken cochlea. In other words, in a gain-of-function scenario, Notch activation can induce sensory fate. The Notch ligand operative in this inductive event is not known, but based on loss-of-function phenotypes and the timing of expression, it is likely to be Jagged1. However, the Notch receptor is not yet known. Interestingly, ectopic activation of Wnt/β-catenin signaling has similar prosensory effects to ectopic Notch activation in the chicken cochlea.

Notch signaling is active at later stages, when hair cells and supporting cells are acquiring their fates. Here, Notch has been associated not with a prosensory fate but rather the opposite: lateral inhibition of hair cell (i.e., sensory) fate. The process of lateral inhibition is thought to be initiated when some cells begin to acquire a hair cell fate. These nascent hair cells use the Jagged2 and Delta1 ligands to activate Notch1 on neighboring cells that make direct contact with them. The receiving cells will downregulate Jagged2 and Delta1 genes, which reduces their effectiveness at signaling back to the nascent hair cell

(however, in mouse, it seems that only the hair cells ever express these genes so the negative feedback may not be necessary). Upon reception of Notch signaling, the surrounding cells will increase the expression of Hairy/Enhancer of Split (Hes) genes which can block proneural genes of the basic helix–loop–helix family. This includes the proneural gene, Atonal1, that promotes hair cell fate. Once inhibited from assuming the primary hair cell fate, these progenitors will instead take on a supporting cell fate as a secondary option. Overall, Notch signaling from nascent hair cells to surrounding precursors generates a perfect mosaic arrangement where every hair cell is surrounded by supporting cells and avoids contacting any other hair cells. Notch signaling may also be involved in keeping supporting cells in a postmitotic state, since they continue proliferating when Notch signaling is perturbed. However, this effect may be secondary to the increase in hair cells and/or the reduction in supporting cells. In the chicken cochlea, Notch signaling has been proposed to have yet another role in supporting cell development: among the pool of cells that will not become hair cells, reciprocal cell–cell signaling via the Serrate1 (Jagged1) ligand may promote or induce the supporting cell fate.

Hair Bundle Polarity

Once hair cells are specified, they begin a process of differentiation that is most obvious at their lumenal ends, where they elaborate a stereociliary bundle (Figure 5). The process begins with the elongation of numerous microvilli surrounding a central true cilium, called the kinocilium. The kinocilium and the nascent stereocilia are connected by thin fibrous strands. Next, the kinocilium moves to the periphery of the apical surface and for the first time a clear planar polarity is evident. However, the initial polarity assumed by this repositioning of the kinocilium is only partially aligned with adjacent hair cells or with the final polarity of the bundles in the mature ear. Instead, a refinement in orientation occurs later by an unknown process: it is not clear if it is only the bundle that rotates, or the entire cell. Before this reorientation, the stereocilia will lengthen, beginning with those nearest to the kinocilium that will become the tallest row of stereocilia. Lengthening of the next row begins before the taller row reaches its final height. As the stereocilia lengthen, the tethers between them appear to be stretched from the tip of a shorter one to the side of an adjacent taller one. It is possible that these tethers eventually become the tip links that are thought to regulate tension on the mechanically gated ion channels in mature hair cells. In the cochlea, the kinocilium degenerates as a final differentiation step, revealing that it is not required for transduction and may primarily be needed to establish a polarized bundle. Once development is completed, all hair cells in the organ of Corti assume the same bundle polarity, with the tallest row of stereocilia located at the outer (abneural or lateral) edge of the spiral.

It has been suggested that there are three levels of planar cell polarity in a hair cell-bearing sensory patch. The first is at the level of the individual cell, where the kinocilium becomes asymmetrically localized to the rim of the apical surface. The second is a local level, where small groups of hair cells assume similar orientations, but these are not perfectly aligned across the entire organ. The final level is global, which in the cochlea is manifest by a near-perfect orientation of the bundles with their axis of maximum sensitivity oriented orthogonally to the long axis of the cochlea. In the search for genes that control bundle polarity, it is at the local level where defects have been reported in various mouse mutants. Several of the responsible genes belong to the so-called PCP pathway because their orthologs in flies have been implicated in similar planar orientation defects. In the cochlea, some of the proteins encoded by PCP genes are known to be asymmetrically localized to either the neural or abneural side of sensory cells near their lumenal surface, shown schematically in Figure 5. Thus the molecules are in the right location to influence cytoskeletal rearrangments directionally across the cell surface along the axis of bundle polarity. In flies, the Frizzled receptors, usually affiliated with signaling via wingless (Wnt) ligands, have been implicated in PCP, even though wingless itself has not been shown to play a role. Instead, the directional polarity within the fly epithelium may be transmitted from cell to cell through direct cell contacts. In contrast, Wnts appear to play a more active role in hair cell polarity in the mammalian cochlea. Not only is there evidence for Frizzleds being involved in hair cell polarity in the mouse cochlea, but changes in Wnt concentrations can also alter bundle polarity of hair cells grown in culture.

Spiral Ganglion Neurons

The first cells that can be recognized during inner ear development are the neuroblasts that arise from the Ngn1-expressing floor of the otic cup and otocyst. Neuroblasts fail to develop in the absence of the neurogenic gene, Ngn1. Neuroblasts are still in a proliferative state at the time they delaminate from otic ectoderm. The neuroblasts migrate around the anterior pole and initially gather into a single ganglion just medial to the otocyst. They will soon split into a dorsal vestibular ganglion and a ventral spiral ganglion

Figure 5 Hair bundle development and PCP proteins. The sequence of events leading to the polarized stereociliary bundle of an outer hair cell is shown as viewed from the neural (medial), or inner hair cell side. PCP proteins (blue) are initially located around the apical circumference of the cell, but then become localized to either the medial rim (as shown) or to the lateral rim, or both. When the kinocilium (gray) moves circumferentially, it tends to localize within 45° of its final location. The directionality of the initial movement and final localization of the kinocilium could be facilitated by the action of asymmetrically distributed PCP proteins interacting with the cytoskeleton. Figure based in part on schematics by Goodyear R, Kros CJ, and Richardson GP (2006) The development of hair cells in the inner ear. (Figure 2). It is not yet known whether the two populations of neuroblasts are distinct at the time of delamination. Lineage studies in the chicken otocyst indicate that clonally related cells can disperse across both ganglia, suggesting that common progenitors are used for both neuronal populations. On the other hand, most clones are restricted to one or the other ganglion, so it is possible that most neuroblasts have already acquired auditory or vestibular identity before they leave the otocyst. One likely candidate for providing auditory identity is the transcription factor Gata3. Gata3 is expressed in the neurogenic region of the otocyst and is retained in spiral ganglion neurons but not vestibular neurons. Furthermore, when the gene is deleted, spiral ganglion neurons fail to form.

Neuronal differentiation requires the basic helix–loop–helix transcription factor, NeuroD. NeuroD null mice generate neuroblasts, but the cells never differentiate and soon die.

Spiral ganglion neurons are bipolar: one process projects out to the organ of Corti and the other projects through the auditory nerve into the cochlear nucleus. The neurons require neurotrophic support from the periphery for their survival. During normal development, a large number of neurons undergo programmed cell death, perhaps responding to the need to balance neuron numbers with hair cell targets. Either NT3 or BDNF can support the survival of spiral ganglion neurons, which express the Trk receptors for both neurotrophins. During normal development, NT3 supports axons innervating the majority of the cochlea, while BDNF supports the most apical fibers. The peripheral processes of the spiral ganglion neurons reach the organ of Corti in advance of the efferent fibers originating from the brain stem. Thus, it is not surprising that the efferents appear to use the afferents to find their way from the nerve to the hair cells. Further discoveries may reveal exactly how growing auditory 'dendrites' find their way to the sensory periphery and how the centrally directed axons navigate into the cochlear nucleus of the brain stem.

Introduction

The performance of the normal mammalian cochlea is quite magnificent. It can detect air pressure fluctuation (sound) as small as 1/2 000 000 000th of atmospheric pressure, which produces vibrations within the cochlea of only atomic dimensions. It can discriminate frequencies separated by only a small fraction of a musical semitone (a 1% frequency change can change vibration tenfold), can cope briefly with a 1 000 000-to-1 range of sound pressure without permanent damage, fits neatly in a bony capsule the size of a pea, provides its own battery, and consumes only about 50 μW, or 1% of the power of a solar-powered calculator. Of course, it also has problems. It distorts so badly (about 3% distortion, comparable to a $5 radio) that some sounds are not heard in the presence of others (called masking or suppression), and when two pure tones are presented together, it produces four or more of its own. Unfortunately, this distortion is no excuse for a cheap stereo: Different frequencies vibrate different areas in the cochlea, and the mechanical separation of frequencies occurs before the distortion takes place. As a result, the ear's distortion is of a special type, and we can discriminate external distortion from our own. This distortion not only colors our perception of music (harmony is unlikely to exist without it), it is used clinically in detecting deafness of mechanical origin. The cochlea also has a tendency to whistle like a poorly fitted hearing aid as a result of internal electromechanical feedback, and in some people these sounds can be heard by others nearby (known as 'objective tinnitus,' different from 'subjective tinnitus,' which is not heard by others). It can also be damaged by excessive sound and various prescription drugs in high doses, including antibiotics, loop diuretics, and even aspirin. It is interesting that it achieves its high performance by combining electrical and mechanical phenomena to cancel internal friction in a way that engineers have only recently used in the surface acoustic wave 'chirp filters' of modern RADAR. Overall, the function of the cochlea is so dependent on the vibration of the organ of Corti within it that a full understanding of normal sound perception and deafness is impossible without an understanding of cochlear mechanics. Here, the processes producing cochlear vibration are summarized, including the frequency-dependent vibration, the active amplification of vibration by hair cells, the nonproportional growth of vibration with sound level, the nonlinear two-tone interactions such as distortion generation and two-tone suppression (masking), and finally how these phenomena are altered to produce sensorineural deafness of cochlear origin.

Cochlear Vibration and the Active Process

In a normal ear, incoming sound vibrates the ear drum and middle ear bones, causing pressure fluctuations in the cochlear fluids and a vibration of the ribbonlike basilar membrane that divides the cochlea roughly in two along its length. The cochlea's coiling is largely irrelevant to its mechanical behavior because the speed of longitudinal sound waves in cochlear fluid is so fast that pressure fluctuations distribute in the cochlea within microseconds, so their wavelengths are far longer than any of the cochlea's structural features (including its coiling). Moreover, the sound vibration detected by the stretch-sensitive hair cells and conveyed to the auditory neurons is not the longitudinal fluid waves but the transverse interface wave along the basilar membrane and organ of Corti (OC). Just as the longitudinal pressure waves within bulk water of a pond travel at about 1000 m s^{-1} while the transverse surface ripples travel at a leisurely few meters per second, the transverse cochlear waves travel at a very slow pace when compared with the longitudinal waves in bulk fluid (with delays of a few milliseconds from base to apex, depending on species). As shown in Figure 1(a), this vibration takes the form of Bekesy's traveling waves or ripples that mostly travel away from the stapes and toward the cochlear apex. For a pure-tone stimulus of a particular frequency, the wave grows as it travels (because the basilar membrane becomes less stiff along its length), before reaching a maximum at its resonant characteristic place, beyond which it collapses abruptly so that no vibration exists beyond its cutoff region. This characteristic place is positioned along the cochlear length according to a species-specific, logarithmic, place–frequency map, with high characteristic frequencies (CFs) toward the cochlear base and lower frequencies closer to the cochlear apex. The mapping is largely determined by the grading in mass and (mainly) stiffness of structures along the cochlear partition (the basilar membrane plus the OC sitting on it). Fortunately, this grading and the cochlear shape have evolved to avoid reflections within. These would

Figure 1 (a) Schematic of the cochlea, uncoiled to show the traveling wave, which normally travels rapidly away from the stapes before slowing and growing as it encounters less stiff regions of the cochlear partition. It is the transverse (up-down) vibration of the partition that stimulates hair cells and neurons. (b) While reflections are minimized, slight reflections occur from multiple sites in any imperfect cochlea, with echoes emerging as transient evoked otoacoustic emissions (TEOAEs). Only outer hair cells (OHCs) in a small active region before each characteristic place assist vibration, which is the reason masking or suppression is most effective for suppressor tones vibrating this region. (c) Some OHCs can become overzealous, oscillating spontaneously, producing spontaneous otoacoustic emissions (SOAEs) that can be detected in the ear canal by quiet sensitive microphones. (d) Two tones with similar frequencies (f1 and f2) interact because of mechanical distortion to produce other traveling waves that propagate to their own characteristic places and also back out through the middle ear to the ear canal, where they can be measured as distortion product otoacoustic emissions (DPOAEs).

be confusing and would limit timing resolution and therefore our directional discrimination, partly derived from timing differences between our two ears. Having said that, a normal (but always imperfect) cochlea does produce slight reflections from small imperfections along its length (Figure 1(b)). Originally known as Kemp echoes, they are now called transient evoked otoacoustic emissions (TEOAEs), are idiosyncratic of any individual, are delayed according to their frequency and travel time from the stapes to the point of reflection and back, and can be measured in the ear canal by a sensitive but quiet microphone. They are evoked by clicks and less often by tone bursts, provide some frequency-specific information, and are used as a rapid screening test for normal cochlear vibration.

Detecting this vibration and communicating it to the brain are the function of the OC, which sits on the basilar membrane and contains two types of vibration-sensitive hair cells: the inner hair cells (IHCs), which lie in a single row and synapse with about 95% of the primary afferent neurons (type I), and the outer hair cells (OHCs), which lie in three or four parallel rows, outnumber the IHCs almost three to one, and synapse with only 5% of the afferent neurons (type II). Experimentally, the molecular vibration has been detected in many ways (see Figure 2, showing the

Figure 2 Most of what we know of cochlear vibration has come from experiments in which the vibration has been observed directly in living animals using many techniques. Optical techniques include direct observation, the parallax detector, the light-lever, the interferometer, and the velocimeter. Doppler shift of gamma ray emission has also been used (the Mössbauer effect), as has the capacitive probe. A great deal can be determined by monitoring cochlear vibration indirectly through responses of hair cells and neurons, detected using electrophysiological techniques. As shown here, the organ of Corti hangs from beneath the basilar membrane. This is most often the case experimentally, when the approach to the vibrating structures is often via the fluid-filled scala tympani. DEMOD., demodulator; OSC., oscillator.

OC upside down, as it usually is in experimentation in which vibration is detected from its scala tympani side). The transverse (up-down) vibration of the OC (point 1 of Figure 3) produces a radial shearing between its tectorial membrane and reticular lamina and ultimately a deflection of the hair bundles at the hair cell apex, leading to the opening and closing of the mechanoelectrical transduction (MET) channels on each stereocilium. This produces a fluctuation in the electrical resistance of the hair cell apex (points 2 and 2′ of Figure 3). Because there is a voltage across the apical membrane of the hair cells which drives K^+ ions into the cells from the K^+-rich endolymph of the fluid compartment of scala media, the opening and closing of the MET channels produces a fluctuating hair cell receptor current. The driving voltage (110 mV for IHCs and 170 mV for OHCs) is made up of two components: the positive potential above the hair cells in scala media (the endocochlear potential (EP) of about +95 mV) and an additional component due to each hair cell's membrane potential (about −40 mV in IHCs and −70 mV in OHCs). The EP is maintained by the cochlea's epithelial 'battery charger' (stria vascularis on the cochlear wall of scala media), while the membrane potentials are maintained by each cell's metabolic resources. The receptor currents (points 3 and 3′ of Figure 3) produce receptor potentials within the hair cells, which also depend on the electrical properties of each 'cell's basolateral wall (points 4 and 4′ of Figure 3). While the receptor potentials within IHCs and OHCs cause the release of neurotransmitters (point 6 of Figure 3) and spiking in the afferent neurons (point 7 of Figure 3), the receptor potential of OHCs also changes the shape of a set of 'motor proteins' (prestin) arranged in a systematic network on the inside surface of the OHC basolateral wall. There appears to be so much prestin that its concerted movement changes the OHC length (electromotility), and possibly similar forces arise from small movements of the hair bundles themselves

Figure 3 The outer hair cells (OHCs) assist cochlear vibration by a process of electromechanical feedback. Transverse vibration of the organ of Corti produces radial shear (R) of the hair bundles (1), opening and closing mechanoelectrical transduction channels at the hair cell apex (2), thereby modulating hair cell receptor current (I; 3) and producing intracellular receptor potentials (V; 4). In outer hair cells, this leads to feedback forces (F) due to either electromotile prestin in the basolateral wall or possibly forces (F) generated by the hair bundles themselves (5). Overall, these OHC forces act to cancel friction within the organ of Corti, producing nearly a 1000-fold increase in vibration at low sound levels. This enhanced vibration is detected by adjacent inner hair cells (IHCs) by an analogous process. Overall, the processes associated with OHCs can be referred to as 'motor processes' and those associated with IHCs can be referred to as 'sensory processes.' Cochlear hearing loss can therefore be subcategorized as motor losses, sensory losses, or mixed cochlear losses when both are disrupted.

(point 5 of Figure 3). Because the opening of MET channels is synchronous with the sound vibration, the receptor current and receptor potential also increase and decrease through a cycle of a pure tone, so neurotransmitter release, neural firing, and OHC length all fluctuate through a cycle of a tonal stimulus. This cycle-by-cycle fluctuation produces feedback forces crucial to normal vibration. Just as children on a swing move their legs back and forth at the swing's natural frequency to increase vibration by canceling friction in the hinge, the OHCs act to cancel friction and increase vibration of the OC. In a normal cochlea, the vibration is increased about 1000-fold (60 dB) relative to the vibration without OHC assistance. The mechanism enhancing vibration is known as the active process, the partial cancellation of friction is known as negative damping, and the combination of all these steps to produce large vibration is often referred to as the cochlear amplifier. As indicated in Figure 3, the processes associated with IHCs and the 95% of afferent neurons synapsing with them (type I) can usefully be called sensory processes because their ultimate role is to 'sense' whatever vibration occurs, while the processes associated with OHCs can be called motor processes because they ultimately allow OHCs to assist vibration, like in-built hearing aids. This distinction is useful because it is possible to subcategorize various types of cochlear hearing loss in this way.

Nonlinear Growth of Macromechanical and Micromechanical Vibration with Sound Level

The overall transverse vibration of the OC in mammals is often referred to as macromechanical vibration, indicating that the OC and basilar membrane are moving as a whole. The vibration of the component

parts of the OC (basilar membrane, hair cells, tectorial membrane, etc.) relative to each other is known as micromechanical vibration. For some time, these two vibration modes were thought to be separable and simply cascaded ('the first and second filters'), but it has become increasingly clear that they must be considered together because their resonances are tightly coupled. This coupling occurs partly because their respective mass and stiffness parameters are not greatly different and partly because micromechanical motion determines hair bundle deflection, production of the electrical signals from vibration (forward transduction), and ultimately the electromotile forces feeding back to the OC (reverse transduction). This action of electromotility (which occurs in a limited active region just before the characteristic place; Figure 1(b)) is crucial to understanding cochlear vibration because it partly (and sometimes wholly) cancels friction, thereby determining cochlear sensitivity, frequency selectivity, and dynamic range (because the electric signals and therefore feedback forces distort or clip at higher sound levels). If OHCs totally cancel friction in a local region, it oscillates, generating sound that propagates back to exit into the ear canal as a spontaneous otoacoustic emission (SOAE; Figure 1(c)). About 50% of people have one, and in some it is heard as an 'objective tinnitus.' In any case, the progressive clipping of the electrical signals and feedback forces at higher sound levels (saturation feedback) not only allows the cochlea to compress a 1 000 000-to-1 range of sound level (its 120 dB dynamic range) into a mere 100-to-1 range of vibration amplitude; it creates dramatic two-tone interactions: low-frequency intermodulation (in which hearing sensitivity fluctuates dramatically through a cycle of an intense low-frequency tone), two-tone suppression at higher frequencies (in which the cycle-by-cycle modulation is not obvious, but vibration due to one tone is reduced by the presence of a second tone of appropriate frequency and intensity), and distortion product generation (in which the nonlinear interaction between two tones produces other frequency components). If one tone has a frequency f1 and the second tone has a slightly higher frequency f2, then the most prominent distortion frequencies in most mammals are f2−f1 (the simple or quadratic distortion tone, which indicates asymmetric distortion) and 2f1−f2 (the cubic distortion tone, which indicates symmetric distortion). These distortion products (Figure 1(d)) are readily detected in the external ear canal of normal ears as distortion product otoacoustic emissions (DPOAEs), which are easily shown to be produced within the cochlea (because the f1 and f2 frequencies must be close, with $f1f2^{-1} \sim 1.3$, indicating sharp filtering, and because cochlear disruption abolishes them). Because the DPOAEs are disrupted by any pathology that disrupts OHC function (the motor processes), they can also be used for objective hearing screening like the TEOAEs, especially in infants. As for which elements in the cochlea cause the nonlinear phenomena, there are potentially five: nonlinear hair bundle gating stiffness, nonlinear mechanoelectrical transduction at the apex of hair cells, further distortion of receptor potentials by nonlinear conductances at the OHC basolateral wall, nonlinear electro-mechanical transduction from OHC membrane potential to prestin forces, and hair bundle adaptation at the apex of the hair cells. In some cases it is clearly the forward transduction of the MET channels that determines the clipping and distortion, but in others the cause is not so clear.

Why Does the Wave Travel from Base to Apex? It's Cochlear Hydrodynamics, Not Stapes Drive

One important point to appreciate about vibration within the cochlea is that it is pressure fluctuations in the fluid surrounding the OC that drives vibration, not forces between adjacent sections along the cochlear length. That is, the traveling wave is not like a ripple traveling along a shaken rug but is more like a row of boats moored next to each other, coupled only by the water movement beneath them. If we push one boat downward, pressure changes in the water are transmitted between adjacent boats, and a wave of boat motion is observed. The consequences of this point are important.

First, the sound energy can be fed to the cochlear fluids at almost any point around the perimeter of the cochlea, and it will travel almost instantaneously (at almost $1000\,\mathrm{m\,s^{-1}}$) to all other regions of the cochlear fluid, producing the usual transverse traveling wave on the basilar membrane, traveling in the same direction, at the same speed, and with the same properties as usual. This point is important because it means that sounds can be fed to the cochlea from almost any point around its perimeter, and by almost any means, and the resultant traveling wave and nerve stimulation will be near normal. For example, although sound is normally fed to the fluid through vibration of the stapes, it can be fed through vibration at the apex, from spontaneous vibration of the OHCs themselves, or through the surrounding bone, and the sound perception is maintained. In fact, this mechanism of 'bone conduction' is the dominant mode of cochlear stimulation when the ear canals or middle ear are blocked (e.g., with wax, exudate, growths, or deformity) and has recently been used in a special implanted hearing aid that vibrates the bone directly (the bone anchored hearing aid).

Second, the transverse traveling wave that travels from base to apex is not stopped by immobilizing the

partition in the base (removing or cementing one boat along a line of boats does not destroy all wave motion beyond the problem boat, whereas cutting a rug along its length does). Rather the hydrostatic fluid pressure simply passes the problem, and the wave recommences on the other side. The implications of this are that moderate damage and scarring of the cochlear partition in the basal regions produce a drop in vibration only in the base, but vibration in more apical low-frequency regions is relatively unaffected. That is, it is possible to have a high-frequency mechanical loss without a consequent low-frequency one. This is precisely what happens with most cases of acoustic trauma, which occurs most often at high frequencies, and is also true in the case of other frequency-specific lesions of many kinds.

Third, because the transverse vibration is driven by pressure fluctuations in the fluid rather than through the partition itself, if the pressure were short-circuited by a small perforation through the cochlear partition, all vibration in surrounding and more apical regions would be reduced or absent. Fortunately, it is unusual to suffer such a punctate hole, because the cochlea is encased in the hard temporal bone. On the other hand, the fluid pressure can be effectively short-circuited if one region of the cochlear partition is resonant, because it has a very low acoustic impedance. As the transverse wave for a pure tone travels along the cochlear partition from base to apex, it will encounter a region where the partition is at or near resonance at that stimulus frequency, and the fluid pressure will be short-circuited (or at least greatly reduced), effectively 'stealing' the fluid pressure required to drive the next section of partition toward the apex. The net result is that a traveling wave travels out from the basal end, initially traveling rapidly and at low amplitude (like a tsunami in the deep ocean), but when it reaches its resonance region, the wave slows dramatically and increases in amplitude (because resonance means low acoustic impedance to vibration) but then suffers a 'cutoff' phenomenon, abruptly falling to a very low amplitude and ultimately extinguishing entirely. This high-frequency cutoff is not evident in ripples on water because it requires that the surface be resonant, requiring the combination of a restoring stiffness and an inertial mass. Although simple water surfaces possess a restoring force (gravity mostly, but partly surface tension), there is very little mass at the surface itself (rather than bulk fluid), and a cutoff phenomenon does not occur, so we are not familiar with it. A cutoff would be observed, however, on a water surface loaded with mass (e.g., boats or water lilies). In any case, the combination of mass, stiffness, and surrounding fluid pressure coupling means that no vibration can travel (forward or backward) along a surface if the stimulus frequency is above the resonance frequency of the surface at that point. Such a wave is said to be 'evanescent.' This has the practical significance that any sound produced by the cochlear partition itself cannot travel outward as a transverse traveling wave if its frequency is above the resonance frequency of its generation site. For example, distortion tones with frequencies higher than that of their generation site (e.g., f2 + f1, 2f1 + f2) are 'stillborn' and unable to propagate. (This does not mean that distortion products higher in frequency than the resonance frequency of their generation site cannot influence distant sites, but this must occur via a longitudinal sound wave and not as a transverse traveling wave.) Conversely, lower-frequency distortion products (f2−f1 and 2f1−f2) can propagate in the forward direction to their appropriate site, to be perceived as Tartini's phantom bass, and backward to the stapes, middle ear, and ear canal, to emerge as DPOAEs.

Sensorineural Hearing Loss and the Frequency Threshold Curve

Hearing loss in humans is normally categorized as conductive, sensorineural, or mixed (conductive plus sensorineural), and the sensorineural component can itself be broken down into its cochlear and retrocochlear components. It is now possible to categorize cochlear lesions into two basic types, as mentioned earlier: motor losses, in which motor processes are disrupted (left half of Figure 3), and a sensory loss, in which sensory processes are disrupted (right half of Figure 3). In some pathologies, both motor and sensory processes are impaired, and we can define a mixed cochlear loss. As an aid to memory, the many types of cochlear hearing loss described below can also be categorized simply as one of the four Bs of cochlear deafness: (1) a 'block' of MET channels or the primary afferent synapse by drugs or overstimulation, (2) a mechanical 'bias' of the hair bundles by osmotic or hydrostatic pressures, (3) a drop in the cochlear 'battery' driving the receptor currents through the outer and inner hair cells, and (4) activation of the crossed olivo-cochlear 'bundle' (drugs such as salicylate may mimic its action). To discuss these cochlear pathologies in detail, we must consider the upside-down 'audiogram' of a single afferent neuron, called its frequency tuning curve (FTC). As shown in Figure 4, the normal FTC of each cochlear afferent neuron has a very sensitive 'tip region' centered around the neuron's CF (where vibration is most sensitive), and a less sensitive 'tail region' at lower frequencies (where the low-amplitude vibration passes the neuron on its way to its own more apical characteristic place). Above the cutoff frequency of a neuron, there is no response at all because

Figure 4 Schematic showing neural frequency tuning curves (FTCs) for neurons spread across the cochlea, and in this case with damaged hearing at higher frequencies. The normal localized vibration of the cochlear partition with pure tone stimulation results in each primary afferent neuron possessing a sharp frequency threshold curve (FTC), which plots the sound pressure required to produce neural firing just above spontaneous rate (vertical scale) versus the frequency of the pure tone stimulus (horizontal scale). Each FTC for each neuron possesses a sharp tip region and a wider low-frequency tail, with no response above the cutoff frequency (because higher-frequency traveling waves never reach that neuron). Taken together, all contributing neurons result in an overall sensitivity contour known as the 'audiogram,' shown here as a dashed curve skimming the tops of all FTCs. Here an example is shown of the change in FTC shape as we move from a normal low-frequency region of the cochlea (the apical regions) into a region with outer hair cell (OHC) damage (e.g., damaged by acoustic trauma). The FTCs in the normal cochlear apex are sharp with a narrow and sensitive tip region (red), but the FTCs in the damaged cochlear base are less sensitive and blunt (blue). As a result, in the normal apical region, sound must be increased substantially above threshold (red arrow) to stimulate adjacent higher-frequency neurons, but in the base only small increases in sound level above threshold (blue arrow) are required to produce an upward spread of recruitment of neural firing. This influence of broader FTCs in regions with damaged OHCs is exacerbated by the loss of nonlinear compression in these regions. The icon of the cochlea above the audiogram and FTCs highlights the normal apex and abnormal base of the example, and that the normal clinical audiogram (125 Hz–8 kHz) does not test the extreme basal region of the human cochlea.

the traveling wave never propagated that far. It is important to note that the mechanical sensitivity around the CF and the FTC tip region relies heavily on the action of the active process of OHCs to cancel friction alone (see Figure 3), and any damage to OHCs alone reduces sensitivity near the tip region without changing sensitivity on the stiffness-dominated low-frequency tail. This is important in understanding the changes in perception with OHC damage, as discussed next.

Motor Losses: OHC Problems with No IHC/Neural Disruption (Noise Trauma, Hydrops, and Fistula)

As illustrated in Figure 4, motor losses that are due to disruption of the active process only are associated with elevation of the single fiber FTC for frequencies near CF, with little change on the low-frequency tail. Because the active assistance of OHCs enhances cochlear vibration about 1000-fold, the motor loss associated with OHC disruption alone is usually limited to this amount (60 dB). A motor loss can be due to blockage of the MET channels of OHCs by moderate noise trauma, ototoxic drugs, or mechanical biasing of the OC by low-frequency sound or hydrostatic/osmotic imbalances, as in perilymph fistulas and endolymphatic hydrops (which in some cases probably produces Ménière's syndrome). Motor losses can also be caused by disruption of OHC motility directly, due to some drugs (e.g., salicylate) or excessive efferent neuron activity. The changes in OC vibration reduce sensitivity, the sharpness of FTC tuning, nonlinear compression, two-tone suppression, and distortion tone generation. These changes dramatically change the perception of speech and music and cause the phenomenon of (hyper) recruitment, which is the abnormally rapid increase in perceived sound loudness as sound level is increased. (Recruitment is best called hyperrecruitment because there is some neural recruitment in any normal ear.) Recruitment clearly has its origin in

cochlear mechanics, and certainly has always been associated with OHC lesions. It has two major aspects. First, although the active assistance of OHCs enhances cochlear vibration by about 60 dB for low sound levels, as sound level increases and the nonlinear processes associated with OHCs clip or saturate, the OHC assistance becomes less important (the so-called saturation feedback process that provides the ear's 120-dB dynamic range). In other words, OHC assistance is important for low-level sounds but largely irrelevant for very high sound levels. As a result of this progressive saturation of the OHC assistance, normal vibration in a healthy ear grows very slowly with sound level ($\sim$0.2 $dBdB^{-1}$). However, once OHC assistance is abolished, there is not only a 1000-fold elevation of hearing threshold (a 60 dB sensorineural hearing loss), but compressive growth of vibration is abolished, and things revert to a simple proportional growth, or linearity results (1 $dBdB^{-1}$). With no compression, the increase in neural firing rate with increase in sound level is perceived as abnormally rapid by a central nervous system, previously programmed to expect a much slower growth. The second factor contributing to recruitment is also mechanical in origin. In a normal cochlea, the resonance of cochlear vibration is so good that the tip of the FTCs of single auditory neurons is extraordinarily sharp. They have low-frequency slopes of a few hundred decibels per octave and high-frequency slopes of almost 1000 dB per octave, with a very narrow bandwidth. As a result, at auditory threshold very few neurons are stimulated, and as sound level is increased, there is little recruitment of adjacent neurons until 40–50 dB above threshold (because all adjacent FTCs are so sharp). Above this sound level, however, neurons innervating more basal (high- frequency) neurons are stimulated, but neurons in more apical regions are not. The rate of this upward spread of recruitment in a normal cochlea with nonlinear compression is very slow. In a cochlea with no OHC assistance to vibration (a motor loss), not only is the nonlinear compression absent but the FTC is much broader, without a well-defined tip region (see **Figure 4**). As a result, although only a few neurons may be stimulated near auditory threshold, just a few decibels above threshold there is already a rapid upward recruitment of neural firing. This abnormally rapid upward spread of recruitment adds to the abnormally rapid increase in firing rate of individual neurons because of the lack of compression, and the increase in sound loudness is perceived as far too rapid and troublesome. Although the absence of nonlinear compression in cochlear vibration can be replaced to some extent by similar nonlinear compression in more-sophisticated hearing aids, the sharp tuning of the individual FTCs cannot be restored. The more-sophisticated hearing aids attempt (with only partial success) to overcome this problem using multiband filtering, with nonlinear compression added independently to each frequency band.

Sensory Losses: IHC/Neural Problems with Normal OHCS

Sensory losses are due to disruptions of IHCs or synaptic function (e.g., Mg^{2+} perfusion into the cochlea) and are associated with elevation of the single fiber FTC across the whole frequency range. Without a mechanical involvement, tuning, nonlinear compression, distortion tone generation, and two-tone interactions are not greatly affected, and there appear to be little or no changes in the OAEs in the ear canal. Such sensory losses do not appear to be common, although one recently recognized form (in perhaps 10% of congenitally deaf infants) is auditory neuropathy, in which OHC receptor currents and OAEs seem normal but cochlear nerve and auditory brain stem responses are abnormal or absent. Some of these cases are likely to benefit from cochlear implantation.

Mixed Cochlear Losses: Drug Blockade, Cochlear Hypoxia, and Morphological Disruption

One of the simplest cochlear manipulations that impairs the function of IHCs and OHCs simultaneously is the introduction of drugs that block MET in both inner and outer hair cells. Such drugs include aminoglycoside antibiotics (e.g., kanamycin, streptomycin, gentamycin), anticancer drugs (e.g., *cis*-platinum), and some antimalarial drugs (e.g., quinine). Another way to disrupt motor and sensory processes and produce a mixed cochlear loss is to reduce the driving voltage for the hair cell receptor currents, which is most easily accomplished by dropping the endocochlear potential above the hair cells by disrupting the cochlea's 'battery charger' (stria vascularis). This can be done with hypoxia (disruption of strial blood supply from stroke or local embolism) or with pharmacological blockade of strial ion transport by pharmacological blockers such as ouabain or the diuretics furosemide, bumetanide, or ethachrynic acid. Changes in the cochlea that are associated with morphological changes to the OC, and to the hair cells in particular, also alter OC vibration. Such changes can occur with intense or prolonged acoustic overstimulation, and high doses for long periods of some ototoxic drugs (e.g., aminoglycosides, anticancer drugs). Such pathology with morphological changes has the added complication that the passive mechanical properties of the

OC (the stiffness, mass, and geometry of its constituent parts) are also altered.

Concluding Remarks

While the description provided here is true of most mammals, the role of cochlear vibration is different in different classes of vertebrates. For example, in lower vertebrates (e.g., Amphibia, turtles), cochlear vibration is relatively simple and not particularly resonant, and neural firing is determined largely by electrical resonance of the basolateral wall of the main sensory hair cells. This is also partly true in birds, but in many reptiles, micromechanical vibration becomes more resonant, more independent of macromechanical vibration, and more important in determining sensitivity and frequency tuning of the neural response. It seems likely that electrical tuning is useful up to a relatively low frequency of a few kilohertz, above which basic constraints of cell surface area, ion channel density, and animal temperature limit its usefulness. Beyond that, micromechanical resonances become useful in determining sensitivity and frequency selectivity, but only if internal friction can be overcome. In some animals with hair cells without electromotile prestin, the negative damping is performed by the hair bundles and MET channels themselves (as appears true in insect sensilla), but in mammals, the evolution of prestin and its electromotility appears to have at least assisted hair bundle motility, if not replaced it. Finally, the extraordinary sensitivity of mammalian hair cells to molecular displacements also requires the cochlea to be protected against excessive displacements. There are many lines of this defense, including the Eustachian tube, the slip joint of the human malleoincudal joint, the hard temporal bone, the pressure bleed of the helicotrema, and the viscous coupling of IHCs to the overlying tectorial membrane. While the hair bundles of OHCs are embedded into the tectorial membrane and are therefore displacement coupled, the OHCs possess a variety of homeostatic mechanisms to dynamically maintain the angle of their hair bundles in the face of constant buffeting, including a slow Ca^{2+}-controlled contractile process, similar to that in smooth muscle.

Introduction

The cochlear implant is the most successful and widely applied neural prosthesis developed to date. According to the National Institutes of Health (NIH) Consensus Statement on Cochlear Implants (1995), "A majority of those individuals with the latest speech processors for their implants will score above 80 percent correct on high-context sentences, even without visual cues." There are now more than 110 000 recipients of cochlear implants, far more than for any other type of neural prosthesis.

Cochlear implants provide an information-carrying interface between electronic systems and neuronal systems. They provide sensations of sound in patients suffering from profound or severe deafness as a result of trauma (either from head trauma or overexposure to intense sounds), administration of ototoxic drugs (e.g., kanamycin, streptomycin, and cisplatin) at damaging levels, or various infectious and hereditary diseases. Each of these insults causes loss of the sensory hair cells in the cochlea, as illustrated schematically in Figure 1 (not to scale). These cells normally transduce the mechanical vibrations of sound waves (entering the fluid-filled cochlear chambers via the middle ear ossicular chain) into neuroelectric impulses to the brain. The axons of the spiral ganglion cells that make up the auditory nerve convey these impulses from the organ of Corti on the basilar membrane (where the hair cells are located) to the cochlear nucleus in the brain stem. In the absence of the hair cells, the remaining spiral ganglion cells cannot respond to sound no matter how loud it is amplified. A cochlear implant activates these cells directly by electrical currents from stimulating electrodes implanted surgically into the scala tympani, one of the cochlear chambers. The auditory nerve activity so elicited is interpreted as sound by the central nervous system, with loudness and pitch generally dependent on the amplitude and location, respectively, of the stimulating current.

During the past 30+ years of active research in this field, over 25 different designs of varying complexity have been developed, three of which are now in widespread use. Each of these current designs share the general components shown in Figure 2, including external parts similar to a hearing aid (battery-powered, wearable control box with a microphone), plus a radio telemetry link that conveys information and power to implanted electronics. The implanted electronic circuitry generates the stimulation pulses and conveys them to the cochlea via the array of electrodes. The designs differ in the number and arrangement of electrode contacts in the cochlea and in the manner in which the acoustic signal is processed to derive the electrical stimulation patterns. In recent revisions of this basic arrangement, the body-worn external processor has been replaced by a behind-the-ear (BTE) processor, similar or identical in shape and appearance to a BTE processor for a hearing aid, as illustrated in Figure 2. Fully implantable systems – with the microphone and speech processor moved to the inside – are under development by each of the three major implant manufacturers and by a research group at the University of Michigan. One or more of these systems may be available within the next several years.

Electrode Arrays

All present-day cochlear prostheses attempt to make use of the tonotopic organization of the normal cochlea, in which high-frequency sounds are transduced at the basal end of the mechanically tuned basilar membrane, and lower frequencies are represented progressively toward the apex of the cochlear spiral. A multielectrode array is implanted in the scala tympani so as to permit local stimulation of subsets of the spiral ganglion cells. The selectivity of this stimulation depends on the condition of the spiral ganglion cells (which may themselves be damaged), the physical proximity of the electrodes to the cells, and the temporospatial distribution of stimulation pulses (see below). The proximity depends on the shape, size, and other design features of the electrode array. Electrode arrays have been built largely by hand from corrosion-resistant metals, such as platinum and iridium, and with flexible carriers, such as silicone elastomer. Their designs have been somewhat constrained in the past by fabrication complexity and desirable surgical handling properties. In general, the spatial specificity of stimulation with implants is much lower than that demonstrated in neural tuning curves for normal hearing, with acoustic stimuli. Such a broad activation of the nerve with electrical stimuli most likely limits the simultaneous number of perceptually separable channels to four to eight, even if more than eight electrodes are used. Substantial improvements in implant performance might be

Figure 1 Illustrations of anatomical structures in the normal and deafened ears. Note the absence of sensory hair cells in the deafened ear. Also note the incomplete survival of spiral ganglion cells and changes in neural processes peripheral to the cells that are still viable. The illustrations do not reflect details of the structures and are not to scale. From Dorman MF and Wilson BS (2004) The design and function of cochlear implants. *American Scientist* 92: 436–445.

realized with an increase in the number of perceptual channels, for example, with new types or placements of electrodes. It is also possible to create 'virtual channels' by distributing the stimulation current between two adjacent, simultaneously active electrode contacts. While this does not permit more perceptual channels to be presented at any one time, it may improve the tonal representation of sound and, hence, the quality of musical perception.

Speech Processors

Most multichannel prostheses use stimulation schemes based on the principle of a frequency-channel vocoder (voice coder) synthesizer. Intelligible speech can be synthetically reproduced acoustically by four or more single-frequency sound sources, each temporally modulated in proportion to the instantaneous power present in the band of frequencies immediately surrounding the center frequency of the source oscillator. Cochlear prostheses filter the incoming acoustic information similarly into bands corresponding to the place-pitch sensations evoked by each available stimulating electrode site. They use the amplitude of each band to modulate the electrical stimulation of the corresponding electrode, compressing the range of modulation greatly to deal with the very limited dynamic range of electrical stimulation from perceptual threshold to uncomfortable loudness (typically 6–20 dB, compared with 100–120 dB for normal hearing).

A block diagram of the most common stimulation strategy, continuous interleaved sampling (CIS), is presented in Figure 3. This strategy filters a microphone input into bands and represents relatively slow envelope variations in those bands as modulated trains of biphasic pulses at the electrodes. The output of each band-pass channel is directed to a single electrode, with low-to-high channels assigned to apical-to-basal electrodes, thereby recreating the tonotopic order of frequency mapping in the normal cochlea. The pulses are delivered in a nonoverlapping sequence across the electrodes in order to eliminate undesirable interactions that otherwise would be produced by summation of electric fields from simultaneously stimulated electrodes.

Parameters in the CIS and other strategies include number of channels and associated electrodes, cutoff frequency of the envelope detectors for each channel, and the rate of pulse presentations at each electrode. Results from recent studies have indicated improvements in speech reception performance with increases in the number of channels up to four to eight, and with increases in rate up to 1500 pulses/second/electrode and beyond, at least for some patients. Results for some patients show quite large improvements with increases to very high rates, for example, 5000 pulses/second/electrode. Rates at and above about 2500 pulses/second are likely to elicit a stochastic pattern of responses within and among auditory neurons, rather than the artefactual synchronization of the neurons at lower stimulus pulse rates. This may underlie the improvements observed with very high rates. We note that benefits of high rates come at a cost, however, because the high-rate stimulation consumes more electrical power and requires much higher data transmission rates between the external speech processor and the implanted stimulator.

Clinical Results

The vast majority of cochlear implant patients have experienced no lasting side effects from their

Figure 2 Components of the Med-El TEMPO+ cochlear prosthesis. Other systems share the same basic components. However, the electrode designs and details of processing and transmission of stimulus information across the skin differ widely among systems. In the TEMPO+ system, the microphone, battery pack, and speech processor are incorporated in a behind-the-ear (BTE) housing, much like the BTEs of hearing aids. A thin cable connects the output of the speech processor (a radiofrequency signal with encoded stimulus information) to an external transmitting coil that is positioned opposite to an implanted receiver/stimulator. The transmitting coil is held in place with a pair of magnets, one in the center of the coil and the other within the housing of the receiver/stimulator. The receiver/stimulator is implanted in a flattened or recessed portion of the skull, behind and slightly above the pinna. The reference or 'ground' electrode is implanted at a location remote from the cochlea, usually in the temporalis muscle. For some implant systems, a metallic band around the outside of the receiver/stimulator package serves as the reference electrode. An array of active electrodes is inserted into the scala tympani of the cochlea through the round window membrane or through a larger drilled opening (cochleostomy) near the round window. In present practice, a cochleostomy is used far more frequently than an insertion through the round window. Drawing courtesy of the manufacturer, Med El GmbH, of Innsbruck, Austria.

surgery or subsequent stimulation, and they have been enthusiastic and regular users of their devices for everyday communications. They differ greatly, however, in their performance on objective tests of speech perception. Some patients can understand speech without visual cues (e.g., over the telephone) almost immediately upon first use of the device, but many others have difficulties, particularly in noisy environments. A minority of patients learn only slowly to cope with distorted sounds that are far from normal hearing. Identification of the factor or factors underlying this variability in outcomes is a focus of current research.

Cochlear implants generally provide only modest benefit for adults who lost their hearing prior to acquiring language, probably because their auditory nervous systems have missed a critical period for development. However, congenitally or perinatally deafened children appear to derive substantial benefits if implanted early (usually before 3 and increasingly before 1 or 2 years of age). They usually acquire sufficient speech perception and production skills to permit their education in 'mainstream' classrooms rather than in special schools for the deaf that teach sign language. The use of cochlear prostheses and educational mainstreaming in young, deaf children originally stirred some controversy in the deaf community, some of whom view deafness as an alternative culture rather than a disability. There are also some patients who are unsuitable for cochlear

Figure 3 Signal processing steps for a CIS strategy for converting an acoustic input into a pattern of stimulation at the cochlear electrode array. The acoustic signal is amplified with pre-emphasis of the most important frequencies, then filtered into bands (BPF) whose center frequencies correspond to the tonotopic place of the electrode contacts (EL-1 to EL-*n*). The energy in each band is extracted by rectification and low-pass filtering (LPF) and its dynamic range is compressed by mapping onto the highly limited range of electrical pulse amplitudes from threshold for hearing to maximal comfortable loudness. This continuously modulated information about the loudness required in each band is converted into biphasic pulses with variable current and fixed duration that are delivered in a sequential, nonoverlapping, and fixed order to the various electrodes in the array.

implants because of mechanical deformation or damage to the cochlea itself. Research is underway to bypass the cochlea and stimulate more central auditory structures directly. Notwithstanding those few exceptions, cochlear implants have emerged as the standard of rehabilitative treatment for most cases of sensorineural deafness.

Cognition in Aging and Age-Related Disease

Introduction

As the average age of the population increases, there is growing interest in understanding the cognitive and neural changes that accompany aging. It is now clear that significant cognitive decline is not an inevitable consequence of advancing age. This realization has spurred researchers to examine what separates high-performing older adults from lower-performing older adults and to investigate how the changes with successful aging differ from those that result from age-related disease. Data acquired using behavioral testing, functional neuroimaging, and structural neuroimaging are beginning to inform these issues, although a number of questions remain.

Cognitive Declines with Healthy Aging

Not all cognitive domains are affected equally by age, and not all cognitive processes show age-related decline. If an older adult were asked to list the cognitive declines that have been most notable to him or her, it is likely that at least one of the following would make the list: problems paying attention to relevant information and ignoring irrelevant information in his or her environment, word-finding difficulties, or problems remembering the context in which information was learned.

Much of the research within the field of cognitive aging is focused on understanding whether the pattern of age-related cognitive decline can be explained by domain-general (or 'core') cognitive changes or whether changes in domain-specific processes are required to describe the data.

Domain-General Theories of Cognitive Aging

Domain-general theories of aging are based on the hypothesis that there is a shared ability that cross-cuts all of the tasks on which older adults are impaired: these theories suggest that although aging affects a range of cognitive functions, there is one central or core deficit underlying the myriad changes. This article focuses on three core deficits that have been proposed to explain the pattern of age-related declines: changes in sensory perception, changes in inhibitory ability, and changes in speed of processing.

Sensory deficits The sensory deficit hypothesis of aging proposes that the cognitive changes with aging may be attributed to changes in sensation (i.e., deficits in vision and hearing). Indeed, aging is associated with dramatic sensory declines: by the eighth decade of life, the majority of older adults have significant hearing loss and a reduced ability to discriminate colors and luminance. Support for the hypothesis that these sensory deficits may underlie cognitive changes has come from two lines of research. First, across a wide range of cognitive tasks, older adults' performance correlates strongly with their sensory abilities. Second, in young adults, cognitive impairments can arise when the to-be-processed stimuli are degraded. For example, when asked to remember words pronounced against a noisy background, or when asked to match digits and symbols written in low-contrast font, young adults perform comparably to older adults. Thus, it is plausible that age-related deficits on many cognitive tasks stem, at least in part, from reductions in sensory processing. For example, changes in audition may result in older adults' slowed performance on tasks requiring auditory processing and could explain older adults' poorer memory for auditory information. It is also possible, however, that in at least some instances the correlation derives from a common influence underlying both the sensory and cognitive changes. For example, individuals who have greater brain atrophy or dysfunction may be more likely to have both sensory deficits and cognitive impairments. Regardless of the precise mechanism through which sensory deficits relate to cognitive ones, evidence of significant sensory changes with age underscores the importance of modifying testing procedures to minimize the influence of sensory deficits on older adults' cognitive test performance (e.g., using louder or higher-contrast stimuli).

Inhibition Hasher, Zacks, and colleagues have proposed that older adults' cognitive deficits may relate to their inability to ignore irrelevant information in the environment while focusing attention on goal-relevant information. If an older adult is seated at a restaurant that has many tables in close proximity to one another, he or she may have difficulty paying attention to the conversation at his or her table while ignoring the conversations at nearby tables. In the laboratory, inhibitory deficits can result in responses to previous (but not current) targets. For example, after reading the sentence "Before going to bed, please turn off the STOVE," older adults will be more likely than young adults to believe that the

target word was LIGHT rather than STOVE. The age-related increase in this type of error is thought to occur because older adults have a hard time inhibiting the strong association present in the 'garden path sentence' (e.g., between the idea of going to bed and the idea of turning off the light). Inhibitory deficits also frequently emerge when older adults are required to task-switch or to set-shift. On these tasks, older adults must first pay attention to one aspect of a stimulus (e.g., match items based on their shape) and then another (e.g., match items based on their color). Older adults often have a harder time than young adults when they must ignore the previously relevant dimension (e.g., the shape of the items) and instead focus their attention on another stimulus attribute (e.g., the color of the items).

These data clearly indicate that inhibitory deficits can occur on a range of tasks requiring the ability to selectively attend to information in the environment or to inhibit a strong association or response. However, inhibitory deficits may impair performance not only on tasks that directly assess inhibitory ability, but also on assessments of working memory capacity: if older adults have a hard time distinguishing relevant from irrelevant information, this likely means that they store task-irrelevant information, reducing the storage capacity available for task-relevant information.

Speed of processing Older adults have a slower speed of processing than young adults. This slowed processing is noted at the motor level, but it also is apparent at a cognitive level. For example, older adults will tend to be slightly slower than young adults when they must slam on the brakes at a red light; this slowing may primarily be due to motor changes, because the association of red = stop remains very strong with aging. The reaction time differences between young and older adults will be exaggerated, however, if older adults must decide whether to slam on the brakes or to hit the gas as they approach a light that has just turned yellow. This additional slowing likely results because of the increased cognitive processing that must occur before the appropriate action can be selected.

Salthouse and colleagues have suggested that this decline in processing speed may underlie the age-related changes in cognitive function. It is apparent how slowed speed of processing could be detrimental to performance on any type of timed task. Importantly, however, a slower speed of processing could also manifest itself on nontimed tasks. For example, imagine that I read aloud the following arithmetic problem, and ask you to solve it in your head, with no time limit: "Jimmy walks up to a store counter with three packs of gum, each costing 50 cents. He gives the sales clerk $5. Because the clerk is out of dollar bills, she gives Jimmy his change in quarters. How many quarters does Jimmy receive from the sales clerk?" On the face of it, this is a task of working memory ability (the ability to store various pieces of information and to update the information as you work through the problem) that might be thought of as being independent from a measure of speed of processing, because there is no time limit for solving the task. However, if it takes someone a little longer to process the phrase "Jimmy walks up to a store counter with three packs of gum," it is possible that they will have a harder time attending to the phrase "costing 50 cents." Similarly, if it takes someone longer to multiply 3 by 50, it is possible that by the time that calculation is completed they will have forgotten the amount of money that Jimmy gave to the clerk. In other words, cognitive performance can suffer because the slowed mental operations cannot be carried out within the necessary time frame, and because the increased time between mental operations can make it more difficult to access previously processed information. Thus, a slower speed of processing may lead to a poorer encoding of information and a reduced ability to store information. In support of the hypothesis that processing speed changes may underlie much of the cognitive decline with aging, controlling for speed of processing often eliminates age differences on cognitive tasks, and longitudinal studies have shown a strong relation between changes in speed of processing and changes in performance on a large number of cognitive tasks.

Domain-Specific Theories of Cognitive Aging

In contrast to the domain-general theories of cognitive aging, domain-specific theories propose that some age-related declines may not be explained by core deficits that affect all aspects of cognition, but rather by changes that have a larger impact on one area of cognition than on another.

Word-finding difficulties and transmission deficits Older adults often have difficulties retrieving the appropriate name for a person, place, or thing. These word-finding problems can be manifest in various ways: excessive use of pronouns (due to difficulty generating the proper nouns), decreased accuracy and increased reaction time when asked to name items, and increased tip-of-the-tongue experiences. The tip-of-the-tongue state occurs when a person has access to a word's meaning, but not the phonological features of the word. The word seems just out of reach. Older adults tend to have more tip-of-the-tongue

experiences than young adults, particularly for proper names, and the accuracy of the phonological information available during a tip-of-the-tongue state (e.g., the first letter of the word, the number of syllables) tends to be more accurate for young adults than for older adults.

Burke, MacKay, and colleagues have suggested that these word-finding difficulties result from the fact that, with age, the links connecting one unit to another within the memory system become weaker. Thus, more links must be active in order for older adults to generate the correct name for an object or a person. This transmission deficit will mean that older adults will be relatively good at generating words when there are lots of links converging onto the word but will show larger impairments when trying to generate words that have fewer associated links. Most everyday objects have many semantic associations (e.g., individuals know that apples are red, of waxy texture, round, etc.). This convergence onto the word 'apple' (referred to by Burke and colleagues as summation of priming) makes it relatively easy to generate the name of the object. In contrast, proper names (with the exception of nicknames) are arbitrary and do not benefit from the same summation of priming (e.g., there is nothing that is required for someone to be a Jane vs. a Linda). Consistent with a transmission deficit, older adults remain relatively good at generating words of everyday objects for which they know a lot of semantic information but show larger impairments when asked to generate proper nouns.

Contextual memory and associative binding deficits Episodic memory can be thought of as including memory for two different types of information: memory for the item previously encountered (which typically can be based on familiarity) and memory for the broader context in which that item was encountered (which requires recollection). For example, when I pass by someone on the street, I might recognize that I have seen the person before (item memory). I also may remember that I met the person at a recent conference (an item–context association) or that the person is my colleague's husband (an item–item association).

Older adults remain quite good at using familiarity to recognize previously encountered people or items. However, older adults are particularly impaired at using recollection to remember the contextual details of an event. They seem to have difficulties binding together multiple event details into one cohesive memory. These deficits arise when trying to remember both item–item associations and item–context associations ('source' memory). Naveh-Benjamin and colleagues have proposed that this associative memory deficit underlies older adults' episodic memory difficulties.

Two broad types of memorial deficits may underlie this decreased ability to remember item–item or item–context associations. First, older adults have difficulties initiating effective encoding 'strategies' that would promote memory for the associative details of an experience (as proposed by Craik, Jennings, and colleagues). When they are given a strategy to use as they learn information (e.g., if they are asked to tell a story that binds the item to its context), older adults often perform as well as young adults on tasks requiring associative or contextual memory. Thus, at least some of the age-related deficits in remembering contextual details seem to result from deficits at encoding. Second, older adults seem to have difficulties either in forming a long-lasting 'bond' between an item and its context, or in retrieving that bound representation. Thus, given retrieval support (e.g., an untimed recognition task), older adults will tend to perform better than when given little retrieval support (e.g., a recall task).

Preserved Cognitive Function with Healthy Aging

Although the previous sections have focused on age-related declines, aging is not associated with across-the-board deficits in cognitive. In fact, some aspects of cognition remain markedly stable, or even improve, as individuals age.

Crystallized Intelligence

Crystallized intelligence refers to the ability to retrieve and use information that has been acquired throughout a lifetime. It often is contrasted with fluid intelligence, the ability to store and manipulate new information. As discussed earlier, fluid intelligence processes tend to be disrupted by healthy aging. Crystallized intelligence, in contrast, remains stable across the life span. Thus, older adults are very good (often better than young adults) at defining words, answering questions that rely on general world knowledge (e.g., "Who wrote the 'Star Spangled Banner'?"), detecting spelling errors, or carrying out skills related to jobs that they have held for many years.

Emotion Regulation

Another important area of preservation (or enhancement) is within the realm of emotion regulation. After about the age of 60, the ability to regulate emotion seems to start to improve. Thus, older adults show lower rates of depression than young adults. Compared to young adults, their good moods last longer,

and they are able to rebound more quickly from negative mood states. Older adults seem to focus more on positive information in their environment and to choose activities (e.g., spending time with close family or friends) based on their potential for emotional fulfillment.

At least some aspects of memory for emotional information also seem to be preserved with aging. While older adults tend to show overall poorer memory than young adults on a variety of tasks requiring retrieval of contextual information, studies of 'flashbulb memories' (memories for a public event that was highly surprising and emotional) have suggested that older adults, like young adults, are more likely to remember contextual details if the event contains emotional relevance than if it does not. The emotional memory benefit for older adults may be particularly pronounced for positive information, although a number of studies have suggested that older adults receive a memory boost when asked to remember negative experiences as well.

Neural Changes with Healthy Aging

Although healthy aging is associated with brain changes, not all regions are affected equally. To date, the vast majority of studies investigating the neural changes with healthy aging have used structural magnetic resonance imaging (MRI) (allowing examination of the volume of various brain regions) and functional MRI (fMRI)or positron emission tomography (PET) (allowing indirect measurements of neural activity as individuals are performing a task). These studies have suggested that the largest changes in structure and function occur in the prefrontal cortex and in the medial temporal lobe, while other cortical and subcortical regions remain relatively preserved across the life span. Current research also is focused on examining how the connections between regions are affected by aging. Diffusion tensor imaging studies are being conducted to examine age-related changes in white matter tracks, and structural equation modeling of fMRI and PET data is being used to investigate age-related changes in the functional connections between brain regions. These methods may provide new insights into the neural changes that mediate older adults' cognitive decline.

Changes in Prefrontal Cortex

The prefrontal cortex shows notable changes with aging. At a structural level, there is evidence of atrophy, both in the gray matter and in the white matter. The gray matter declines may reflect reductions in the number of cells (due to cell death) or may be a sign of neuronal shrinkage. The white matter changes reflect axonal abnormalities and may result in slowed neurotransmission. It is plausible that these white matter changes may mediate the cognitive slowing that accompanies healthy aging.

Prefrontal function also is altered with aging. Across a range of working memory and episodic memory tasks, older adults seem to show a different pattern of prefrontal activity than young adults, with reduced activity in some prefrontal regions and increased activity in other regions. As noted by Cabeza and colleagues, particularly in the prefrontal cortex, older adults often show a hemispheric asymmetry reduction. In other words, on tasks leading to unilateral prefrontal activity in young adults, older adults will tend to show bilateral recruitment. It is not yet clear whether this bilateral recruitment reflects compensatory activation, or whether it is a result of pathological changes (e.g., hemispheric release from inhibition). Some of the strongest evidence in favor of the compensatory view has come from studies comparing the pattern of neural recruitment in older adults who perform a task as well as young adults (high performers) and in older adults who perform the task more poorly (low performers). These studies have found that the high performers tend to recruit the prefrontal cortex bilaterally, whereas the low performers show unilateral prefrontal activity. To the extent that the prefrontal activity underlies the initiation of goal-relevant task strategies, it would make sense that the older adults who recruit additional prefrontal regions would be those who would be best able to perform the tasks. Nevertheless, future studies are required to clarify whether this compensatory hypothesis can account for all of the findings of bilateral prefrontal recruitment with age.

Medial Temporal Lobe Changes

The hippocampus proper is the other region that shows large age-related change. While there are structural changes in the hippocampus, it is not clear whether there is significant cell loss in the hippocampus with aging, or whether the structural changes are related more to neuronal atrophy (shrinkage). There also is ambiguity regarding the regions of the hippocampus that are most affected by aging. High-resolution MRI, allowing the distinction of the various hippocampal subfields (CA1, CA3, dentate gyrus, subiculum) may allow better assessment of the structure (and function) of these regions.

Functionally, the hippocampus tends to be under-recruited by older adults during both the encoding and the retrieval phases of recollective or associative memory tasks, and these functional changes often

correlate with the older adults' reduced performance on the tasks. Given the critical role of the hippocampus in forming vivid and detailed memories, it makes sense that the functional and structural changes in this region would correspond with older adults' difficulties in remembering the context in which information was learned.

Changes in Emotion Processing Regions

The fact that older adults show improved emotion regulation, and a memory enhancement for many types of emotional information, is consistent with the neural evidence indicating that emotion processing regions (particularly the amygdala and orbitofrontal cortex) are relatively spared in healthy aging. The amygdala shows minimal atrophy with healthy aging; its atrophy is on par with the decline in whole-brain volume (with a 1–3% reduction in volume every decade). Similarly, the orbitofrontal cortex seems to undergo little volumetric decline with age, particularly as compared to other regions of the prefrontal cortex.

Mild Cognitive Impairment

As discussed previously, some cognitive impairment is a natural part of the aging process. For some adults, however, advancing age is associated with fairly severe impairments in recent memory. Although the deficits do not impair their ability to function in daily life (and thus they do not meet the criteria for dementia), these individuals have cognitive impairments that exceed those that typically accompany healthy or successful aging. 'Benign senescent forgetfulness' was the first term used (by Kral and colleagues) to describe these individuals' impairments, although there were no strict diagnostic criteria associated with the concept. 'Age-associated memory impairment' (proposed by Crook and colleagues) was the first attempt at a standardized definition, requiring an individual to have subjective memory complaints and to perform at least 1 standard deviation below the mean for young adults on a standardized memory task. This concept was criticized by a number of researchers, who believed that the concept was too restrictive. Mild cognitive impairment (MCI) (defined by the Mayo Clinic Alzheimer's Disease Research Center) is the most recent in a series of attempts to characterize these individuals who straddle the boundary between healthy aging and dementia. A diagnosis of MCI requires subjective memory complaints and impairment in one area of cognition (scores must be more than 1.5 standard deviations below age-scaled norms), but with deficits not severe enough to interfere with activities of daily living or to result in a diagnosis of dementia.

There has been tremendous interest in defining this group of individuals, because as treatments that slow or reverse the development of Alzheimer's disease (AD) become available, it will be critical to have a method for diagnosing individuals at risk for, or in the prodromal stages of, the disease. Individuals with MCI seem to be an excellent population to be the targets of such treatments, because they are at increased risk for development of dementia, and of AD in particular. In fact, by some estimates, the vast majority of patients with MCI will eventually meet the diagnostic criteria for dementia.

The link between MCI and AD is supported not only by the high conversion rate, but also by the overlapping neuropathological and genetic features. Like AD patients, those with MCI have significant structural and functional changes in the medial temporal lobe. They also have alterations in the concentration of amyloid beta protein, the protein associated with neuritic plaque formation in AD. Moreover, the $\varepsilon 4$ allele of the apolipoprotein E, associated with an increased risk of developing AD, is overrepresented among individuals with MCI.

Alzheimer's Disease

AD was first described by Alois Alzheimer in 1907. In the landmark publication, Alzheimer reported a case study of a woman with severe psychiatric symptoms and memory deficits. An autopsy conducted upon her death revealed a large quantity of intracellular neuritic plaques and extracellular neurofibrillary tangles, now recognized as the pathologic hallmarks of AD.

Cognitive Changes in AD

Although dementia (a loss of intellectual function severe enough to interfere with daily activities) can result from a variety of etiologies, AD is by far the most common cause, accounting for an estimated two-thirds of all cases of dementia. Because AD can only be confirmed at autopsy, its clinical diagnosis must be an exclusionary one. Thus, the clinical profile of AD requires memory impairment plus decline in one other area of cognition (language, motor function, attention, executive function, personality, or object recognition). The deficits must have a gradual onset, and they must progress continually and irreversibly. When these criteria are met, a diagnosis of 'probable' AD is given. When made by a trained clinician, this diagnosis will be accurate in the vast majority (80–90%) of cases.

Episodic memory In contrast to healthy older adults, who remain able to successfully remember

previously encountered information (though perhaps not the context in which it was encountered), the most notable deficit for patients with mild AD is an inability to remember information encountered in the recent past. This deficit extends across different types of encoding tasks (e.g., incidental or intentional; deep or shallow processing) and exists regardless of the stimulus materials (e.g., pictures, words, faces, autobiographical events, emotional stimuli) or the task's retrieval demands (e.g., recall, forced-choice recognition, yes–no recognition). In fact, deficits in episodic memory tend to be the best way of distinguishing people with AD from healthy older adults.

Semantic memory In contrast to episodic memory, semantic memory (general world knowledge) is relatively spared with mild AD. As the disease progresses, however, significant semantic deficits arise. The deficits are particularly pronounced on word-finding tasks, with the extent of such deficits being useful for tracking the severity of AD. Current research is examining the extent to which the breakdown in semantic memory is due to changes in the structure of the memory networks (i.e., to a problem with the storage of such knowledge) or to difficulties retrieving the stored information (i.e., a problem with access).

Working memory and executive function In addition to deficits in long-term memory, Alzheimer's patients also show deficits in the online processing of information (working memory). Deficits are particularly pronounced on tasks requiring dual-task performance, suggesting that a primary deficit in AD may be in executive functions, the ability to flexibly shift attention and to attend to goal-relevant information.

Neural Changes in AD

Although plaques and tangles often are apparent throughout the brain in the later stages of AD, early in the course of the disease, the medial temporal lobe regions are those most affected. Even early in the disease, the hippocampal formation shows marked atrophy, and a volumetric reduction in the entorhinal cortex (which serves as the site of input to the hippocampus) is one of the best indicators that an individual has early AD. Given the essential role of the hippocampus for memory formation and retrieval (as demonstrated by the link between hippocampal damage and amnesia), it makes sense that patients with mild AD would be best identified by their difficulties remembering recently learned information (as discussed previously).

The amygdala is another region of the medial temporal lobe that is affected early in the disease process. This region, through its interactions with other medial temporal lobe structures, is thought to be essential for enhancing individuals' memories for highly emotional events. It is likely because of the amygdalar damage that patients with AD do not show a memory benefit for emotional information.

In addition to the medial temporal lobe changes, the nucleus basalis also shows significant cell loss in mild AD. This region of the ventral forebrain contains many of the brain's cholinergic neurons; thus, the damage to this region impedes cholinergic neurotransmission. Many of the first approved therapies for AD have been aimed at increasing the amount of acetylcholine in the brain, by blocking the function of acetylcholine esterase (the enzyme that breaks down the neurotransmitter acetylcholine). The minimal effectiveness of these acetylcholine esterase inhibitors in affecting cognitive function in AD patients suggests that the acetylcholine deficiency is not the only cause of the cognitive dysfunction in AD (and, indeed, at least by late-stage AD, there is marked depletion of other neurotransmitters, including norepinephrine, dopamine, and serotonin). The underwhelming effect of the cholinesterase inhibitors has led to continued research on alternate therapeutic options for AD, which may prove to be more effective in altering the progression of the disease.

Neural Changes in Later-Stage AD

In later stages of the disease, there is increased atrophy throughout the medial temporal lobe, and the cellular abnormalities also become apparent in the frontal lobe and throughout the temporal lobe. Because the frontal lobe is essential for higher-level executive functions, and the temporal neocortex is critical for the ability to retrieve semantic information, the advancing neuropathology in these regions clearly is linked to the cognitive deficits that arise in moderate AD. By the very late stages of AD, neuropathology is abundant throughout the cortical and subcortical structures, even within primary sensory regions (e.g., auditory, visual, and motor cortex).

Individual Differences in Aging

Unlike many diseases or illnesses that can be linked to a specific cause, MCI and AD appear to arise due to a combination of many factors, both environmental and biological. Research has begun to elucidate some of the traits that can increase the likelihood of disease development ('risk factors' such as prior head injury, mutations in the apolipoprotein, presenilin-1, and presenilin-2 genes, or having the $\varepsilon 4$ allele of apolipoprotein E) or that seem to reduce the probability of disease ('protective factors' such as high education

level, intake of antioxidants, or having the ε2 allele of apolipoprotein E). Research continues to investigate the reliability of these factors in predicting disease development and to examine whether any of the protective factors can alter disease progression once the pathological hallmarks of disease are present.

More broadly, researchers are beginning to recognize the necessity of taking an individual-differences approach to understanding the cognitive and neural changes that accompany aging. Research is now exploring the potential differences between high-performing and low-performing older adults. It is plausible that a better understanding of what differentiates the most successful agers from those who age less gracefully will lead to ideas for behavioral or neurobiological interventions that can boost the performance of individuals who experience significant age-related cognitive decline.

Anatomical Techniques

Anatomical techniques are used in a variety of ways in the service of the study of cognition, for example, to localize neuropathies in patients with cognitive disabilities or to compare the size of specific brain structures between groups of subjects through volumetric analysis. Additionally, anatomical techniques are used in conjunction with functional techniques in order to localize brain activity.

The earliest technique for imaging brain structure was computed tomography (CT). Today, it has been largely replaced by the much more powerful technique of magnetic resonance imaging (MRI). MRI provides excellent detailed structural information and enables the naked eye to distinguish gray matter (neuronal cell bodies) from white matter (myelinated tracts). New anatomical techniques, such as diffusion tensor imaging, have been developed to specifically visualize myelinated tracts. These methods can be used to track the normal and abnormal development of neural pathways in childhood.

Functional Techniques

Functional techniques have been the dominant force in cognitive neuroscience because they enable us to determine when and where neural activity in the brain is associated with the ability to perform a particular cognitive task. These techniques allow us to examine the workings of the human brain throughout the life span, in sickness and in health.

It is common to design several task variants that differ slightly in terms of task requirements. On the basis of this approach, differences in brain activation between the task variants enable us to isolate brain structures that are implicated in hypothesized cognitive processes. For example, if one wanted to identify brain regions involved in actively maintaining information in mind (referred to as working memory), one might parametrically vary the number of items (or the load) that subjects needed to maintain and then identify brain regions in which the level of activation varied according to working memory load. Although parametric variation is arguably the most powerful functional brain imaging manipulation, a more standard approach is to compare two task variants that differ only in that task 1 but not task 2 is hypothesized to engage a specific cognitive process. This approach relies on the assumption of 'pure insertion'; that is, the assumption that the insertion of the new task requirement affects only the cognitive process of interest.

Classes of Functional Neuroimaging Techniques

A variety of noninvasive functional neuroimaging techniques are available for use in humans (Figure 1); these techniques are categorized into two main classes. The first consists of methods for directly measuring electrical activity associated with neuronal firing, such as electroencephalography (EEG) and magnetoencephalography (MEG). The second main class consists of methods for indirectly measuring neuronal activity, which operate under the principle that neural activity is supported by increased local blood flow and metabolic activity. These methods include positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and near-infrared spectroscopy (NIRS). More information on each of these methods is provided in the following sections.

Direct measures of neural activity: EEG and MEG
EEG is the oldest functional brain imaging technique, dating back to Berger's discovery in 1929 that brain electrical activity could be recorded from electrodes placed on the scalp. This technique is still widely used today because of its ability to provide real-time measurements of brain activity. EEG records transient electrical dipoles generated by the net flow of electrical current across the cellular membrane during neuronal depolarization associated with postsynaptic potentials. Global EEG is used to measure neural activity during different brain states, such as sleeping and waking. A more powerful tool for cognitive neuroscience than global EEG measurements consists of event-related potentials, which refer to EEG activity averaged over a series of instances (or trials) triggered by the same event (e.g., the presentation of a visual stimulus).

Whereas EEG records the electrical activity associated with neuronal depolarization, the newer technique of MEG records the magnetic field produced by this electrical activity. The signal measured by both techniques results primarily from the activity of pyramidal neurons, which constitute roughly 70% of cells in the neocortex and are oriented perpendicular to the cortical sheath. EEG records electrical activity oriented perpendicular to the surface of the brain,

Figure 1 Relative spatial and temporal sensitivities of different functional brain imaging techniques. The level of invasiveness of each technique is indicated by a grayscale; more highly invasive techniques are shown in darker gray. Techniques used in animals only are outlined with a dashed line. Adapted from Cohen MS and Bookheimer SY (1994) Localization of brain function using magnetic resonance imaging. *Trends in Neuroscience* 17(7): 268–277.

whereas MEG records activity oriented parallel to the surface of the brain. Thus, EEG measures the activity of pyramidal cells in cortical gyri and the depths of the sulci, whereas MEG is sensitive primarily to the activity of pyramidal cells in the superficial parts of the sulci, and it is therefore more limited in its scope.

The major challenge with both EEG and MEG is referred to as the 'inverse problem,' which is the challenge of identifying the source of the underlying signal. This source can be a great distance from the point on the scalp at which it is measured, and it is affected by factors such as head shape and dipole location and orientation. Thus, it is necessary to build source localization algorithms to determine the likely source of a signal. One advantage of MEG over EEG is that the signal is less sensitive to factors such as head shape. Thus, the two techniques are complementary in that EEG samples from more neurons, but MEG is less sensitive to signal distortion. As such, some researchers take the approach of measuring EEG and MEG simultaneously to take advantage of what each technique has to offer.

Indirect measures of neural activity: PET Roy and Sherrington first showed in 1890 that brain stimulation led to a local increase in blood flow to active populations of neurons. Landau and others subsequently used radioactive tracers to measure regional cerebral blood flow (rCBF) in animals (1955), and in 1963 this technique was first applied to humans. The most widely used radioactive tracer is $^{15}O_2$, an oxygen molecule in which one electron has been removed from the atom to give an unstable form that will emit one positron to revert to the stable form $^{16}O_2$. In a PET scan, a small amount of radioactive tracer is injected into a vein. The tracer enters the brain after approximately 30 s, and in the following 30 s radiation in the brain rises to its maximal value; a picture of the rCBF is taken during this time frame.

The greatest advantage of PET over the more recent method of fMRI is the choice of radioactive tracer. Researchers can synthesize radiopharmaceutical compounds that bind to dopamine or serotonin receptors (C-11 or F-18 *N*-methylspiperone), opiate receptors (C-11 carfentanil), etc. PET is likely to continue to be important for understanding the role of various neurotransmitters in cognition. However, there are several disadvantages of PET that have led to its being surpassed by fMRI as the most widely used indirect measure of brain activity. The first of these is cost; PET facilities require not only a PET camera but also a cyclotron, which is used to produce the radioactive tracers. The second disadvantage is the poor temporal resolution – on the order of 1 min compared to 6–8 s for fMRI. Finally, PET is more invasive than fMRI, requiring the injection of a radioactive tracer (albeit one with a half-life of a few minutes), and thus it is not suitable for use in children or other special populations.

Indirect measures of neural activity: fMRI fMRI is currently the most widely used brain imaging technique for a number of reasons, including (1) widespread availability of MRI scanners and technology,

(2) relatively low cost per scan, (3) the lack of recognized risks for properly screened subjects, (4) good spatial resolution, and (5) better temporal resolution than other indirect neuroimaging methods.

In addition to observing that brain activity was associated with local changes in blood flow, Roy and Sherrington noted that the increase in total oxygenated blood delivered far exceeded the demand. It is this surplus of oxygen that is detected with fMRI, with what is known as the blood oxygen-level dependent (BOLD) contrast. Oxygenated hemoglobin, or oxyhemoglobin, has magnetic properties different from those of deoxyhemoglobin. Thus, the deployment of a strong magnetic field (typically 1.5–4 tesla when used in humans) enables one to measure changes in the ratio of oxy- to deoxyhemoglobin in local draining venules and veins. An increase in blood flow in response to a specific stimulus (be it brain stimulation or the presentation of a visual or auditory stimulus) is referred to as a hemodynamic response. This response is sluggish with respect to the underlying neural activity; for example, the hemodynamic response in visual cortex to a brief (e.g., 30 ms) visual stimulus peaks roughly 4–6 s after the onset of the stimulus.

Related Techniques

Perfusion fMRI enables direct measurement of the hemodynamic response, unlike BOLD fMRI, which relies on the comparison of hemodynamic responses under different conditions. This technique is less widely used than BOLD fMRI because of its much lower sensitivity. Magnetic resonance spectroscopy is used to measure the relative concentration and distribution of specific ions or compounds, such as hydrogen, phosphorus, or carbon.

Optical Brain Imaging

NIRS operates according to the same principle as optical brain imaging techniques that have been used in animals. Both techniques capitalize on the fact that changes in hemoglobin concentration in cortical tissue affect the absorption of infrared light by the tissue. However, NIRS is noninvasive, whereas optical imaging in animals is accomplished by exposing the surface of the brain. Because the cortical surface is not exposed in NIRS, light scattering by the skull leads to reduced spatial resolution.

During the past few years, Gratton, Fabiani, and colleagues have developed a new analytic approach to the analysis of optical data, known as the event-related optical signal (EROS). The EROS signal is based on measures of the optical properties of cortical tissue, which change when the tissue is active. The changes in these optical properties are likely to be due to changes in light scattering as a function of neuronal activity. Because this type of optical signal is directly linked to neural activity, rather than blood flow, it provides a much higher temporal resolution than the signal typically analyzed in NIRS studies. Additionally, the EROS signal has a high degree of spatial resolution, in that it can be localized to an area of less than 1 cm^3.

A drawback of all three optical imaging techniques noted previously is that they can only be used to measure activity on or near the surface of the brain (within 3–5 cm of the surface). However, these techniques are advantageous in that they are relatively inexpensive and completely noninvasive. Furthermore, because these techniques are not as sensitive to head movement as fMRI, they hold much promise for the study of clinical populations and children.

Trade-Offs between Temporal and Spatial Resolution

Direct measures of neural activity, such as EEG and MEG, have exquisite temporal resolution. They are sensitive to changes in neural activity on a millisecond resolution. However, these methods have poor spatial resolution in that it is difficult to pinpoint the precise origin of the signal. In contrast, indirect measures of neural activity have better spatial resolution than EEG or MEG but poor temporal resolution. The spatial and temporal characteristics of these various methods are shown in Figure 1. Thus, there is currently a trade-off between high temporal precision and high spatial precision. One solution to this problem is to use fMRI data to limit the possible sources of neural activity in EEG and MEG data; another – and even more challenging – solution is multimodal imaging, for example, the concurrent acquisition of fMRI and EEG data.

Advantages and Limitations of Neuroimaging Techniques

To date, much of what we know about the functions of different brain regions comes from neuropsychological studies in humans and lesion studies in animals. A distinct drawback of neuroimaging techniques is that, unlike neuropsychological and lesion techniques, they cannot demonstrate the necessity of a brain region for a specific cognitive process. However, neuroimaging techniques can demonstrate that humans without neurologic damage routinely recruit this region to perform the task. Moreover, it is possible to compare levels of activation across individuals and to state that greater activation of this region is

associated with better performance on a task. Better yet, it is possible to compare activation between trials within an individual and to state that on trials in which the subject made an error, activation was lower in this region than on trials in which the subject performed correctly. Thus, functional brain imaging techniques can be used to characterize a region's contribution to specific cognitive processes. Moreover, brain imaging techniques can be paired with techniques for temporarily disrupting neural activity in a temporally and spatially precise manner (transcranial magnetic stimulation).

There are several important advantages of neuroimaging techniques over neuropsychological ones. First, neuropsychological studies necessarily rely on the output of behavior as the critical dependent measure, whereas neuroimaging studies can focus on cognitive processes that take place prior to – or are not associated with – a behavioral response. For example, it is impossible to determine whether lesions that result in a long-term memory impairment are associated with a deficit at encoding and/or retrieval. With brain imaging, however, one can identify brain regions associated with the effective encoding of memories separately from brain regions associated with effective retrieval.

Second, neuroimaging techniques enable us to identify the entire neural circuit underlying a cognitive process. Lesion studies in animals can accomplish this only piecemeal by lesioning each area in turn. Neuropsychological studies in humans would be hard-pressed to accomplish this at all, given the limited availability of patients with specific brain lesions. This point is an important one because with lesion studies it is possible to completely overlook – or instead to overestimate – the contributions of a specific region to cognitive function. For example, the hippocampus has long been thought to be the primary structure contributing to the encoding and retrieval of memories. However, brain imaging has demonstrated that in the healthy brain, prefrontal cortex routinely contributes to memory encoding and retrieval.

The third point is also related to the limited availability of neuropsychological patients: neuroimaging techniques enable one to examine the role of a given human brain region in cognition even if one does not have access to specific patient groups. Moreover, it can be very difficult (or next to impossible, depending on the brain region) to find a patient with a lesion limited to the region in which one is interested because most brain lesions are rather coarse. Furthermore, cortical reorganization can lead to recovery of function over time, which could lead one to assume mistakenly that a lesioned brain region is not normally involved in a specific cognitive process.

Finally, neuroimaging techniques with high temporal resolution, such as EEG and MEG, provide us with important clues about brain mechanisms. It is helpful to say that brain regions X and Y are involved in memory retrieval, but if we can say that brain region X is active a short time after region Y, we can begin to gain insight into the cascade of events leading to memory retrieval.

A common criticism of neuroimaging studies is that they can be highly unconstrained and atheoretical. Like any scientific tool, however, brain imaging can be used wisely or foolishly. Certainly, many exploratory brain imaging studies have been conducted, particularly in the initial phase of brain imaging, when it was important to validate the new techniques. However, the second generation of imaging studies, starting in the late 1990s, has been much more focused. On the whole, cognitive neuroscientists carefully devise experimental manipulations designed to test psychological theories or specific predictions about brain function. Brain imaging techniques are likely to be an important force in cognitive neuroscience for the foreseeable future.

Contributions to the Study of Cognition

Neuroimaging research has been used to enrich our understanding of the neural basis of a wide variety of cognitive abilities, including attention, language, and memory. In addition, neuroimaging techniques have been used to gain insight into the etiology of neurobehavioral disorders, for surgical planning, and to assess functional recovery after brain damage.

One area in which neuroimaging studies are making important contributions is that of memory. For example, studies of long-term semantic memory have begun to uncover the ways in which stored information is organized in the brain. These studies show that different attributes of an object are stored in a distributed manner across several brain regions, with visual form information stored in a region that processes form, and functional information stored near a region that processes motion. Furthermore, studies of memory encoding have been able to pinpoint the precise regions for which level of activation during stimulus processing predicts subsequent memory for that stimulus. Additionally, studies of memory retrieval are being used to adjudicate between models of episodic memory positing that recollection (i.e., distinct remembrance of an item and the context in which it was previously encountered) and familiarity (a vague sense that the item has previously been encountered) are either distinct processes or merely

on a continuum of memory retrieval. These examples show how brain imaging studies can be used to test or adjudicate between psychological models.

Perhaps the most important contribution of neuroimaging to the field of cognition will be in the study of higher cognitive functions, which are not highly developed in nonhuman species and are therefore best studied in humans. Carefully designed brain imaging experiments have begun to fractionate the cognitive processes that underlie language, reasoning, problem solving, and other high-level mental functions, but further investigation is necessary.

Cognition: Basal Ganglia Role

Published by Elsevier Ltd.

Introduction

The basal ganglia receive widespread input from the cerebral cortex and thalamus and return that projection through output to thalamocortical pathways. The basal ganglia also receive important neurochemical inputs, in particular a prominent dopaminergic projection from the midbrain. Because damage to the basal ganglia – in a broad range of neurological disorders – produces impairments in movement, expert opinion long held that the basal ganglia had an exclusively motor role. It is now clear, however, that these structures also contribute to a wide range of cognitive functions. These functions include learning, memory, skill, planning, switching, sequencing, timing, and the processing of rewards and other feedback. This article reviews evidence relating some of these cognitive functions to the basal ganglia.

Anatomical and Neurochemical Considerations

To understand how the basal ganglia contribute to cognitive functions, it helps to consider the pathways linking their component structures: the striatum, globus pallidus, substantia nigra, and subthalamic nucleus (STN) (Figure 1). Some of these pathways facilitate basal ganglia output, others inhibit it. In the next section, we discuss how different pathways engage in initiating, inhibiting, and switching behaviors, and also briefly mention a role in sequencing a series of behaviors.

In addition to the pathways illustrated in Figure 1, larger circuits – often called loops or modules – link different parts of cortex with distinct regions within the basal ganglia (Figure 2). Each of these circuits, which involve cortex, striatum, pallidum, and thalamus, carry different kinds of information. The terms often applied to the loops, such as associative (or complex), motor, oculomotor, and limbic, or, as illustrated in Figure 2, motor, spatial, visual, and affective, are not particularly significant. More important is the concept, which contrasts with earlier ideas about the anatomy of cortex–basal ganglia interactions, that many inputs and outputs of the basal ganglia involve cortical areas that have little direct sensory or motor function. The outputs of the basal ganglia do not, as previously believed, preferentially target motor areas of the cerebral cortex; instead, they target multiple sectors of cortex, including prefrontal cortical regions implicated in cognitive processing. This fact explains how damage to the striatum, such as occurs in Huntington's disease, can produce a range of cognitive and affective symptoms, even before motor performance deteriorates. The modules illustrated in Figure 2 take the form of open rather than closed loops. That is, different loops share information, through corticocortical connections among others, so that diverse influences can contribute to the basal ganglia's final output. Most behaviors probably require cycling through multiple loops in an interactive fashion.

The neurochemical inputs to the basal ganglia also play a vital role in their function (Figure 3). In particular, prominent dopaminergic pathways originating in the substantia nigra pars compacta (SNc) and the ventral tegmental area (VTA) of the midbrain primarily innervate the dorsal and ventral striatum, respectively. As elaborated in the following discussions, several current models posit that the dopaminergic input to the dorsal striatum provides a reinforcing signal that binds the representations of stimuli and responses into stable associations, whereas the dopaminergic input to the ventral striatum plays a key role in rewarding or affective aspects of motivated behavior.

Overall, the cognitive function of the basal ganglia could be viewed as one of assigning behaviorally or biologically relevant feedback (Figure 3) to the computations performed by the various parallel loops involving the cerebral cortex, thalamus, and basal ganglia (Figure 2), with the basal ganglia's output controlled by the several different pathways converging on the pallidum (Figure 1). In the next section, these pathways are discussed in the context of preparing, initiating, inhibiting, and switching behaviors, while the subsequent two sections address the role of the basal ganglia in the processing of reward and feedback, and in the learning of new actions.

Cognitive Control: Preparing, Initiating, Inhibiting, and Switching Responses

Many lines of evidence in humans, nonhuman primates, and rodents implicate frontal cortex–basal ganglia loops in the control of responses, including both lower-order stimulus–response behaviors and the higher-order rules guiding such behaviors.

Figure 1 (a) Schematic diagram of hyperdirect, direct, and indirect pathways through the basal ganglia. Open arrows represent excitatory glutamatergic connections; filled arrows represent inhibitory γ-aminobutyric acid (GABA)ergic connections. Cx, cerebral cortex; STN, subthalamic nucleus; GPe, external segment of the globus pallidus; Str, striatum; GPi, internal segment of the globus pallidus; SNr, substantia nigra pars reticulata; Th, dorsal thalamus; glu, glutamatergic projections. (b) Schematic diagram showing the center-surround model of dynamic basal ganglia function, depicting activity changes in thalamus or cortical targets across time (vertical) caused by sequential inputs through the hyperdirect pathway (top), which inhibits all thalamocortical programs, the direct pathway (middle), which disinhibits some thalamocortical programs with concurrent suppression of alternatives, and the indirect pathway (bottom), which provides further inhibition of currently active programs to facilitate sequencing, among other functions. Stimulus–Response Behavior

In some studies of stimulus–response behaviors, participants receive a cue that signals which task – of two or more tasks – they should perform once a stimulus appears. According to current thinking, this task cue evokes a top-down process by which the prefrontal cortex biases response channels within the basal ganglia. This bias could be understood to result from frontal inputs to the striatum, which excite a subpopulation of striatal cells and therefore prime the striatum for a particular type or class of sensory input (Figure 4(a)). If the expected stimulus appears, then the participants' reaction times will be quicker. Consistent with this model, individuals respond more quickly with adequately long intervals between the task cue and the subsequent stimulus, whereas they respond more slowly with shorter intervals. Functional imaging and neurophysiological data support these behavioral observations by showing that predictive cues lead to increased activation of striatum, compared to nonpredictive cues.

Response initiation begins once the stimulus appears. As illustrated in Figure 5(a), this event engages the direct pathway of the basal ganglia, eventually leading to sufficient activation of motor cortex to generate the motor response or support an ongoing motor command initiated through other mechanisms. Inhibiting an already initiated response could occur via frontal activation of the STN, either via the hyperdirect or indirect pathways (Figure 5(b); also see Figure 1). The STN, in turn, activates the internal segment of the globus pallidus (GPi), which inhibits thalamocortical output. Functional imagining has shown activation of the STN by response inhibition in humans. Further, patients with implanted STN stimulators (for treatment of Parkinson's disease) have improved response inhibition when the stimulator is turned on compared to when it is turned off, and rodents with lesions of the STN have impaired response inhibition.

In addition to their role in inhibiting already initiated responses, the basal ganglia may also be important for inhibiting incongruent or irrelevant responses or those recently performed as a movement sequence unfolds. For example, in performing a sequence of movements in which an action by the index finger is followed by a programmed movement of the thumb, the neural representation of the index-finger movement should be inhibited after the completion of the first part of the sequence. This kind of inhibition could also depend on the indirect pathway (Figure 1(a)).

Figure 2 Cortical–basal ganglia loops, modified from the scheme of Alexander et al. Four parallel loops are shown, with possible functions labeled at the top. In the top row of rounded rectangles, the cortical areas in the left parts of bisected boxes are those that receive the thalamic projections indicated. The second row represents the striatum, the third row the pallidum, and the bottom row the dorsal thalamus. Dashed lines indicate net inhibitory influences of the indirect striatal output pathway. SMA, supplementary motor area; PMC, premotor cortex; SSC, somatosensory cortex; DL-PF, dorsolateral prefrontal cortex; PPC, posterior parietal cortex; VL-PF, ventrolateral prefrontal cortex; IT, inferior temporal cortex; ST, superior temporal gyrus; OFC, orbitofrontal cortex; Cing, anterior cingulate cortex; HC, hippocampal cortex; BLA, basolateral amygdala; V putamen, ventral putamen; GPe, external segment of globus pallidus; STN, subthalamic nucleus; GPi, internal segment of the globus pallidus; SNpr, substantia nigra pars reticulata; VP, ventral pallidum; VLo, oral (anterior) part of the ventrolateral thalamic nucleus; VA, ventral anterior nucleus of the thalamus, including the magnocellular (VAmc) and the parvocellular (VApc) parts; MDmc, magnocellular part of the mediodorsal nucleus of the thalamus. Subdivisions of the pallidum are labeled as follows: cv, caudoventral; cl, caudolateral; dm, dorsomedial; r, rostral; rm, rostromedial. Reproduced from Lawrence A, Sahakian BJ, and Robbins TW (1998) Cognitive functions and corticostriatal circuits: Insights from Huntington's disease. *Trends in Cognitive Sciences* 2: 379–387, with permission from Elsevier.

Task Switching

The same ideas that apply to stimulus–response behavior could contribute to understanding task switching, as well. A cardinal function of the basal ganglia involves switching between different tasks (or responses). Switching between tasks can be tested with a paradigm such as that shown in Figure 4(b). On some trials, the experimenter cues the subject to respond according to the 'letter' task (say aloud the letter in the upcoming stimulus, and ignore the digit), whereas on other trials the cue instructs a response according to the 'digit' task (say aloud the digit, and ignore the letter). Individuals have a slower reaction time on trials in which the they switch to a different task compared to trials on which they repeat the same task, a phenomenon known as the switch cost (Figure 4(c)). Switching likely requires a combination of both facilitating (or preparing) some responses and inhibiting others. Many studies have shown that patients with Parkinson's and Huntington's disease are impaired at switching tasks, and neuroimaging studies in healthy persons have shown increased activation of the striatum for trials with switches, compared to trials lacking them.

In terms of the model shown in Figure 4(a), frontostriatal inputs assist switching. As described earlier, the prefrontal cortex may bias the relevant response channels within the striatum in advance of the stimulus. If the expected stimulus later appears, then reaction time will be quick. If the respondent repeats the same task or response, reaction time will stay quick, because the relevant response channels remain primed, both by the top-down signal and by the just-performed response. However, if the respondent needs to switch tasks, the prefrontal cortex needs to activate or bias new response channels, and possibly inhibit previously

Figure 3 (a) Schematic diagram of striatal microcircuitry involved in reward-related motor learning. Corticostriatal axons make glutamatergic synaptic contacts (open circles) with the medium spiny projection neurons and cholinergic interneurons, thought to be the tonically active neurons (TAN). Nigrostriatal axons make dopaminergic synapses (filled circles) in the vicinity of corticostriatal synapses (as illustrated) and thalamostriatal synapses (not shown). Spiny projection neurons make γ-aminobutyric acid (GABA)ergic synapses (black triangles) on other spiny projection neurons and TANs, which, in turn, make cholinergic synapses (gray triangles) on spiny projection neurons. Phasic activity in the dopamine neurons produces pulses of dopamine able to act on corticostriatal and thalamostriatal synapses. This leads to strengthening of some synapses and weakening of others, which in turn facilitates selection of particular pathways. (b) Dopamine neurons convey an error in the prediction of reward. Each line of dots indicates a trial and each dot signifies the time that a single dopamine neuron fired an action potential in relation to the alignment event (middle vertical line). Top: No conditioned stimulus (CS). A drop of liquid reward (R) occurs unexpectedly, which constitutes a positive error in the prediction of reward, and the neuron increases its discharge rate. Middle: A learned, conditioned stimulus predicts a reward, and the reward occurs according to the prediction; hence, no error in the prediction of reward. The dopamine neuron does not respond to the predicted reward (at the time indicated by R), but instead increases its discharge rate following the reward-predicting CS (left). Bottom: Omission of predicted reward. The activity of the dopamine neuron decreases at the approximate time of an expected reward. (a) Adapted from Wickens JR, Reynolds JN, and Hyland BI (2003) Neural mechanisms of reward-related motor learning. *Current Opinion in Neurobiology* 13: 685–690, with permission from Elsevier. (b) Reproduced from Schultz W, Dayan P, and Montague PR (1997) A neural substrate of prediction and reward. *Science* 275: 1593–1599.

active ones. The interference between a currently relevant response and the recently primed one could partly explain the switch cost.

Rewards: Modulation of Striatal Signal Processing by Biological Feedback

Initiating, switching, inhibiting, and sequencing responses applies most to human behaviors in which task instructions are well understood or performance is relatively automatic. However, in many real-world situations the task to perform is not obvious and must therefore be learned or selected on the basis of biologically relevant feedback.

In many research settings with human participants and in nearly all studies with nonhuman ones, feedback is given in the form of primary reinforcers, such as water or food. Neurobiologically, feedback is coded by the firing rate of dopaminergic cells of the midbrain (Figure 3). In monkeys, this rate does not change significantly for highly overlearned behaviors, but, during the process of learning, these cells show significant modulation, which conveys to the basal ganglia either a reward signal or a signal that reflects an error in the prediction of reward. Therefore, as illustrated in Figure 3(b), when an unpredicted reward occurs, the dopaminergic cells increase their discharge rates, but for highly predicted rewards they do not. When a predicted reward fails to materialize, these cells decrease their discharge rate. With repeated experience, the cells become unresponsive to rewards *per se*, but discharge in response to signals, such as

Figure 4 (a) A schematic model of how the prefrontal cortex could create top-down bias within the striatum to guide responding. The model is shown in three panels, representing different stages of task processing. Left panel: The person's knowledge of the upcoming task (letter task) creates bias over a subpopulation of striatal response channels by biasing 'A' and 'K.' Middle panel: The visual stimulus is shown ('K2'), which triggers striatal response channels for both a letter and a digit. Right panel: The striatal response channels are in mutual competition (e.g., via lateral inhibition), and the top-down prefrontal bias creates an advantage in favor of the letter channel, so that response is 'K.' (b) Illustration of a task-switching paradigm. On each trial the person responds as fast as possible to a stimulus such as 'K2' or '7A' by attending to the relevant task (letter or digit), which is cued (either 50 or 1000 ms) prior to the stimulus by means of a green- or yellow-colored rectangle. The third trial in the series is a switch trial because the subject must now attend to the digit, whereas previously the letter was relevant. In this paradigm, there are runs of two: the first position is always a switch (of task), the second position is always a repeat (of task). (c) Switching the task is associated with a longer reaction time (RT) than is repeating the task, and this effect is especially evident when the cue–stimulus interval is short (50 ms). This phenomenon is called the preparation effect.

conditioned stimuli, that predict reward. In accord with these findings in monkeys, studies in rats show that dopamine release increases as they approach a lever that they press to produce a reward. In rats trained to associate an initially neutral cue with the reward, the presentation of those cues also leads to an increase in dopamine release.

These data thus show that the dopaminergic signal to the basal ganglia provides feedback about response outcome in biologically significant terms. This feedback has the proposed function of strengthening some striatal synapses and weakening others. This synaptic plasticity, in turn, facilitates specific striatal output pathways, thus increasing the probability that a given input will trigger a given response. Empirical evidence provides support for this model. Neurons in the basal ganglia are highly sensitive to locations or movements associated with different levels of predicted reward. When monkeys choose to turn a handle leftward or rightward, and each choice leads to a different likelihood of reward, the activity of many striatal neurons correlates best with the predicted value of one of the two movements. Fewer neurons have activity that reflects the relative value of the two choices or the movements selected. Similar properties have been observed in the eye-movement part of the striatum, a part of the caudate nucleus. When monkeys make saccadic eye movement to either a left or a right target, and, for example, only saccades to the left target produce a reward for a given block of trials, neuronal activity is greater for leftward saccades than it is during a subsequent block of trials, when the same saccade fails to produce a reward. This higher level of activity correlates with quicker reaction times for the saccade target that will produce a reward. In terms of the model discussed earlier (Figure 4(a)), the higher

Figure 5 Functional imaging of executing a motor response and inhibiting an already initiated motor response. (a) Executing a motor response with the right hand. Activation is seen in the left (contralateral) supplementary motor area, striatum, pallidum, thalamus, and left motor cortex, consistent with the direct pathway through basal ganglia (right panel). (b) Inhibiting an initiated right-hand response activates the right subthalamic nucleus (confirmed by a high-resolution scan; see (c), in which the subthalamic nucleus is outlined by the white line, one in each hemisphere). This activation could result from inputs from the hyperdirect pathway (right panel), by which motor areas of the cortex excite the subthalamic nucleus, which, in turn, excites the pallidum and so suppresses thalamocortical output. Activation also occurs in the right inferior frontal cortex, consistent with the long-standing idea that the prefrontal cortex plays a key role in behavioral inhibition. At the top, the numbers in red denote Montreal Neurological Institute positions (in millimeters, posterior or anterior to the midpoint of the anterior commissure–posterior commissure line) of coronal slices through the brain. In the far right, unfilled arrows signify inhibitory projections, filled (white) arrows indicate excitatory ones. Adapted from Aron AR and Poldrack RA (2006) Cortical and subcortical contributions to Stop signal response inhibition: Role of the subthalamic nucleus. *Journal of Neuroscience* 26: 2424–2433.

level of activity reflects the current priming or bias for movements to that location, based on the prior probability of rewards.

Many functional imaging studies confirm a reward signal in the basal ganglia, especially in the ventral striatum. In some studies, activation in the striatum correlates with predicted reward; in others, it correlates with errors in the predicted reward or with negative reinforcement. Overall, it is thought that the response-channel biases described in the previous section occur in the striatum as a result of biologically relevant feedback from the midbrain dopaminergic system. In the aforementioned studies of eye movements, the striatum receives both cortical inputs bearing spatial and motor signals and dopaminergic inputs signaling reward or errors in reward prediction. This integrated signal, then, influences the motor system through its pallidal output. A key component of the basal ganglia's role in cognition thus involves the assignment of biologically relevant feedback to the computational operations of each of the loops illustrated in Figure 2, especially those involving the prefrontal cortex. In modulating the information processing of all cortical–basal ganglia loops at the striatal level, the dopaminergic inputs can influence a wide range of cognitive behaviors, including learning, memory, skills, and habits, the topics of the next section.

Learning, Memory, Skills, and Habits

Given its role in the adjustment of behavior based on feedback, it is not surprising that the basal ganglia play an important role in the learning of new skills and habits. For example, disorders of the basal ganglia impair learning of new motor skills, such as

rotary pursuit, in which the individual attempts to keep a stylus positioned on a moving turntable. Because patients with basal ganglia disorders have impaired motor control, it can be difficult to interpret any deficits strictly in terms of an impairment in motor skill learning. However, it has been shown that these patients are impaired at motor learning even when the task is made easier, assuring that the patients and the controls start out at the same level of performance. Interestingly, some forms of motor skill learning, such as mirror tracing, are not impaired in patients with basal ganglia disorders. This can be explained based on the model that the basal ganglia may play a role in learning those tasks that require predictions generated internally (known as open-loop tasks, such as rotary pursuit), but not in tasks in which behavior is directly guided by external stimuli (known as closed-loop tasks, such as mirror tracing). This is consistent with the observation that patients with basal ganglia disorders are disproportionately impaired on tasks that require self-initiated movements, compared to visually guided ones.

The involvement of the basal ganglia in learning extends to perceptual and cognitive skills, as well. One paradigm that has been extensively investigated is probabilistic classification learning, in which an individual learns to classify stimuli into categories based on imperfect feedback (see Figure 6(a)). Patients with Parkinson's or Huntington's disease are impaired at this form of learning (Figure 6(b)), and neuroimaging studies have demonstrated activity in the striatum and dopaminergic midbrain areas during classification learning in normal persons (Figure 6(c)). This form of learning is often referred to as habit learning

Figure 6 Probabilistic classification task. (a) The task involves the presentation of cards, which the person classifies as either predicting rain or sunshine. The stimulus is similar to a set of playing cards, and the feedback indicates a rain or sunshine outcome. (b) Patients with Parkinson's disease (PD) are impaired at learning the probabilistic classification task relative to controls (CON), particularly for advanced PD (PD^{+}), whereas patients with amnesia (AMN) due to medial temporal lobe damage have little or no impairment. It has been argued that the impairment in PD results from dysfunction of the basal ganglia. (c) Activation of basal ganglia and midbrain structures (putatively the substantia nigra and ventral tegmental area) during different phases of probabilistic classification in normal controls. Functional images are shown in axial format, starting at –30 mm beneath the anterior commissure–posterior commissure line, and rising dorsally to +6 mm above it. The stimulus (top row) and the feedback (bottom row) activate midbrain, as well as ventral and dorsal regions of the striatum, compared to a no-task baseline. This finding is consistent with the proposed role of the nigrostriatal system in mediating stimulus–response learning. The delay period (middle row) between the person's response and the outcome is associated with much less activation. Blue denotes 'deactivations' (i.e., regions of the brain where the functional magnetic resonance imaging signal is less for stimulus, delay, or feedback, compared to baseline); red/orange regions indicate the reverse. because it involves the gradual acquisition of stimulus–response associations without the necessity of conscious memory: this kind of probabilistic classification learning occurs normally in amnesic patients, who cannot consciously remember the details of the task.

As discussed in the previous section for stimulus–response learning, one important role of the basal ganglia in classification learning involves the processing of feedback. Neuroimaging studies have shown that learning with feedback more strongly engages the striatum than does learning without feedback. Patients with Parkinson's disease, who are impaired at learning the task with feedback, can learn the same information normally if they do not need to process feedback to do so. Thus, the role of the basal ganglia in some forms of learning may relate to a more general role in the integration of behaviorally relevant feedback with response selection and adjustments to ongoing behavior.

Learning is associated with changes in activity in medium spiny projection neurons (MSNs) and tonically active cholinergic interneurons (TANs) in the striatum. MSNs show changes as rats learn to run a maze. MSNs shift from firing throughout the behavior to firing selectively at the beginning and end of the behavior sequence. These patterns are also sensitive to extinction and reacquisition of the maze-running skill, and their firing is highly predictive of the animal's behavior. In primates, the observed learning-related changes in the putamen, as well as in the prefrontal cortex, closely mirror behavioral learning curves. In the caudate nucleus, similar changes appear earlier during the learning process, when cells appear to code for stimulus–response contingencies before they are fully reflected in behavior. These results are consistent with lesion studies which suggest that the caudate is responsible for learning of new stimulus–response relations (perhaps by quickly coding the reward associations of individual places or responses to those places), whereas the putamen is responsible for the learned expression of these relations. TANs in the striatum appear to be sensitive to the motivational relevance of stimuli regardless of their valence (appetitive or aversive).

The range of findings suggests that the striatum may in some cases compete with the medial temporal lobe to determine behavior. For example, in a cross-maze task, rats must learn to run from a particular starting point to a particular arm of the maze in order to receive food. The rat's response from a different starting point in the maze can be used to probe how it learns the task; early in training, rats will go to the same place in the maze (the place-learning strategy), which is dependent upon the hippocampus, whereas later in training they will make the same movements (a response-learning strategy), which is dependent upon the striatum. However, inactivation of the hippocampus or stimulation of the striatum early in training leads to the use of a response-learning strategy, whereas inactivation of the striatum or stimulation of the hippocampus late in training causes the animal to revert to a place-learning strategy. Thus, both systems appear to be able to drive behavior, and performance is determined by the relative balance of activity between the two systems. An alternative view is that early in training rats use external cues, such as those from vision, to determine the distance and direction to their next goal, whereas later in learning they use internal signals. These internal signals consist of efference copy, which matches the motor command that produces the response, and proprioceptive feedback that tells the motor system whether the current response is proceeding as planned. Thus, the place-learning strategy might be better construed as an exteroceptive strategy, and the response-learning strategy as an interoceptive one. This formulation agrees with the idea, expressed previously, that the basal ganglia's core function may involve a general role in the integration of behaviorally relevant feedback with response selection. Along these lines, functional imaging studies in human study participants show that activity in the striatum and medial temporal lobe correlates negatively across participants and across learning trials. Further, dysfunction of the basal ganglia is associated with a general increase in the engagement of the medial temporal lobe during the learning of tasks that are normally dependent upon the striatum. The mechanisms by which this competition occurs are not yet understood, but they could rely upon biasing signals from the prefrontal cortex (**Figure 4(a)**).

Synthesis

The basal ganglia play a nearly ubiquitous role in cognition. Their contribution can perhaps best be appreciated by considering them as a device that resolves the selection demands that confront a behaving organism. These demands require prioritizing, scheduling, planning, sequencing, and generally controlling the way in which context elicits behavior in accordance with external and internal constraints. Which behavior occurs depends on many factors: top-down biases from the prefrontal cortex that prime particular response channels, the salience and prior rewarding properties of stimuli, the prepotency of various alternatives, and the degree of competition from other cognitive systems. By integrating different information through the interconnections among parallel cortical–basal ganglia loops, moderating this flow

according to the various pathways that influence basal ganglia output, and incorporating signals from neurotransmitter systems that monitor outcomes in biologically relevant terms, the basal ganglia can control systems of thought as well as action.

Cognition: Cerebellum Role

J E Desmond and C L Marvel, The Johns Hopkins Medical Institutions, Baltimore, MD, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The cerebellum has been historically linked to the control of posture, gait, and skilled voluntary movement. Yet, numerous cases have been reported – dating back to the early 1800s – of nonmotor deficits, such as mental impairment, in patients with cerebellar degeneration and atrophy. Despite these reports, a distinct bias persists among many researchers and physicians that cerebellar-related cognitive deficits are attributed to some type of motor response or to lesion encroachment onto other brain regions. Indeed, some of the earliest functional neuroimaging studies used cerebellar metabolism as a baseline from which neocortical cognitive activation was compared because it was assumed that the cerebellum was silent during cognition.

A new wave of interest in nonmotor functions of the cerebellum began to emerge in the early 1990s. With functional neuroimaging in the hands of a rapidly increasing number of neuroscientists, increasingly more cerebellar activations that were difficult to explain in terms of simple motor processes were reported, and these results were seen to converge with results reported in the patient literature. This article reviews some of the relevant findings supporting a role for the cerebellum in executive function. Executive function refers to some of the highest levels of cognitive control, including planning, organization, decision making, problem solving, and logical analysis. Executive function is typically required when information needs to be coordinated or manipulated, or when prepotent or habitual responses need to be inhibited. Transynaptic neuroanatomical tracing studies have provided convincing evidence that lateral and posterior regions of the cerebellar cortex project through ventral portions of the dentate nucleus and the thalamus to connect with dorsolateral prefrontal regions implicated in executive control. Thus, an anatomical foundation exists by which cerebro-cerebellar networks can influence higher level cognition.

Functional Neuroimaging Studies

Functional neuroimaging methods such as positron emission tomography and functional magnetic resonance imaging (fMRI) are sensitive to regional metabolic changes in blood flow that occur as a result of increased neuronal activity. As summarized here, neuroimaging has revealed cerebellar activation in many investigations that focus on executive function.

Verbal Working Memory

Cerebellar activations have been consistently observed by a number of researchers in verbal working memory tasks. In their simplest form, these tasks require the online maintenance of verbal information via a 'phonological loop' – that is, the refreshment of phonological information through repeated articulatory rehearsal. For example, keeping a phone number in mind long enough to dial a telephone would typically require verbal working memory. Manipulation of the stored information is hypothesized to engage 'central executive' processes of working memory. For example, the *n*-back task entails sequentially presenting letters to the subject, whose task is to decide if the present letter matches the one that occurred *n* letters ago. Comparisons of activation in the *n*-back task relative to those observed in more maintenance-based tasks have shown that although the cerebellum responds to both kinds of working memory tasks, more lateral cerebellar activations are observed for the manipulation task, in conjunction with greater dorsolateral prefrontal activation.

Verbal Fluency

Verbal fluency is a frequently used measure of executive function. Common neuropsychological testing involves asking a subject to say as many words as possible in 60 s that begin with a specific letter. Usually, this procedure involves organizing output into meaningful clusters in order to speed responses. For example, if prompted with the letter S, one may first try to think of S words that begin with the letters S–E (set, settee, sell, self, seep, etc.). When neural activations during letter fluency are compared to a control condition (e.g., counting forward from 1), subjects increase activation in the left prefrontal cortex and right cerebellum.

Some of the earliest demonstrations of cognition-related cerebellar activations were reported for a particular type of verbal fluency task referred to as verb generation. This involves the presentation of a noun, such as 'ball,' and the subject responds with an appropriate action verb, such as 'throw.' As a control condition, the noun is simply read and repeated. This and other fluency tasks, such as word stem completion, are associated with robust right posterior cerebellar and left prefrontal activations. Interesting practice-related effects have been associated with

these activations. If subjects are given a second run of the verb-generation task using the same set of nouns that they saw on the first run, left prefrontal and right cerebellar activation diminish concurrently and increase again when novel nouns are presented. These results demonstrate the close functional coupling of the cerebro-cerebellar network during cognitive operations. However, this coupling may reflect complementary rather than redundant functionality. For example, in the stem completion task, word stems with few possible completions (e.g., PSA__) elicit greater cerebellar activation compared to completion of stems with many possible completions (e.g., STA__), whereas the reverse is true for activation in left prefrontal regions. One possible explanation for this dissociation is that cerebellar activation during word stem completion is related to word search operations, whereas prefrontal activation is related to word selection.

Cognitive Flexibility

A popular neuropsychological test for assessing the ability to shift cognitive sets according to changes in stimulus contingencies is the Wisconsin Card Sorting Test (WCST). In the WCST, subjects are required to sort cards according to one of three possible dimensions: number, color, or shape. The subject must determine the correct sorting strategy on the basis of right/wrong feedback that is presented after the subject's response to each card. The experimenter can change the correct sorting strategy suddenly without warning, and the subject must then determine the new dimension for sorting. Impaired performance on the task is observed as a tendency to perseverate on the incorrect strategy in light of new information that contingencies have changed. As a neuropsychological test, the WCST appears to be sensitive to frontal lobe dysfunction, but the specificity of the test to the frontal lobes has been questioned. Indeed, neuroimaging studies have revealed a large network of cortical and subcortical activations, including bilateral cerebellum, when contrasting WCST performance with sensorimotor control tasks. Such control tasks effectively rule out simple visual- or response-elicited explanations for cerebellar activation, but they do not address whether the cerebellum may be responding to the nonexecutive working memory requirements of the task, such as the need to keep the current relevant dimension of the stimuli in mind. Recent investigations, however, have tried to separate higher order from lower order cognitive operations in the task. For example, by contrasting the WCST task with a task that cues the subject when a dimension change occurs, simple working memory maintenance operations are presumably subtracted out, and what remains are the most executive components of the task. Cerebellar activations have been shown to persist when such subtractions are performed.

Reasoning/Planning

A number of different studies have examined the neural substrates of higher order skills used in hypothesis testing and logical inference. These investigations have applied one of three main approaches. The first requires the subject to solve a puzzle, with the control condition attempting to equate the sensorimotor aspects of manipulating puzzle pieces in the absence of planning. The second requires the subject to form a hypothesis about features presented within a group of multidimensional stimuli (e.g., containing letters, numbers, shapes, and colors or composed of a large grid of squares, a subset of which are filled, whereas others are unfilled). On each trial, the subject determines which features of the stimuli are relevant or correct. Control conditions typically involve presenting identical stimuli but asking the subject to attend and respond to only one dimension. The third approach requires subjects to decide whether three-sentence syllogisms, presented with either semantic or nonsemantic content, are logically valid. An effective control condition for this type of study replicates much or all of the working memory requirements of the reasoning task. It entails reading three sentences, the first two of which are plausible premises, whereas the third contains unrelated content and therefore requires no reasoning. For each of these approaches, prominent cerebellar activation has been observed, suggesting a role for the cerebellum in reasoning and planning.

Dual Tasks

Patients with executive dysfunction often exhibit profound difficulties performing multiple tasks at once. In healthy subjects, performance typically declines for both tasks relative to performance in either task alone, but subjects are nevertheless able to perform both tasks to some degree. Dual-task performance has thus been used by neuroimagers to investigate whether there are specific neural correlates of cognitive coordination. Of particular interest are tasks that show unique regions of activation during dual-task performance relative to single-task performance. Such studies have shown that in cases in which neither prefrontal nor cerebellar activation are evident for either task alone, dual-task performance recruits new prefrontal, parietal, and cerebellar regions.

Random Number Generation

Random number generation (RNG) requires a subject to randomly generate numbers, usually 1–10, while suppressing the natural tendency to count in sequence or to repeat the same number habitually. Thus, RNG involves both fluency and inhibition. When subjects are forced to generate random numbers at increasing rates, numbers tend to become less random and more sequential. Neuroimaging investigations have thus used pacing stimuli to control the rate of RNG and have typically contrasted activation for this task with that obtained from counting in sequence. Medial portions of the cerebellum have been shown to increase activation with increasing rate of performance, consistent with either motoric or timing functions. However, more lateral portions of the cerebellar hemispheres have exhibited diminution of activation at faster rates of RNG compared to serial counting. These occur in parallel with similar diminutions seen in dorsolateral prefrontal and parietal regions. These results suggest that a cortical–subcortical executive network is involved in suppressing habitual responses and that at increasing rates, network activity and behavioral performance begin to break down.

Theory of Mind

The ability to infer intention or mental states in others is an important aspect of human social interaction and has been referred to as possessing a 'theory of mind.' Both verbal and nonverbal approaches have been used in neuroimaging investigations of theory of mind. An example of a nonverbal approach would be to present a subject with frames of a cartoon and ask the subject to choose an ending frame from two or three choices using a button press. For the theory of mind condition, the choice of the ending requires inferring the intention of the character depicted in the cartoon, whereas the control condition requires understanding physical causality but does not involve making inferences of motives. An example of a verbally based approach would be to ask subjects in the theory of mind condition to read a brief story describing the actions of a character and then to make up a story explaining the conditions that led to the character's behavior. As a control condition, subjects read aloud a story that requires no attribution of intentions, thereby equating the same amounts of reading and word production produced by the theory of mind task. In both approaches, strong cerebellar activation has been observed in the theory of mind condition relative to the control condition. For the nonverbal tasks, left cerebellar/right prefrontal activation has been observed, whereas the laterality of frontocerebellar activation is reversed for the verbally based approach.

Patient Studies

Evidence for cerebellar contribution to executive function can be drawn from neuroimaging and neuropsychological studies of cerebellar-affected clinical populations. In these cases, the cerebellum may be disrupted early on as a result of maldevelopment or during adulthood following years of normal function.

Neurological Disorders

Compelling evidence for the cerebellum's participation in executive function comes from studies of patients with neurological disorders confined to the cerebellum. These data have been derived from neuropsychological studies of patients with cerebellar stroke, tumor resection, cerebellar degeneration, and cerebellitis. In general, executive dysfunction seems to be most pronounced in cerebellar patients with large bilateral infarcts, followed by those with unilateral infarcts, and least in those with pancerebellar involvement. However, deficits are not always evident or as severe as might be expected given the size of the lesion. Heterogeneity of lesion type and time since lesion onset are two key factors that affect a patient's degree of impairment. Improved function has been noted in those with nonprogressive lesion types (e.g., stroke) after several months of recovery.

Relatively few studies have directly addressed the cognitive contributions of the cerebellum in clinical populations. This is due, in part, to the difficulty in acquiring patients with diseases confined to the cerebellum with an absence of disease elsewhere in the brain. However, one seminal study, conducted by Schmahmann and Sherman, tested 20 patients with cerebellar diseases on a variety of neuropsychological tests that involved executive skills. Patients were most impaired in working memory manipulation, verbal fluency, and complex figure copying. During complex figure copying, one is presented with a drawn design and asked to copy it while the figure is in plain view. Although this may appear to be a straightforward task, patients have difficulty copying the figure if they cannot develop a drawing strategy, such as where to begin. They may also be unable to organize and maintain a long-term plan for drawing so that the design is redrawn in sections. There may be a focus on details without consideration for the overall configuration. This results in a drawing of several geometric

Figure 1 Copying complex figures relies on executive skills, such as planning, organizing, and maintaining a strategy for sequential actions. In these drawings, a copy of the Rey–Osterreith complex figure (ROCF; left) was drawn by a patient with a symptomatic postcerebellitis infection. The same patient copied the Taylor complex figure (TCF; right) 3 months later. Using the colored pencil lines as a key to the sequence of the patient's actions, one can see that the patient applied a part-based approach to the ROCF. She drew the figure piecemeal, completing the major sections of the right side first (black). Next, she drew the general composition of the left side (red) and then went back to fill in details on the right side (blue). Finally, she returned to the left side to add a few more details to complete the drawing (green). The final construction is awkward in design but includes all relevant pieces of the original figure. In sharp contrast, 3 months later the patient applied a highly organized copying strategy that included a configurational approach to the TCF. The patient began by drawing the general outline of the figure (black). She worked her way clockwise by filling in the upper left and right quadrants next (red). Finally, she filled in the bottom right and left quadrants (blue). This efficient strategy allowed her to complete the figure quickly before being asked by the experimenter to draw with the green pencil. In addition to improving her copying speed, the recovered patient drew neater, stronger lines that rendered a highly accurate depiction of the complex figure. Reproduced from Schmahmann JD and Sherman JC (1998) The cerebellar cognitive affective syndrome. *Brain* 121(Part 4): 561–579, by permission of Oxford University Press.

shapes that are not well integrated into a whole. Often, figure parts are misplaced or missing altogether. Without intact skills for creating and implementing a copying strategy, a patient can eventually produce a rough version of the figure but inefficiently and usually with errors. To illustrate such deficits, Figure 1 shows two copies of complex figures drawn by a patient during the symptomatic phase of a postcerebellitis infection (left, Rey–Osterreith complex figure) and by the same patient 3 months later during recovery (right, Taylor complex figure). It is clear that during the symptomatic phase of the illness the patient was unable to appreciate the overall configuration, which resulted in an inefficient part-based approach to figure copying. After recovery, the patient was able to rely on her improved executive skills to use a configurational approach, which yielded a highly organized and accurate replication.

Although patients with cerebellar disease may exhibit executive dysfunction, the current opinion posits that disrupted communication between the cerebellum and the frontal lobe contributes to these deficits. A breakdown in the frontocerebellar network may result in an inability of the cerebellum to contribute to the frontal lobe's temporal organization of mental processes. Consequently, an otherwise coordinated sequence of cognitive events unravels, leading to a phenotype of cognitive impairment. The term dysmetria of thought has been given to describe this phenomenon in patients with cerebellar disease.

Developmental Disorders

There are a number of developmental disorders that involve the cerebellum. However, maldevelopment is not typically confined to the cerebellum and often influences additional areas of the brain. With increasing popularity in the use of neuroimaging tools, however, researchers have been able to associate structural and functional abnormalities of the cerebellum with executive dysfunction in several developmental disorders, as summarized here.

Attention-deficit/hyperactivity disorder Attention-deficit/hyperactivity disorder (ADHD) is characterized by inattention and hyperactive or impulsive behavior. Executive dysfunction is a prominent feature of ADHD and may be related to an underlying core disturbance in response inhibition. A fairly consistent finding in ADHD brain research is reduction in total cerebellar size, most markedly in the posterior vermis (lobes VIII–X). Although nearly all brain imaging research in ADHD has been conducted

in children and adolescents, evidence suggests that cerebellar abnormalities are not progressive and are not related to medication treatment. Studies using fMRI in ADHD have reported decreased cerebellar activation during verbal working memory and response inhibition. However, the severity and consistency of cerebellar-related cognitive impairments in ADHD has not been firmly established. For example, several fMRI studies of executive-type tasks in ADHD children have implicated frontal–striatal rather than frontocerebellar pathways. It is possible that cerebellar disturbances in ADHD disrupt executive function through miscommunications with a larger neural network that includes the frontal lobe and basal ganglia.

Autism spectrum disorder Autism spectrum disorder (ASD) is marked by impaired interpersonal relations, poor communication skills, and reduced or repetitive interests and behaviors. It is believed that poor cognitive planning, flexibility, and inhibition underlie the social and behavioral abnormalities associated with ASD. The most consistent postmortem finding in ASD is decreased cerebellar Purkinje neurons in the absence of neurodegeneration. Genetic disturbances in cerebellar development may lead to a disruption in normal cerebellar functions and contribute to the onset of autistic symptoms. fMRI studies that target cerebellar functions in autism are beginning to emerge in the literature. For example, decreases in cerebellar activation have been reported in ASD subjects while observing (but not while imitating) emotional expressions. Attention-related decreases in cerebellar activation also have been reported. Cognitive and social deficits that are inherent to ASD may be attributed to maldevelopment of the cerebellum and/or its communication with other brain structures. However, there is an obvious need for future studies on this topic in order to better characterize the role of the cerebellum in autism.

Dyslexia Dyslexia is a developmental disorder identified in children who fail to attain reading and writing skills commensurate with their level of education and intelligence. Poor motor coordination and delayed motor milestones have also been noted in dyslexic children. Although there are several hypotheses regarding the fundamental disturbance in dyslexia, one view is that dyslexics have cerebellar-related difficulties with automatization of skills. Automaticity – the ability to perform a skill fluently and without conscious effort in doing so – is essential for multitasking. Impaired automaticity in dyslexia may contribute to difficulties in phonological processing, word recognition, verbal working memory, and, ultimately, fluent reading. It is generally accepted that the cerebellum plays a key role in automatization, and that cerebellar damage can force one to pay extra attention to skill sequences that never become automatic. Accordingly, dyslexics have difficulties performing tasks that require the blending of two or more skills. For example, balancing ability (e.g., standing on one foot) becomes disproportionately affected when dyslexics perform a counting task at the same time. Cerebellar structural abnormalities, such as decreased anterior lobe volume, have been reported in this population. Moreover, these abnormalities have been correlated with cognitive tests of verbal ability, such as spelling, word identification, and rapid letter naming. Although there is persuasive evidence to support cerebellar-related cognitive deficits in dyslexia, there has not been full agreement on this in the literature. Notably, some researchers maintain that the cerebellum is only secondarily related to dyslexic cognitive impairments, with primary deficits attributed to cortical areas. However, the cerebellar hypothesis provides an interesting and parsimonious explanation for both the motor and the cognitive deficits observed in this disorder.

Schizophrenia Schizophrenia is a psychiatric disorder that involves an array of perceptual, emotional, motor, and cognitive impairments. Cognitive deficits are widespread but are found in several important components of executive function, such as attention, working memory, sequencing, and problem solving. Data supporting cerebellar-related cognitive disturbances in schizophrenia have come from functional neuroimaging studies of working memory, verbal recall, and social cognition. In addition, structural imaging studies have found decreased cerebellar volume, especially of the vermis, although some reports have also noted increased cerebellar volume or normal cerebellar volume. Perhaps the most compelling study to date on this topic, conducted by Ho and colleagues, examined 155 neuroleptic-naive schizophrenia patients on a comprehensive cognitive battery. In addition, patients were examined for cerebellar soft signs (motor impairments referable to the cerebellum), including unsteady tandem gait, intention tremor, poor balance, and flaccid muscle tone. Thirty-two patients were identified as having cerebellar soft signs. Relative to the 123 patients without cerebellar soft signs, these 32 patients exhibited specific deficits of attention, working memory, problem solving, and figure copying in addition to having overall smaller cerebellar volume. These results suggest that decreased cerebellar volume in

schizophrenia is related to impairments of motor coordination and higher order cognitive skills. Given that cerebellar abnormalities have been reported in many, but not all, regional brain volume studies of schizophrenia, this phenomenon may apply to only a subset of patients.

Individuals born very preterm Children born very preterm (i.e., <33 weeks of gestation) often show signs of putative cerebellar dysfunction, such as clumsiness and poor motor coordination. Although neuroimaging studies are only beginning to emerge on this topic, data suggest that total cerebellar volume is decreased in these individuals. Moreover, volumetric decreases in lateral cerebellar hemispheres have correlated with performance on tests of abstract reasoning and visuospatial construction. Functional neuroimaging of adolescents born preterm has revealed bilateral reductions in cerebellar activity during response inhibition, despite normal task performance. Because the pre-, peri-, and neonatal periods represent a vulnerable time for brain formation, individuals who are unable to complete the full gestation (approximately 38 weeks) run the risk of maldevelopment. This risk is not specific to the cerebellum, and indeed, abnormalities have been reported in multiple cortical and subcortical brain areas in this population. Therefore, cerebellar contributions to cognitive and motor deficits observed in preterm individuals may be further attributed to underlying factors, such as hypoxia, sepsis, or malnutrition around the time of birth.

Substance Abuse

A recent view on substance abuse holds that executive dysfunction is responsible for the loss of self-control that leads to drug and alcohol addiction. Evidence implicating the cerebellum in substance abuse suggests that the cerebellum may contribute to cognitive deficits (e.g., poor inhibition) that segue into drug-seeking behavior. Structural brain imaging of alcoholics has revealed volume reductions throughout the cerebellum, particularly in the anterior vermis. Similar cerebellar abnormalities have been reported in children exposed to high prenatal doses of alcohol. Functional neuroimaging has shown that activity in the left anterior cerebellum and cerebellar vermis increases during alcohol craving. Moreover, alcoholics have demonstrated excessive right anterior cerebellar activation while performing a task of verbal working memory. Studies have also shown that abnormal cerebellar blood flow is associated with the use of cocaine, marijuana, methylphenidate (Ritalyn), 3,4-methylenedioxymethampetamine (MDMA, or ecstasy), and amphetamine. For example, blood flow to the cerebellar vermis increases in cocaine users when viewing cocaine-related cues. Over-responsive activity in the left cerebellum of cocaine users has been associated with high demands on working memory and self-inhibition. A similar pattern of excessive left cerebellar activity has been observed in heavy marijuana users while performing a complex decision-making task. In nearly all cases, findings from the structural and functional imaging studies described previously have implicated the prefrontal cortex in conjunction with the cerebellum. This pattern suggests that a disrupted frontocerebellar circuit contributes to drug and alcohol addiction. However, specifying the contributions of the cerebellum to substance dependence first requires a deeper understanding of the cerebellum's role in cognition.

Cerebro-Cerebellar Interactions

Most complex behaviors require a response of some kind, and this inevitably invokes motor systems. Given the involvement of the cerebellum in motor control, it may be difficult to completely separate cognitive- and motor-related cerebellar functions. However, the results of Hulsmann et al. illustrate how cognitive and motor involvement of the cerebellum falls along a continuum, reflecting progressive activation of cerebro-cerebellar closed loops, rather than a dichotic absolute. Figure 2 shows that for a self-paced finger response (button press), activations occurring close in time to the finger response, and soon thereafter, are observed in primary sensorimotor cortex as well as in medial spinocerebellar regions. In contrast, looking 3 or 4 s prior to the response, activations are observed in neocortical areas associated with motor planning, such as supplementary and premotor cortex, as well as in more lateral regions of the neocerebellum. This example is derived from a relatively simple behavior. However, it is not difficult to extrapolate from these results and hypothesize that as higher order planning is required – occurring even more remotely in time from the final motor response – neocortical regions, such as parietal and dorsolateral prefrontal regions, are in communication with the most lateral and posterior regions of the cerebellum during executive planning operations. As described in the introduction, anatomical studies have demonstrated the existence of these closed-looped cerebro-cerebellar circuits. The successive activation of these circuits during the time course of simple and complex behaviors gives us a beginning framework for understanding why the cerebellum is active in so many functions, from motor control to cognition.

Figure 2 Color-coded map depicting the time course of maximum activation relative to a self-paced thumb movement. Earliest activations prior to movement are depicted in blue and green and occur in cingulate motor areas, supplementary motor, and premotor areas, as well in the lateral neocerebellar regions. Activations occurring at the time of movement and slightly thereafter are observed in primary sensory and motor cortex as well as in medial spinocerebellar regions. The sequential progression of regional activations during this simple motor behavior demonstrates how cerebro–cerebellar interactions could progress in similar closed-loop circuits during executive function. The prefrontal cortex (PFC) is instrumental in coordinating, controlling, and executing cognitive and emotional processes using appropriate judgment, flexibility, and attention. The ability to organize appropriate responses to a changing environment requires maintenance and updating of relevant information as well as control over the processing of new incoming information. This careful choreography allows the regulation of impulses, language, attention, decision making, and error correction and is commonly referred to as the executive functions. These abilities require the representation of information not currently in the environment (sometimes referred to as working memory) and are mediated by the PFC. The PFC receives ascending inputs from diverse areas of the brain. The dorsal and lateral surfaces of the PFC interconnect with the sensory and motor association cortices and are key for the regulation of behavioral responses and attention; the ventral and medial regions of PFC interconnect with brain regions involved with emotion, such as the amygdala, hypothalamus, and nucleus accumbens. The ventral surface is often referred to as the orbital frontal cortex (OFC) because it sits above the orbits of the eyes. In rodents, the PFC is much smaller; there is a medial portion (the prelimbic and infralimbic mPFC) that is needed for cognitive control and an orbital area more ventral-laterally that has functions similar to the OFC in primates. The homology of the mPFC in rodents to the dorsolateral PFC in primates is controversial. It is likely that it is more homologous to the mPFC in primates and involves a combination of affective and cognitive functions.

Single-unit recording studies in monkeys have shown that PFC neurons are able to hold modality-specific information online over a delay and to use this represented information to guide behavior in the absence of environmental cues. PFC neurons can also fire in relationship to an abstract rule that is used to govern action. A unique feature of PFC neurons is their ability to maintain information in the presence of distracting stimuli. Delay-related firing also can serve as the basis for behavioral inhibition (e.g., having to look away from a remembered visual stimulus or reverse reward contingencies). Neuromodulators can have powerful effects on the patterns of PFC neuronal response and on PFC cognitive functioning.

The PFC is highly sensitive to its neurochemical state. Evidence to date suggests that the dorsolateral PFC is particularly sensitive to catecholamines (dopamine (DA) and norepinephrine (NE)), whereas the ventromedial PFC is more influenced by serotonin (5-HT). This view has emerged from both lesion studies in nonhuman primates that selectively deplete catecholamines (vs. 5-HT) and from pharmacological studies in humans that preferentially block catecholamine (vs. 5-HT) transporters. However, there are critical exceptions to this generalization; for example, NE α2A-adrenoceptor stimulation can improve ventromedial PFC functions, and 5-HT2A receptor blockade can impair dorsolateral PFC function. Acetylcholine (ACh) also has powerful influences on PFC functions, although there has been little research on cholinergic mechanisms in the monkey PFC. Most of the research examining direct cholinergic mechanisms in PFC have been performed in rats using attentional tasks, and thus it is difficult to compare results across paradigms.

It is noteworthy that the PFC also projects back down to the monoamine and ACh cells, and thus it is positioned to regulate its own modulatory input. Interestingly, the NE and DA cells respond to informative cues and receive projections from the dorsolateral PFC, whereas the ACh cells respond to rewards and response choices, and these cells receive inputs from the OFC. Recent studies indicate that NE cells also receive projections from the OFC and anterior cingulate and that these projections may regulate their tonic firing rate rather than the response to specific stimuli. Thus, there is a coordinated interplay between the subregions of the PFC and their modulatory inputs.

Dopamine

The pioneering work of Goldman-Rakic first revealed the powerful influences of DA on the working memory functions of the dorsolateral PFC. This initial study found that depleting catecholamines in PFC was as destructive as removing the cortex itself. Although this first study focused on DA, it is now known that the depletion of both DA and NE may be especially deleterious.

The DA inputs to the PFC arise from the dorsal cells of the substantia nigra and from the ventral tegmental area in the midbrain. DA neurons project throughout the primate cortex, with highest levels in primary and secondary motor cortices. Within the PFC, the medial PFC actually has a denser innervation than the

dorsolateral PFC, despite the established importance of DA to dorsolateral PFC function. Thus, the quantity of innervation cannot be equated with the importance of an input because it is possible that some delicate inputs may be relatively sparse because they are so powerful.

There are two families of DA receptors: the D1 family (D1 and D5) and the D2 family (D2, D3, and D4). There are currently no drugs available that distinguish between D1 and D5 receptors; thus, reference to D1 usually means D1 or D5. The highest levels of DA receptors in the PFC are the D1 family, and these receptors have been the focus of most research on DA mechanisms in the PFC. D1/D5 receptors can be found in both superficial and deep layers of the PFC, with D1 receptors concentrated on spines and D5 receptors on shafts of pyramidal cells. In contrast, the D2 receptor family is more concentrated in layer V, the cells that project to the basal ganglia. Thus, the D2 family may be especially involved with modulating the response output. D4 receptors are especially numerous on γ-aminobutyric acid (GABA)ergic interneurons in the PFC.

Most research on DA influences on PFC cognitive function has focused on spatial working memory. In monkeys, spatial working memory generally has been assessed using an oculomotor or classical delayed response task. This paradigm requires the monkey to remember a spatial location over a brief delay (seconds). The location changes on each trial so that memory must be continuously updated. Electrophysiological studies of PFC neurons record single units from monkeys performing the oculomotor version of this task. Many neurons in PFC exhibit spatially tuned firing during the delay period; that is, the cells fire more for a preferred than for a nonpreferred direction. This is considered the electrophysiological signature of spatial working memory. In rats, spatial working memory is often assessed in a spatial delayed alternation task, within a T-maze, or using automated operant procedures. Delayed nonmatch-to-position is often substituted for delayed alternation, but it is substantially easier due to diminished proactive interference. In humans, spatial working memory is tested in a variety of paradigms, including a search task on the CANTAB battery and N-back tasks developed from the monkey delayed-response task. In addition, human studies often use the Wisconsin Card Sorting task, Stroop Interference task, and Stop-Signal tasks, which emphasize the inhibitory functions of the PFC.

The D1 family of receptors has powerful effects on spatial working memory function. Either too little or too much D1/D5 receptor stimulation impairs working memory; that is, there is an inverted-U dose–response curve that occurs within normal physiological parameters (see Figure 1). Insufficient levels of DA D1 stimulation probably contribute to cognitive deficits in Parkinson's disease and may also contribute to normal age-related cognitive decline. Excessive levels of D1 receptor stimulation occur during stress exposure and contribute to stress-induced PFC dysfunction. This inverted U in working memory abilities has been observed in monkeys, rats, mice, and human subjects. In humans, an inverted U has been observed in relation to the COMT genotype, whereby the substitution of methionine for valine weakens enzymatic degradation of DA and shifts the U curve rightward. An inverted U is also observed in single-unit recordings of monkeys performing a spatial working memory task. D1 receptor stimulation is especially important for suppressing cell responses to nonpreferred spatial directions. These suppressive effects are mediated by the activation of cyclic adenosine monophosphate (cAMP) intracellular signaling. The effects of D1 receptor stimulation probably depend on the endogenous state of the neuron (e.g., whether it is broadly or narrowly tuned) and on the cognitive demands on the subject. This may explain why D1 receptor blockade or DA depletion has little effect on some kinds of executive function such as self-ordered tasks.

The influence of the D2 family is more complex and less well studied. There has been almost no research on D3 receptors mechanisms in the PFC, and drugs which distinguish between D2 and D3 receptors are scarce. Early studies showed that D2/D3 receptor blockade did not impair working memory, but rat studies suggest that D2/D3 receptor stimulation (e.g., during stress exposure) may impair

Figure 1 A schematic representation of the inverted-U relationship between D1/D5 receptor stimulation and PFC function; moderate levels of receptor stimulation produce enhanced delay-related firing in PFC neurons as well as optimal performance on working memory tasks, whereas insufficient or excessive D1/D5 receptor stimulation erodes spatial mnemonic tuning and impairs working memory. PFC, prefrontal cortex; PTSD, posttraumatic stress disorder.

working memory performance. Electrophysiological studies show that D2 receptor stimulation increases response-related firing, but not delay-related firing, of PFC neurons in monkeys performing a working memory task. Because some response-related firing occurs after the motor response is initiated, it may act as corollary discharge, informing the brain that a motor command has been initiated. This may have particular relevance to schizophrenia, in which hallucinations may involve weakened corollary discharge.

Recordings from rat PFC slices and from awake monkeys indicate that D4 receptor stimulation inhibits GABAergic interneurons via G_i inhibition of cAMP signaling. Thus, D4 receptor stimulation may have an overall excitatory effect on PFC circuits. However, D4 also appears to inhibit some pyramidal cells, and so the picture may be more complex. Behavioral studies of D4 antagonists may find an inverted-U dose–response curve on working memory, but these agents have not been studied extensively. It should be noted that NE has a higher affinity for D4 receptors than for adrenoceptors and thus that the D4 receptor should properly be considered a catecholamine receptor rather than a DA receptor.

Norepinephrine

It is now appreciated that NE has just as powerful an effect on NE function as DA. In contrast to DA D1, NE appears to dissociate its beneficial and detrimental effects at different types of adrenoceptors. Thus, these may be more practical targets for pharmacological treatment of PFC dysfunction.

The NE innervation of the PFC arises from the locus coeruleus (LC) in the pons. As with DA, there is a delicate innervation of both the supragranular and granular layers, with particular density in layer I. The superficial layers are the focus of cortical–cortical connections and have dense α1- and α2-adrenoceptor binding. There are three α2 subtypes; of these, the α2A subtype is particularly prominent in the monkey PFC. Electron microscopy studies have documented α2A receptors postsynaptically in the spines and dendrites of PFC pyramidal cells, as well as in presynaptic locations on NE axons and terminals. β-Receptor binding is densest in the middle layers (i.e., layer IV), which receives projections from the thalamus.

As with DA, NE has dual effects on PFC function depending on the amount of NE release. Moderate levels of NE release during normal waking have vital, beneficial effects on PFC function via higher-affinity postsynaptic α2A-adrenoceptors, whereas high concentrations of NE released during stress impair PFC function via lower-affinity α1-adrenoceptors and possibly β1-adrenoceptors (see Figure 2). In most parts of brain, NE has potent effects via β-adrenoceptors. In contrast, the PFC seems more dramatically altered by α-adrenoceptors. Figures 3(a) and 3(b) illustrate the

Figure 2 Levels of NE release determine the functional status of the PFC based on varying affinities for adrenergic receptors. Moderate concentrations of NE during the nonstressed, alert state lead to improved PFC function via binding to higher-affinity α2A-adrenoceptors (shown in blue). Higher concentrations of NE release in the PFC, which are observed in conditions of stress, lead to PFC impairment due to the binding to lower-affinity α1- and possibly β1-adrenoceptors. Recent studies have started to uncover downstream, intracellular signaling mechanisms that mediate these NE actions. In contrast, the amygdala is modulated in a manner opposite to the PFC, whereby α2-adrenoceptors impairs, and β- and α1-adrenoceptors strengthen, amygdala regulation of behavior. Thus, NE may act as a chemical switch to determine whether behavior is regulated by higher-order PFC operations or more primitive mechanisms mediated by the amygdala. AC, adenylyl cyclase; cAMP, cyclic adenosine monophosphate; DAG, diacylglycerol; IP_3, inositol triphosphate; NE, norepinephrine; PFC, prefrontal cortex; HCN, hyperpolarization-activated cyclic nucleotide-gated channels; PKC, protein kinase C; PLC, phospholipase C.

Figure 3 The delay-related activities of neurons of the monkey PFC provide a cellular representation of working memory: (a) the oculomotor delayed-response task often used for *in vivo* electrophysiological recordings; (b) an electrode is lowered into the monkey's dorsolateral PFC to record responses while the monkey is performing the task; (c) the response of delay-related neurons altered by the iontophoretic application of phenylephrine, an $\alpha 1$ agonist, acting on adrenoceptors; (d) the response of delay-related neurons altered by the iontophoretic application of guanfacine, an $\alpha 2A$ agonist, acting on adrenoceptors. As shown in (a), following a cue at a specific orientation, there is a delay period during which the monkey must keep the previously presented cue in mind in order to guide the appropriate saccade (response). As shown in (c) and (d), cells show preferences for particular orientations (preferred vs. nonpreferred), and specific neurons fire selectively during either the cue, delay, or response periods. The iontophoretic application phenylephrine suppresses delay-related firing (c), whereas the application of guanfacine enhances delay-related firing (D). PS, principle sulcus; As, arcuate PFC, prefrontal cortex. This figure was generously supplied by Dr. Min Wang, Yale University.

influence of $\alpha 1$- versus $\alpha 2$-adrenoceptor stimulation on the delay-related firing of PFC neurons in monkeys performing an oculomotor delayed response task. Stimulation of $\alpha 1$-adrenoceptors with phenylephrine reduces delay-related cell firing for the preferred direction (Figure 3(c)), whereas stimulation of $\alpha 2A$-adrenoceptors with guanfacine enhances delay-related firing for the preferred direction (Figure 3(d)). However, β mechanisms are just beginning to be understood and may involve opposing actions at $\beta 1$ versus $\beta 2$ receptors that are obscured with nonselective compounds. The administration of $\alpha 2A$ agonists improves spatial working memory in mice, rats, monkeys, and humans, especially in subjects with PFC dysfunction. In addition to working memory, the $\alpha 2A$ agonist, guanfacine, has been shown to improve a number of other PFC functions, such as lessening distractibility, improving reversal performance and other measures of behavioral and cognitive inhibition (e.g., in humans, improving performance on the Stroop interference task), and strengthening conditional motor learning. It has little effect on posterior cortical functions and, indeed, can impair amygdala function. Conversely, the blockade of endogenous $\alpha 2$ receptors in the PFC with yohimbine impairs working memory, weakens no-go responding, and induces locomotor hyperactivity. Thus, this system is particularly relevant to attention-deficit hyperactivity disorder (ADHD). Recordings from PFC neurons in monkeys performing spatial working memory tasks show similar effects; $\alpha 2A$-adrenoceptor stimulation increases delay-related firing for the preferred direction (see Figure 3(d)), whereas yohimbine suppresses delay-related firing. These enhancing effects on working memory result from the stimulation of postsynaptic $\alpha 2A$ receptors in the PFC, inhibiting cAMP production, closing HCN channels on dendritic spines, and strengthening the functional connectivity of PFC circuits. Based on

research in animals, guanfacine is now in use for the treatment of ADHD, Tourettes syndrome, posttraumatic stress disorder (PTSD), and mild traumatic brain injury. Recent studies indicate that mutations on the Disordered In Schizophrenia 1 (DISC1) gene may lead to excessive cAMP signaling in patients with schizophrenia-like illnesses and that agents such as guanfacine may be useful in treating PFC deficits in these disorders as well.

In contrast to α2A-adrenoceptors, stimulation of α1-adrenoceptors impairs working memory. α1-Adrenoceptor antagonists have no effect on working memory when infused into the PFC during nonstress conditions, but they protect PFC cognitive function under conditions of uncontrollable stress. Conversely, infusions of α1-adrenoceptor agonists such as phenylephrine mimic the stress response and impair working memory. These detrimental actions are mediated by phosphotidyl inositol–protein kinase C intracellular signaling. Detrimental α1-adrenoceptor actions have been observed at the cellular levels as well, at which iontophoresis of phenylephrine onto PFC neurons decreased the delay-related cell firing necessary for working memory function (see **Figure 3(c)**). As with cognitive performance, this collapse in delay-related firing was reversed by a protein kinase C inhibitor. These mechanisms are especially relevant to PTSD, bipolar disorder, and schizophrenia, all of which are caused by, or worsened by, stress exposure. The α1-adrenoceptor antagonist prazosin is now used to treat patients with PTSD, and all atypical antipsychotic medications have α1 and 5-HT2 receptor-blocking properties. 5-HT2 receptors, like α1 receptors, are coupled to phosphotidyl inositol–protein kinase C intracellular signaling. Genetic and biochemical studies suggest that phosphotidyl inositol–protein kinase C intracellular signaling is overactive in bipolar disorder and schizophrenia (e.g., due to loss of function mutations in the genes encoding for DAG kinase or RGS4). Most antimanic agents reduce the activity of this signaling pathway. Thus, these agents may restore PFC regulation of behavior, thought, and affect by normalizing phosphotidyl inositol–protein kinase C intracellular signaling.

Serotonin

The raphe nuclei send widespread and dense 5-HT projections throughout the cortex, including the PFC. Electron microscopy studies indicate that these 5-HT projections make connections with both pyramidal cells and interneurons in the PFC. PFC neurons project back to the raphe nuclei, where they may have an inhibitory influence. There are a multitude of 5-HT receptor subtypes (at least 13); however, the localization and function of these receptors within the PFC are poorly understood. The 5-HT1 family appears to be more densely localized in superficial layers, whereas 5-HT2 receptors are more concentrated in middle layers.

It is well established that 5-HT plays a critical role in affective regulation by the OFC, whereas its effects on dorsolateral PFC function appear to be more complex. The most unambiguous evidence for the role of 5-HT in executive processes comes from studies of reversal learning in marmoset monkeys. In reversal learning, subjects are presented with two stimuli and initially learn to associate reward with one stimulus. After this pairing has been established, a subsequent reversal between stimulus and reward takes place, such that the animals must now make the previously unrewarded response in order to receive a reward. Studies in humans as well as lesion studies in nonhuman primates indicate that the performance of this task depends on the OFC as well as the ventromedial PFC. Selective reductions in 5-HT via injections of 5,7-dihydro-testosterone (DHT) directly into the OFC of marmoset monkeys impairs performance on serial discrimination reversal tasks. In contrast, performance is preserved on an attentional set-shifting task that requires subjects to reverse rules and learn new rules regarding a perceptual dimension of a stimulus (i.e., shape or color) or a specific feature of a percept (see **Figure 4**). Monkey studies have shown that set-shifting performance depends on the dorsolateral PFC. Similar results have been observed in humans, in whom rapid tryptophan depletion impairs reversal learning while preserving attentional set-shifting performance. Interestingly, studies in monkeys as well as rats have shown that OFC depletion of DA had no effect on performance of a serial reversal learning task.

In addition to regulating attentional set shifting, the lateral PFC inhibits inappropriate motor responses, which can be evaluated by performance on a stop-signal task. A study in humans found that increases in NE, via NE reuptake inhibition, led to faster reactions on a stop-signal task. Performance on a probabilistic learning task, an analog to reversal learning, was not affected by NE reuptake inhibition. Conversely, increased basal 5-HT levels produced impairments on a probabilistic learning task but did not influence stop-signal performance. These findings support the findings from depletion studies in humans and monkeys. Together, these data have led to the hypothesis that 5-HT and catecholamines have dissociable and specific roles in the modulation of PFC operations.

One significant barrier to interpreting studies using global depletions or enhancements of 5-HT action is

Figure 4 Effects of prefrontal serotonin depletions on learning and attention: (a) depletions of prefrontal serotonin (but not prefrontal dopamine) disrupt discrimination reversal learning; (b) prefrontal serotonin depletions have no effect on shifting an attentional set. In (b) note the greater number of errors made in performing a discrimination requiring a shift of attentional set (EDS) compared to one involving the maintenance of a previously acquired attentional set (IDS), in both groups. 5-HT, serotonin; DA, dopamine; EDS, extra-dimensional shift; IDS, intradimensional shift. Courtesy of Dr. Angela Roberts, Cambridge University, UK.

unraveling the heterogeneous actions of different receptor subtypes. Future studies need to examine the role of specific 5-HT receptor subtypes and determine whether dorsolateral PFC operations are altered when the 5-HT system is probed more selectively. For example, electrophysiological studies indicate that 5-HT2 receptors may influence spatial working memory operations, and these findings need to be pursued at the behavioral level.

In summary, 5-HT plays a distinct, if complicated role in the affective flexibility and the execution of primed behaviors and many of the activities of the mPFC and the OFC. Through its connections with limbic areas, the medial OFC is critical in connecting associative information regarding outcomes with the representational memory processes of the PFC. Ultimately, this positions the OFC to regulate the generation and use of outcome expectancies, which underlie the ability to make adaptive decisions. Thus, it is not surprising that studies of major depressive disorder in humans implicate dysfunction of the OFC as well as the dorsal raphe nucleus. Future studies using receptor-selective agents and behavioral paradigms probing a wide array of PFC-mediated cognitive functions will bring an improved understanding of the complex role of 5-HT in higher-order cognitive and affective processes.

Acetylcholine

Cholinergic neurons project from the basal forebrain to virtually all layers and all regions of the cortex, with approximately 75% of cholinergic cortical innervation originating from the nucleus basalis. Cholinergic axons make synapses in all layers of the monkey PFC, targeting pyramidal, and nonpyramidal cells. Most synapses on pyramidal cells target dendritic shafts, although there are some on spines and very few on the cell bodies. There are two general families of cholinergic receptors: muscarinic and nicotinic receptors. There are five muscarinic subtypes. Of these, the M2 receptor serves as both a presynaptic autoreceptor and a postsynaptic receptor on PFC pyramidal and nonpyramidal cells. In PFC pyramidal cells, M2 receptors are observed on dendritic spines receiving excitatory (asymmetric) inputs. The M1 receptor is also found postsynaptically on dendritic shafts and spines. Nicotinic receptors are often found presynaptically on the terminals of monoamine or ACh axons, where they can regulate transmitter release. They are most dense in layer I of the monkey PFC, which contains the highest levels of catecholamine fibers.

Although there have been detailed anatomical studies of the ACh inputs to the PFC, there has been little or no research on the function of these inputs in monkeys. Many studies have found alterations in working memory with systemic administration of muscarinic and nicotinic compounds, but these agents have powerful actions throughout the brain (e.g., in the thalamus), and thus alterations in cognitive performance cannot be necessarily attributed to PFC actions. In contrast, there has been a great deal of progress outlining ACh actions in the rodent mPFC, in which

infusions of muscarinic blockers such as scopolamine directly into the mPFC induce working memory deficits. Much of this research has focused on the important role of ACh in attention, specifically vigilance. These effects are evident both in the early stages of sensory processing and in subsequent top-down processing, which is regulated by the PFC.

It is widely accepted that ACh-mediated enhanced processing of sensory information underlies the cognitive process of attention. Attention encompasses a variety of operations that together contribute to the detection and discrimination of stimuli; and the integrity of attention processes contributes to the efficacy of higher-order cognitive functions such as learning and memory. Numerous behavioral studies have implicated basal forebrain cortical cholinergic inputs in sustained attention functioning. Tasks measuring sustained attention, or vigilance, require an animal to distinguish signal trials, which typically use a panel of lights illuminated for a short duration of time, from nonsignal trials, in which no light is illuminated. Accuracy is measured by training the animals to make a designated response for both signal and nonsignal trials. A range of stimulus intensities, presentation intervals, and the introduction of distracters are often used to manipulate the difficulty of this task.

Performance on sustained attention as well as distracter tasks stimulates ACh release. Behavioral and electrophysiological studies have implicated the association areas of the cortex, most notably the mPFC, in the ACh facilitation of sustained attention. First, the PFC appears particularly sensitive to ACh. In rats, local administration of ACh stimulated mPFC neuronal activity. In addition, several studies have indicated that the mPFC requires ACh to effectively suppress the processing of irrelevant or distracting information. One study observed increases in ACh release in the frontal cortex of rats as they recovered from a distracter introduced in a sustained attention task. A separate study found rats with ACh depletion to be unimpaired on tasks of attention under normal conditions; however. the introduction of distracters into the task resulted in a significant decrease in performance as compared to their sham counterparts. These findings further support the importance of ACh to the maintenance of information and attention under challenging or unpredictable conditions, such as the presentation of distracters or the erosion of signal.

The modification of information processing and more complex operations by knowledge-driven or goal-oriented information is referred to as top-down regulation. Basal forebrain cortical cholinergic input is mediated by efferent projections from the PFC; thus, the PFC is well positioned to orchestrate cholinergic innervation throughout the brain. PFC-driven top-down control of signal processing is thought to be one mechanism through which the PFC filters distracting stimuli and directs thought and behavior appropriately. In primates, ACh cells probably receive information from the OFC regarding reward or other affective information that may motivate attentional state. It was recently shown in rodents that PFC cholinergic stimulation resulted in increased ACh release in the posterior parietal cortex, a region that has been implicated with attention. Thus, following stimulation, the PFC is positioned to deploy ACh release in other cortical regions.

Overactivity of ACh has been linked to attention performance deficits, specifically to an increased response to nonsignal stimuli. This impaired signal-to-noise processing results in overprocessing, leading to generically amplified and unfiltered information and ultimately to false-positive responses. However, underactive cholinergic input to the cortex may likewise contribute to cognitive and attention deficits. In Alzheimer's disease, cholinergic inputs from the basal forebrain deteriorate, and this loss of input is may contribute to impaired signal detection as well as subsequent impairments in the PFC-mediated or top-down regulation of attention. Although this ACh dysregulation appears to contribute to the symptoms of disorganized thought and behavior, at this time, no conclusive studies have distinguished the ramifications of ACh underactivity from gross impairments in executive centers that would otherwise direct this input. In sum, studies of dysregulated ACh processing in disease states reiterate that moderate levels of ACh are necessary for the appropriate signal-driven activation of cortical processing centers and for the subsequent regulation of attention via PFC-dictated ACh release.

Summary

The PFC subserves executive functions by organizing information required for future thought and action. A vast body of literature across species indicates that the cognitive tasks of the PFC are sensitive to a variety of neurochemicals and that different neurotransmitter systems have distinct roles in cognitive functions of the PFC. However, there are several formative obstacles to fully delineating the neurochemical modulation of executive functions, most notably, the myriad actions of specific receptors and the broad range of tasks regulated by the various subregions of the PFC. Understanding the intricacies of these powerful neurochemical influences on PFC function is key to our understanding of the etiology and treatment of many neuropsychiatric illnesses, including schizophrenia, ADHD, and PTSD, as well as the decline in PFC cognitive functions with advancing age.

Cognitive Control and Development

Immature cognition is characterized by a greater susceptibly to interference from competing inputs, representations, or responses. Cognitive control is the ability to reduce this interference. This ability has been included in a number of theories of attention and memory and referred to in a number of ways, including executive function, attentional bias, and supervisory attention. Each of these coined terms is suggestive of a mechanism that is required to direct or guide our attention or actions. The following question is addressed in this article: How is it that we gain this ability with development?

Measures of cognitive control across development are necessarily constrained by the changing repertoire of behaviors available at different points in development and by age-appropriate techniques. At the core of these tasks is the demand for selection of one target, action, location, or dimension in the presence of competing alternatives. While holding this defining feature constant, researchers have been able to manipulate aspects of cognitive control paradigms to be appropriate for use at different ages while still allowing valid examination of this one construct. We review findings from paradigms used across development.

Evidence of Cognitive Control in Infancy

In the context of the infant, the environment is full of sensory and perceptual information competing for attention. For learning to take place, there must be a developing control mechanism that allows for suppression of irrelevant information so that selection of information relevant for current learning or behavior is possible. Some of the earliest research targeting control over behavior in infancy made use of reaching paradigms and originally posited that cognitive control was not apparent until the end of the first postnatal year. However, research into the development of the oculomotor system has shed new light on control over behavior in infancy using an age-appropriate measure. Although it is clear that cortical influences on behavior are in place at birth, robust endogenous or voluntary control over eye movements is not apparent until approximately 3–4 months of age, with earlier behavior being largely reflexive and subcortically mediated. In this context, the developing ability to voluntarily suppress responses to one stimulus in order to select another reflects emerging components of cognitive control.

Infant eye-tracking studies have used negative priming paradigms to index cognitive control. In a negative priming paradigm, a distractor object or location that has previously been ignored on one trial becomes the target to be selected on the next trial. Typically, responses to it are slowed relative to a control stimulus. The simultaneous presentation of the target and distractor generates competition that needs to be resolved by inhibition of the distractor in favor of the target. Infants have been shown to have the capacity to suppress an irrelevant stimulus in order to select a competing salient alternative.

An attempt has been made to link observable changes in oculomotor control in infancy to the development of certain visual pathways. Endogenous control over eye movements indicates the development of the frontal eye fields and the strengthening of its projections to the oculomotor basal ganglia thalamocortical circuit. This circuit, one of several closed loops that project from cortex to the basal ganglia and subsequently back to cortex, receives projections from both the frontal eye fields and the parietal cortex and appears to be critical for the production of voluntary saccades. Infants as young as 4 months have been shown to be capable of inhibiting an automatic saccade to a peripheral flashing target, suggesting rudimentary functioning of this circuit early in life. Overriding an orienting response takes effort because the visual system is designed to orient to salient or novel stimuli in the environment.

By the end of the first postnatal year, manual dexterity (e.g., reaching for objects) provides another measure beyond simple looking behavior to document the development of cognitive control. The classic Piagetian A-not-B task that relies on reaching behavior has been used to document changes in cognitive control between 8 and 12 months. Infants watch a toy hidden in location A and are prompted to reach and retrieve it. After several trials of the toy being hidden at location A, the toy is hidden in location B in full view of the infant. Infants younger than 12 months show the A-not-B error (i.e., they perseverate and continue to search in location A). This error appears to be a failure in the ability to suppress a response to the salient competing location in favor of the correct one (i.e., cognitive control).

Nonhuman primate lesion studies suggest that the A-not-B task is dependent on development of the prefrontal cortex. Neural processes underlying this behavior in humans have been examined using a looking

version of the task in combination with scalp electrode recordings. These recordings show an increase in frontal as well as posterior power values for only those infants who do not commit the A-not-B error, implicating the prefrontal cortex and related posterior circuitry in accurate performance of the A-not-B task.

Evidence of Cognitive Control in Early Childhood

Cognitive control paradigms in preschool children tend to focus on emerging proficiency in rule use and representational thought. In general, young children have difficulty if they are required to override a competing rule or dimension. Errors of cognitive control have been shown using tasks originally adapted from the adult neuropsychology literature, including the Stroop task and Wisconsin Card Sorting Task. In the Stroop task, subjects are required to name the color of the ink in which a word is written. The classic finding is a slowing of response times when the color of the ink is incongruent with the word (e.g., the word 'blue' written in red ink) relative to a color–word congruent example. Variations of this task have been developed for use with children, especially preschoolers who are nonreaders. For example, in the day–night Stroop-like task, subjects are asked to respond "day" to a card depicting a night scene and "night" to a card depicting a day scene. In both the adult and the child versions of the Stroop task, subjects must suppress the interfering salient information (color or image) in order to respond according to the appropriate rule. Children 3–5 years of age tend to have difficulty overriding the prepotent response, with performance not becoming more adultlike until later childhood. Manipulations that reduce the competing demands of the task or provide young children with more time to compute the answer result in even 4-year-olds performing well.

The Dimensional Change Card Sort is a simplified version of the Wisconsin Card Sorting Task and a more complicated version of the A-not-B task. Three- and 4-year-old children are presented with two cards that can be sorted in either of two ways (e.g., a red truck can be sorted by either color or shape). Children are generally able to sort the cards accurately by the preswitch dimension (e.g., color), but 3-year-olds perseverate on this dimension during the postswitch phase. That is, when the rules change such that they are required to respond based on the other dimension (e.g., shape), these children continue to sort by color, even though they can articulate the new rule. This behavior is consistent with the child not being able to suppress aspects of the situation that were previously relevant in the service of making the goal-appropriate action.

Evidence of Cognitive Control in Late Childhood and Adolescence

As children's fine motor skills improve, more precise measures of cognitive control, which index improvements in reaction time as well as accuracy across a wide age range, can be applied. Tasks used to measure cognitive control during this period of development include negative priming, Stroop tasks, go/no-go tasks, and Simon tasks. In all cases, children have a more difficult time ignoring or inhibiting irrelevant salient information or prepotent responses in favor of the relevant items or responses. In the Simon task, for example, a stimulus attribute is relevant for a response (e.g., left button press), whereas its location (e.g., right side of display) is interfering and irrelevant (e.g., a blue square appears on the left of the screen but requires a response with the right hand). The Simon effect is the difference in accuracy or reaction time between trials in which stimulus and response are on the same side and trials in which they are on opposite sides, with responses being generally slower and less accurate when the stimulus and response are on opposite sides. The size of the Simon effect decreases with age, suggesting that susceptibility to interference decreases with age.

Behavioral evidence from developmental studies of antisaccade tasks and go/no-go tasks in this age range provide similar results. In a go/no-go task, subjects are asked to respond to one stimulus (target) and withhold responding to a different stimulus (nontarget) as the stimuli are presented in succession. Both measures provide evidence of continued improvement in cognitive control into adolescence. Similarly, attention tasks that include distracting peripheral information, as in the case of the flanker task and stop signal tasks, show comparable developmental changes. Performance across these tasks continues to develop over childhood and does not reach full maturity until approximately 12 years (**Figure 1**). Importantly, these age-related differences are not observed on these tasks in the absence of interfering information.

Cortical Organization Underlying the Development of Cognitive Control

Advances in neuroimaging techniques have provided developmental scientists the opportunity to safely track cognitive and neural processes underlying

Figure 1 Model of developmental change in cognitive control with age as a function of accuracy and reaction time. From Casey BJ, Frontostriatal and frontocerebellar circuitry underlying cognitive control. In: Mayr U, Awh E, and Keele SW (eds.) *Developing Individuality in the Human Brain*. American Psychological Association, Washington, DC, 2005, reprinted with permission.

human development. These methods have advanced the field of developmental neuroscience by providing evidence of changes in cortical organization in the developing brain *in vivo*. Although these measures provide only an indirect index of a very dynamic process of regressive and progressive changes in brain structure and function across development (e.g., changes in myelination, dendritic pruning, and vascular, neuronal, and glial density), they provide information about regional changes in brain development.

One of the most influential magnetic resonance (MR) methods is functional magnetic resonance imaging (fMRI). This method provides *in vivo* measures of brain activity by indexing changes in blood oxygen levels in the brain. Studies using this method have begun to track developmental changes in patterns of brain activity that coincide with changes in cognitive control across childhood.

Prefrontal involvement in the development of cognitive control in children has been demonstrated most convincingly in fMRI studies that parametrically manipulate the salience of the competing information that must be suppressed. By definition, cognitive control is the ability to attenuate interference from competing sources and thus should be needed more when the interfering information becomes increasingly salient. For example, in the case of the go/no-go task, as the number of go trials preceding a no-go trial increases, so too do the number of errors (i.e., incorrectly responding on a no-go trial). The imaging data show that correctly withholding a response on a no-go trial is associated with activity in the ventral prefrontal cortex and basal ganglia, and activity in these regions correlates with successful task performance. Adults show a monotonic increase in prefrontal and parietal cortices as the number of go trials preceding a no-go trial increase. Children, on the other hand, maximally activate these regions regardless of whether they have to withhold a response following one, three, or five go trials (responses) and make significantly more errors. These findings provide evidence that susceptibility to interference is greater in children than adults but is attenuated with age. This increase in cognitive control with age is paralleled by maturational differences in the recruitment of underlying prefrontal and parietal cortices.

Many paradigms besides the go/no-go task have been used to study the neural development of cognitive control (e.g., antisaccade, Simon, flanker, and Stroop tasks). Children with effective cognitive control on these tasks typically recruit additional or larger portions of prefrontal cortex than those activated by adults, suggesting age-related differences in recruitment of this region. Children also recruit posterior parietal regions consistently activated in adults on these tasks, unless they have poor cognitive control, in which case they do not recruit these regions. These findings suggest that the improved ability to suppress irrelevant information may first require mature activation of posterior parietal regions prior to maturation of prefrontal regions. Tasks of lesser cognitive demand (e.g., selective attention tasks without response competition) do not appear to show age-related differences. This developmental pattern of brain activity parallels that of behavioral performance on cognitive tasks that do not require suppression of competing information, for which children also show an adultlike pattern.

Collectively, these imaging studies of cognitive control show that children recruit distinct but often more diffuse regions of prefrontal cortex than do adults. Based on cross-sectional and longitudinal studies, the pattern of activity within brain regions central to task performance becomes more focal or fine-tuned with increased activity, whereas regions not correlated with task performance show attenuation in activity with age. This pattern, observed across a variety of paradigms, has been suggested to reflect development within, and refinement of, projections to and from these regions.

Development of Brain Connectivity and Cognitive Control

Another MR method that has begun to be used in developmental research is diffusion tensor imaging (DTI). This method detects changes in white matter microstructure based on properties of diffusion.

Diffusion of water molecules in white matter tracts is affected by myelin and the orientation and regularity of fibers. As such, this method provides an index of regional brain connectivity and strengthening of connections among regions. Together with fMRI, this methodology has been used to track the refinement of cortical circuits involved in the fine-tuning of systems underlying the development of cognitive control.

Only a small number of studies have linked brain connectivity and cognitive development measures, although indirect measures of white matter suggest regional development in prefrontal cortex and presumably function. Across all these studies, strengthening of connections throughout the brain is shown to occur with development; however, connections between those regions implicated in cognitive control appear to be protracted and are also shown to correlate with behavioral performance. One such study showed that development of working memory was positively correlated with prefrontal–parietal connectivity consistent with imaging studies showing differential recruitment of these regions in children relative to adults. A second study examining the degree of connectivity between the prefrontal cortex and the basal ganglia and performance on the go/no-go task showed a tight association between connectivity and performance that was not present in a comparison corticospinal fiber tract that also showed changes with development.

Findings from the imaging literature suggest that development of cognitive control is paralleled by a fine-tuning of cortical systems, with protracted refinement of prefrontal regions relative to posterior cortical and subcortical regions. The reported shift in cortical architecture and function is presumably an experience-driven maturational process that reflects fine-tuning of neural systems with experience and development, and strengthening of cortico-cortical and cortico-subcortical connections. These imaging studies map onto findings from animal and human postmortem studies indicating that pruning and elimination of connections, in combination with strengthening of relevant ones, occur during this time period, and illustrate the subtle interplay between neuroanatomic and physiologic changes in neural circuitry and cognitive maturation.

A Developmental Model of Cognitive Control

The imaging literature on the development of cognitive control suggests that maturity of prefrontal regions is critical for the improvement of this ability with age. However, two other regions, the parietal cortex and basal ganglia, have been implicated repeatedly in directing or guiding attention and actions. Specifically, the basal ganglia have been implicated in signaling prefrontal cortex when competing actions require top-down adjustment of behavior, whereas the posterior parietal cortex has been implicated in signaling prefrontal cortex when competing stimuli require top-down biasing of attention in favor of one stimulus attribute or location over another. Both of these regions (basal ganglia and parietal cortex) are part of unique circuits that project both to and from prefrontal cortex, thus providing a means for signaling prefrontal regions to help impose top-down control of behavior (Figure 2).

Although these structures are neuroanatomically intact at birth, refinement of function and connectivity within and between these regions continues gradually across development. In this regard, each region has been suggested to have different developmental trajectories, whereby subcortical systems such as the basal ganglia develop before cortical systems. Within cortical systems, posterior regions (parietal cortex) have been suggested to develop before anterior ones such as the prefrontal cortex. The regional differences in functional development of brain regions may explain the protracted development of cognitive control. For example, intact signaling by subcortical regions, but immature top-down control due to

Figure 2 Simplified drawing of prefrontal circuits implicated in cognitive control. Each circuit has projections both to and from the prefrontal cortex. The basal ganglia and posterior parietal systems signal the prefrontal cortex when new or competing response or sensory information is encountered so that the prefrontal cortex can immediately adjust behavior to accommodate or suppress new or salient information during goal-oriented actions. Poor cognitive control early in development results from immature top-down control of prefrontal cortico-cortical and cortico-subcortical projections.

immature cortico-subcortical or cortico-cortical connections, could result in poor regulation of attention and behavior as seen in the review of studies of cognitive development. This developmental model of cognitive control suggests more of a refinement in the functional representations of intact brain regions as connections between brain regions are strengthened through experience over the course of development, as opposed to reorganization of brain circuitry with development or the development of new functional regions.

Conclusions

A hallmark of cognitive development is the ability to select information and actions from competing sources. Collectively, this article tracks this ability across development and shows how cognitive control emerges early in development and continues to be refined into adulthood. A recurring theme across all ages discussed in this article is the propensity to commit perseverative errors early in the development of cognitive control. For example, after frequent presentations of a toy at location A in the A-not-B task, infants cannot shift their response to a toy hidden at location B and continue to perseverate and search for the toy in location A. In the card sorting task, preschoolers have difficulty switching to a new rule after using another rule to sort cards. In the go/no-go task, increasing the number of go trials preceding a no-go trial increases the interference from a competing prepotent response and results in a decrease in the ability to withhold responding to the nontarget. Across the different tasks, the pattern of behavior suggests immature maintenance of relevant information (e.g., current hiding location and rule or task demands) from interference from the competing representation of a prior action.

Cognitive development is characterized as the growing ability to filter and suppress irrelevant information and actions in favor of more relevant ones as these neural systems develop. The prefrontal cortex has been shown to be involved in guiding actions by supporting representations of relevant information against interference from competing sources. Thus, developmental changes in prefrontal circuitry observed throughout childhood presumably contribute to the emergence of this ability.

Cognitive Deficits in Schizophrenia

D S Manoach, Massachusetts General Hospital, Charlestown, MA, USA

Why Study Cognitive Deficits in Schizophrenia?

For many years, schizophrenia was considered to be a profound mystery, beyond the reach of science. Over the past several decades, major advances in the neurosciences have drastically changed the way schizophrenia is viewed, have deepened our understanding of it, and have led to better treatments. Most of all, it has become abundantly clear that schizophrenia is a brain disease. It is characterized by 'positive' psychotic symptoms such as hallucinations and delusions and by 'negative' symptoms such as amotivation, social withdrawal, and apathy. Positive symptoms are the most dramatic manifestations of schizophrenia and have been the primary focus of drug development. They can be effectively managed by medications in the majority of individuals, but a full return to premorbid levels of function is rare. The focus on symptoms has contributed to a relative neglect of the subtler but severely disabling cognitive deficits until recently.

Since the initial conceptualization of the disease as 'dementia praecox,' cognitive dysfunction has been recognized as integral to schizophrenia. Rather than being an epiphenomenon of psychosis, cognitive deficits reflect the pathology that gives rise to schizophrenia. They are probably more closely related to predisposing genes and are better predictors of social function and outcome than are the symptoms that define schizophrenia. Increasingly, the goal of schizophrenia research is to understand the nature and neural basis of cognitive deficits and to effectively treat them. Aside from the obvious benefits of treatment, there are other important reasons to understand cognitive deficits. First, because cognitive abnormalities predate the onset of illness, they may identify individuals at high risk for developing schizophrenia and enable early intervention. Second, their presence in healthy relatives of individuals with schizophrenia suggests that cognitive deficits are markers of genetic vulnerability to illness that can help to identify genes that confer increased risk of schizophrenia. Third, schizophrenia is a heterogeneous illness, and identifying core cognitive deficits and their genetic bases may lead to more valid subtyping, which has important implications for treatment and prognosis. In summary, understanding cognitive deficits, along with relatively preserved abilities in schizophrenia, will implicate underlying neural circuitry, guide the search for neuropathology, lead us to susceptibility genes, and thereby provide clues to etiology (or etiologies) and contribute to a theoretical understanding of this enigmatic disorder.

Article Overview

The literature documents impairments in a wide range of neurocognitive functions in schizophrenia. In fact, most meta-analytic studies of cognition in schizophrenia demonstrate that no domain tested is spared. The aim of this article is not to provide an exhaustive list of cognitive deficits; rather it is to highlight a subset that seems most central to schizophrenia and that holds the most promise for shedding light on its pathophysiology. One criterion for identifying core deficits is whether they are present in increased rates in healthy relatives of patients with schizophrenia. This would suggest that they are markers of genetic vulnerability to illness, or 'cognitive endophenotypes.' The endophenotype concept in psychiatry is discussed in the section titled 'Cognitive endophenotypes.' Meta-analytic studies of relatives show the strongest effect sizes for impairments on tasks with high executive function demands, such as set-switching, inhibition, and working emory (see 'Executive function deficits'). Disturbances of memory, thought, and language are described in the sections titled 'Declarative memory' and 'Thought, language, and semantic memory disturbances.' The section titled 'Challenges and potential confounds in the study of cognition' outlines some of the difficulties in identifying specific cognitive deficits. And the section that asks 'Are there fundamental deficits that give rise to widespread cognitive disturbance?' considers whether there are more elementary deficits that can parsimoniously account for the range of cognitive dysfunction. Finally, the advent of sophisticated neuroimaging techniques and the revolution in genetics hold tremendous promise for illuminating the neural basis of cognitive deficits in schizophrenia (discussed in the section titled 'Promising advances in the study of cognition').

Cognitive Endophenotypes

Schizophrenia arises from a poorly understood and complex interaction of multiple genetic, environmental, and epigenetic risk factors. Identifying genes that predispose to schizophrenia will lead to early

identification of individuals at risk, foster a better understanding of schizophrenia at a molecular level, improve pharmacotherapy, and guide the development of preventive interventions. Since only a small portion of individuals who have genes that predispose to schizophrenia will become ill, we cannot rely on the presence of symptoms alone to identify individuals who carry susceptibility genes. Because cognitive deficits are associated with illness within families and are present at a higher rate among family members than in the general population, they are can be used to identify individuals who lack any overt symptoms of illness but who carry susceptibility genes. These cognitive deficits can be considered endophenotypes, or markers of genetic vulnerability to illness. (The endophenotype concept was first presented in relation to psychiatric disorders by Gottesman and Shields in 1972.) Endophenotypes are manifestations of pathology that may not be obvious without specialized testing and that are thought to be more closely related to the genes that predispose to illness than are symptoms. Because endophenotypes fill gaps in the causal chain between genes and more distal, complex disease manifestations such as symptoms, they may provide clues to etiology. The characteristics of useful endophenotypes are listed in Figure 1. Candidate cognitive endophenotypes include deficits in executive functions such as working memory and inhibition. Abnormalities in several psychophysiological measures have also been proposed as candidate endophenotypes. These include smooth pursuit eye tracking, the P300 event-related potential, and indices of sensorimotor gating such as backward masking, prepulse inhibition of the startle blink, and gating of the auditory P50 event-related potential component. These abnormalities in early information processing are mentioned here because they might have ramifications for cognitive processing down the line, although such links are still more theoretical than established.

Executive Function Deficits

Executive functions are a diverse set of cognitive abilities that allow flexible rather than reflexive responses to events. They are necessary for coordinating thought and action in the pursuit of goals. These goals may be immediate, such as finding food, but they are often remote, higher order goals such as earning an academic degree. Executive functions include switching flexibly from one task to another; inhibiting strongly called for, but inappropriate, response tendencies; problem-solving; planning; and using context to select an appropriate response. The prefrontal cortex is thought to play a pivotal role in mediating executive function on the basis of studies of monkey neurophysiology, frontal lesion patients, and human neuroimaging. Neuroimaging studies consistently implicate prefrontal neural circuitry in the executive function deficits of schizophrenia.

In schizophrenia, executive function deficits are reflected in behavior that is stimulus-bound rather than guided by context, perseverative, and stereotyped. The seminal studies that first established a direct link between deficient executive function and abnormal prefrontal activity employed the Wisconsin Card Sort Test (WCST) (Figure 2). Although clinically rich and sensitive to prefrontal network dysfunction, the WCST is a complex, multidimensional task that requires sustained attention, concept formation, performance monitoring, task switching, and working memory for successful performance. Therefore, poor performance and differential brain activation in schizophrenia compared to healthy individuals cannot be attributed to a specific deficit. More-recent studies employ tasks that constrain demands to identify specific executive processes that are intact or impaired.

Inhibition

Inhibition is the ability to suppress automatic or prepotent responses (e.g., looking toward a suddenly appearing object). Individuals with schizophrenia consistently show increased errors and frequently also show increased latencies for correct responses on tasks requiring inhibition, such as the Stroop interference paradigm, the go, no-go task, and the antisaccade task (Figure 3). In real life, deficits in inhibition might translate into behavior that is impulsive and stimulus-bound.

Task Switching

Task switching refers to moving flexibly from one set of rules to another in response to changing environmental contingencies. Task switching requires processes that are not necessary when simply repeating the same task and generally incurs costs in the form of increased response latency and errors. Clinical observations of perseveration – the contextually inappropriate and unintentional repetition of responses – and performance of neuropsychological tests such as the WCST have led to the presumption of task-switching deficits in schizophrenia. Using tasks that isolate cognitive processes, however, several groups have reported that task switching is normal. For example, while performing random sequences of prosaccades and antisaccades (Figure 3), patients showed normal task-switching costs. But unlike healthy individuals, their errors tend to be in the same direction of the prior saccade. This suggests an abnormally strong influence of the prior response. Thus, instead of reflecting

Figure 1 A schematic model of the frequency (left) and characteristics (right) of a cognitive endophenotype (e.g., inefficient working memory, formal thought disorder, antisaccade errors). It is most frequent in schizophrenia, then in schizophrenia spectrum disorders, then in unaffected family members, and then in the general population. It is presumed to reflect the influence of a susceptibility gene or genes. Enodophenotypes are a subset of biological markers that can be distinguished by the criteria listed, which suggests that they are genetic in origin (as opposed to primarily environmental, epigenetic, or multifactorial). The right side of the figure is adapted from Gould TD and Gottesman II (2006) Psychiatric endophenotypes and the development of valid animal models. *Genes, Brain, and Behavior* 5: 113–119 with permission from I. Gottesman, who owns the copyright.

Figure 2 WCST: the participant is presented with four prototype cards and given a stack of cards to match to one of the prototypes by placing it beneath the prototype in a separate pile. The participant is not told the sorting rule (color, shape, or number) but has to figure it out on the basis of feedback from the examiner (i.e., a statement indicating that the match was correct or incorrect). If participants make a mistake, they must try again with the next card. Following ten correct sorts, unbeknownst to the participant, the rule changes, and the participant must again figure out the operative sorting rule based on feedback.

a problem with switching rules, perseveration may reflect an unwanted repetition of responses. Such dissociations between intact and impaired ability suggest that there are selective impairments of executive function in schizophrenia that can help pinpoint dysfunction in specific neural circuitry.

Working Memory

Working memory refers to actively holding information 'online' in the mind's eye and manipulating it in the service of guiding behavior. It is hypothesized to be a temporary store whose contents are continually updated and scanned in response to immediate information processing demands. Daily activities, from mentally rehearsing a phone number to considering alternative perspectives and outcomes, depend on it. In schizophrenia, there is abundant evidence of both behavioral impairment and anomalous patterns of brain activity during working memory performance. What is less clear is whether particular subcomponents of working memory are differentially affected. Working memory is comprised of distinct stages (encoding, maintaining and manipulating information, and then selecting the appropriate response) and operates on different domains of information (e.g., spatial, verbal, and object features). Neuroimaging and neurophysiological evidence suggests that different stages and domains of working memory require different strategies and cognitive processes for success and are therefore associated with distinct patterns of neural activity, although there is also a great deal of overlap in these patterns. Regardless of which subcomponents of working memory are disrupted in schizophrenia, impoverished internalized representations may lead to behavior that is unduly driven by external stimuli.

Response Monitoring

To perform well on any challenging task, it is necessary for one to evaluate one's performance so as to learn

Figure 3 An example antisaccade paradigm. The cross hair represents the point of regard. A trial begins with a visual cue instructing either a prosaccade or an antisaccade (in this case an orange circle for prosaccades and a blue X for antisaccades). Following the disappearence of the cue, participants maintain fixation on the center until a stimulus appears over one of the two peripheral dots, the side randomly determined. Participants are instructed to look toward the suddenly appearing stimulus on prosaccade trials. For antisaccade trials, they are instructed to look in the opposite direction. After stimulus offset, fixation returns to the center as participants await the beginning of the next trial. While prosaccades are a relatively automatic response, antisaccades require executive control. To perform an antisaccade correctly one must suppress the prepotent response of looking toward a suddenly appearing stimulus (i.e., prosaccade) and generate the novel behavior of looking in the opposite direction. Out come measurements include directional accuracy of the saccadic eye movement and latency to initiate the saccade. Individuals with schizophrenia generally perform normally on prosaccade trials but show increased errors (failures of inhibition) and, depending on task parameters, may also show increased latency for correct responses on antisaccade trials.

from errors and, if an error was made, slow down on the next try. These processes – performance evaluation, reinforcement learning, and remedial performance adjustment on the subsequent trial (i.e., post-error slowing) – are all thought to rely on the anterior cingulate cortex. Diminished performance evaluation and diminished reinforcement learning in schizophrenia are presumed on the basis of relative reductions in anterior cingulate cortex activity and error-related negativity (ERN) following error commission on a range of cognitive tasks. ERN is an event-related potential that is thought to reflect error-based reinforcement learning, or the modification of stimulus–response mappings in order to optimize behavioral outcomes. In spite of these abnormalities, post-error slowing and error positivity (PE), an event-related potential associated with both error awareness and post-terror slowing, are often found to be intact. Such dissociations have been observed within single studies and suggest that performance evaluation and remediation are implemented by separate systems, only one of which may be impaired in schizophrenia. Because response monitoring is essential to optimal performance, a deficit could lead to generalized performance impairments and contribute to rigid, perseverative behavior.

Declarative Memory

Clinical observation suggests that individuals with schizophrenia have problems with memory. But memory is a broad term that encompasses the myriad ways that experience leaves durable traces in the brain. Declarative memory, particularly for verbal materials, has been a focus of research and is found to be deficient. Declarative memory includes both episodic memory (memory for events) and semantic memory (memory for facts) and can be divided into stages that engage distinct neural circuits: acquiring and organizing new information (encoding), filing and retaining it (storage), and retrieving it when necessary. Encoding and retrieval are both active processes that are vulnerable to disruptions of attention and depend on prefrontal networks. The storage of new information, in contrast, is not under voluntary control and is critically dependent on hippocampal mediation. There is

ample evidence of deficient encoding and retrieval in schizophrenia, but in spite of reports of structural and functional hippocampal abnormalities, storage deficits, as distinct from encoding and retrieval deficits, are mild or nonexistent.

Thought, Language, and Semantic Memory Disturbances

In addition to abnormalities in the content of thought (i.e., delusions and hallucinations), individuals with schizophrenia also have abnormalities in the form of thought. Formal thought disorder refers to impairments in the organization and control of thoughts as expressed through language. It ranges in severity and type, from disturbances of logical concept formation to peculiar word usage. Although viewed as a symptom, formal thought disorder has cognitive origins, and milder manifestations have been documented in healthy relatives, suggesting that it may be an endophenotype. Whether formal thought disorder reflects a primary thought or language disturbance has been debated since it was first described by Bleuler as "loosening of associations." Although not specific to schizophrenia – it is seen in other psychotic disorders, and even healthy individuals show instances of thought slippage – qualitatively, the flavor of formal thought disorder in schizophrenia is unique. It is frequently characterized by confusion, instability, and unusual word and phrase usage, in contrast to, for example, the loosely combined ideas and jocularity often seen in mania. At its most extreme, language is incoherent. Milder manifestations include vagueness (language that lacks specific information) or its opposite, overly specific and excessively qualified speech (e.g., a four-legged pig).

Even patients without overtly thought disordered language may show abnormalities of language production and comprehension at the levels of individual words, sentences, and discourse. Studies examining the organization and retrieval of individual words from semantic memory suggest that there is no loss of lexico-semantic knowledge in schizophrenia, but that the storage and/or access to words is less organized than in healthy individuals. At the level of whole sentences, patients have difficulty in the 'online' use of semantic context to constrain their expectations of what will follow, and this impairs comprehension. This may arise because patients have difficulty in building up context, due to deficits in combining semantic with syntactic information within sentences and in generating bridging inferences across sentences. This can lead sentence and discourse processing to be inappropriately dominated by semantic associative relationships between individual words at the expense of constructing a more complete meaning.

Challenges and Potential Confounds in the Study of Cognition

Characterizing deficient versus preserved cognitive abilities has proved an elusive goal in schizophrenia, and the literature is replete with ambiguous or contradictory results. Several factors contribute to this difficulty.

Heterogeneity

Schizophrenia is a heterogeneous illness with no known etiology or pathognomomic signs. In most cognitive studies, only a subset of patients shows deficits on any given measure, and the particular subset showing a deficit varies from measure to measure. Thus, compared with demographically matched healthy individuals, patients with schizophrenia show a greater range of values on outcome measurements ranging from simple reaction time to indices derived from neuroimaging studies. The effects of course variables (e.g., first episode vs. chronic, acute exacerbation vs. partially remitted state), medication, severity of illness, and the interaction of illness with factors that normally contribute to individual differences (e.g., gender, age, intelligence) also contribute to measurement heterogeneity. Thus, depending on the composition of the sample, a particular cognitive deficit may or may not be detectable.

Paradoxically, in spite of this heterogeneity, schizophrenia has defied meaningful subdivision. Most subtyping schemes are based on phenomenology rather than biology, lack temporal stability, and fail to provide an adequate account of the variability in neuroanatomic abnormalities, cognitive dysfunction, outcome, response to medications, and other signs of schizophrenia. The failure of phenomenology to map onto specific biological substrates suggests that it may not be the most valid organizing principle for illness heterogeneity. Identifying core cognitive deficits that can be mapped onto specific neural substrates may lead to more meaningful subtyping.

Variability

In addition to showing a wide range of performance across individuals, there is more variable cognitive performance within individuals, both within a single session (i.e., from trial to trial) and over separate sessions (i.e., test–retest) compared with demographically matched healthy individuals. For example, while performing a working memory task, patients with

schizophrenia show greater variability of response time within a single session and reduced test–retest reliability of brain activation across sessions. Even the demonstration of hand preference on simple tasks is less stable over two sessions. Increased variability and unreliability of performance are among the most consistent findings in schizophrenia research. Although frequently viewed as a measurement confound, it may be more productive to regard variability as intrinsic to schizophrenia and as having a neurological basis that requires explanation. This is supported by findings that frontal lobe damage in humans leads to increased variability of cognitive performance.

Amotivation

Amotivation is a core negative symptom of schizophrenia that makes it difficult to determine whether poor performance reflects a true deficit or that the patient was unwilling or unable to exert the effort necessary for optimal performance. Because tasks differ in the amount of effort required, amotivation may be more detrimental to the performance of some tasks than to others.

Medications

Antipsychotic medications have thus far targeted symptoms rather than cognition, and there is a vast and often contradictory literature on whether conventional antipsychotics impair cognition and whether atypical agents might improve it. Adjunctive anticholinergic drugs may also be detrimental to memory and other cognitive abilities.

Generalized Deficit

Meta-analytic studies demonstrate widespread cognitive dysfunction, suggesting that schizophrenia is characterized by a global blunting of performance. In addition to potential impairments attributable to amotivation and medication, patients may appear to have a generalized cognitive deficit because schizophrenia interferes with education and occupational attainment and many cognitive measurements are sensitive to these factors. In addition, acute psychosis and associated disruptions of attention may prevent optimal engagement in cognitive testing. For these reasons, simply demonstrating that patients perform worse on a particular task is not terribly revealing.

To some extent, the concept of a 'generalized deficit' is a straw man. Existing data do not support such a simplistic explanation. And a generalized deficit cannot account for the findings of highly selective cognitive deficits in unaffected relatives. Sorting out cognitive deficits that reflect the pathology of schizophrenia from those that are epiphenomena of having and being treated for a severe, chronic mental illness is an ongoing challenge. Strategies for identifying specific deficits in schizophrenia include demonstrating a pattern of both proficient and deficient performance across tasks that are matched for discriminating power and finding tasks on which a cognitive abnormality is actually advantageous to performance. Successful employment of this superiority strategy is illustrated by a series of numerosity studies in which the intact perceptual organizational ability of controls interfered with the rapid counting of elements (i e., perceptual gestalts had to be broken for elements to be counted). Because patients failed to form gestalts, they were faster at counting.

Are There Fundamental Deficits That Give Rise to Widespread Cognitive Disturbance?

The seeming generality of neurocognitive deficits in schizophrenia leaves one searching for a parsimonious explanation – are there more-basic problems that can organize and account for the diverse deficits seen? Some investigators have hypothesized that many cognitive deficits stem from deficient working memory, which leads to a failure to guide behavior on the basis of internalized representations such as schemata and ideas. Deficits earlier in the information processing pipeline, such as in sensorimotor gating, have been proposed to account for higher order difficulties in inhibiting thoughts, speech, and action. While a theoretical case can be made for a number of integrative explanations, empirical evidence of links between elementary and higher order deficits is lacking.

Attention

A wide range of cognitive deficits in schizophrenia could be viewed as failures of the effective deployment and control of attention. The term attention refers to a broad array of cognitive functions that enable the individual to select relevant aspects of either the internal or external milieu (i.e., thoughts or environmental stimuli) for further processing while keeping others at bay. Particularly during acute phases of schizophrenia, patients describe difficulties filtering the continuous barrage of stimuli present at every moment and focusing on what is relevant. For example, they may have difficulty selectively attending to the voice of the person addressing them rather than to noise from the refrigerator. Inattention, however, cannot account for findings of deficits when attention is controlled or for information processing deficits on measurements

that minimize its contribution, such as the auditory mismatch negativity, an event-related brain potential that is sensitive to stimulus deviation from a repetitive pattern and that is reduced in chronic schizophrenia.

Deficient Automation

In healthy individuals, practice can increase the speed of performance and reduce both the variability of responses and the error rate, reflecting a shift from controlled to more automatic processing and a corresponding shift in the brain networks that support performance. Tasks, or components of tasks, that have become automated proceed efficiently with reduced demands on attention. If schizophrenia were characterized by deficient automation, increased attention would be required for task components that should have been automated, and consequently fewer resources would be available for other, higher-order task demands. Although there are only a few studies of automation *per se* in schizophrenia, deficient automation provides a plausible account for increased variability and unreliability of performance across a range of tasks.

Context Processing

As illustrated in the section titled 'Executive function deficits,' the balance between past and present influences on behavior is upset in schizophrenia. Patients have trouble learning from error feedback, suggesting that the influence of previous experience is too weak. On the other hand, they also show perseveration of responses from trial to trial, indicating that the influence of the recent past is too strong and/or the influence of the current contingency is too weak. These difficulties in appropriately using information from both the past and the present to optimize behavior can be said to reflect deficient context processing. A number of executive functions are subsumed under the term 'context processing' (e.g., working memory since a representation of context has to be held online). Computational models have shown that a deficit in a single context processing module can mimic patient performance on a variety of cognitive tasks.

Promising Advances in the Study of Cognition

Imaging Genetics

An extremely promising avenue of research, made possible by advances in genetics, links variability in cognitive function and associated brain activation to genetic variation. This work is strengthening the case for suspected susceptibility genes and identifying potential mechanisms for the development of schizophrenia. For example, in groundbreaking work, Egan and colleagues in 2001 reported that a common functional polymorphism in the catechol-*O*-methyltransferase (COMT) gene, which reduces the amount of dopamine available in the synapses of the prefrontal cortex, and is slightly more common in individuals with schizophrenia than their unaffected family members, was associated with both poorer performance of the WCST and increased prefrontal cortical activation during performance of a working memory task in both patients with schizophrenia and healthy control participants. This suggest that prefrontal cortex function is influenced by genes that increase susceptibility to schizhophrenia. Increased prefrontal activation is thought to reflect inefficient function (i.e., increased resources are necessary to support a given level of performance). Several groups have shown that prefrontal inefficiency is also present in unaffected siblings of schizophrenia patients. The siblings showed greater activation than controls even though their task performance did not diffuse (Figure 4). These findings suggest that physiological indices derived from neuroimaging, because they more directly reflect the effects of genes (e.g., increased metabolism of dopamine), may prove more sensitive endophenotypes than behavioral ones.

Failures to find increased frequencies of the high risk COMT polymorphism in schizophrenia in some studies (e.g., of Asian populations) are not surprising given the number of factors that contribute to variability in association studies and point to the need for caution in generalizing these findings. In addition, particular polymorphisms account for only a small portion of the variance in cognitive performance and regional activation, as would be expected in a complex, multigenetic illness. A gene such as COMT likely interacts with other genetic and environmental factors to either diminish or exacerbate its effect on brain function, and investigations of the effects of gene–gene and gene–environment interactions on cognition are just getting under way.

Neuroimaging Advances

Neuroimaging findings continue to form the crux of many theoretical conceptualizations of schizophrenia, and continued technical advances hold tremendous promise for understanding its pathophsiology. The search for the neural basis of cognitive dysfunction in schizophrenia has evolved from key brain regions (e.g., prefrontal cortex or hippocampus) to also considering the integrity of neural circuits and

Figure 4 Regions of increased, inefficient fMRI activation in the unaffected siblings of schizophrenia patients relative to demographically matched control participants during performance of a working memory paradigm. Behavioral performance did not discriminate between the groups, but fMRI activation did, suggesting that imaging indices may be more sensitive to genetic risk for schizophrenia. Regions of increased activation include right dorsolateral and ventrolateral prefrontal cortices. Statistical group difference maps are rendered onto canonical single-participant lateral brain surfaces. Adapted from figure 2 in Callicott JH, Egan MF, Mattay VS, et al. (2003) Abnormal fMRI response of the dorsolateral prefrontal cortex in cognitively intact siblings of patients with schizophrenia. *American Journal of Psychiatry* 160: 709–719.

the timing of neuronal processes across different regions. Advances in functional magnetic resonance imaging (fMRI) are providing ever higher spatial resolution. In combination with methods that provide high temporal resolution such as magnetoencephalography and electroencephalography, it is possible to examine the neural correlates of cognitive processes at each stage of performance and pinpoint exactly where and when they go awry. Complementary structural MRI can reveal morphological correlates of abnormal activation and cognitive performance. Since performance of even simple cognitive tasks is the product of coordinated activity in a distributed network, it is also of interest to assess the integrity of white matter, which can be done *in vivo* using a relatively new MRI technique, diffusion tensor imaging. Recent evidence suggests that white matter physiology contributes to individual differences in cognitive processing in health, and an emerging literature in schizophrenia links regionally reduced white matter integrity to cognitive dysfunction. By impairing communication in local circuitry and between connected brain regions, white matter pathology may contribute to cognitive dysfunction in schizophrenia. Together, these techniques can identify the functional and structural correlates of cognitive dysfunction, guide the search for neuropathology, and provide targets for intervention aimed at improving cognition in schizophrenia.

Cognitive Dysfunction in Psychiatric Disorders

D M Barch, Washington University in St. Louis, St. Louis, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

Schizophrenia is an extremely disabling neuropsychiatric disorder that affects approximately 1% of the general population. Researchers and theorists have long recognized that abnormalities in cognitive function are a key component of schizophrenia, and the past two decades have witnessed a relative explosion of research on cognition in schizophrenia, much of it couched within the framework of understanding the cognitive neuroscience of schizophrenia. This emphasis is partly due to the research suggesting that cognitive function in schizophrenia is one of the most critical determinants of quality of life in schizophrenia and because of the hope that understanding the neurobiology of cognitive dysfunction in schizophrenia will provide clues to the etiology of this disorder. Research on cognitive function in individuals with schizophrenia has identified deficits in many different cognitive domains, and it is beyond the scope of this article to review the literature relevant to all possible cognitive deficits in schizophrenia. Instead, this article focuses on the three cognitive domains that received the majority of research attention and consistent evidence suggesting impairment in schizophrenia: (1) working memory, (2) executive control, and (3) episodic memory.

Working Memory

Working memory is typically defined as the ability to maintain and manipulate information over short periods of time. It is widely agreed that working memory involves several different component processes. Baddeley's influential theory of working memory distinguishes among four major subcomponents: (1) a short-term storage buffer for visual information that is often referred to as the visual–spatial scratch pad, (2) a short-term storage buffer for verbal information referred to as the phonological loop that includes articulatory rehearsal and phonological storage, (3) a central executive component that guides the manipulation and transformation of information held within the storage buffers, and (4) the recently described episodic buffer. A number of studies suggest that articulatory rehearsal is particularly dependent on regions of left ventrolateral prefrontal cortex (VLPFC), including Brodmann's areas 44 and 45. Figure 1 shows the location of these regions. In contrast, the processing or storage of phonological representation is thought to dependent on regions of left posterior parietal cortex (PPC) (see Figure 1), again based on data from both lesions studies and imaging studies in healthy humans.

The specific component processes of the visual–spatial scratch pad are less clear, although it has been hypothesized that we use covert shifts of attention to the spatial locations to be remembered, a process that has been referred to as attention-based rehearsal, thought to be supported by regions such as right PPC. Studies of spatial working memory also consistently activate regions such as the frontal eye fields and the supplementary eye fields, regions in which information about the direction of visual saccades may be processed and/or maintained. There are a host of different processes that may fall into the central executive, including those involved in the manipulation of information being stored in the buffers, protection from interference due to competing information or decay across time, temporal coding or sequence, and updating of the contents of working memory. Many of these have been assumed to be supported by the dorsolateral regions of prefrontal cortex (DLPFC; see Figure 1), typically Brodmann's areas 46 and 9 bilaterally. In addition, the dopamine system is thought to be critical for a range of working memory functions.

Working Memory in Schizophrenia

Phonological Loop

Research on working memory in schizophrenia has suggested that the operation of the phonological loop is relatively intact in this disorder. For example, a number of studies have shown that individuals with schizophrenia demonstrate (1) relatively intact performance on digit span forward tasks, particularly when the number of items is at or below working memory span (7 ± 2) and when there is no verbal interference; (2) no disproportionate impairment for recall of lists with phonologically similar versus dissimilar items, suggesting an intact ability to represent phonological information; (3) intact serial position curves among individuals with schizophrenia; and (4) equal impairments on verbal and nonverbal working memory tasks. However, some studies have suggested greater impairments in verbal than tone working memory and a small but significant impairment in digit span on meta-analysis.

The vast majority of the working memory functional activation studies report intact activation of VLPFC regions during working memory performance in individuals with schizophrenia, one of the regions

Figure 1 Frontal and parietal regions involved in the central executive and phonological loop function of working memory, and frontal regions involved in semantic processing. Regions plotted in red are the dorsolateral prefrontal and dorsal parietal regions thought to support a range of central executive functions. The left hemisphere regions plotted in green are the ventrolateral prefrontal and parietal regions thought to support phonological loop function. The left hemisphere inferior prefrontal regions plotted in blue are those thought to be involved in semantic processing.

thought to support the phonological loop. These findings are consistent with results of postmortem work which did not find cell density changes in Brodmann's area 44, although such changes are found in Brodmann's area 9.

A number of these same studies report abnormal activation in PPC in schizophrenia, in terms of either the degree of activation or connectivity with other brain regions. However, there are two dissociable regions of PPC activated by working memory tasks, with a left ventral PPC region (see Figure 1) sensitive to the type of information (verbal vs. nonverbal) that may support phonological storage. More dorsal and bilateral regions of PPC (see Figure 1) are sensitive to load irrespective of material type, and they may play a role in the maintenance or updating of information in working memory across stimulus domains. To date, it is not clear whether the PPC regions showing abnormal activation in schizophrenia should be characterized as ventral or dorsal. However, work specifically focused on this question does suggest impaired dorsal PPC activation in schizophrenia but intact ventral PPC activity.

Visual–Spatial Scratch Pad

In terms of the visual-spatial scratch pad in schizophrenia, there is certainly a large body of evidence for impairments on visual–spatial working memory tasks and on classic measures of the visual–spatial scratch pad, such as memory-guided saccade performance. There are relatively few functional neuroimaging studies in schizophrenia that have used visual–spatial working memory tasks that could not be accomplished by verbal recoding (small numbers of spatial locations are typically verbally labeled by participants, turning the task into a verbal working memory task). However, work using an occulomotor delayed response task demonstrated impaired activity in the frontal eye fields, supplementary eye fields, and inferior parietal lobule among individuals with schizophrenia – regions that may support visual scratch pad function.

Central Executive Function

There is very consistent evidence that individuals with schizophrenia have difficulty with processes that are part of the central executive component of working memory. For example, individuals with schizophrenia show deficits on (1) working memory tasks with all different material types, with little evidence for differential deficits across material types; and (2) measures of a range of central executive functions, including manipulation, interference control and/or dual-task coordination, and information updating and temporal indexing. In addition, the first-degree relatives of individuals with schizophrenia also show evidence of consistent impairments in central executive components of working memory.

As described previously, the cognitive neuroscience literature has linked many of the central executive components of working memory to DLPFC function. Many, although not all, functional neuroimaging studies using tasks that engage central executive components of working memory have found disturbed DLPFC activation in schizophrenia. These studies

have used tasks such as the Wisconsin Card Sorting Task, mental arithmetic, self-ordered pointing, the Sternberg Item Recognition Task, and various versions of the Nback and delayed response tasks. The most common finding on these tasks is that individuals with schizophrenia show reduced DLPFC activation. However, several studies have reported increased activation in DLPFC among individuals with schizophrenia that sometimes co-occurred with decreased DLPFC activation in different regions. One interesting hypothesis put forth to explain these differential findings of hypo-versus hyper-DLPFC activity is the idea that the memory load–DLPFC response curve may be different for individuals with schizophrenia compared to healthy controls. Specifically, it may be that at low load levels, individuals with schizophrenia need to devote more resources to working memory, leading to hyperactivation, but that higher load levels exceed their capacity, leading to reduced DLPFC activity. However, relatively few studies have reported such hyper-DLPFC activation in schizophrenia, and the regions that show hyperactivation tend not to overlap for the most part with regions showing hypoactivation because they are located either anterior (particularly on the right) or more inferior (particularly on the left).

Although many studies of working memory in schizophrenia report abnormalities in the activation of specific regions during working memory tasks, a growing number of studies suggest that individuals with schizophrenia demonstrate altered patterns of connectivity between DLPFC and other working memory-related regions such as PPC and temporal cortex. Furthermore, there is evidence from methods other than functional imaging for altered DLPFC function in schizophrenia, including (1) reduced gray matter volume; (2) cellular and molecular abnormalities; (3) reduced *N*-acetylaspartate concentrations, particularly in dorsal regions; and (4) a relationship between poor working memory performance (as measured by the Nback task) and altered D1 receptor availability in DLPFC. Although there have been negative findings in each of these areas as well, the weight of the evidence suggests structural, cellular, and molecular abnormalities as well as functional abnormalities in the DLPFC of individuals with schizophrenia.

Executive Control in Schizophrenia

Context Processing

Individuals with schizophrenia also show impairments in other aspects of executive control thought to be dependent on DLPFC and potentially dopamine function. For examine, a growing body of research suggests that individuals with schizophrenia show deficits in the ability to represent and maintain context information, a process thought to be dependent on intact function of dopamine in DLPFC. A number of studies have demonstrated impaired context processing in schizophrenia, in individuals at risk for schizophrenia, and in individuals with schizotypal personality disorder. In addition, a number of studies have demonstrated impaired DLPFC activity during performance of context processing tasks in schizophrenia among both medication naïve first-episode patients and chronic patients.

Conflict Detection/Error Monitoring

An alternative (or complimentary) theory suggests that disturbances in the ability to detect conflict or errors in ongoing processing, due at least in part to the function of anterior cingulate cortex (ACC), may lead to deficits in the ability to recruit and regulate cognitive control functions that may be subserved at least in part by DLPFC regions. There is mixed behavioral evidence in schizophrenia regarding impairments on indices thought to reflect the ability to detect or respond to conflict or errors, with some studies finding evidence for impairments and others not. However, event-related potential (ERP), functional magnetic resonance imaging (fMRI), and positron emission tomography (PET) studies have provided more consistent evidence for altered conflict/error processing and abnormal ACC function in schizophrenia. There is also evidence for ACC abnormalities in schizophrenia from structural and postmortem studies. However, only a handful of the functional neuroimaging studies on working memory in schizophrenia have reported abnormal ACC activity, and most of these have been in the direction of greater ACC activity. It is possible that such results reflect the increased errors and conflict experienced by individuals during ongoing cognitive processing, which would be expected to lead to enhanced ACC activity. Further research is needed to clarify the nature of functional abnormalities in ACC among individuals with schizophrenia and to clarify their relationship to DLPFC deficits.

Episodic Memory

As with trying to understand the nature of working memory deficits in schizophrenia, it is useful to briefly discuss the cognitive neuroscience literature on the processing and brain regions involved in episodic memory. Research has long indicated the importance of the hippocampal formation in the formation

of long-term memories, with most theories of hippocampal function focusing on its role in the rapid binding of novel configurations of information. These theories have been supported by both human functional imaging studies and work in amnestic patients. However, it is also very clear that PFC structures also make important contributions to episodic memory. Damage to the PFC can also lead to episodic memory deficits, although these deficits are not selective to episodic memory. It has been hypothesized that PFC regions contribute to episodic memory via their strategic contributions to memory formation and retrieval. Consistent with this hypothesis, studies have shown activation of prefrontal regions such as Brodmann's areas 45 and 47 when participants are asked to process verbal information using semantic elaboration strategies and increased activation during encoding in frontal regions such as Brodmann's areas 45 and 47 are very strongly predictive of subsequent memory performance. Work on episodic memory has also distinguished between recollective versus familiarity-based processing in episodic memory. Recollection is the ability to retrieve information associated with specific learning episodes, whereas familiarity refers to feelings of knowing that may be related to prior exposure to information. Imaging and lesion data suggest that the DLPFC is important for recollection compared to familiarity, although there is opposing evidence. In contrast, imaging and lesion data suggest that the hippocampus is important for both recollection and familiarity, although there are conflicting views on this.

Episodic Memory in Schizophrenia

Binding Functions

A meta-analysis comparing performance on associative and item memory tests in individuals with schizophrenia concluded that there was evidence for a 20% greater impairment in associative compared to item memory in individuals with schizophrenia. However, few of the studies that have compared item and associative memory have dealt with the ubiquitous problems of discriminating power. Recent studies have used tasks derived from the animal literature on hippocampal function, such as the transitive interference test. Other research has shown that individuals with schizophrenia are impaired on the critical conditions of this task that require relational processing but not on conditions that require the learning of simpler associative reinforcement mappings. Taken together, these results suggest impairments in relational processing or binding in schizophrenia of the type thought to be specifically supported by the hippocampal formation.

Many recent functional imaging studies of episodic memory have provided relatively consistent evidence for abnormal hippocampal activation in schizophrenia, at both encoding and retrieval. These failures to show task-related hippocampal activity at retrieval have been interpreted as reflecting a failure in explicit recollection among individuals with schizophrenia. There are a number of other sources of evidence that individuals with schizophrenia have deficits in hippocampal volume and shape. The evidence for hippocampal abnormalities in schizophrenia extends to the cellular level as well, with much theoretical and empirical work focusing on *N*-methyl-D-aspartate (NMDA) receptor hypofunction. NMDA receptors are dense in the hippocampus, and NMDA receptor antagonists disrupt hippocampal long-term potentiation, one of the mechanisms thought to support memory encoding and/or binding. In humans, NMDA receptor antagonists such as ketamine or phenycyclidine (PCP) can impair episodic memory and elicit many clinical phenomena analogous to the symptoms of schizophrenia, including hallucinations, delusions, and disorganized speech. Thus, many theorists have argued that such NMDA receptor hypofunction contributes to hippocampal abnormalities and episodic memory deficit in schizophrenia.

Impairments in Strategic Contributions to Episodic Memory

A number of researchers have hypothesized that individuals with schizophrenia experience deficits in the use of beneficial strategies that may be supported by PFC. A number of studies suggest that individuals with schizophrenia are impaired in their ability to generate effective mnemonic strategies and encode information less elaborately than controls. However, when provided with strategies that promote successful episodic encoding, individuals with schizophrenia are typically able to benefit as much as controls from these strategies. Importantly, individuals with schizophrenia show evidence of impaired recollection but relatively intact familiarity, which may relate to both binding deficits and strategic impairments. For example, when individuals with schizophrenia are asked to make judgments about the source of their responses, they consistently provide fewer responses indicative of recollective experiences.

Prefrontal Abnormalities in Schizophrenia during Episodic Memory

Many of the functional imaging studies of episodic memory in schizophrenia have demonstrated abnormalities in a range of prefrontal regions, including both decreased and increased activity. These studies have revealed consistent abnormalities in PFC function, but

in different regions than those found to be impaired in studies of working memory in schizophrenia. For example, episodic memory studies of schizophrenia consistently find reduced activity in Brodmann's areas 47 and 45 (Figure 1), regions associated with semantic elaboration or encoding of information in episodic memory. Abnormal activity in these regions may reflect deficits in the ability to generate or apply effective encoding or retrieval strategies that utilize semantic processing. However, people with schizophrenia can appropriately engage these regions when given external support in the use of effective encoding strategies.

Specificity of Cognitive Deficits to Schizophrenia

A number of studies have examined whether the pattern or profile of cognitive impairments found in schizophrenia are specific to this disorder or found in other psychiatric disorders as well. There are several levels at which one could address the question of specificity. One could ask whether the pattern of cognitive deficits and associated neurobiological abnormalities is specific to schizophrenia as opposed to any psychiatric disorder, such as nonpsychotic major depression. At the behavioral level, a number of studies have shown that individuals with nonpsychotic major depression do not show the same impairments (either no deficit or less of a deficit) in working memory and executive function as shown by individuals with schizophrenia, although individuals with major depression do show impairments in episodic memory function. Furthermore, individuals with major depression do not show the same impairments in DLPFC function during working memory and/or executive control tasks as found in schizophrenia. Individuals with bipolar disorder can show deficits in many of the same domains as individuals with schizophrenia, particularly in terms of working memory and episodic memory, with impairments more severe during manic than euthymic states. However, there is evidence that these impairments tend to be less severe than those found in schizophrenia. There has been little work directly comparing individuals with schizophrenia and those with bipolar disorder on functional brain activation during cognitive performance. However, there is evidence for reduced anterior middle frontal gyrus activity among euthymic bipolar patients performing a Stroop interference control task.

It is more difficult to distinguish between individuals with schizophrenia and those with other psychotic disorders (e.g., schizoaffective, brief psychotic disorder, delusional disorder) in terms of behavioral impairments, although there are data suggesting that cognitive deficits are more stable in individuals with schizophrenia compared to those with other psychotic disorders. There is preliminary evidence that impairments in DLPFC function are more severe among individuals with schizophrenia. Further work comparing both behavioral and functional brain activation in a range of cognitive domains between individuals with schizophrenia and individuals with other types of psychosis (both affective and nonaffective) will help to clarify the specificity of cognitive deficits and functional brain activity disturbances found in schizophrenia.

Summary

Individuals with schizophrenia show deficits in a range of cognitive domains; disturbances are particularly apparent in working memory, executive function, and episodic memory. Within the domain of working memory, individuals with schizophrenia show relatively little evidence of impairments in the phonological loop and relatively little impairment in activation of ventral prefrontal cortex regions (e.g., Brodmann's area 44) or dorsal PPC regions associated with this subcomponent of working memory. Individuals with schizophrenia do not show evidence of differential impairments in spatial working memory, but they do show evidence of impaired visual–spatial scratch pad function and altered dorsal PPC activity, a region that may support the visual–spatial buffer. There is consistent evidence for impairments in the central executive components of working memory, associated with impaired DLPFC and dorsal PPC functions. Individuals with schizophrenia also show clear evidence of impairments in other types of executive controls functions associated with DLPFC, such as context processing. There is mixed behavioral and imaging evidence for impairments in error detection and conflict processing associated with ACC function in this disorder. In the domain of episodic memory, individuals with schizophrenia show deficits suggestive of impairments in both relational processing and the generation and application of effective encoding strategies. Furthermore, individuals with schizophrenia show evidence of alterations in hippocampal activity, as well as impairments in the activation of regions associated with semantic encoding and successful subsequent memory retrieval. The types of cognitive impairments and changes in functional brain activation found in schizophrenia are dissociable from those found in depression and affective psychoses (e.g., bipolar disorder). However, further research is needed to determine what cognitive and functional brain abnormalities are specific to schizophrenia compared to other nonaffective psychoses.

Cognitive Neuroscience: An Overview

C M Wessinger and E Clapham, University of Nevada, Reno, NV, USA

© 2009 Elsevier Ltd. All rights reserved.

Understanding how brain enables mind is the goal of cognitive neuroscience. More broadly stated, cognitive neuroscience is concerned with understanding the neurobiological basis of mental processes – in other words, thinking about how the brain is involved in thinking. Thinking about thinking. There is little doubt that human brains can engage in the task of thinking about thinking and likely have been able to do so for some time. Unfortunately, throughout most of human history, more practical concerns necessarily occupied human thought. Humans were more concerned with thinking about and acting on behaviors that were related to their survival: storing enough food to enable them to survive the winter, killing the bear before the bear killed them, and finding shelter. They had to concentrate on understanding and working within their environment in order to survive to struggle another day. Anything that did not specifically contribute to their survival was a luxury. Thus, thinking about thinking would have been a luxury – a luxury that humans could not afford. However, as soon as civilization developed to a point that day-to-day survival did not occupy every waking thought, humans could afford to think about thinking. They began to think about how others thought and why they did what they did. Oedipus Rex, the ancient Greek play that deals with parent–child conflicts, as well as Mesopotamian and Egyptian theories designed to explain religion and the universe are excellent early attempts to understand why people act the way they do. Unfortunately, there are significant pieces of the equation missing. These thinkers and philosophers did not systematically explore the relationship between brain, behavior, and mind. This is where modern-day science and scientific methodology come into play. The notion that we must observe, manipulate, and measure the environment in order to understand the world and our place within it is central to scientific methodology. When we apply such techniques to understanding how the brain enables mind, we call that cognitive neuroscience.

Certainly, one could make a case that cognitive neuroscience has been around ever since scientists in different disciplines began exploring the common goal of understanding how brain enables mind. Such early explorations were quite illuminating and many have stood the test of time. Some early theories that specific areas of the brain gave rise to specific functions were put forth by the phrenologists Franz Joseph Gall and J G Spurzheim, who declared that the brain was organized around 35 distinct functions ranging from such basic cognitive functions as language and color perception to more philosophical concerns such as hope and self-esteem. Each of these areas was supported by a specific brain region, and with increased proficiency in one of these areas, the corresponding brain representation would grow in size, in turn causing a corresponding bump on the skull. However, once subjected to strict scientific methodology, phrenology was shown to be untrue. It took the great neurologist John Hughlings Jackson to again substantiate that a structure–function relationship between the brain and behavior existed. Rather than being associated with bumps on the skull, his hypotheses were based on careful clinical observations of patients. While seizing, some of his epileptic patients would move in characteristic patterns, almost with a systematic rhythm. This led him to propose a somatotopic organization – that is, a map of the body in the brain. Also at approximately this time, the French neurologist, Paul Broca, reported perhaps the most famous neurological case – one of his patients had suffered a stroke and now was unable to speak but was still able to understand speech. Postmortem examination showed damage in the left frontal area, which is now known as Broca's area and still believed to play a major role in language output. In contrast, German neurologist Carl Wernicke reported a patient who babbled incessantly following a stroke, but that is all it was – babbling – the words kept coming but made no sense. Wernicke's patient had a lesion in a more posterior region in the left hemisphere, which has become known as Wernicke's area, and it is still believed to play a major role in understanding language. Neuroanatomists were realizing similar divisions of the brain, but on a more cellular level. Perhaps the most famous is Korbinian Brodmann, who analyzed cellular organization of the cerebral cortex using a Franz Nissl developed stain to visualize the different layers of cortical neurons, dividing the cerebral cortex into more than 50 distinct regions. This method of looking at cellular differences in cortical layers is known as cytoarchitectonics. Many others contributed to this work, including Constantin Von Economo, Gerhardt von Bonin, and Percival Bailey. More recently, similar techniques have been used to demonstrate more than 30 different cortical areas in the visual system alone. Such early

investigations still guide cognitive neuroscience today, particularly with regard to helping the field understand structure–function relations within the brain and how these combine to enable mind.

The formal birth of the field known as cognitive neuroscience was relatively recent. One story as to how the field developed involved a taxi ride shared by two eminent brain scientists – biopsychologist Michael S Gazzaniga and behavioral-turned-cognitive psychologist George Miller – on the way to a dinner meeting in the early 1970s. The dinner was being held so scientists from many different disciplines could discuss how to pursue a common goal: understanding how the brain enables the mind. Such a joining of forces deserved an appropriate name – not just a renaming of biopsychology or cognitive neuropsychology, well-respected disciplines already striving to understand the structure–function relations of the brain–mind problem, but a name that incorporated the investigations of information processing akin to cognitive science: one that reflected a merging of all of these many disciplines and more. After much discussion, the term 'cognitive neuroscience' seemed ideal. Another story concerning the birth of the field involves a similar meeting with other eminent brain scientists such as Larry Squire, a neuroscientist renowned for his research exploring the biological basis of memory, and Stephen Kosslyn, a cognitive psychologist well-known for his mental imagery research. However, the exact events that led to the adoption of the term cognitive neuroscience are not important. What is important is the fact that many scientists using quite varied methodologies are working together, and making headway, toward the common goal of cracking the code of the brain and understanding how this approximately 6-pound lump of soft, squishy, neuronal tissue allows us to think and feel and emote and cry and to dream – how the brain enables mind. Many of the varied methodologies that contribute to this exciting and rapidly expanding field are described here.

In order to help us understand the inherently multidisciplinary approach of cognitive neuroscience, we need to understand some of the key methodologies. Techniques ranging from exploring the molecular basis of the brain to exploring consciousness are utilized, combined, dissected, and manipulated by researchers in the quest to understand the neurobiological underpinnings of mental operations. However, cognitive neuroscience is more than a simple recombination of various methodologies and techniques. The field is extremely innovative in that it borrows the best techniques from the best disciplines in order to provide the best innovative insights into how brain enables mind. Such innovation can be more fully appreciated by exploring some of the key methodologies and techniques.

One key avenue in understanding how brain enables mind is grounded in understanding the relationship between brain anatomy and cognition. Many studies have tried to relate differences in intelligence to differences in brain size and structure. Differences in neuronal type, size, density, and connectivity have also been explored in trying to understand structure–function relations between brain anatomy and cognition. These explorations of brain structure can be loosely grouped under the term neuroanatomy. Formally, neuroanatomy is the study of structure of the nervous system. Primary questions of interest to neuroanatomy are identifying the various parts and components of the nervous system, as well as describing how these parts and components are interconnected. To further complicate matters, it is necessary to use specialized techniques and methods to ask these questions at multiple levels. Not only is it important to know the size and shape of a neuron but also it is important to know where that neuron connects. Where does the input come from and where does the output go? This very debate was truly a key development in the birth of neuroscience, and neuroscience is key to cognitive neuroscience. Two brilliant neuroanomists were debating the interconnectivity of the nervous system. Camillo Golgi invented a silver stain that permitted visualization of single neurons. Using Golgi's stain, Santiago Ramón y Cajal demonstrated that the neurons were discretely bound, individual entities that did not touch. This view was contrary to that of Golgi, who believed the whole brain was a continuous mass of tissue sharing a common cytoplasm, or syncytium. Cajal extended the field by being the first to identify the unidirectional (from axon to dendrite) nature of electrical transmission within neurons. These findings were elucidated with early microanatomical techniques. Microanatomy or fine anatomy has now developed to the point of exploring the organization of neurons and the connections. This is opposed to gross anatomy, which is concerned with the general structures and connections visible to the naked eye. Gross and microanatomical techniques continue to inform the field of cognitive neuroscience by providing essential knowledge concerning brain and neuronal structure and connectivity.

Another key technique employed by cognitive neuroscientists that is grounded in neuroscience is physiology. This is a branch of neuroscience that deals with the functions and processes of life, as well as the physical actions and reactions associated with these processes. Simply stated, physiology measures bodily responses such as blood pressure, heart rate, and

neuronal electrical activity to the environment. One physiological measure of great import is neuronal electrical activity. Despite the fact that the electrical potential is extremely small, when large numbers of neurons are active simultaneously, they produce enough electrical signals that when summed can be measured by electrodes placed on the scalp. Electroencephalography (EEG) involves recording a continuous stream of overall brain activity while the person performs a variety of tasks, sometimes in an experimental setting and sometimes as part of everyday life. These continuous recordings of continuous activity have proven extremely useful clinically and have helped with epilepsy, sleep disorders, and anxiety.

EEG can only provide limited information when exploring cognitive processes because the recordings tend to reflect global brain activity, as opposed to specific cognitive or perceptual processes and functions. However, by synchronizing EEG collection with specific cognitive and perceptual events, it is possible to disentangle the brain waves and see changes in electrical activity associated with changes in cognitive and perceptual processes. This technique is called event-related potential (ERP) because the neuronal potentials are related to specific events. Given that neurons produce unidirectional electrical transmission and constraints of Farady's law of induction (which states that a changing electric field produces a magnetic field orthogonal to the direction of flow of electricity), they produce miniscule magnetic fields. Magnetoencephalography (MEG) records these summed magnetic potentials at the scalp in a manner similar to ERPs.

One great advantage of these techniques is that millisecond accuracy is possible in terms of linking summed electrical signals specific to an event; thus, cognitive neuroscientists can understand exactly when and how the brain is responding to a specific event. One major drawback of these techniques is the very notion of summed electrical signals. Such summing results in limited spatial resolution. Furthermore, because the summed signals must be collected at the scalp, localization of depth is also problematic. It is difficult to determine where in the brain the signals occur.

This problem can be overcome by taking advantage of the inherently multidisciplinary nature of cognitive neuroscience by bringing other techniques to bear. One technique that can help inform EEG, MEG, and a variety of other cognitive neuroscience techniques is magnetic resonance imaging (MRI). Formally, MRI is a branch of neuroimaging that is a clinical specialty that uses noninvasive techniques to produce images of the brain. Interestingly, MRI also takes advantage of Faraday's law in that it uses a supercooled, superconducting electromagnet to produce a strong electrical field. This magnetic field is then systematically manipulated to produce images of the body. These images currently provide great detail concerning the gross anatomy, and even microanatomy, of the nervous system. Such information, when coupled with ERP and/or MEG techniques, can provide essential structure–function relations within the human brain. Such techniques can help surgeons understand not only tumor location but also functions compromised by the tumor and weigh them against functions that may be compromised by the surgery.

A recent interesting use of MRI in conjunction with other techniques involves trying to understand the biological basis of autism, an increasingly more problematic developmental disorder. Hutsler and colleagues showed that increases in dendritic spine density could be related to increases in autistic symptoms. Certainly, these data do not indicate that dendritic spine density is responsible for autism, just that there is some connection, and this connection needs to be investigated further. This is an excellent example of the utility of cognitive neuroscience: by combining neurology, neuropsychology, radiology, and microneuroanatomy, researchers are making tremendous strides in understanding the biological basis of autism.

Within the past 15 years, MRI has been extended to include a functional component. By taking advantage of what from a radiologist's viewpoint is noise, cognitive neuroscientists are able to see the brain in action – almost. It is well-known that changes in cognitive and perceptual activity result in localized changes in neuronal activity, which result in localized changes in metabolic needs, which result in localized changes in blood flow, which result in localized changes in blood oxygenation. The end of this cascade, the localized changes in blood oxygenation, can be visualized with functional magnetic resonance imaging (fMRI) in order to infer localization of function. Also, when MRI signals are time locked to cognitive and perceptual changes, localization of function, as well as localization of time, can be inferred. This is similar to positron emission tomography (PET), another neuroimaging technique that can image the blood flow change portion of the cascade to infer localization of function, except that PET uses ionizing radiation and fMRI does not. Another advantage that fMRI has over PET is greater spatial and temporal resolution. PET provides resolution in terms of minutes and centimeters for temporal and spatial properties, respectively. However, fMRI, particularly event-related fMRI, can provide temporal accuracy in seconds and spatial accuracy in millimeters.

So far, we have reviewed several biologically based techniques and have a greater understanding of the neuroscience part of cognitive neuroscience. But what about the cognitive part? Is there really a need for more when trying to understand how brain enables mind? Certainly. Without the 'cognitive,' there would be no true understanding of the mind portion of the equation.

Cognition can be defined as any form of information processing, mental operation, or intellectual activity such as thinking, reasoning, remembering, imagining, or learning. Thus, cognitive psychology, a major contributor to the field of cognitive neuroscience, is the study of behavior related to cognition. The principles and goals of cognitive psychology rest on two key concepts. First, mental operations depend on internal representations. Second, mental operations undergo transformations.

The notion that mental operations depend on internal representations is not that far-fetched; after all, by definition, if the operations are mental and taking place in the mind, then they are necessarily internal. It is also easy to accept and understand the notion that mental operations have to undergo transformations. After all, we do not directly perceive and act in the world; rather, our perceptions, thoughts, and actions depend on what our sensory systems are designed to detect within our environment, and our senses are not capable of translating everything in our environment into useable information. For example, we do not readily see infrared light or directly sense changing electrical and magnetic fields, but these physical properties do exist in the environment – they are just not detectable by our sensory systems. We need to use other physical-detection tools specifically designed to detect these aspects of our environment. Nonetheless, we still perceive, think about, and act within our environment reasonably well. This is because our brains take the information provided by our sensory systems and transform it into signals that can be understood, interpreted, and acted upon. Michael Posner and Richard Mitchell first conducted a classic study illustrating both of these key principles in the mid-1970s. Using a series of letters, they were able to clearly demonstrate that mental processes were internal and that these processes were necessarily manipulated and transformed when acting on them. The experiment is quite simple: it requires only that one present letter pairs to participants and ask them if the letters are the same or different. Why is it a classic experiment? Because of how the letters were paired and how the question of same or different was asked. In the simplest form, four different letters are used – two consonants and two vowels – and they are displayed in either upper or lower case. Using these stimuli, different levels of sameness can be asked. The lowest level is based on the physicality of the letters: are they physically the same? AA and aa are two examples of stimuli that would be judges as physically the same, Aa and aA are examples that would be correctly judged not the same. The next level of question involves identity, or the name of the stimuli. The previous four examples would all be judged the same based on name identity. AB and AE are examples of stimuli that would be judged as different. The next higher question involves judging if the letters are the same or different based on more detailed information concerning the letters – whether the letters are consonants or vowels. Reaction time data were collected during this experiment and clearly show that the mental processes cannot necessarily be overtly witnessed (they are internal) and various mental processes take various amounts of time, depending on the level of complexity involved in the process (or number of transformations necessary to perform the task). That is, the physical judgment was the easiest and fastest, the type judgment task was the most difficult and slowest, and the identity task (naming) was somewhere in between.

Another key technique that is often considered under the cognitive domain of cognitive neuroscience is neuropsychology. This is a science that seeks to integrate psychological observations of behavior and mind with neurological observations of the nervous system and the brain. This field is closely related to neurology, a branch of medicine concerned with understanding and treating disorders of the nervous system. One difference is that neuropsychology is specifically concerned with understanding and treating cognitive, perceptual, and other psychological deficits related to nervous system compromise. Such deficits can come in the form of vascular disorders such as strokes or bleeds, tumors, trauma, and disease.

These deficits of structure can also cause deficits of function, which is where cognitive neuroscience can benefit. The real strength of cognitive neuroscience is the ability to take a variety of seemingly disparate technologies and bits of data and integrate them into a coherent explanation of how brain enables mind. One of the most fruitful paradigms in cognitive neuroscience that depends on converging data involves the effects of brain lesions on behavior. Fundamental concepts, such as the notion that language resides primarily in the left hemisphere and the fact that the left hemisphere controls the right side of the body (and vice versa), are grounded in such a combination of techniques. The logic is pretty straightforward. If mental processes and behavior depend on processing within a certain brain region, then damage

to this region should impact the processes and behavior. Unfortunately, it is not that straightforward. Just because behaviors are disrupted following brain damage does not necessarily mean that the region damaged is responsible for the disrupted process, only that it is involved in the processes.

This is why cognitive neuroscientists often design research paradigms that involve at least two tasks, and two different types of brain compromise. Such a combination of techniques provides the most information because it is useful in dissociating structure–function issues. This notion of separating or dissociating various mental processes into relatively independently functioning units is quite attractive. A classic example of this approach can be illustrated by considering the findings of Broca and Wernicke. Broca's patient had trouble with speech output, but his language comprehension was intact. Wernicke's patient has problems with language comprehension, but his speech output was intact. These were two different language disorders in two different people. Behaviorally, these two language functions are dissociable. By adding the component of neuroanatomy – what part of the brain is compromised – the dissociation is strengthened. A modern example of a similar double dissociation can be illustrated with the phenomenon of blindsight. Blindsight is extremely interesting because it allows cognitive neuroscientists to pursue what is perhaps the highest level of cognition possible by the human brain – consciousness – in an established patient model. Blindsight comes about following damage to cortical regions of the primary visual pathway. Such damage results in corresponding regions of blindness in the visual field. Under certain testing conditions, some patients demonstrate residual vision within this area of blindness – residual vision without awareness. That is, they can respond correctly to some stimuli while denying actually having 'seen' the stimuli. Hence the term blindsight.

Interestingly, few patients with such damage demonstrate blindsight, and those who do so demonstrate the phenomenon differently. A study by Wessinger and colleagues showed this in terms of a dissociation: one participant (FN) can detect direction of motion but cannot detect differences in shape, whereas another participant (CLT) can detect differences in shape but not differences in motion. These data suggest a dissociation of motion and shape processing in blindsight. Interestingly, MRIs demonstrate differences in the location and extent of their damage. FN has greater damage in his inferior occipital lobe and CLT has greater damage in his parietal lobe – both have limited sparing around the calcarine fissure. These data suggest that it is not the damage to primary visual cortex that results in differences in blindsight; rather, it is compromise of higher order visual processing (i.e., extrastriate) modules. CLT's motion module is damaged, and thus does not have motion blindsight, but it does have shape blindsight because his form regions are less damaged. The opposite is true for FN: his form processing capabilities are too damaged to provide any useful form processing data, but his motion processing capabilities still provide some limited information – information that is sufficient to drive motion blindsight. Overall, these data indicate that blindsight may depend on surviving remnants of primary visual cortex and vestiges of connections to surviving, albeit severely compromised, extrastriate visual modules.

Blindsight is not the only interesting exploration of consciousness undertaken by the multidisciplinary approach of cognitive neuroscience. In an extremely interesting combination of philosophy and neuroscience, Benjamin Libet has made a career of investigating consciousness.

In a groundbreaking and often controversial series of experiments, Libet investigated the neural time factors in conscious and unconscious processing. These experiments are the basis for his 'backward referral hypothesis.' Libet and colleagues conclude that awareness of a neural event is delayed ~500 ms following the onset of the stimulating event, and more important, this awareness is referred back in time to the onset of the stimulating event. Thus, we are not aware of the event until after it occurs, although we often think we are aware of the event from the onset. Fortunately, backward referral of our consciousness is not so delayed that we act without thinking. The actual beginning of the act occurs sufficiently after the awareness of the intent to act, giving us time to override inappropriately triggered behavior. This ability to detect and correct errors is what Libet believes is the basis for free will. Cognitive neuroscience is investigating consciousness and free will and making headway.

Certainly, this is not an exhaustive review and explanation of the methods that converge to form the field of cognitive neuroscience. In fact, there are a whole host of animal techniques not covered. By definition, the field of cognitive neuroscience – a multidisciplinary science that borrows from many seemingly disparate fields in order to develop coherent explorations of the neurobiological underpinnings of cognition – is dynamic. The field is in constant flux, always expanding and growing and exploring new questions related to furthering our understanding of how brain enables mind. To some, such constant change may seem disconcerting, but to others it is what makes cognitive neuroscience exciting. Such constant change is in fact why cognitive

neuroscience came about in the first place. By combining the best of many disciplines, cognitive neuroscience is asking and answering interesting questions about how the brain enables mind, putting the field at the forefront of helping humans understand their place within the world.

Given that scientists from many seemingly disparate fields were already pursuing the common goal of understanding how brain enables mind, why was it necessary to formally define a multidisciplinary approach that has now become known as cognitive neuroscience? It is hoped that by raising exciting issues ranging from the development of the neuron doctrine to the use of cytoarchitectonics to relate brain morphology to autism, from the collection of behavioral data in cognitive paradigms to the integration of converging data in dissociation paradigms, and the combination of philosophy and neuroscience to understand consciousness, this article helps you understand why cognitive neuroscience emerged as a new multidisciplinary field of study. In sum, it was to accurately represent the merging of many different brain sciences, ranging from a neuroscientific and structural approach to a cognitive and functional approach. A neuroscientific approach is concerned with understanding the basic mechanisms of neural action that result in processing and communication of information within neuronal assemblies. It is also necessary to consider the anatomical substrates or structures that are composed of these neuronal assemblies. A cognitive approach is concerned with characterizing the cognitive processes that lead to specific functions or behavior. Cognitive neuropsychology is concerned with similar characterizations with the added dimension of trying to understand what structures are necessarily involved in various cognitive processes. Similarly, cognitive science is concerned with characterizing the computational algorithms necessary for such cognitive processes. By incorporating the concerns of these wide-ranging disciplines, cognitive neuroscience is more than just a sum of its parts; rather, it is a stronger, more comprehensive approach to understanding how the brain enables the mind – one that begins at the molecular level and continues to the problem of understanding human conscious experience.

Color Vision

P Gouras, Columbia University, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Color vision is best known by humans' perception of it. It creates an aspect of vision that cannot be appreciated by any other means. But it is an illusion of reality that comes from the interaction of millions of neurons within the darkness of our skull projecting us into a multicolored universe, which would otherwise remain unknown. In addition to an esthetic impact, color vision facilitates detecting objects in the external world (Figure 1).

Color vision uses two properties of light to create visual contrasts. One property is effective energy, that is, the number of quanta in the light. The other is the frequency of vibration, or wavelength, of the absorbed quanta. How our brain separates these two properties of light and then recombines them to create color is the mystery of color vision.

All colors perceived by humans can be quantitatively defined by the mixtures of three international standards. Colors can also be described by three psychological concepts: their hue, best realized by each of the four most basic colors, red, green, yellow, and blue; their saturation, which is determined by the whiteness or blackness mixed with hue; and last, their luminance, or brightness. Describable by these variables, about 2 million different colors are perceivable by humans.

Relating color perception to physical and psychological dimensions, however, does not explain the physiology that creates these impressions in our brain. The purpose of this chapter is to try to explain the physiological basis of color. But explaining color vision by the responses and circuitry of neurons has pitfalls. Most of the information available at present comes from peripheral levels of the nervous system, the retina and thalamus, and even here, questions remain. The perception of color involves the entire brain, especially cerebral cortex. Color vision is also associated with the perception of form and the state of consciousness, about which our understanding is still vague. Nevertheless, progress is being made in exploring these higher levels of visual perception and color vision, especially with new techniques that can now monitor many neurons simultaneously in multiple parts of the brain in conscious humans or trained nonhuman primates.

In this description of color vision mechanisms, the human visual system is emphasized because we have a unique form of color and have much less of an idea of color perception in other animals. In addition, human color vision has been intensively studied over centuries, providing valuable insight into this process and intriguing us to find physiological explanations. But there are many diurnal animals, such as birds and fish, that have an even more elaborate form of color vision than humans and all other mammals.

The Photodetectors, Opsins

Unique proteins coupled to an isomer of vitamin A, 11-*cis* retinaldehyde, are the means by which we detect light. These proteins are located in the lipid membrane of a specialized organelle, the outer segment of photoreceptor cells, where they absorb light transmitted through the eye and focused on a monolayer of these receptors. Absorption of a quantum of light alters a double bond in 11-*cis* retinaldehyde, which activates the opsin molecule, allowing it to catalyze a complex biochemical reaction leading to a change in the electrical properties of the photoreceptor that can either stop or start the release of a synaptic transmitter molecule onto second-order retinal cells. This process, called 'phototransduction,' amplifies the energy transfer of a single quantum of absorbed light a million times and more.

Each opsin molecule is an antenna tuned to a particular band of the visible spectrum. By altering the amino acid composition of the opsin molecule, nature can tune these opsins to absorb light from the infrared to the ultraviolet region of the spectrum. The absorption spectra of the opsins an organism uses reflect the particular ecology of the organism, and this is under strong evolutionary pressure. The genes for the three human cone opsins have been cloned by Jeremy Nathans – a major contribution to understanding the initial stages of color vision.

The Evolution of Vision

Vision must have begun with diurnal organisms that could distinguish light from dark. The earliest photoreceptors, undoubtedly developing in broad daylight, were conelike, as first surmised by the comparative biologist Gordon Walls and confirmed by recent molecular genetics. Rods, which are extremely sensitive nocturnal photoreceptors, evolved later. Rods play no significant role in color vision; their response saturates at light levels at which cone function and

Figure 1 Difference between color vision using both wavelength and energy contrasts (top) and achromatic vision using only energy contrasts (bottom).

Figure 2 Key points in cone circuitry of human retina. Cones synapse on two types of bipolar cells, called on- and off-bipolars, which synapse on two types of ganglion cells, called on- and off-ganglion cells. In the fovea, these bipolars synapse with only one cone; elsewhere such bipolars synapse with several cones, which reduces their spatial resolution. Horizontal cells mediate antagonistic interactions between neighboring cones. Amacrine cells also mediate antagonistic interactions in the inner plexiform layer but have been omitted in this figure for simplicity.

color vision are optimal. In the evolution of vision, shadows must have been triggers for the detection of movement. A shadow depolarizes a cone, causing the release of a synaptic transmitter that depolarizes (excites) a second-order neuron, called an 'off-bipolar.' The reappearance of light with movement hyperpolarizes the cone, stopping transmitter release. This disinhibits (excites) a parallel second-order bipolar cell, an 'on-bipolar.' These two bipolar cell systems form a 'push–pull' circuit signaling dark and light, respectively. Cone bipolar cells excite third-order retinal ganglion cells, which transmit their signals to the central nervous system (Figure 2).

Cones respond optimally over enormous ranges of ambient illumination, owing to their ability to adapt to light. As ambient light increases, a cone's sensitivity decreases, but its response speed and temporal accuracy increase. This adaptation results in large part from the biochemistry of the cone photo-transduction process converting light into a neural signal.

Cones receive negative feedback from second-order neurons called horizontal cells. Horizontal cells are depolarized by the transmitter released by cones, being depolarized when cones are depolarized and hyperpolarized when cones are hyperpolarized. Horizontal cells send an antagonistic (inhibitory) signal back to cones, which counteracts the cone's response to light or dark. Whenever cones are hyperpolarized by light, horizontal cells are also hyperpolarized, stopping the release of their inhibitory transmitter, which after a slight synaptic delay depolarizes groups of neighboring cones, that is, opposes their response to light. This antagonism also occurs when cones are depolarized by darkness. Such negative feedback increases spatial and temporal resolution. With two cone types, as needed for color vision, this feedback can also narrow the spectral response of cones.

Color Vision

In a world seen by cones, all with the same opsin, objects appear brighter or darker but colorless, as in a black and white photograph (Figure 1). Whether an object is bright or dark depends on a comparison between the light energy it reflects and that reflected by its background. The lighter the background, the darker an object appears. The darker the background, the brighter an object appears. Absolute energy is discarded for relative energy, which is all that is needed for survival.

Inhabiting a world with only energy contrasts is a handicap because most objects differ in spectral reflectance, which is often a stronger clue to their presence than is their energy reflectance. Energy contrasts are also more misleading because of shadowing. Therefore, early in the evolution of vision, a mechanism to detect spectral as well as energy contrast must have evolved to create color vision. For this, at least two different cone types are needed, one absorbing best at one part and the other absorbing best at another part of the visible solar spectrum (Figure 3). This allows the brain to compare the responses of two cone systems to assess spectral contrast and create color vision.

Figure 3 Normalized absorption spectra of the short (S-cone) and long (L-cone) wavelength-sensitive opsins that provide a divariant color vision system to many mammals and 2% of human males. When plotted against the fourth root of wavelength, opsin absorption curves have similar shapes. The horizontal lines under the absorption spectra indicate how the solar (white) spectrum is split into blue and yellow regions.

The primordial cones must have started with an opsin sensitive to longer wavelengths in the spectrum, an 'L-cone' opsin. Here, chromatic aberration is less than at short wavelengths, and sufficient quantal energy exists to activate opsins. Subsequently, a second cone system must have evolved with a short wavelength-sensitive ('S-cone') opsin (Figure 3). Short wavelengths are poorly transmitted by the ocular media and also exhibit considerable chromatic aberration. For this reason, the human S-cone system has been relegated to detecting only spectral and not energy contrast. Energy contrast provides a higher spatial resolution than does spectral contrast and therefore is more disturbed by chromatic aberration. Some small animals with tiny eyes and relatively large lenses, which provide greater depth of focus that reduces chromatic aberration and allows more ultraviolet light to reach the retina, have ultraviolet rather than blue-sensitive opsins expanding their range of vision. This has allowed many highly diurnal organisms, birds, fish, and reptiles, to expand the range and richness of their color vision.

Adding an S-cone system to the mammalian retina led to the evolution of unique S-cone-responsive ganglion cells (Figure 4).

On-bipolars from S-cones excite one dendritic arbor of this ganglion cell, and off-bipolars from L-cones excite a more superficial arbor of dendrites from the same ganglion cell. The inner plexiform layer of the retina is layered into off- and on-bipolar laminas, undoubtedly to prevent off-bipolars from exciting on-ganglion cells and on-bipolars from exciting off-ganglion cells, and this is reflected in the dendritic inputs to this ganglion cell.

Figure 4 A circuit that transmits signals of S-cones from the retina to the brain. Each of such retinal ganglion cells receives excitatory inputs from S-cone-specific on-bipolars and L-cone-specific off-bipolars. L, long; S, short.

Such S-cone-activated ganglion cells are optimized to detect the appearance of short wavelengths as long wavelengths leave their receptive field. The L-cones excite the cell as long wavelengths leave the receptive field and as short wavelengths (blue light) enter the receptive field. This is an example of 'successive color contrast.' It illustrates a principle in the processing of neural signals for spectral contrast. The signals from the two different cone mechanisms are either antagonistic or out of phase with each other. The S-cones produce on-responses and the L-cones produce off-responses. This facilitates the response to maximum spectral contrast, that is, when short wavelengths enter as long wavelengths leave the receptive field of the cell.

The evolution of an S-cone system also added a new horizontal cell type to the retina. This so-called H2 horizontal cell allows L-cones to antagonize S-cones but may not allow S-cones to antagonize L-cones, although this latter point is controversial. H1 horizontal cells mediate antagonistic interactions among L-cones, being both pre- and postsynaptic to all L-cones they contact. H2 cells are presynaptic to both L- and S-cones but are likely only postsynaptic to S-cones and therefore do not antagonize L-cones. This arrangement appears likely because many ganglion cells in primate retina receive inputs from L-but not S-cones. If S-cones were presynaptic to L-cones, S-cone signals would be detected in all L-cone-responsive cells, which is not the case.

Color vision with these two cone systems splits the 'white' solar spectrum in half, with one cone mechanism more sensitive to one end and the other more sensitive to the opposite end of the visible spectrum. This arrangement allows the brain to determine whether an object reflects more or less light from these two different parts of the spectrum, a key to determining its color.

Energy versus Spectral Contrast

Energy contrast is determined by comparing the outputs of neighboring cones, but this cannot work for spectral contrast. To detect spectral contrast, the brain must compare the output of groups of cones containing both cone types in the same area of visual space. Spectral contrast requires a comparison different from that required for energy contrast. Small spots or narrow slits provide insufficient clues for determining spectral contrast because they do not cover a sufficient population of cones, but they are sufficient for detecting energy contrast. That is why the spatial resolution of chromatic vision is much less than that of achromatic vision (Figure 5).

Figure 5 shows two output cells, both of which can be retinal ganglion cells. The circuitry of the cell hypothetically coding for blue is well established, as illustrated in Figure 4. There is, however, another way to interpret the blue cell in Figure 5. It may be transmitting a signal for the presence of short-wave light, which could be used at a higher level to code for both blue and white. This hypothesis envisions color-specific cells to be formed in cerebral cortex. The existence of 'yellow on–blue off' cells is moot at present because such cells are rare in the retina.

This touches on an important point in the formulation of human color vision. The German physiologist Ewald Hering proposed that when blue and yellow colors are mixed, the color perceived does not appear as a mixture of yellow and blue but as a color that appears white or gray without any trace of blue or yellow. This concept led to the idea of 'opponent' colors. Certain color pairs such as blue and yellow or red and green (see below) are antagonistic to each other. Certainly at the level of retina one finds that cells excited by S-cones are being inhibited by L-cones, mediated by horizontal cells and probably amacrine cell antagonism. But there is a difference between such cone antagonism and color antagonism. The antagonistic interactions between different cone mechanisms narrow the relatively broad action spectrum of cone opsins, very much as oil drops do in the cones of certain diurnal birds, reptiles, and fishes. Antagonism

Figure 5 A mosaic of S- and L-cones needed for divariant color vision. S-cones are less common than L-cones because only the latter are involved in energy contrast while both cone types are involved in spectral contrast. To compare the responses of L-with those of S-cones, necessary for color vision, a relatively large group of cones must be sampled. For energy contrasts, single L-cones can be compared with their neighboring L-cones. L, long; S, short.

between colors, however, may occur only after the neural processing of cone signals is sufficient to create color-selective neurons, which seems to occur first in visual cortex.

But regardless of where in the brain the cells uniquely selective for color are located, the logic by which S- and L-cone signals can be used to code for color can be understood, as shown in Figure 6. Here both energy and spectral factors are considered to illustrate what arrangements must be used to code for colors in a divariant color vision system. The lightness or darkness of objects is determined by the achromatic L-cone system. The chromatic quality is determined by the activity of both cone types. If the S-cone system is absorbing light strongly, that is, its on-system is active, the colors perceived will be white, gray, or blue. Whether it is white or gray will depend on how strongly the L-cone-on system is active to detect an object that is being compared to its background. If the L-cone-on system is inactive, the L-cone-off system will be active, and the color perceived will be blue and not too bright. If the S-cone system is not absorbing light, the S-cone-off system is active, and the colors perceived will be yellow or brown. If the L-cone-off system is also active, the color will be black and dark.

Figure 6 Divariant Color Vision.

Trivariant Color Vision

A major change occurred in primate vision when the gene for the long wavelength-sensitive opsin on the X chromosome reduplicated into two tandem genes with slightly altered sequences, probably in parallel with the evolution of a fovea in primates. This created two different longer wavelength opsins, each expressed in separate cones by gene programming. This split the long wavelength or yellow region of the spectrum into a red and green region (Figure 7).

These are called middle (M) and long (L) wavelength-sensitive opsins, the former absorbing more in the middle and the latter more in the long wavelength part of the spectrum. Because they straddle the yellow region of the divariant spectrum, they are closer together spectrally than the S- and L-cones of the primordial system. This may be why there is a separate H1 horizontal system interacting exclusively with L- and M-cones to physiologically narrow the action spectrum of these cones.

The Midget System's Double-Duty Role

This second system for obtaining chromatic contrast differs from the earlier divariant system because the retinal ganglion cells involved in this new system

Figure 7 Splitting the long wavelength sensitive cone opsin into two slightly different opsins enables a new comparison of spectral reflectance operating over the longer wavelength part of the spectrum to occur. The L strong bar on the left is due to the greater absorption of the L-cone compared to M-come opsin in this short wave region of the spectrum, the so-called beta band.

transmit 'both' chromatic and achromatic contrast information. The new system is intimately involved with the midget cells of the fovea, which mediate high-resolution vision (Figure 2). Each L- and M-cone-mediating midget ganglion cell has a 'double-duty' role transmitting both high-resolution achromatic and low-resolution chromatic contrast. Models (Figure 8) exist that can explain how visual cortex separates these two forms of contrast by specific and parallel circuits.

For achromatic contrast, the small receptive field centers of single L- or M-cones detect local 'lightness' or 'darkness' by comparing the outputs of neighboring on- and off-center cells respectively, achieving the spatial resolution of single foveal cones. For chromatic contrast, on the other hand, a larger number of single cone signals are pooled in a highly selective way. L-cone-on and M-cone-off signals excite the same cell, and M-cone-on and L-cone-off signals excite another cell. These two cells sensing the same region of chromatic space could also inhibit one another to increase their selectivity for color. To minimize the center-surround antagonism present in each midget cell input, many adjacent cells are pooled, which increases the ratio of center to surround to make their receptive fields more coextensive and therefore more ideal for spectral contrast detection.

Figure 8 Trivariant system for chromatic and achromatic vision. Both chromatic and achromatic contrast detection can be derived from the same population of midget cells. For achromatic contrast, single long (L) and middle (M) on-cells excite a cortical cell and off-cells excite another cortical cell in linear arrays producing orientation-selective cells for light or dark with high spatial resolution. For chromatic contrast, L on-cells and M off-cells or L off-cells and M on-cells excite the same cortical cell in a coextensive, nonoriented manner to develop spectrally selective cells. A cell responsive to red may inhibit one responsive to green in the same area of chromatic space. Such cells reflect single color opponency.

The color gamut discriminable by a trivariant system is increased by the addition of a second comparison of L- and M-cones which occurs in parallel with the earlier divariant system. These two systems are generally described as red/green and blue/yellow opponent systems. Now the latter system compares the mixed signal of L- and M-cones with that of the S-cones (Figure 9).

The Retinex Theory

An interesting problem arises when the responses of two different cone systems sensing an area of visual space are compared in order to determine color. If the illuminant contains more energy from one end of the spectrum than from the other, as occurs with tungsten versus sunlight, colors will change in the direction of the illuminant. Human vision is only minimally affected by such a change, a phenomenon called 'color constancy.' Edwin Land examined this phenomenon over many years and suggested a mechanism that could be responsible for color constancy.

Land's 'retinex' (retina + cortex) model involves a mechanism that normalizes the responses of each cone mechanism before they are compared to determine color. This model can accurately predict the appearance of colors. Therefore, it is reasonable to expect that such a normalizing occurs at a point in the nervous system before the comparisons of cone mechanisms are made to determine color.

Double Opponent Cells

An insight into how normalizing could occur physiologically has come from the detection of so-called double opponent neurons in the visual cortex of

Figure 9 Trivariant color vision. Figure shows the variety of colors that can be discriminated by a trivariant color vision system combining chromatic and achromatic contrasts and their relationship to the three cone responses.

monkeys. Double opponent cells are organized to maximize spectral contrast by constructing concentrically organized cells which have one type of color-sensing cell exciting it in the center and the opposite color-sensing cell exciting and the same type of color-sensing cell inhibiting it in its surround (Figure 10). This arrangement illustrates the extraordinary selectivity of neural circuitry.

Double opponency will facilitate 'color constancy,' as Land's model requires, because it produces widespread antagonism of responses affecting each cone mechanism separately. This will tend to normalize the response of each cone mechanism before it is compared with another cone mechanism for color perception. Double opponency also provides an explanation of 'simultaneous color contrast,' in which colors are enhanced by surrounding them by an opposite, 'opponent,' color. A red color, for example, will appear 'redder' when surrounded by green.

It is important to realize that the creation of color-selective cells from the input of midget ganglion and geniculate cells must occur in visual cortex because such red and green color-selective cells, illustrated in Figures 8 and 10, have coextensive receptive fields, a phenomenon not seen in precortical midget cell responses. This supports the hypothesis that color-selective cells are formed ultimately in visual cortex.

Figure 10 Double opponency; pure spectral contrast detection. A single opponent cell that is excited by L-cone-on and M-cone-off inputs can be transformed into a double opponent cell that is specific for red/green spatial contrast, pure spectral contrast. All the neighboring color-selective cells affect the central cell in the following ways. The neighboring 'red-selective' single opponent cells serving adjacent areas of space inhibit the central cell; all the neighboring 'green-selective' cells excite the central cell. Similar interactions among this population of cells will transform all such single opponent cells into double opponent cells. Similar double opponent cells can be formed for green, blue, or yellow selective cells. L, long; M, medium.

The Organization of Color Vision in Visual Cortex

Information on this topic is still rudimentary, but some important concepts are apparent (Figure 11). There is anatomical segregation of the inputs from the parvo and magno systems of the lateral geniculate nucleus. Only the parvo system is involved in high spatial resolution vision and color vision, the subject of this chapter. The magno system uses a different and parallel system of retinal ganglion cells that receive synergistic inputs from L- and M-cones and is thought to be involved in the detection of motion. The parvo system has often been referred to as the 'what is it' system and the magno to the 'where is it' system.

There is evidence that the signals of the parvo system used for chromatic contrast targets a different part of visual cortex than those for high spatial resolution achromatic vision. The former targets cytochrome oxidase rich 'blobs' whereas the latter targets larger 'interblob' regions of the cortex. Double opponent cells have been found in blobs. Blobs take less space than those devoted to achromatic processing, probably reflecting the higher spatial resolution of the latter. The parvo system targets the lower part of layer 4C and from there projects to layers 2 and 3 in striate cortex (V1). The parvo system projects from V1 to V2, V3, and V4, where separation from the magno system becomes more complete. The magno system targets upper layer 4C, where cells project to layer 4B

Figure 11 Synaptic targets of the different functional types of cells projecting to striate cortex from the lateral geniculate nucleus. There is a separation of parvo from magno cells, and within the former system, there is segregation of chromatic contrast-detecting cells into chromatic areas (blobs) and achromatic areas (interblobs). The S-cone system targets only the chromatic areas. S, short; V, visual cortex.

Figure 12 Turtle cones filtered by oil droplets. Panels on the left show the microscopic appearance of avian oil droplets: red, yellow, pale green, and transparent (Teruya Ohtsuka). On the right (above) are the absorption spectra of the four varieties of cones involved in the color vision of the bird Budgerigar (*Melopsittacus undulatus*); the graph below illustrates how oil droplets narrow these spectra (Timothy H. Goldsmith).

and from there to a higher area of visual cortex, V5, after passing through V2.

Color and Form Vision

A key point in understanding color vision is to determine how clues from chromatic contrast are used together with those from achromatic contrast to detect and distinguish objects. In this, both contours and surface textures must be important. The texture of objects is perhaps more determined by chromatic clues and associated with their colors. The achromatic clues provide higher spatial resolution, and the chromatic clues may provide greater reliability. Some mechanism must sort through these clues from contrast to assemble the most 'logical' representation of an object. Some of this logic must be influenced by the memory of known objects, and here the interactions of higher visual areas may be important.

Is There a Separate Color Area in Visual Cortex?

This question is closely associated with the discovery that visual cortex is subdivided into multiple areas where there is a separate re-representation of visual space. Evidence has been presented that area V4 contains cells processing only colors, but this hypothesis has not received strong support. The strongest support for such a hypothesis comes from extremely rare cases of people who lose color vision because of a disease in adult life but retain high spatial resolution vision. Such clinical material is often difficult to interpret. There are no examples of a genetic abnormality that dissociates these two processes from birth. Further studies will ultimately clarify this controversial topic. Color represents a combination of clues from both chromatic and achromatic contrast detectors. This computation must be tagged to objects which are detected by clues from these same detectors. It would seem reasonable that all visual areas processing form cannot easily separate, in time or space, chromatic from achromatic contrast detectors.

Tetravariant Color Vision

Primates with trivariant color vision and all other mammals with divariant color vision are deprived of the full universe of colors that is available to diurnal birds, fish, reptiles, and lizards that have tetravariant color vision, having added an ultraviolet-sensitive cone mechanism to increase their ability to detect chromatic contrast and colors. Figure 12 shows that birds do at both ends of the solar spectrum what primates do only at the yellow end. They have evolved an ultraviolet-sensitive cone which expands spectral contrasts at the short wavelength end of the spectrum. Such diurnal animals also use a unique method to narrow the action spectrum of each cone mechanism by having a carotenoid-containing oil droplet within the light path of each cone (Figure 12, left). Red, yellow, pale green, and transparent oil droplets are present in their L-, M-, S-, and ultraviolet-sensitive cones, respectively. This strategy narrows the action spectrum of these cones, as shown in Figure 12 (below, right), and this increases their chromatic contrast detection. The oil droplets also reduce the cones' sensitivity to light, but these organisms are active only in the presence of abundant sunlight, making sensitivity to light trivial.

Higher primates have not used either of these strategies to expand their color vision, probably because their eyes are so large that much less ultraviolet light

reaches their photoreceptors and oil droplets decrease the ability of mammals to operate at dim light levels.

Coma

S Laureys, M Boly, G Moonen, and P Maquet, University of Liège, Liège, Belgium

Two Dimensions of Consciousness: Arousal and Awareness

Consciousness is a multifaceted concept that has two dimensions: arousal, or wakefulness (i.e., level of consciousness), and awareness (i.e., content of consciousness). One needs to be awake in order to be aware (rapid eye movement (REM) sleep and lucid dreaming being notorious exceptions). Figure 1 shows that in normal physiological states (green), level and content are positively correlated (with the exception of the oneiric activity during REM sleep). Patients in pathological or pharmacological coma (i.e., general anesthesia) are unconscious because they cannot be awakened (pink). The vegetative state (VS; blue) is a unique dissociated state of consciousness (i.e., patients are seemingly awake but lack any behavioral evidence of 'voluntary' or 'willed' behavior). There is, of course, an irreducible philosophical limitation in knowing for certain whether any other being possesses a conscious life. Awareness is a subjective first-person experience, and its clinical evaluation is limited to evaluating patients' motor responsiveness. In addition to its clinical and ethical importance, studying these disorders offers a still largely underestimated means of studying human consciousness. In contrast to unconscious states such as general anesthesia and deep sleep (in which impairment in arousal cannot be disentangled from impairment in awareness), VS is characterized by a unique dissociation of arousal and awareness, offering a lesional approach to identifying the neural correlates of awareness. A major challenge is to unequivocally disentangle patients residing in the clinical 'gray zone' between the vegetative and the minimally conscious state (MCS). The locked-in syndrome (LIS) is a rare but horrifying situation in which patients awaken from their coma fully aware but remain mute and immobile; it is called a 'pseudodisorder of consciousness' because patients superficially look unconscious but in reality are fully aware only unable to show it due to severe paralysis.

Arousal is supported by several brain stem neuronal populations (i.e., the reticular activating system) that directly or via nonspecific thalamic nuclei project to cortical neurons. Hence, focal damage of the brain stem or diffuse damage of the cerebral hemispheres may cause reduced arousal. The evaluation of eye-opening and brain stem reflexes is a key to the clinical assessment of the functional integrity of the arousal systems. Awareness depends on the functional integrity of the cerebral cortex and its reciprocal subcortical connections (each of its aspects partly residing in spatially defined brain areas), but its underlying neural code remains to be elucidated. Therefore there is, at present, no validated objective 'consciousness meter.' The estimation of the multiple dimensions of consciousness requires the interpretation of several clinical signs, mainly based on the observation of 'voluntary' interaction with the examiner or the environment. Brain death, coma, VS, MCS, and LIS (see Figure 2) are all solely defined by clinical criteria. Many scoring systems have been developed for a standardized assessment of consciousness in severely brain-damaged patients.

Nosology of Disorders of Consciousness

Brain Death

Brain death means human death determined by neurological criteria. The current definition of death is the permanent cessation of the critical functions of the organism as a whole (i.e., neuroendocrine and homeostatic regulation, circulation, respiration, and consciousness). Most countries, including the US, require death of the whole brain including the brain stem, but some (e.g., UK and India) rely on the death of the brain stem only, arguing that the brain stem is at once the through-station for nearly all hemispheric input and output, the center generating arousal (an essential condition for conscious awareness), and the center of respiration. Clinical assessments for brain death, however, are uniform and are based on the loss of all brain stem reflexes and the demonstration of continuing cessation of respiration (by performing a standardized apnea test) in a persistently comatose patient (Table 1). There should be an evident cause of coma, and confounding factors such as hypothermia, drugs, and electrolyte and endocrine disturbances should be ruled out.

Brain death is classically caused by a massive brain lesion (e.g., trauma, intracranial hemorrhage, anoxia) which increases intracranial pressure to values superior to mean arterial blood pressure and hence causes intracranial circulation to cease and damages the brain stem due to herniation. Using the brain stem formulation of death, however, unusual but existing cases of catastrophic brain stem lesion (often of hemorrhagic origin) sparing the thalami and cerebral cortex can be declared brain death in the absence of clinical brain stem function, despite intact intracranial circulation. Hence a patient with a primary brain

stem lesion (who did not develop raised intracranial pressure) might theoretically be declared dead by the UK doctrine but not by the US doctrine.

Coma

Coma is a state of unarousable unresponsiveness characterized by the deficiency of the arousal systems (clinically assessed as the absence of stimulation-induced eye opening after having ruled out bilateral ptosis) and thus also by absence of awareness. The comatose patient lacks the sleep–wake cycles that can be observed in the VS. To be clearly distinguished from syncope, concussion, or other states of transient unconsciousness, coma must persist for at least 1 h. In general, comatose patients who survive begin to awaken and recover gradually within 2–4 weeks. This recovery may go no further than VS or MCS, or these may be stages (brief or prolonged) on the way to more complete recovery of consciousness. There are two main causes of coma: (1) bihemispheric

diffuse cortical or white matter damage secondary to neuronal or axonal injury and (2) brain stem lesions bilaterally affecting the subcortical reticular arousing systems (i.e., pontomesencephalic tegmentum and/or paramedian thalami).

VS

VS was defined in 1972 by Bryan Jennett and Fred Plum to describe those patients who 'awaken' from their coma (meaning they open their eyes spontaneously or on stimulation) but remain unaware of self or environment (meaning they show only reflex motor responses; Table 2). According to the *Oxford English Dictionary*, the term 'vegetative' describes "an organic body capable of growth and development but devoid of sensation and thought." It is very important to stress the difference between persistent and permanent VS, which are, unfortunately, too often abbreviated identically as PVS, causing unnecessary confusion. 'Persistent VS' has been arbitrarily defined as a VS still present 1 month after the acute brain damage, but the term does not imply irreversibility. In 1994, the US Multi-Society Task Force on PVS concluded that 3 months following nontraumatic brain damage and 12 months after traumatic injury, the condition of VS patients may be regarded as 'permanent.' Only in cases of 'permanent VS' do the ethical and legal issues surrounding withdrawal of treatment arise. It is essential that experienced examiners employing adapted standardized clinical assessment scales repeatedly establish the behavioral absence of any sign of conscious perception or deliberate action before making the diagnosis of VS.

MCS

In 2002, the Aspen Neurobehavioral Conference Workgroup published the diagnostic criteria for MCS to subcategorize patients above VS but unable to functionally communicate their thoughts and feelings. On a reproducible or sustained basis, MCS patients show limited but clearly discernible evidence of awareness of self or environment (Table 3). The emergence of MCS is characterized by the recovery of interactive communication or functional use of objects. Further improvement is more likely than in VS patients. However, some patients may remain permanently in MCS. At present, no time intervals for 'permanent MCS' have been agreed on.

'Akinetic mutism' (a condition characterized by severe poverty of movement, speech, and thought without associated arousal disorder or descending

Table 1 Criteria for brain death (American Academy of Neurology guidelines)

- Demonstration of coma
- Evidence for the cause of coma
- Absence of confounding factors, including hypothermia, drugs, electrolyte, and endorcrine disturbances
- Absence of brain stem reflexes
- Absent motor responses
- Apnea
- A repeat evaluation in 6 h is advised, but the amount of time is considered arbitrary
- Confirmatory laboratory tests are required only when specific components of the clinical testing cannot be reliably evaluated

Table 2 Criteria for the vegetative state (US Multi-Society Task Force on Persistent Vegetative State guidelines)

- No evidence of awareness of self or environment and an inability to interact with others
- No evidence of sustained, reproducible, purposeful, or voluntary behavioral responses to visual, auditory, tactile, or noxious stimuli
- No evidence of language comprehension or expression
- Intermittent wakefulness manifested by the presence of sleep–wake cycles
- Sufficiently preserved hypothalamic and brain stem autonomic functions to permit survival with medical and nursing care
- Bowel and bladder incontinence
- Variably preserved cranial nerve and spinal reflexes

Table 3 Criteria for the minimally conscious state (Aspen Neurobehavioral Conference Workgroup)

Clearly discernible evidence of awareness of self or environment, on a reproducible or sustained basis, by at least one of the following behaviors:

- Purposeful behavior (including movements or affective behavior that occurs in contingent relation to relevant environment stimuli and are not due to reflexive activity), such as:
  - Pursuit eye movement or sustained fixation occurring in direct response to moving or salient stimuli
  - Smiling or crying in response to verbal or visual emotional (but not neutral) stimuli
  - Reaching for objects demonstrating a relationship between object location and direction of reach
  - Touching or holding objects in a manner that accommodates the size and shape of the object
  - Vocalizations or gestures occurring in direct response to the linguistic content of questions
- Following simple commands
- Gestural or verbal yes/no response (regardless of accuracy)
- Intelligible verbalization

Emergence from the minimally conscious state requires reliable and consistent demonstration of at least one of the following behaviors:

- Functional interactive communication: accurate yes/no responses to six of six basic situational orientation questions (including items as, "Are you sitting down?" and "Am I pointing to the ceiling?") on two consecutive evaluations
- Functional use of two different objects (such as bringing a comb to the head or a pencil to a sheet of paper) on two consecutive evaluations

motor tract impairment) is an outdated term that should be avoided and is now considered to be a subcategory of the minimally conscious syndrome.

LIS

The category of LIS (pseudocoma) was introduced by Fred Plum and Jerome Posner in 1966 to refer to the constellation of quadriplegia and anarthria brought about by the disruption of, respectively, the brain stem's corticospinal and corticobulbar pathways. The syndrome describes patients who are aroused and awake but selectively deefferented (i.e., have no means of producing speech or limb or face movements). Usually the anatomy of the responsible lesion in the brain stem is such that locked-in patients are left with the capacity to use vertical eye movements and blinking to communicate their awareness of internal and external stimuli. Acute vascular bilateral ventral pontine lesions are its most common cause. Patients with such lesions often remain comatose for some days or weeks, needing artificial respiration, and then gradually wake up, remaining paralyzed and voiceless, superficially resembling someone in a coma or a VS. Table 4 lists the clinical criteria of LIS. The syndrome is subdivided, on the basis of the extent of motor impairment, into (1) classical LIS (characterized by total immobility except for vertical eye movements or blinking); (2) incomplete LIS (permitting remnants of voluntary motion); and (3) total LIS (consisting of complete immobility including all eye movements, combined with preserved consciousness).

Clinimetric Evaluation, Diagnosis, and Prognosis

Consciousness Scales

In 1974, Graham Teasdale and Bryan Jennett published the Glasgow Coma Scale (GCS). This standardized bedside tool to quantify arousal and awareness now is the gold standard in coma research. The GCS has tree components assessing eye opening and verbal and motor responses. Some authors have disagreed that evaluation of spontaneous or stimulation-induced opening of the eyes is sufficiently indicative of brain stem arousal system activity and have proposed coma scales that include brain stem reflexes. However, only the GCS has known a widespread use because the others generally are more complex. A simpler system, the Glasgow-Liège Scale (GLS), combines the GCS with five brain stem reflexes (i.e., fronto-orbicular, oculocephalic, pupillary, and oculocardiac reflexes). The increasing use of intubation and mechanical ventilation has rendered the verbal component of the GCS unassessable in many coma patients. Recently, the Full Outline of Un-Responsiveness (FOUR; also the number of components tested: eye, motor, brain stem reflexes, and respiratory function) scale proposed a hand-position test (i.e., asking the patient to make a fist or a 'thumbs-up', or 'V-for-victory' sign) as an alternative to the verbal component of the GCS.

The GCS, GLS, and FOUR scales lack reliability in assessing chronic disorders of consciousness. For these patients, more-sensitive scales are the Coma Recovery Scale-Revised (CRS-R), the Sensory Modality Assessment and Rehabilitation Technique (SMART), and the Wessex Head Injury Matrix (WHIM). The CRS-R is a recent scale specifically developed to differentiate VS from MCS and explicitly incorporating current diagnostic criteria. The basic structure of the CRS-R is similar to the GCS, but its subscales are much more detailed, targeting more-subtle signs of recovery of awareness.

Table 4 Criteria for the locked-in syndrome (American Congress of Rehabilitation Medicine)

- Sustained eye opening (bilateral ptosis should be ruled out as a complicating factor)
- Quadriplegia or quadriparesis
- Aphonia or hypophonia
- A primary mode of communication that uses vertical or lateral eye movement or blinking of the upper eyelid to signal yes/no responses
- Preserved awareness of the environment

Brain Death

Because many of the areas of the supratentorial brain (including the neocortex, thalami, and basal ganglia) cannot be tested for clinical functions accurately in a comatose patient, most of the bedside tests for brain death (such as cranial nerve reflexes and apnea testing) directly measure functions of only the brain stem. Since the first clinical definition of brain death nearly 50 years ago, no patient in apneic coma properly declared dead on the basis of neurological criteria has ever regained consciousness. Complementary neurophysiological tests such as electroencephalography (EEG), event-related potentials (ERPs), angiography, Doppler sonography, and scintigraphy reliably and objectively confirm the clinical diagnosis.

Coma

The management and prognosis of coma depend on many factors, such as etiology, the patient's general medical condition, age, clinical signs, and complementary examinations. After 3 days of observation,

absence of pupillary or corneal reflexes, stereotyped or absent motor response to noxious stimulation, isoelectrical or burst suppression pattern EEG, bilateral absent cortical responses on somatosensory evoked potentials, and (for anoxic coma) biochemical markers such as high levels of serum neuron-specific enolase are known to herald bad outcome. Visual and brain stem auditory evoked potentials are of limited prognostic use. Prognosis in traumatic coma survivors is better than in anoxic cases. Predicting outcome in toxic, metabolic, and infectious comatose states is challenging, and many unexpected cases of recovery have been reported.

VS

Whereas coma and brain death characteristically are acute conditions (lasting no more than days to weeks), the VS and MCS may become chronic entities. Vegetative patients, unlike brain dead or comatose patients, can move extensively, and studies have shown how difficult it is to differentiate 'automatic' from 'willed' movements in these patients. This results in an underestimation of behavioral signs of awareness and hence a misdiagnosis. It is known that when the diagnosis is made with insufficient care, up to one in three 'vegetative' patients actually are at least minimally conscious. Physicians also frequently tend to erroneously diagnose VS in older demented nursing home residents. Clinical testing for absence of awareness is much more problematic and slippery than testing for absence of arousal, brain stem reflexes, and apnea in irreversible coma. Given appropriate medical treatment, meaning artificial nutrition and hydration, VS patients may survive for many years.

Over the past decade, investigators have struggled to find an objective test that could reliably predict outcome for vegetative individuals. In contrast to coma and brain death, there are no validated diagnostic or prognostic markers for VS patients. The chances of recovery depend on the patient's age, etiology (worse for anoxic causes), and time spent in the VS. Recent data suggest that damage to the corpus callosum and brain stem indicate bad outcome in traumatic VS.

MCS

Because criteria for MCS have only recently been introduced, there are few clinical studies of patients in this condition. As stated above, it remains very challenging to behaviorally differentiate minimally conscious from vegetative patients because both are, by definition, noncommunicative. VS is one end of a spectrum of awareness, and the subtle differential diagnosis with MCS necessitates repeated evaluations by experienced examiners. As with VS, traumatic etiology has a better prognosis than does nontraumatic (anoxic) MCS. Preliminary data show that overall outcome for MCS is better than for VS.

LIS

In acute LIS, eye-coded communication may be difficult because of fluctuating arousal and limited control of voluntary eye movements. More than half the time, it is family members, not the physician, who first realize that the patient is aware. Distressingly, the diagnosis takes on average more than 2.5 months. In some cases it has taken 4–6 years before aware and sensitive patients, locked in an immobile body, have been recognized as being conscious. Some memoirs written by locked-in patients well illustrate the clinical challenge of recognizing the syndrome. Striking examples are *Look Up for Yes*, by Julia Tavalaro, and *Only the Eyes Say Yes*, by Phillippe Vigand.

While motor recovery remains very limited in LIS, life expectancy (with adequate medical care) may be several decades. Sensory evoked potentials are not reliable predictors of prognosis, but motor evoked potentials might evaluate the potential motor recovery. Eye-controlled computer-based communication technology now allows patients to control their environment, use a word processor coupled to a speech synthesizer, and access the Internet. Outsiders often assume that the quality of life with LIS is so poor that it is not worth living. Recent surveys, however, have revealed that chronic LIS patients self-report meaningful quality of life and that the demand for euthanasia is infrequent.

Residual Cerebral Function

Brain Death

The EEG in brain death shows absent electrocortical activity (i.e., isoelectric recording) with a sensitivity and specificity of around 90%. This makes the EEG the most validated and, because of its wide availability, preferred confirmatory test for brain death. Somatosensory evoked potentials typically indicate arrest of conduction at the cervicomedullary level, and brain stem auditory evoked potentials usually show only a delayed wave I (originating in the cochlear nerve). Cerebral angiography and transcranial Doppler sonography document with very high sensitivity and 100% specificity the absence of cerebral blood flow in brain death. Similarly, radionuclide cerebral imaging such as single-photon emission computed tomography (CT) and positron-emission tomography (PET) demonstrate the hollow-skull sign confirming

Figure 3 Cerebral metabolism in conscious wakefulness, in brain death (hollow skull sign confirming the absence of neuronal function in the whole brain in irreversible coma), physiological (slow wave sleep) and pharmacological (general anesthesia) modulation of arousal reflecting massive global decreases in cortical metabolism (in REM sleep, metabolic activity is paradoxically prominent); and in wakefulness without awareness (i.e., the vegetative state). Note that recovery from the vegetative state may occur without substantial increase in overall cortical metabolism, emphasizing that some areas in the brain are more important than others for the emergence of awareness. Images of halothane-induced loss of consciousness from Alkire M, Pomfrett CJ, Haier RJ, et al. (1999) Functional brain imaging during anesthesia in humans: Effects of halothane on global and regional cerebral glucose metabolism. *Anesthesiology* 90: 701–709.

the absence of neuronal function in the whole brain (Figure 3).

Anatomopathology in brain death patients receiving maximal artificial means of support will inevitably end up showing the so-called respirator brain, and after about a week, an autolyzed liquefied brain will pour from the opened skull.

Coma

The electrical activity of the brain as measured by the EEG tends to become nonreactive and slower as the depth of coma increases, regardless of the underlying cause. As stated above, the bilateral absence of cortical potentials (called N20 waves because they occur after about 20 ms) on somatosensory evoked potentials herald bad outcome. In cases in which cortical potentials are present, so-called endogenous ERPs might be useful. The presence of 'mismatch negativity,' that is, a negative component elicited after 100–200 ms by any change or 'mismatch' in a sequence of monotonous auditory stimuli (i.e., an 'oddball paradigm') indexes some persistent automatic information processing and is correlated with recovery of at least minimal consciousness.

Cortical metabolism in coma survivors is on average 50–70% of normal reference values. Cerebral metabolism correlates poorly with the level of consciousness, as measured by the GCS, in severely head-injured patients. A global depression of cerebral metabolism is not unique to coma. When anesthetic drugs are titrated to the point of unresponsiveness, the resulting reduction in brain metabolism is similar to that observed in pathological coma. Another example of transient metabolic depression can be observed during slow wave sleep. In this daily physiological condition, cortical cerebral metabolism can drop to nearly 40% of normal values, although in REM sleep, metabolism returns to normal waking values (Figure 3).

VS

In VS the EEG most often shows a diffuse slowing (i.e., generalized polymorphic delta or theta rhythm); only sporadically is it of very low voltage or isoelectric. Somatosensory evoked potentials may show preserved primary somatosensory cortical potentials, and brain stem auditory evoked potentials often show preserved brain stem potentials in vegetative patients. Endogenous evoked potentials measuring, for example, the brain's response to complex auditory stimuli such as the patient's own name (compared with other names) record a so-called P300 response (i.e., a positive wave elicited around 300 ms poststimulus when patients detect an unpredictable target in the regular train of stimuli). In brain-damaged patients, the use of emotionally meaningful stimuli such as the patient's own name increases the chances of obtaining

a P300 response. Recent data show that the P300 is not a reliable marker of awareness but rather indicates automatic processing, because it could be recorded in well-documented VS patients who never recovered (Figure 4).

In contrast to the functional decapitation observed in irreversible coma or brain death, vegetative patients show substantially reduced (40–50% of normal values) but not absent overall cortical metabolism. In some vegetative patients who subsequently recovered, global metabolic rates for glucose metabolism did not show substantial changes (Figure 3). Hence, the relationship between global levels of brain function and the presence or absence of awareness is not absolute. It rather seems that some areas in the brain are more important than others for its emergence.

Anatomopathologic features in anoxic VS encompass multifocal laminar cortical necrosis, diffuse leucoencephalopathy, and bilateral thalamic necrosis; VS following blunt head injury classically shows diffuse white matter damage with neuronal loss in thalami and hippocampi. However, these postmortem studies have not permitted a detailed regional topography of cerebral damage characteristic of VS. Voxel-based statistical analyses of metabolic PET data have identified a metabolic dysfunction in a wide frontoparietal network encompassing the polymodal associative cortices: bilateral lateral frontal regions; parietotemporal and posterior parietal areas; and mesiofrontal, posterior cingulate, and precuneal cortices (Figure 5), known to be the most active 'by default' in resting nonstimulated conditions.

In some other conditions, patients also show merely reflex or automatic motor activity while behaviorally seeming 'awake.' In absence seizures (characterized by brief episodes of unresponsiveness and staring, frequently accompanied by purposeless eye blinking and smacking), functional magnetic resonance imaging (MRI) studies have shown decreases in blood oxygen level-dependent signals in a wide

Figure 4 Endogenous event-related potentials to the patient's own name (thick traces) and to other first names (thin traces) in five healthy controls, four patients with locked-in syndrome, six minimally conscious state patients, and five vegetative state patients. Note that the differential P300 response (in pink) can also be observed in some well-documented VS patients (who never recovered) and hence is not a reliable indicator of awareness. Adapted from Perrin F, Schnakers C, Schabus M, et al. (2006) Brain response to one's own name in vegetative state, minimally conscious state, and locked-in syndrome. *Archives of Neurology* 63: 562–569.

Figure 5 The common hallmark of the vegetative state is a metabolic dysfunctioning of a widespread cortical network encompassing medial and lateral prefrontal and parietal multimodal associative areas. This might be due to either direct cortical damage or corticocortical or thalamocortical disconnections (schematized by blue arrows). Also characteristic of the vegetative state is the relative sparing of metabolism in the brain stem (encompassing the pedunculopontine reticular formation, hypothalamus, and basal forebrain, represented in green), allowing for the patients' preserved arousal and autonomic functions. Adapted from Laureys S (2005) The neural correlate of (un)awareness: Lessons from the vegetative state. *Trends in Cognitive Sciences* 9: 556–559.

frontoparietal network, similar to that identified in VS patients. In some temporal lobe seizures that impair consciousness (coined 'complex partial') while preserving automatic activities such as picking, fumbling, or even cycling, single-photon emission CT has shown similar widespread deactivation in frontal and parietal association cortices. In contrast, temporal lobe epilepsy with sparing of consciousness (termed 'simple partial') is not accompanied by such frontoparietal dysfunction. Another example of transient nonresponsiveness with preserved automatic behavior such as ambulation can be observed in sleepwalkers. Again, deactivations in large areas of frontal and parietal association cortices were demonstrated by means of SPECT imaging during sleepwalking. Taken together, these observations point to the critical role of the frontoparietal associative cortices in the generation of conscious awareness.

However, awareness seems not exclusively related to the activity in this 'global workspace' cortical network but also, it is important to note, to the functional connectivity within this system and with the thalami. Long-range frontoparietal and thalamocortical (with nonspecific intralaminar thalamic nuclei) 'functional disconnections' have been identified in VS. Moreover, recovery is paralleled by a functional restoration of this frontoparietal network and part of its thalamocortical connections.

The most relevant question regards possible residual perception and cognition in vegetative patients. In well-documented VS patients, noxious high-intensity electrical stimulation (experienced as painful in controls) resulted in activation in brain stem, thalamus, and primary somatosensory cortex, but hierarchically higher-order areas of the pain matrix encompassing the anterior cingulate cortex failed to activate (Figure 6). It is important to note that the activated cortex was isolated and functionally disconnected from the frontoparietal network, considered critical for conscious perception. Similarly, auditory stimulation in VS was found to activate primary auditory cortices but not higher-order multimodal areas from which they were disconnected. The activation in primary cortices in awake but unaware patients confirms Crick and Koch's early hypothesis (based on visual perception and monkey histological connectivity) that neural activity in primary cortices is necessary but not sufficient for awareness.

Figure 6 High-intensity somatosensory stimuli fail to induce any subcortical or cortical neural activation in irreversible coma with clinical absence of brain stem reflexes (i.e., brain death). In the vegetative state, subcortical (upper brain stem and thalami) and cortical (primary somatosensory cortex; red circle) activation can be observed. However, this preserved cortical activation is limited to the primary cortex and fails to reach higher-order associative cortices from which it is functionally disconnected. In healthy volunteers, reporting the stimuli as painful, stimulation resulted in a wide neural network activation (the so-called pain matrix) including the anterior cingulate cortex (green ellipse). Data from Laureys S, Faymonville ME, Peigneux P, et al. (2002) Cortical processing of noxious somatosensory stimuli in the persistent vegetative state. *Neuroimage* 17: 732–741 and shown on 'glass brains.'

MCS

PET studies measuring cerebral metabolism at rest are unable to reliably differentiate vegetative from minimally conscious individuals. Functional imaging can here be of utmost value in objectively differentiating activation patterns measured during external stimulation characteristic of either clinical entity. Complex auditory stimuli with emotional valence, such as personalized narratives or the patient's own name, activate language-related cortical areas not observed during presentation of meaningless stimuli in MCS. Such context-dependent higher-order auditory processing in MCS patients (often is not assessable at the patient's bedside) indicate that content does matter when talking to MCS patients.

However, given the absence of a thorough understanding of the neural correlates of consciousness, functional neuroimaging results must be used with caution as proof or disproof of awareness in severely brain-damaged patients. Recently, Adrian Owen, from Cambridge, proposed a more powerful approach for identifying 'volition without action' in noncommunicative brain-damaged patients (rather than the use of passive external stimulation paradigms): scanning patients when they are asked to perform a mental imagery task. Reproducible and anatomically specific activation in individual patients during tasks that unequivocally require 'willed action' or intentionality for their completion unambiguously reflect awareness. Of course, negative findings in the same circumstances cannot be used as evidence for lack of awareness. In one exceptional VS patient, task-specific activation was observed, unequivocally demonstrating conscious awareness in the absence of reliable behavioral motor signs of voluntary interaction with the environment. It is interesting that the patient subsequently recovered. Other studies also showed that VS patients with atypical brain activation patterns on functional neuroimaging afterwards showed clinical signs of recovery of consciousness, albeit sometimes many months later.

Investigations using MRI diffusion tensor imaging, which gauges the integrity of the white matter, are increasing scientific understanding of the brain mechanisms underlying recovery from VS. A team led by Nicholas Schiff of Cornell University, for instance, recently used diffusion tensor imaging to show the regrowth of axons in the brain of Terry Wallis, an Arkansas man in posttraumatic MCS who started talking in 2003 after 19 years of silence.

LIS

Classically, the EEG is relatively normal (or minimally slow) and reactive to external stimuli in LIS, but unreactive alpha rhythms (i.e., 'alpha coma' patterns) may also be observed. Cognitive ERPs and brain–computer interfaces may document awareness and permit communication in the extremely challenging cases of complete LIS. Residual cognition in LIS has long remained *terra incognita*. Recently, standard neuropsychological testing batteries have been adapted and validated for eye response communication. In classical LIS caused by a brain stem lesion, these studies have shown preserved attention, memory, executive functioning, and phonological and lexicosemantic performance.

PET scanning has shown significantly higher metabolic levels in the brains of patients in LIS compared with patients in VS. Voxel-based comparisons with healthy controls showed that no supratentorial cortical area has a significantly impaired metabolism in classical LIS. Conversely, hyperactivity was observed in bilateral amygdala of acute, but not chronic, LIS patients. The amygdala is known to be involved in emotions, especially negative emotions such as fear and anxiety. The absence of metabolic signs of

reduced function in any area of the gray matter reemphasizes the fact that LIS patients suffer from a pure motor de-efferentation and recover an entirely intact intellectual capacity. The increased activity in the amygdala might relate to the terrifying situation of an intact awareness in a mute but sensitive being. Healthcare workers should be aware of this condition, adapt their bedside behavior, and consider pharmacological anxiolytic therapy.

Conclusion

Brain death, coma, VS, and MCS represent different pathological alterations of both dimensions of consciousness (involving arousal and awareness) or, for LIS, of the motor signs of consciousness. At the bedside, the evaluation of conscious perception and cognition in these conditions is difficult and sometimes erroneous. Electrophysiological and functional neuroimaging studies can objectively describe the regional distribution of cerebral activity at rest, under various conditions of passive stimulation, and during 'active' mental imagery tasks. These studies are increasing our understanding of the neural correlates of arousal and awareness and will improve the diagnosis, prognosis, and management of disorders of consciousness. But at present, much more data and methodological validation are awaited before functional neuroimaging studies can be proposed to the medical community as a tool for disentangling the clinical gray zone that separates conscious from unconscious survivors of acute brain damage.

Coma and Other Pathological Disorders of Consciousness

N D Schiff, Weill Medical College of Cornell University, New York, NY, USA

© 2009 Published by Elsevier Ltd.

Introduction

Coma is an unconscious brain state that may be produced by a variety of acute or chronic brain insults. Coma is uniquely characterized by the total absence of patterned behavioral arousal; comatose patients are completely unresponsive and lay motionless in an eyes-closed state. There are no spontaneous periods of wakefulness, nor induced eye opening with vigorous stimulation that may be observed in other unresponsive brain states. By definition, and to distinguish coma from syncope, concussion, or other forms of transient unconsciousness, the term coma implies that the state has endured for at least 1 h. Coma is a transient condition and, if uncomplicated by concurrent systemic illness, comatose patients who survive begin to awaken within 10–14 days. Some patients recover rapidly, whereas others recover more gradually, first entering into a vegetative state or minimally conscious state (as defined later) or other global disorders of consciousness that may be confused with coma. Time frames and probabilities of recovery from coma, vegetative state, or minimally conscious state depend greatly on the nature of the underlying brain injury producing the initial coma. In addition to pathologic causes of coma, general anesthesia reflects a pharmacologically induced coma and studies suggest some overlap in mechanisms at the neuronal circuit level between regional effects of anesthetics and focal brain injuries that may produce acute coma. This article briefly reviews the common mechanisms producing coma and related disorders of consciousness. Emphasis is placed on the neuronal circuits supporting forebrain arousal and integrative cerebral function disrupted in these conditions. Finally, some suggestions regarding the possible overlap of selective brain injuries producing coma and the mechanisms of action of general anesthetics are proposed.

Underlying Mechanisms of Pathologic Coma

Although coma may resemble deep, sleep-like unconsciousness, it is differentiated by a total lack of purposeful response to internal or external stimuli. The motionless resting state of a comatose patient may give way with effortful stimulation to a grimace in response to painful stimuli or stereotyped withdrawal movements of the limbs generated by spinal reflexes. Such movements, however, do not localize the source of external stimulation nor demonstrate organized sequential components characteristic of purposeful avoidance. As coma progresses to deeper stages, such primitive reflex responses may not be evident.

Coma results from a complete disabling of the brain's arousal mechanisms that maintain the alert waking state, including responsiveness to external stimuli, intentional behaviors, and postural control. Arousal regulation includes control of the overall level of neuronal activity (firing rates and metabolic demand) in the brain and organization of spatiotemporal dynamics (patterns of cerebral activity reflected in the electroencephalogram (EEG) and in the spinal cord associated with wakeful behavior). Many different neurological conditions can produce coma, but statistically most coma arises as a result of very diffuse global damage to the brain resulting either from a loss blood flow during cardiac arrest or from severe head trauma typically due to road traffic accidents. As a general rule, if a patient is comatose, one of three possible mechanisms (or combinations of these three) accounts for this level of brain dysfunction: (1) the patient has a diffuse metabolic disturbance (loss of blood flow, oxygen deprivation (e.g., smoke inhalation), poisoning, etc.), (2) the patient has sustained bilateral injuries to the cerebral hemispheres, or (3) the patient has sustained focal injuries to a relatively small set of regions of the upper brain stem or thalamus.

There are several different neuronal populations concentrated in the brain stem and basal forebrain that contribute to maintaining the state of wakefulness, collectively grouped as the 'arousal systems.' The concept of an ascending arousal system located in the dorsal regions of the upper brain stem and central thalamus arose in the 1940s. Initially, the roles of the midbrain reticular formation (MRF) and the central thalamus (primarily intralaminar thalamic nuclei (ILN) and closely associated regions) were emphasized as the origin of this system. Experimental studies demonstrated that electrical stimulation of the midbrain and central thalamus produced EEG desynchronization and behavioral arousal as evidenced by eye opening and eliciting of purposeful movements in lightly anesthetized animals. A modern view incorporates these early observations into a conceptual framework that identifies the control of arousal *per se* as interdependent on the output of glutamatergic and cholinergic neurons located in both the brain stem and the basal forebrain, and several other brain stem neuronal populations including serotoninergic

and noradrenergic neurons, as well as histaminergic nuclei and orexin-producing neurons located in the hypothalamus. Many experimental studies have sought to identify a specific subset of necessary or sufficient neuronal groups uniquely responsible for arousal reflected in the EEG and behavior without clear evidence that any single group is indispensable. Consistent with the results of these experimental studies, it has been seen that only relatively large bilateral injuries to the dorsal regions of the upper pons, midbrain, or central regions of the thalamus produce coma in humans on the basis of a small structural brain injury. Moreover, such comas arising from focal injuries are usually quite short lived, lasting only hours or a few days.

Circumscribed injuries to the brain stem that produce acute coma are concentrated bilaterally in the rostral pons and dorsal midbrain – regions containing cholinergic neurons and other afferents from the brain stem arousal systems that have strong anatomical projections to the basal forebrain, central thalamus, and wide regions of the cerebral cortex. Bilateral focal injury to the central thalamus may also produce acute coma when the injuries involve both sides of the brain and affect either the anterior or the posterior thalamic intralaminar nuclei. This type of injury often includes bilateral brain stem lesions centered on the upper midbrain (MRF). Both isolated injuries of the dorsal brain stem or the central thalamus may produce initial coma with an invariably short duration. Restricted bilateral brain stem lesions often give way to faster and more complete recoveries than bilateral ILN injuries (particularly if the midbrain is involved on one or both sides along with the central thalamus). Patients with brain stem injuries producing coma may recover consciousness within 1 week if they survive. In contrast, patients with isolated central thalamic injuries producing acute coma may show recovery of eye opening and patterned arousal within 1 or 2 days but remain behaviorally unconscious for many weeks or months, if recovering at all. Of note, some patients with bilateral injuries involving the central thalamus and midbrain do recover from enduring global disorders of consciousness over very long intervals. The mechanisms underlying this protracted recovery process are not well understood.

Although coma may arise in the setting of such focal injuries, in most cases coma is associated with widespread neuronal dysfunction or death due to loss of oxygen (anoxia) following a cardiac arrest or head trauma that produces disconnection of neurons by shearing injury of their axonal projections. Nonetheless, in the setting of coma produced by anoxia or brain trauma, it is the severity of damage to the thalamus that best indexes the likely outcome.

Related Global Disorders of Consciousness

Following a coma produced by a severe brain injury (traumatic or nontraumatic), patients either worsen with progressive neuronal damage leading to brain death (total cessation of all brain function) or improve with the initial signs of recovery heralded by brief periods of eye opening without behavioral responsiveness. Comas that do not resolve with more complete recovery of consciousness give way to the vegetative state, minimally conscious state, and other related clinical syndromes. These conditions are often confused with coma, particularly in the popular press, but each is distinct in clinical presentation and natural history following coma.

Vegetative State

In 1972, Jennett and Plum defined the clinical syndrome of the 'persistent vegetative state' noting the dissociation of a limited recovery of arousal as judged by the recovery of an 'eyes-open' state that alternates with an 'eyes-closed' state in a patient with otherwise no evidence of awareness of self or their environment. Understanding of the mechanisms underlying the clinical syndrome of vegetative (VS) has evolved since that time, particularly with respect to the basis of enduring VS in patients who survive cardiac arrest. Current usage arbitrarily identifies VS lasting more than 30 days as the persistent vegetative state. The modifier 'persistent' is often misinterpreted to indicate the likely permanence of VS. An expectation for the permanence of VS, however, depends on both the mechanism of injury and the elapsed time from the injury.

Because VS typically arises following coma, it is not surprising that patterns of structural injuries producing VS overlap those producing coma. Autopsy studies of patients remaining in VS show a common pattern of widespread disconnection of the corticothalamic system leading to extensive loss of thalamic neurons, particularly the central thalamic neurons of the ILN and closely adjacent components of thalamic association nuclei that can alone when damaged produce coma. This pattern is seen following both diffuse axonal injury (DAI) from brain trauma and oxygen deprivation resulting from cardiac arrest, with more cortical damage seen with the latter type of injury. Significant brain stem damage, however, is not commonly found at autopsy for patients remaining VS after structural injuries, emphasizing that VS is primarily a disorder of cerebral integration at the level of the corticothalamic systems. The damage to the thalamus following DAI is indirect as a result of

transneuronal degeneration, whereas oxygen deprivation causes rapid neuronal death after approximately 6 min. This underlying difference in mechanism is likely to play an important role in the very different expected time course of recovery and point beyond which permanence is expected in VS resulting from traumatic brain injury compared to cardiac arrest and similar injuries.

Neuroimaging studies of VS patients have focused on measurements of brain energy usage and functional activation of cerebral networks in response to sensory stimuli. Studies of cerebral metabolism in VS patients using positron emission tomography scans show that the brain in VS is severely reduced in resting metabolism, usually remaining at 30–50% of normal levels. These observed metabolic levels are lower than those found in pharmacologic coma produced by surgical anesthesia. Functional neuroimaging studies of VS patients show a widespread failure of functional connections with loss of responses to elementary sensory stimuli in cortical regions remote from the primary sensory cortices. Specific deficits of integrative responses in the medial parietal region have been consistently observed in VS patients. Occasionally, behavioral and physiological variations of VS have been identified, including evidence of isolated islands of metabolic activity. In one patient who had remained clinically in VS for 20 years, rare single understandable words were emitted, without contingent relationship to environmental stimulation. In this VS patient, left frontotemporal cerebral structures that operated at an abnormally low metabolic rate, but at nearly twice the rates of remaining brain, correlated with remaining elements of the human language system. Similar isolated behavioral fragments have been identified in other VS patients. Typically, patients express easily identifiable, stereotypical, emotional–limbic responses such as grimaces. These emotional expressions likely reflect isolated limbic mechanisms activated by brain stem and basal forebrain structures that lie outside of the thalamocortical systems that typically undergo overwhelming injury in VS.

Minimally Conscious State

VS is importantly differentiated from minimally conscious state (MCS) by evidence of unequivocal but inconsistent evidence of awareness of self or the environment. Behavioral evidence of responsiveness in MCS varies widely from isolated tracking of objects in the visual field to high-level responses such as intermittent verbalization and communication. Although the findings distinguishing VS and MCS patients on the clinical exam may be subtle, pathological studies suggest significant differences in the underlying structural pathology associated with each condition. Some patients with clinical histories consistent with MCS demonstrate no evidence of thalamic injury or severe DAI – findings never observed in VS patients at autopsy. The differences indicate a potential anatomical substrate for residual cerebral function in some MCS patients. Consistent with this picture from autopsy studies, a small number of neuroimaging studies show preservation of distributed network activation in response to auditory stimuli involving cortical association regions in the superior temporal gyrus not seen in VS patients and evidence in some MCS patients of large-scale networks responsive to human language. The presence of recruitable large-scale cerebral networks in some MCS patients suggests a potential substrate for further recovery in these patients. The observations likely underlie the rare, but verified, cases of late recovery of spoken language in some severely brain-injured patients with clinical histories consistent with long-standing MCS.

Akinetic Mutism

The syndrome of akinetic mutism spans a range of related behavioral disturbances in which patients may outwardly appear attentive and vigilant (as often evidenced by deliberate visual tracking of the examiner around the room) but exhibit a paucity of behaviors even when prompted. The pattern of brain injury most commonly associated with this syndrome is bilateral damage of the anterior medial regions of the cerebral cortex, typically arising as a result of a rupture of an arterial aneurysm located at the connection of the anterior cerebral arteries between the two cerebral hemispheres. These cortical regions are closely associated with the central thalamus and basal ganglia, and a similar syndrome can arise from bilateral injuries to these subcortical structures (as well as the MRF). This behavioral syndrome is also sometimes referred to as akinetic mutism and is characterized by severe memory loss, markedly slowed behavioral responses, and a listless appearance. The pattern of injuries associated with this syndrome overlaps with those producing acute coma and VS.

Prognosis in Coma, Vegetative State, and Minimally Conscious State

Coma is a very serious illness and studies indicate that 40–50% of patients in a coma after brain trauma, and 54–88% of patients comatose after a cardiac arrest, will die. Although few studies have evaluated outcomes other than survival or death, patients suffering traumatic brain injuries have a significantly higher likelihood than cardiac arrest patients to make

a good recovery. This is possibly because of the younger age of patients with traumatic brain injuries and the delayed mechanisms of neuronal death following brain trauma and axonal disconnection. Recovery after prolonged traumatic coma is well described and, unlike nontraumatic causes, unconsciousness for 1 month does not necessarily preclude significant recovery. Specific prognostic factors in coma are too numerous for review herein.

Prognosis in VS depends similarly on the underlying mechanism of brain injury. Patients who remain in VS for 3 months after a cardiac arrest or other nontraumatic brain injury producing a loss of blood flow or brain oxygen are considered to be in a permanent vegetative state. Time frames for recovery following posttraumatic VS are considerably longer, and 1 year is required for the expectation of permanence. Very few studies have continued to follow patients remaining in VS at 1 year after brain trauma, and some reports suggest that a small percentage of such patients may show some recovery of conscious awareness past the 1 year time frame.

Prognosis in MCS is the least well characterized because the diagnostic category is relatively new and available studies indicate that significant further recovery after 1 year in MCS can occur. Importantly, MCS patients show faster changes in rate of recovery within the first year after injury from either traumatic or nontraumatic injuries compared to VS patients. Thus, it is important that the sometimes small clinical distinctions be made between these two conditions within the first year after injury. All verified examples of late recovery of communication in severely brain-injured patients have come from the MCS patient population.

Underlying Mechanisms of Pharmacologic Coma

The previous discussion identified an important role for specific brain stem, basal forebrain, and central thalamic neuronal populations in mechanisms of coma and other global disorders of consciousness. Functional neuroimaging studies suggest that pharmacologic coma induced by anesthetics is associated with regionally selective reductions in cerebral metabolic activity or blood flow in the same structures that produce coma with structural injury. In most studies, general anesthetics lower average resting cerebral metabolism to approximately 60–65% of normal level when unconsciousness is achieved. As noted previously, this is a somewhat higher level of metabolism than identified in VS patients. Similar profiles of overall reduction in metabolic activity and regional effects on cerebral substructures have been seen for volatile anesthetics such as halothane and intravenous agents (e.g., propofol). Frontal and parietal cortices (higher level association areas of cerebral cortex) appear to be more strongly affected by anesthetic agents, and a marked reduction of cerebral metabolism in the thalamus and midbrain has been noted for most anesthetics. Decreased co-activation of these cortical and subcortical neurons is interpreted to account for the initial reductions in attention, working memory, and arousal associated with general anesthetics. These functional studies hint at an intersection of common action of anesthetics in MRF and thalamus. The selective suppressive effects of anesthetics on the midbrain and thalamus overlap with the clinical evidence provided previously that functional disturbances of these structures play a key role in mechanisms underlying coma and vegetative state. It is possible that, in general, anesthetics act first to disable selective integrative cerebral functions followed by more global impairment of the corticothalamic system as overall neuronal firing is suppressed through disabling of the midbrain and thalamus systems. It is problematic, however, to assess the functional contribution of specific structures to loss of consciousness seen with anesthetic agents because all generate widespread reductions of cerebral blood flow and metabolism. It is not clear whether anesthesia primarily overwhelms and suppresses neuronal firing rates or whether it might alter specific patterns of neuronal activity within the distributed networks of the frontal and parietal cortices (particularly the medial parietal regions). The further elucidation of the relative importance of the alteration of global cerebral activation versus specific patterns of forebrain activity associated with anesthetic agents will further elaborate the precise relationships between pathological and pharmacological forms of unconsciousness.

Command Systems

J Jing, Mount Sinai School of Medicine, New York, NY, USA

Introduction

Animals are characterized by their ability to adaptively distribute their activity among various behaviors, such as foraging, predator avoidance, and reproduction, and do so by integrating the sensation, motivation, and learning experiences. In animals with a well-developed central nervous system (CNS), most, if not all, of these behavioral activities are organized by the CNS. Once a behavior is selected, it has to be executed in an appropriate spatial and temporal patterning. Accordingly, one of the most basic question facing neuroscientists is to elucidate the underlying neural mechanisms that select, initiate, and generate coordinated behavioral activity. One central issue is whether there are specific neural substrates that are responsible for the initiation and generation of behaviors (localist representation), or whether these brain functions are distributed among neuronal elements (distributed representation). The concept of command neurons/systems was initially used to describe some specific neuronal elements/systems that are important for initiation of behavior, and would be consistent with an encoding scheme more closely related to a localist representation. This article provides a historical and current account of the 'command' concept and illustrate how this concept may be essential to our understanding of brain functions, such as sensorimotor transformation, neural coding, and decision making.

Command Systems: Command versus Decision Making

Historical Issues

The debate between proponents of localist and distributed representation or processing has been going on since the beginning of modern studies of the brain in the 1800s and has undergone a variety of manifestations. Currently, most neuroscientists agree that the CNS utilizes both strategies of information processing. Historically, however, it is important to demonstrate that there are specific elements, such as command neurons, that can initiate or release a distinct behavior. Because of apparent utilities of invertebrate preparations where some neurons are large enough to be easily accessible to electrophysiological recordings, many early studies were carried out using these relatively simple preparations. Indeed, the 'command neurons' concept came into usage in the 1960s after Wiesma and Ikeda found that stimulation of a small bundle of neuronal fibers in the ventral nerve cord of crayfish drove the metachronal beating of swimmrets. Subsequently, similar neurons/fibers that can evoke/release a specific pattern of behavior have been identified in both invertebrates (e.g., tail flip escape in crayfish, swimming in leech, escape in the mollusk *Tritonia*, and feeding in the mollusk *Pleurobranchaea*) and vertebrates (e.g., startle escape in teleost fish).

Demonstration of command neurons shows that in the CNS there are specific neuronal elements that occupy a privileged position by releasing a specific behavior; therefore, these neurons may be critical decision-making sites where expression and coordination of different behaviors may be determined. However, in the late 1970s, Kupfermann and Weiss were concerned with the free usage of the term 'command neuron' by some investigators, and they wrote an article to clarify its definition. One of their main suggestions was that command neurons, if useful for understanding the neural basis of behavior, should be used to refer to specific neurons or a neuronal population (as command systems) that are both necessary and sufficient for a behavior, in addition to their substantial activity when the behavior naturally occurs. This strict definition was intended to help investigators characterize actual roles of command neurons/systems in a behavior and exclude pretenders, such as neurons that are not essential for expression of the overall behavior but may initiate a component of the motor pattern when activated (e.g., motor neurons). However, experts' reactions to the criteria at the time were diverse and controversial, and currently only a few examples that meet all these criteria have been found. Here, we adopt a view that, rather than limiting ourselves to a strict definition, a more fruitful approach is to examine the neural basis of behavior from the perspective of network architecture and determine, in this context, what may constitute a command system.

Network Architecture: Command and Central Pattern Generators

Consider a prototypical hierarchical network organization of a motor system (Figure 1(a)). From an evolutionary standpoint, sensory neurons and motor neurons are perhaps the earliest developed neuron types controlling movements. As animals and their behaviors become more complex, interneurons emerge to situate between sensory and motor elements, thus providing additional computational capabilities.

Figure 1 Network architecture underlying behavior. (a) A prototypical motor network organized in a hierarchical manner. The four most basic layers of neural elements organized hierarchically are shown: sensory neurons, interneurons including command systems and pattern generators (or central pattern generators), and motor neurons. In the scheme shown here, sensory inputs act on the sensory neurons, which then act on the command systems, which in turn act on the pattern generators. Finally, pattern-generating elements act on the motor neurons to produce a behavior. (b) Schematic diagram of putative inhibitory interactions between two behavioral networks that may mediate suppression of one incompatible behavior by another.

In addition, in some motor networks, interneurons differentiate further into two layers: a command system and a pattern-generating circuit or a central pattern generator (CPG). The command system integrates sensory information from sensory neurons and activates the CPG, which in turn drives motor neurons to produce a motor pattern. From the perspective of sensorimotor transformation, it is apparent that command neurons are closer to the sensory processing, whereas CPG elements represent movement features. The mechanisms for generating specific motor patterns are intrinsic to the local circuits formed by CPG elements, whereas command system provides excitatory, inhibitory, or modulatory inputs to the CPG.

There are two caveats in considering the prototypical network as a representation of a motor system. First, not all motor networks can be strictly stratified into these layers of elements; actual networks may be variants of this organization. For example, although we can clearly identify command neurons in crayfish lateral giant and fish Mathner cell-mediated escape circuits, there are no pattern generators that intervene between the command neurons and the motor neurons, perhaps because escape is a reflex-like behavior which does not require a dedicated CPG. Another example of a variation is the crustacean stomatogastric network, in which many of the pattern-generating elements are motor neurons rather than interneurons. In contrast, in vertebrate motor systems, there is a proliferation of more layers of neurons at sensory and cognitive processing stages. Despite these differences in network structure, some fundamental principles are commonly applicable in different networks.

Hierarchical and Parallel Organizations

A second notable point is that many neuroscientists now recognize that realistic motor networks do not follow a strict hierarchical organization as depicted in Figure 1(a). Rather, there are multiple parallel, feedforward and feedback interactions among network elements. Historically, hierarchical organization was recognized first. Then, in the 1980s, there was an emphasis on parallel organization (and de-emphasis on hierarchical organization) in neural networks. The current consensus is that both types of organizations are present in the CNS.

Some aspects of the parallel pathways within a hierarchical network are illustrated in Figure 2, which also includes the peripheral structures that are involved in motor behaviors, such as head and other sensory organs that may gather salient information regarding the environment or the goal object, and the plant or motor apparatus that implements the motor behavior. Notably, sensory neurons may provide inputs not only to command systems but also to pattern generators or even motor neurons. How much sensory information is channeled to each of the components may depend on the type of

Figure 2 A schematic diagram illustrating a motor network with both parallel and hierarchical organizations. Also depicted are the peripherals: head and other sensory organs that detect salient information about the environment and goal objects, and the plant or the motor apparatus that implements the behavior. Sensory information may be conveyed to command systems, pattern generators, and motor neurons. There are also bidirectional interactions between command systems and pattern generators. Although sensory information is channeled in parallel to different layers, different types of sensory information may preferentially influence different network elements. In one possible scheme illustrated here, information about the goal object that is detected through vision, or tactile/chemical sensory processors, may preferentially act on the command system to select an appropriate behavior, whereas plant state information through proprioceptive receptors may preferentially act on the pattern-generating elements and motor neurons to adjust the motor behavior online to execute behavior adaptively.

behavior. For example, in a reflex behavior, sensory neurons may predominantly act on motor neurons; whereas in a rhythmic behavior sensory neurons may act more via interneurons (command systems/CPG elements). In some cases, this parallel organization of sensory pathways may also be correlated with the types of sensory inputs involved. Thus, object information from the head sensory organs may preferentially act on the command systems to select an appropriate behavior, whereas the proprioceptive information from the plant may preferentially act on the CPG or motor neurons to adjust motor behavior online to execute behavior adaptively. Another feature of the depicted network is that some interactions between layers of elements are not one way but, rather, both ways; for example, feedback from CPG elements to command systems has been well documented. In fact, some command neurons have been shown to serve pattern-generating functions as well. Because structure is clearly related to function, it is critical to determine the network architecture for the motor system under study and also the implications of the architecture for its network functions.

Drivers and Modulators

From the network architecture perspective, it appears that command neurons that drive a CPG circuit are present in many behaviors, especially stimulus-dependent behaviors, that require external stimuli to activate the CPG. Even for autoactive behaviors, higher order neurons may modulate CPG, thereby producing multiple versions or types of motor outputs. Furthermore, with the exception of a few specialized networks in which single neurons may act as a command, it is common for an ensemble of neurons to be involved in command function; therefore, use of command systems or higher order neurons is preferable. In such a command system, at least two major types of interneurons can be distinguished: one type is the drivers, which are the so-called command neurons, and the other is the modulators, which may not initiate a full-blown behavior but, rather, modulate motor outputs. Thus, command systems, as broadly defined here, include both command elements and modulatory elements. Because these elements in command systems are important for expression of specific behaviors, contemporary research focuses on the decision-making role of these neurons – that is, how they act on pattern-generating circuits and how they interact with each other to produce adaptive behaviors. To illustrate these and other relevant issues, we use model systems to discuss the command functions.

Model Systems and Command Functions

As with all branches of biology, many problems are studied using model organisms. Vertebrate models are necessary for ultimate understanding of ourselves. Invertebrate models are particularly informative in uncovering fundamental principles, many of which have been verified in vertebrate models. In terms of command functions, the most extensively studied invertebrates include mollusks (e.g., *Aplysia*, *Clione*, *Lymnaea*, *Pleurobranchaea*, and *Tritonia*), leech, and crustacean (crayfish lateral giant, stomatogastric nervous systems (STNS)). Well-known vertebrate model systems include teleost fish escape, frog prey capture, turtle scratching, locomotory networks (e.g., lamprey), and primate saccade. In the following sections, selected examples are used to discuss how command function contributes to expression of behaviors. In particular, it is useful to distinguish command functions for related behaviors implemented by a single motor apparatus and those for different behaviors implemented by different motor apparatus. Note that such a distinction is operational and only for the convenience of discussion.

Related Behaviors: Reconfiguration of Multifunctional Central Pattern Generators

Our ability to generate a variety of behaviors using a single or related motor apparatus contributes to the

flexibility and diversity of behavioral production. For instance, using our legs, we walk, run, and jump, and we can walk forward and backward. Indeed, one of the major principles derived from work with model systems is that the CPGs that control these motor apparatus are multifunctional; that is, the CPGs can generate multiple motor patterns. Specifically, the operations of CPG depend on the multiple nonlinear processes at the cellular, synaptic, and network levels. Neuronal properties have a set of building blocks at

Figure 3 Generation of a variety of related behaviors. (a) Crustacean stomatogastric nervous system and actions of modulatory projection neurons on motor patterns. (a1) Schematic diagram of stomatogastric nervous system showing neuronal distributions in the three ganglia: commissural (CoG) or esophageal (OG) ganglia and the stomatogastric ganglion (STG), involved in the control of foregut movement including pyloric and gastric mill rhythm. Modulatory projection neurons are located in the CoG or OG, which are connected to STG through stomatogastric nerve (stn). CPG elements, many of which also innervate muscles through peripheral nerves (dgn, mvn, and lvn), are located in the STG. (a2) Three projection neurons – MCN1, MPN, and MCN7 – all contain peptide protoclin, but they promote distinct motor patterns as shown in the activity of CPG elements PD, IC, VD, LG, and DG in part because they contain different complements of cotransmitters (e.g., GABA and peptide CabTRP). (b) *Aplysia* CNS involved in feeding and combinatorial actions of cerebral–buccal interneurons (CBIs) on the CPG to effect motor program switching. (b1) Schematic diagram of *Aplysia* CNS showing neuronal distributions in cerebral ganglion and buccal ganglion involved in the control of radula movements. Higher order neurons, or CBIs, are located in cerebral ganglion, whereas CPG interneurons and motor neurons are located in buccal ganglion (the left side shows cells on the rostral surface and the right side shows cells on the caudal surface). Food information enters the brain, in part, through the cerebral nerves (AT, UL, and PT), whereas the buccal mass (including the

each level – for example, cellular-level properties (ionic channels and active and passive electric properties of the cell) and synaptic-level properties (nature of synapses, short-term dynamics, and long-term plasticity). All these nonlinear processes can be modulated by neurotransmitters and hormones, and therefore the CPG can assume a variety of functional configurations that correspond to different motor outputs. One of the most well-studied systems is the crustacean stomatogastric ganglion (STG), which contains all CPG elements necessary for control of movements of the foregut, including pyloric and gastric mill rhythms. A large body of work has shown that a variety of neuromodulators (e.g., dopamine, serotonin, and neuropeptides) can alter cellular and synaptic properties of stomatogastric CPG neurons to produce different motor patterns.

Importantly, higher-order neurons/command systems are also prominent sources for many of the neuromodulators, in addition to fast-acting neurotransmitters. Two examples illustrate how elements of a command system are composed of a heterogeneous population of interneurons, which allows the command system to reconfigure or modulate the CPG, thereby producing a variety of motor patterns. In STNS, these higher-order neurons are termed projection neurons. Their somata are located in commissural or esophageal ganglia, but their axons innervate the STG, where they release neurotransmitters and neuromodulators to act on the CPG (**Figure 3(a1)**). An important insight gained from this work is that projection neurons with the same neuropeptide may elicit different versions of motor patterns because these neurons contain different complements of cotransmitters. As shown in **Figure 3(a2)**, all three projection neurons contain proctolin. However, the motor patterns that these projection neurons promote are distinct, in part due to the fact that they have different complements of cotransmitters.

In *Aplysia* feeding network, two major ganglia are involved (**Figure 3(b1)**). The cerebral ganglion contains a number of higher-order interneurons, termed cerebral–buccal interneurons (CBIs), that receive sensory information from head sensory organs and project their axons to the buccal ganglion, where they activate and/or modulate the feeding CPG. The buccal ganglion contains the feeding CPG elements and also motor neurons that innervate the feeding apparatus, the radula. Notably, the *Aplysia* feeding system may entail an additional level of complexity, not present in some simpler networks, in that most of the CPG elements are interneurons, which form a local circuit that underlies motor patterns and provides timing information to motor neurons. Furthermore, studies suggest that the CPG interneurons did not evolve as a duplicate of single motor neurons to simply provide excitatory drive to them. Rather, CPG interneurons provide both excitation and inhibition to motor neurons and represent a higher-level abstraction in that they appear to be organized as functional modules that encode behaviorally relevant movement parameters. In particular, the radula produces two major types of motor programs, ingestive and egestive, that involve different coordination patterns of two sets of radula movements: protraction–retraction versus opening–closing. Protraction initiates first, and it always precedes retraction in each cycle of a motor program. In ingestion, closing occurs during retraction; in egestion, closing occurs during protraction. Different CPG interneurons are responsible for protraction or retraction. Furthermore, because closing occurs at different times in the two programs, two sets of CPG interneurons control radula closing for these two programs, and therefore the activity levels of these interneurons will determine what types of programs are generated.

Such a modular organization engenders an elegant mechanism with which higher-order neurons can act on the CPG to produce different motor patterns.

feeding apparatus, the radula) and the gut are innervated by buccal nerves (N1, N2, N3, RN, and EN). I2 is a branch of RN and contains the axons of protraction motor neurons (PM), such as B31/32. Closing motor neuron (CM), B8, exits the buccal ganglion through RN. (b2) Motor program switching. The pattern-generating network appears to be organized in a modular manner. Protraction interneuron, B63, and retraction interneuron, B64, mutually inhibit each other and mediate alternative protraction (open bar) and retraction (filled bar) movements. Two sets of CPG elements, B20–B4/5 and B40, mediate closing B8 activity for egestive and ingestive programs, respectively. In egestive programs, B20 excites B8 during protraction, whereas B4/5 inhibits it during retraction; thus, B8 is mostly active during protraction (green). In ingestive programs, B40, active during protraction, provides fast inhibition and slow excitation on B8 so that B8 is mostly active during retraction (green). The ability of CBI-2 to induce a motor program is mediated in part by its excitation (using ACh and possibly peptide FCAP) on B63, which is a critical initiating element of the CPG. (Left) CBI-2 promotes an egestive program by exciting B20, which in turn excites B4/5 (the latter connection not shown for clarity). (Right) Coactivation of CBI-3 with CBI-2 converts the program to ingestive because CBI-3 inhibits B20 through a fast GABAergic synapse, whereas it inhibits B4/5 through a peptidergic (APGW) mechanism. CBI-3 also promotes B40 activity, reinforcing the ingestive program. Data are summarized from Jing J and Weiss KR (2001) Neural mechanisms of motor program switching in *Aplysia*. *Journal of Neuroscience* 21: 7349–7362; Jing J, Vilim FS, Wu JS, Park JH, and Weiss KR (2003) Concerted GABAergic actions of *Aplysia* feeding interneurons in motor program specification. *Journal of Neuroscience* 23: 5283–5294; and Hurwitz I, Kupfermann I, and Weiss KR (2003) Fast synaptic connections from CBIs to pattern-generating neurons in *Aplysia*: Initiation and modification of motor programs. *Journal of Neurophysiology* 89: 2120–2136, and references cited within.

Figure 3(b2) illustrates how two CBIs use their different sets of cotransmitter complements to initiate and modulate programs to effect motor program switching. Specifically, CBI-2 contains the fast-acting excitatory neurotransmitter ACh and peptide cotransmitter FCAP, both of which promote activation of the CPG (in this case, an egestive program). By contrast, when coactivated with CBI-2, CBI-3 exerts fast GABAergic and slow peptidergic (APGW) inhibitions separately on the two egestive CPG elements active at two different phases to convert the program to ingestive. Similarly, combinations of other sets of CBIs (e.g., CBI-2 and CBI-12) can act on the modular CPG to produce changes in other movement parameters, thus constituting a flexible and adaptive mechanism for generation of a variety of related behaviors. In summary, the CPG contains basic mechanisms that underlie motor patterns, whereas various combinations of higher order interneurons act on the CPGs and sculpt a functional configuration appropriate for any given condition.

Different Behaviors: From Behavioral Hierarchy to Adaptive Decision Making

We constantly make behavioral decisions. In addition to selecting a behavior from related behaviors that are generated by a single or related motor apparatus, we also choose among behaviors that are implemented by different motor apparatus. In an early series of studies, Davis and others asked why animals generally perform one type of behavior at any given time. Specifically, animal behaviors appear to be organized into a priority sequence and some behaviors take precedence over others, which has been termed a 'behavioral hierarchy.' In terms of the neural mechanisms, it is presumed that some type of inhibitory interactions might exist between the networks that mediate incompatible behaviors. Although interactions may involve elements in both the command systems and the CPG, elements of command systems appear to be one of the major sites of actions (Figure 1(b)). Indeed, inhibitory interactions between command elements in one network and neural elements in the other network have been identified in several model systems, such as *Pleurobranchaea* (feeding inhibition of withdraw and swimming over feeding), *Clione* (withdraw/hunting over swimming), and leech (feeding over tactile responses).

Recent studies of behavioral selection, however, have revealed a more complex picture, which can be illustrated by work on *Pleurobranchaea* and leech. First, even suppression of incompatible behaviors does not have to be mediated by pure inhibition, as is the case in the suppression of avoidance turning by escape swimming in *Pleurobranchaea* (Figure 4(a)). Mild noxious stimuli cause prolonged activity in the serotonergic interneurons that support avoidance turning by providing excitation to turning interneurons. Strong noxious stimuli, however, set the network in a state in which the serotonergic interneurons as well as turning interneurons are co-opted into a swimming rhythm and prevented from driving avoidance turning. Second, interactions between network elements may involve both excitation and inhibition. In *Pleurobranchaea*, although suppression of feeding by escape swimming involves inhibition of feeding command neurons by command and CPG elements in the escape swimming network, the serotonergic neurons involved in swimming do not inhibit feeding command neurons. Rather, they provide monosynaptic fast and slow excitation to feeding modulatory neurons that enhance feeding activity, and they also provide slow, albeit weak, excitation to feeding command neurons. Similarly, in the interactions between networks that mediate shortening and swimming in leech (Figure 4(b1)), there are prominent excitatory inputs from interneurons for shortening to the triggering and gating swimming interneurons that are part of swimming command systems, with only one of the swimming gating neurons being inhibited by the shortening interneurons. Based on these and other findings in the leech, Kristan and colleagues proposed a combinatorial code scheme that could account for how leech makes a behavioral decision to shorten, swim, crawl, or bend (Figure 4(b2)). It is suggested that a different but partially overlapping population of interneurons is active at any given time, and this specific combination of interneurons determines which behavior is to be expressed (see also Figure 3(b2)).

Two major insights can be gained from the previously described studies. First, they support the postulate that the neurons that comprise behavioral networks constitute a heterogeneous population. Although some neurons are more dedicated to a single behavior, most neurons are multifunctional. For instance, although the serotonergic interneurons in *Pleurobranchaea* and *Tritonia* were initially identified as part of escape swimming CPG, studies performed to date indicate that these neurons may also function as gating mechanisms because they are activated by mild to strong noxious stimuli, and the activity level in these neurons then determines which behavior is expressed. At lower levels of activation, these neurons enhance the overall arousal level of the animal and promote withdrawal, avoidance, locomotion, or even feeding by providing both fast and slow modulatory excitations to networks mediating these behaviors. At higher levels of activation, these neurons promote escape swimming, resulting in more dedicated swimming

Figure 4 Interacting neural networks underlying behavioral decisions. (a) Highly interactive networks that mediate feeding, escape swimming, and avoidance turning in *Pleurobranchaea*. Suppression of feeding by escape swimming is mediated by inhibition of feeding command neurons by swimming command-like neurons and other CPG neurons. However, serotonergic swimming interneurons As1–4 do not inhibit feeding command neurons; rather, they provide slow, albeit weak, excitation to them (not shown). In addition, As1–4 provide fast and modulatory excitations to feeding modulatory neurons that enhance the feeding. As1–4 are also integrative members of the turning network by providing strong excitation to turning interneuron A4 to promote A4 unilateral activity that underlies avoidance turning. Suppression of avoidance turning by escape swimming is mediated in part by co-option of As1–4 and A4 into swimming rhythm when sufficiently strong noxious stimuli set the network in a state to produce escape swimming. Finally, As1–4 may also promote locomotion by driving activity in locomotor neurons (not shown). 5-HT, serotonin. Data are summarized from Jing J and Gillette R (2000) Escape swim network interneurons have diverse roles in behavioral switching and putative arousal in *Pleurobranchaea*. *Journal of Neurophysiology* 83: 1346–1355; and Jing J and Gillette R (2003) Directional avoidance turns encoded by single interneurons and sustained by multifunctional serotonergic cells. *Journal of Neuroscience* 23: 3039–3051, and references cited within. (b) Network interactions underlying decision making in leech. (b1) Interactions between shortening and swimming networks. Although shortening suppresses swimming, shortening interneurons only inhibit one swimming interneuron (204) while providing excitations to many other swimming interneurons. (b2) A combinatorial code scheme for decision making. It is proposed that at any given moment, an overlapping but distinct set of interneurons is activated (black rectangle) that determines which behavior – swimming, shortening, crawling, or bending – is expressed. Names of interneurons of the three neuron types, A–C, that have already been documented are indicated in parentheses at left, whereas cell types D and E are postulated. interneurons phasically inhibiting other behavioral networks to prevent incompatible behaviors from occurring. From this perspective, these neurons are functionally analogous to vertebrate arousal networks such as the raphe nucleus and locus coeruleus. Second, these highly interactive networks may well contribute to the flexibility in behavioral selection and expression in animals. Thus, even simple animals such as mollusk and annelid are not rigid robots and do not act as servants to a multitude of environmental stimuli. Rather, animals have an intrinsic repertoire of motor behaviors that can be gracefully recruited into action by these decision-making neurons/systems which form elaborate networks and choose to respond appropriately to salient stimuli at any given time. Indeed, vertebrates are characterized by further development of decision-making systems into more complex forebrain structures (e.g., cortex, basal ganglia, and hypothalamus).

More Elaborate Neural Networks Involved in Motor Commands in Vertebrates

The work in invertebrate model systems is informative for the understanding of neural organization of vertebrate motor systems. For example, motor system organization for a number of vertebrate behaviors, such as locomotion, scratching, respiration, occulomotor control, and feeding, shares a grossly similar architecture with some behaviors in invertebrates (Figure 5). This similarity is first reflected in the fact that there are clearly CPG networks, either in the spinal cord or in the brain stem, that are responsible for execution of these motor behaviors. These CPG networks are composed mostly of interneurons, and unlike some invertebrates, each functional group is composed of a population of a large number of interneurons rather than one or a few. However, the essential building blocks for the CPG networks (or, as termed by Grillner and others, motor infrastructure) are similar to those in invertebrates. Interestingly, based in part on experimental work and theoretical/computational analysis in turtle scratching, lamprey locomotion, and other limb behaviors, Bizzi, Grillner, Stein, and others proposed a modular organization for limb control (compare the modular organization proposed for an invertebrate CPG in *Aplysia* feeding). One version of the proposal stipulates that extensor and flexor of the hip and knee are controlled by separate functional modules or unit CPGs such that a variety of motor behaviors (e.g., different forms of scratching and locomotion) can be constructed through flexible combinations of these modules.

Whereas CPG networks are mostly located in spinal cord or brain stem, command signals largely originate from descending fibers of the higher brain centers, such as brain stem (midbrain and hindbrain), diencephalon (thalamus and hypothalamus), and telencephalon (basal ganglia and cortex) (Figure 5(a)). These command signals can activate/modulate the specific CPG network appropriate for a given condition. Indeed, vertebrate higher level networks that fulfill command and other higher-order functions are much more elaborate. First, there may be multiple command sites for a behavior, such as the two command sites demonstrated for locomotion – that is, the mesencephalic (MLR) and the diencephalic locomotor (DLR) regions that may provide more flexible means to access the locomotor CPG. Second, there may be multiple layers of commands that exert more sophisticated controls of a behavior. For example, Swanson proposed that motivated behaviors such as ingestive/reproductive/defensive and exploratory/foraging behaviors are controlled by command sites in the brain stem (e.g., MLR) called 'motor pattern initiators,' which in turn are controlled by 'pattern controllers' in the diencephalon (e.g., DLR).

Increased complexity of vertebrate motor systems results from additional, higher levels of control centers (Figure 5(b)). These control centers include basal ganglia, whose output nuclei, pallidium, are spontaneously active and exert a tonic GABAergic inhibitory control over lower command sites and the CPGs. On the other hand, input nuclei, the striatum, are normally quiescent, and when active they inhibit palladium also using GABA, thereby initiating behaviors through a disinhibitory mechanism. An additional level of control is the excitatory influence from the cortical networks that are responsible for aspects of sensory processing, motor control, and cognition. There are multiple parallel and hierarchical interactions in subcortical and cortical regions, such as those involved in primate saccade: superior colliculus, visual cortex; lateral intraparietal area (parietal cortex); frontal eye fields (prefrontal cortex); and medial eye fields (premotor cortex). Finally, vertebrates also evolved specialized neural systems that can significantly influence behavioral decisions: for example, the cerebellum for motor learning and precision motor control, prefrontal cortex for working memory, and hippocampus for declarative memory.

Importantly, similar to invertebrate motor networks, variations in network architectures are also present in vertebrates. For instance, teleost fish developed a specialized Mauthner cell-associated command system in the brain stem for startle, and the Mauthner cell's excitatory outputs to spinal motor neurons are direct, which is adaptive considering the importance of response speed in escape. Some primate behaviors, such as reaching and, in particular, fine motor skills (e.g., speech and hand/finger

Figure 5 Neural organization of vertebrate motor networks. (a) Illustration of vertebrate CNS including spinal cord, brain stem, cerebellum, basal ganglia and cerebral cortex. In the spinal cord and brain stem are the CPG networks or motor infrastructure that mediate a variety of behaviors, such as protective reflexes, locomotion, breathing, chewing, swallowing, and eye movements. Eating and drinking are also heavily influenced by neural networks located in the hypothalamus. Fine motor skills (e.g., speech and hand–finger control) are under increasingly direct control of cortical neurons, particularly in primates. (b) Simplified diagram of vertebrate motor systems involved in behavioral selection. Motor networks for locomotion, posture, and saccade, as illustrated here, are organized in at least two major layers – the CPG networks located in the spinal cord or brain stem and the command sites (likely gultaminergic (glut.)) in midbrain. The command sites are further under the control of cerebral cortex/pallium and basal ganglia (input nuclei, striatum; output nuclei, pallidum). In general, command sites are under tonic GABAergic inhibition of pallidum which is spontaneously active. Specific striatum neurons which have high activation threshold and are normally inactive may be activated, in part, from appropriate sensory input, channeled through thalamus. Upon activation, these striatum neurons, also GABAergic, inhibit pallidum, thus initiating a behavior through a disinhibitory mechanism. Cortex also exerts excitatory influence on striatum to initiate an appropriate behavior. Also illustrated are midbrain dopaminergic (DA) neurons that exert a modulatory influence to striatum to promote expression of specific behaviors. Reproduced from Grillner S (2006) Biological pattern generation: The cellular and computational logic of networks in motion. *Neuron* 52: 751–766, with permission from Elsevier.

control), represent another type of specialization in which the cortical neurons play a larger role in direct control of these behaviors, although spinal/brain stem interneurons may still play a role.

Summary

This article presented an overview of the command concept in the context of neural architecture underlying behavior, which may be a useful vantage point for understanding network functions in both invertebrate and vertebrate motor systems. With regard to sensorimotor transformations, the command systems lie between neural elements responsible for sensory processing and motor execution, and they function as decision makers and serve other higher order functions by transforming sensory information into signals that activate and modulate CPG networks for an appropriate behavior. In particular, command systems that comprise only dedicated command neurons are rare. More commonly, command systems are composed of a population of neurons that can be differentiated based on their morphology, synaptic inputs and outputs, transmitter phenotype, etc. Some may play a role in driving the CPG, whereas others may play a role in modulating the CPG.

These interneurons function based on the principle of 'division of labor' commonly observed in evolved systems, such as biological and social systems. A major theme of current and future research, therefore, is to delineate the functional roles of these heterogeneous neural components in the command systems, in particular, and any neural system in general. In this regard, the advantage to directly link a neuron or a neuronal population to their functional roles in a behavior in invertebrate model systems is and will remain essential. Furthermore, developments and improvements in techniques in both invertebrates and vertebrates (e.g., use of genetic organisms, computational approaches, and recording of neural populations) promise to provide a more integrative understanding of how animals make behavioral decisions and how the behavioral sequences are mediated.

Communication in Frogs and Toads

M J Ryan, University of Texas, Austin, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Anurans, commonly known as frogs and toads, are among the most vociferous of animals. Their nocturnal cacophony characterizes many landscapes and seasons, such as vernal ponds in the temperate-zone spring and rainforests in the neotropical wet season. This serenade is an annual mating ritual. Males broadcast long-distance calls to attract females and repel other males, and females use these calls to choose mates.

Anuran sexual communication has emerged as an especially tractable system for integrative studies of brain, behavior, and evolution. There are about 5000 species of frogs, and the long-distance mating or advertisement calls is their most obvious signal. A caveat, however, should be implicit throughout this account. Anurans encompass incredible diversity in communication, and this article merely describes some of the more common themes in the manner in which these animals acoustically communicate with each other.

Frogs have a variety of calls that communicate different types of information. These include long-distance mating or advertisement calls, territorial calls, aggressive calls, encounter calls, distress calls, release calls, short-distance courtship calls, and rain calls. Not all species produce all these call types, and most have a rather modest repertoire. One glaring exception, however, is *Boophis madagascariensis* (Rhacophoridae), a frog found in the forests of eastern Madagascar. Call notes produced by these males have been classified into 28 types (Figure 1), the largest known call repertoire of any anuran, although little is known of the function of these call types.

Most studies of anuran communication concentrate on one call in the frog's repertoire, the mating call, which mediates social interactions during mate attraction. Because the mating call figures so strongly in female mate choice, this dyadic interaction is critical in ensuring successful reproduction; furthermore, it can drive speciation between populations by promoting mate recognition of only local populations, and female preferences among appropriate mates can cause the evolution of increasingly elaborate signals through the action of sexual selection.

Origin and Mechanisms of Sound Production

Modern frogs produce sound by expelling air from the lungs through the larynx. The larynx sits on a ring of cricoid cartilages on the hyoid plate. It consists of two arytenoid cartilages that close on the top of the larynx and which, inside, support a pair of vocal folds, one extending across the interior of each arytenoid cartilage (Figure 2). As air passes through the lungs, it vibrates the vocal folds, and it is this vibration that brings about the pressure fluctuations that are perceived as sound. The mass and tension of the vocal folds are primarily responsible for the spectral properties of the emitted sound. In some species such as the túngara frog, *Physalaemus pustulosus*, masses can be added to the vocal cord to decrease its fundamental frequency of vibration (Figure 2). The opening and closing of the arytenoid cartilages can shape the waveform of the sound.

The frog's larynx opens into the floor of the mouth. In many frogs, there are vocal slits in the mouth that open into a vocal sac that expands as the call is produced. The vocal sac is usually quite thin and enhances the coupling of the sound to the environment. The vocal sac seems not to be a cavity resonator; in *Pseudacris crucifer* and *Physalaemus pustulosus*, the dominant frequency of the call does not change when males call in a helium–oxygen mixture (as it would if it were a resonator, since frequency is the speed of sound divided by wavelength, and the speed of sound varies with medium density while the emphasized wavelength of a resonator remains constant). In an unusual case of sound coupling, the large external tympanic membrane of the male bullfrog couples sound to the environment. Thus these frogs call as well as hear through their ears. Frogs can also make use of the external environment to enhance signal coupling. A treefrog in Malaysia, *Metaphrynella sundana*, for example, calls in tree holes and varies the call's dominant frequency to match the hole's resonance.

Vocal sacs can be quite varied in appearance (Figure 3) and have other functions besides acoustic coupling. Air is recycled between the vocal sac and the lungs; thus buccal pumping is not required to inflate the lungs after each call. This saves energy, in *P. pustulosus* at least, and allows males to call at a faster rate, which is more attractive to females. A male frog's large pulsating vocal sac can also serve as a visual cue. In both *Hyla squirella* and *P. pustulosus*, the vocal sac is a visual cue that further increases the attractiveness of the acoustic cue to the female.

Figure 1 Waveforms and sound spectrograms of representative call notes produced by males of *Boophis madagascariensis*: a, toc note; b, short click note; c, short rip note; d, loud click note; e, tone-like note with a fundamental frequency of 670 Hz; f, long rip note; g, creak note; h ± p, iambic (I) notes with increasing numbers of pulses: (h) I2, (i) I3, (j) I4, (k) I5, (l) I6, (m) I7, (n) I8, (o) I9, (p) I23. Except for I21, all notes from I10 to I22 were also produced, but are not illustrated. Analysis filter bandwidth: a and b: 300 Hz; c and d: 150 Hz; all other spectrograms: 59 Hz. Ambient recording temperatures were in the 18–22 °C range. Timescale for sound spectrograms a ± e has been magnified to provide increased temporal resolution. Reproduced from Narins PM, Lewis ER, and McClelland BE (2000) Hyper-extended call note repertoire of the endemic Madagascar treefrog *Boophis madagascariensis* (Rhacophoridae). *Journal of Zoology (London)* 250: 283–298, with permission from Blackwell Publishing.

Receivers

In frogs, more so than in most other animals, the neural properties of the receiver are inextricably linked to sexual communication. This is most clearly illustrated by Capranica's matched-filter hypothesis, which suggests that among species, the tuning of two auditory end organs matches the distribution of spectral energy in the mating call.

The Auditory System

Most research has concentrated on how the frog's auditory system decodes the mating call. But frogs do attend to other sounds. Reed frogs (*Hyperolius nitidulus*) in Africa can hear the roar of fire rolling across savanna, and they respond by jumping into the water. But there is little doubt that the hearing of frogs has primarily evolved to enhance sexual communication.

All anurans have two inner ear organs, the amphibian papilla (AP) and the basilar papilla (BP), that are sensitive to airborne sound. Furthermore, the saccule is sensitive to surface vibrations. In some frogs, such as the white-lipped frog, *Leptodactylus albilabris*, the surface vibrations that result from the vocal sac's striking the ground are perceived by the receiver as a salient part of the vocal display.

Tympanic membrane and middle ear Frogs lack pinnae. Some frogs, such as some members of the genus *Atelopus*, lack both external ears and middle ears, even though these frogs clearly communicate acoustically.

Reproduced from Gridi-Papp M, Rand AS, and Ryan MJ (2006) Complex call production in túngara frogs. *Nature* 441: 38, with permission.

Figure 3 A sample of the diversity of vocal sacs of frogs. Clockwise from top left: African reed frog (*Hyperolius bayoni*), from www.exploratorium.edu/frogs/mainstory/hbayoni.html; Amazonian arboreal frog (*Phrynohyas coriacea*), from Hofrichter R (ed.) (2000) *Encyclopedia of Amphibians* (p.162). Toronto, Canada: Key Porter Books; squirrel treefrog (*Hyla squirella*), American toad (*Bufo americanus*), and carpenter frog (*Rana virgatipes*), all from www.naturesound.com.

In most frogs, however, there is a tympanic membrane on the outside of the head and a collumella in the middle ear, which transduces outer ear vibrations to the oval window of the inner ear. This vibration causes disturbance of the inner ear fluid, which in turn causes movements of membranes in both the AP and BP.

Inner ear Both the AP and BP are involved in sound detection, but the details of these structures are quite different. The AP has about 1000–1500 hair cells in the bullfrog, *Rana catesbeiana*, and its membrane is tonotopically organized. The AP is most sensitive to lower frequencies, from a few hundred Hz

to about 1500 Hz. The AP usually has two peaks of frequency sensitivity. In the bullfrog, for example, there is a lower peak of about 100–200 Hz and a mid-frequency peak of about 500–600 Hz. Neurons most sensitive to the lower-frequency peak exhibit two-tone suppression, but this is not true of the mid-frequency peak. The BP, by comparison, has fewer hair cells, 60–90 in the bullfrog, and is not tonotopically organized. The hair cells in the BP tend to be most sensitive to the same frequency, about 1400–1500 Hz in bullfrogs.

The tuning of the AP and BP of a species tends to coincide with the frequency peaks in its mating call. In frogs that call in a narrow frequency range, there is a match between the tuning of either the AP or the BP and call frequency, whereas in frogs that call over a wider frequency range, the tuning of both end organs match frequency peaks in the call. A recent review of these data showed that species variation in the carrier frequency of calls explains 82% of the variation in the tuning of the inner ears organs (Figure 4).

At least one species of frog, the concave-eared torrent frog (*Amolops tormotus*), uses ultrasonics in communication. This Chinese frog calls near rushing streams, and the ultrasonics are above most of the spectral energy in the background noise. There is

Figure 4 Scatter diagram of the spectral peaks of the advertisement calls of 24 anurans (plus three populations of one species) versus estimates of the best excitatory frequency of the peripheral auditory system. Green circles represent data in which closed-field stimulation was used in the neurophysiological recordings, and gray symbols show data in which free-field stimulation was used. Squares represent low frequencies attributed to the amphibian papilla (AP), and circles represent sensitivities attributed to the basilar papilla (BP). The white and gray backgrounds estimate the range of frequency sensitivities of the AP and BP, respectively. Modified from figure 7.1 of Gerhardt HC and Schwartz JJ (2001) Auditory tuning and frequency preferences in anurans. In: Ryan MJ (ed.) *Anuran Communication*, pp. 73–85. Washington, DC: Smithsonian Institution Press.

some behavioral evidence to suggest that the ultrasonics influence the male's calling behavior, and neurophysiological studies of evoked potentials show clearly that the frogs can hear these sounds.

Central Processing

Much of the integration of acoustic information from the two inner ear organs takes place in the torus semicircularus, a large auditory nucleus in the midbrain homologous to the mammalian inferior colliculus. Electrophysiological studies show more complex processing in the torus than in the inferior colliculus: Some cells respond to simple stimuli such as tones, whereas others respond only to specific combinations of sounds such as those found in the species' mating call. Studies using electrophysiology and immediate early gene (IEG) expression have mapped spatial variation in auditory activity in the torus in response to call variation and found evidence for parallel processing of different aspects of acoustic stimuli. In túngara frogs, combining IEG expression measures throughout the torus provides sufficient information to discriminate between conspecific and heterospecific calls as well as between simple and complex conspecific calls.

Further acoustic processing takes place in thalamic auditory nuclei. As with the torus, parallel processing occurs here. Lesioning studies in gray treefrogs show that female phonotaxis requires a functioning torus semicircularis but not dorsal thalamus. Dorsal thalamic nuclei might function in motivation or attention relative to phonotactic readiness.

Thalamic and midbrain auditory nuclei have anatomical projections to various forebrain regions that receive inputs from multiple sensory modalities. Electrophysiological and metabolic measures have found acoustic responsiveness in auditory system targets in the hypothalamus and telencephalon. In the túngara frog, IEG analyses have also shown that correlated patterns of neural activity within the hypothalamus vary with signal salience. Lesioning dopaminergic cells in the green treefrog, *Hyla cinerea*, impaired phonotaxis behavior, and the residual phonotaxis behavior correlated with the number of surviving dopamine cells in one region of the hypothalamus. These IEG and lesioning studies suggest the existence of social neural networks that integrate auditory and motivation information and influence the motor outputs that constitute phonotaxis.

Behavior and Evolution

Other Modes and Multimodal Communication

Frogs communicate in modalities besides the auditory one. Tadpole social behavior, for example, is strongly

Figure 5 Visual signaling in *Phrynobatrachus kreftii*. Female (above left) and male without vocal sac expansion (above right), with partly expanded vocal sac (below right), and with fully expanded vocal sac (below left). Note the bright yellow subgular region of the male. Photograph by Walter Hödl at Zigi River (Amani Nature Reserve), Tanzania. From figure 1 of Hirshmann W and Hödl W (2006) Visual signaling in *Phyrnobatrachus krefftii* Boulenger, 1909 (Anura: Ranidae). *Herpetologica* 62: 18–27.

influenced by olfactory cues. In aggregations of tadpoles of the American toad, *Bufo americanus*, siblings are more likely to be found in proximity to one another than to nonsiblings. These and many species of tadpoles can discriminate sib from nonsib and paternal half-sib from sib using odor cues that become incorporated into the jelly matrix of the nest.

Visual cues are important in sexual communication in many diurnal frogs, such as the poison frogs of the family Dendrobatidae. *Dendrobates pumilio* on different islands in the Bocas del Toro region of Panama show striking differences in color pattern, and females' preference for local males is strongly influenced by visual cues. Other diurnal frogs, such as *Hylodes* and *Atelopus zeteki*, have dynamic visual displays, waving their limbs at other frogs in a stereotyped pattern. Both frogs live near rushing streams, where the background noise might not be conducive to acoustic communication when rain is abundant.

The vocal sac can also serve as a visual cue. Male poison frogs, *Epipedobates femoralis*, attack models with pulsating vocal sacs. In a diurnal frog from Tanzania, *Phrynobatrachus krefftii*, males silently inflate their bright yellow vocal sacs as a visual signal (Figure 5). The vocal sac can also contribute to multimodal communication.

Male Calling

Most frogs form choruses to vocally advertise for females. As choruses are associated with reproduction, there are seasonal patterns; choruses form in the breeding season but not out of it. There are also diurnal patterns. Most frogs call at night, but some, perhaps most notably poison frogs, call during the day. There are also diel patterns as most frogs do not call from dusk to dawn. In the El Verde forest of Puerto Rico, which is rich in frogs of the genus *Eleutherodactylus*, there is acoustic partitioning of frequencies within choruses, but when call frequencies are similar between sympatric species of *Eleutherodactylus*, they call at different times at night.

Temporal patterning also occurs at a finer scale. Only a few species of frogs, such as the neotropical *Smilisca sila*, synchronize their calling. In this case, synchronization makes the frogs less susceptible to predation by the frog-eating bat *Trachops cirrhosus*. Most frogs, however, alternate calls. Call alternation usually occurs within a small neighborhood, and thus, the summed acoustic output of an entire chorus can lack any easily discernible structure. Some of the best studies of these types of interactions have been conducted with the neotropical treefrogs *Hyla microcephala*, *H. phlebodes*, and *H. ebraccata*. Males of these species adjust their patterns of calling to avoid overlap of calls with conspecifics as well as similar-sounding congenerics. Males of both *Eleutherodactylus coqui* and *Hyperolius broadleyi* have especially impressive abilities to produce calls in gaps between the calls of other males.

In many species of chorusing frogs, nonrandom spacing of calling males occurs whether or not males defend territories such as oviposition sites. In some species, such as the neotropical *Eleutherodactylus diastema* and the North American spring peeper,

Pseudacris crucifer, the amplitude of the nearest neighbor's call, rather than the neighbor's physical distance, appears to be more important in determining nearest-neighbor distances.

Mate Recognition

One of the most important decisions an animal can make is with whom to mate. This single act can ensure reproduction between individuals and the persistence of a genetic lineage. The mating call is the dominant cue used by males to advertise their presence and identity to females, and females attend carefully to call attributes when choosing a mate. There is variation in mating calls among species, populations, and males within populations. Much of this signal variation is salient to a female and influences her choice of mates.

Species recognition Species recognition occurs when individuals recognize and prefer members of their own species as mates over members of other species. As noted above, the frog's auditory system is biased toward perceiving and responding to calls of their own species in preference to calls of other species. This functional correlation between sender and receiver predicts that females should be able to discriminate easily among calls in favor of conspecifics. Phonotaxis experiments with numerous species have shown this to be the case. In addition, a number of studies have used synthetic calls and systematically deconstructed them to demonstrate the features salient to females. Two main points have emerged. Not all the acoustic detail is salient, and different species rely on different constellations of call parameters for call recognition. An especially interesting example is mate discrimination between two treefrogs *Hyla cinerea* and *H. gratiosa*. These species co-occur throughout much of their range, and when they do so, their calls are more similar to one another than they are to any of the other local species. Females from each species are able to discriminate between the two calls, but they do so differently. *H. cinerea* uses spectral cues to make the discrimination whereas *H. gratiosa* attends mostly to temporal features.

If there is strong selection on females to mate with conspecific males rather than heterospecific ones, then the constellation of species at the breeding site should influence aspects of one another's communication system. This phenomenon is known as reproductive character displacement, and its occurrence has been perhaps best demonstrated by studies of frogs. These studies usually compare signal variation of two species in areas in which they do not co-occur (allopatry) and in areas where they do co-occur (sympatry). Reproductive character displacement predicts that calls of the two species evolve to be more different in sympatry. This is the case in two species of chorus frogs in Florida, *Pseudacris nigrita* and *P. ferriarum*. Their calls are a series of pulses, and the pulse rate is known to be important in mate recognition. In the area of sympatry, *P. ferriarum* has a faster pulse rate compared with allopatry, about 30 pulses s^{-1} compared with 20 pulses s^{-1}. This faster rate enhances the difference between *P. ferriarum* and *P. nigrita*, whose rate is about 20 pulses s^{-1} whether these frogs are sympatric or allopatric with *P. nigrita*. A similar situation occurs in the Australian frogs *Litoria ewingii* and *L. verreauxii* (Figure 6). Their pulse rates are similar in allopatry. But the calls of each species differ between sympatry and allopatry. Specifically, in sympatry the *L. ewingi* call is slower (68 versus 73 pulses s^{-1}) and the call of *L. verreauxii* is much faster (138 vs. 84 pulses s^{-1}). In phonotaxis experiments, the species can distinguish each other's calls in sympatry, but *L. ewingii* in sympatry cannot distinguish its call from the similar calls of *L. verauxii* in allopatry. Thus not only have the calls of the two species diverged in sympatry, but these differences are salient to the receiver, and if the calls had not diverged in sympatry, there would be breakdown of species recognition.

Most studies of reproductive character displacement have concentrated on evolutionary changes in the signal rather than the receiver, but the receiver can also respond to selection to better avoid calls of sympatric heterospecifics. There are two species of gray treefrogs, *Hyla chrysoscelis* and *H. versicolor*, that are indistinguishable morphologically but differ in chromosome number (diploid and tetraploid) and the pulse pattern of their call (short pulses and long pulses). *H. chrysoscelis* is usually allopatric with

Figure 6 The geographic distributions of *Litoria ewingii* (L. e.) and *L. verreauxi* (L. v.) and the waveforms of their advertisement calls. The two species are sympatric in the crosshatched area. Modified from Halliday T (1980) *Sexual Strategy* (p. 74). Chicago: University of Chicago Press.

H. versicolor, and females prefer the longer-pulsed calls produced by their males. When they are sympatric with *H. versicolor*, however, such a preference could increase their chances of mating with the wrong species. In sympatry, this preference for longer-pulsed calls among conspecific males by *H. chrysoscelis* is significantly reduced.

Sexual selection Sexual selection by female choice occurs when female mating preference results in some males in the population having greater reproductive success than others. The most thorough studies in frogs show that (1) there is female choice of mates, (2) there is substantial variation in male mating success as a function of some aspects of the male's phenotype, (3) there is a correlation between this aspect of the male's phenotype and some aspect of his call, and, (4) those aspects of the call make the male more attractive to females in phonotaxis experiments. As an example, larger male túngara frogs in the wild have greater mating success than smaller ones do, larger males have lower-frequency calls because they have a larger larynx, and in phonotaxis experiments, females are more attracted to synthetic calls with lower frequencies than to those with higher frequencies.

Females of species in addition to túngara frogs prefer lower-frequency calls. Even more species prefer calls with faster pulse rates. A general theme is that females prefer more acoustic energy. They often tend to prefer faster calls, longer calls, higher-amplitude calls, and calls that stimulate one rather than two peripheral end organs. A recurrent question ever since Darwin is why females prefer some males over others. One hypothesis is that females should choose males who provide an immediate and direct benefit in reproductive success. There is good evidence for this in frogs. In some cases, females prefer males that increase the number of offspring sired. In bullfrogs, larger males have territories that afford the eggs more protection from leech predation. In other cases, females prefer larger males because they fertilize more eggs. This is not because of differences in sperm supply, however, but because there is mechanically a better match of the male's and female's gononpores during external fertilization. The better the match, the more the sperm come into contact with the eggs. Females of some species, such as túngara frogs, accrue this advantage in fertilization success through a simple preference for larger males, while others, such as the Australian frog *Uperoleia rugosa*, choose males who are not only larger than average but of a specific size relative to the female's own size.

Another hypothesis for the evolution of female choice is based on indirect benefits: Females should choose males whose genotypes are superior for survival. In one study, male gray treefrogs that made energetically more expensive calls were preferred by females, and half-sib breeding experiments have shown that tadpoles of these males metamorphose faster and at larger size. This effect, however, is exhibited only under certain ecological conditions. The call, in this case, seems to advertise genetic variation for at least some components of survival. Another type of genetically based choice is to shun matings with genetically similar males to avoid inbreeding. In American toads, information about male relatedness is encoded in the calls, and females prefer calls of less-related males. An analogous study in túngara frogs, however, showed no such an effect.

A more recent hypothesis to explain female mate choice is sensory exploitation. As mentioned above, the response properties of the female's auditory system are biased toward acoustic parameters of the species' mating call. Males are under selection to make their calls more attractive to females, and one way to accomplish this is to evolve calls with acoustic parameters that exploit the females' sensory, neural, and cognitive biases. In túngara frogs, males always produce a whine whose dominant frequency matches the best excitatory frequency of the AP, and males can add up to seven secondary components or chucks that stimulate the best excitatory frequency of the BP. Males add chucks to their calls when they vocally compete with one another. Simple calls, whines only, are both necessary and sufficient to attract females and elicit calling from other males. The chuck by itself is not salient to either sex, but the addition of chucks to a whine makes the whine more attractive to females and elicits more calling from males. There seems to be nothing special about the chuck except that it stimulates the female's auditory system. Other sounds, such as noise, tones, bells, and whistles, increase the whine's attractiveness to the same degree as a chuck.

Closely related species that do not produce a chuck have the same BP tuning, so it seems clear that the chuck and its dominant frequency evolved in túngara frogs to stimulate the tuning of the inner ear organ that already existed. In addition, in some of these closely related species without chucks, females prefer the calls of their own species to which the chuck of a túngara frog is added. As this short review of female choice shows, there are a number of different scenarios that can favor the evolution of female choice among conspecifics, and these forces could act in concert.

Eavesdroppers on Frog Communication by Predators

When animals communicate, there is, at minimum, a sender and an intended receiver. But other animals

Figure 7 The frog-eating bat *Trachops cirrhosus* capturing a calling male túngara frog. Photo by Merlin Tuttle, Bat Conservation International.

might be listening to exploit the communication system. These other animals are called eavesdroppers. They are especially common in sexual communication systems in which long-distance signals are loud and conspicuous.

The best known eavesdropper on frog calls is the frog-eating bat *Trachops cirrhosus* (Figure 7). These bats feed on frogs, and in Panama they are especially fond of túngara frogs. These bats are especially sensitive to the relatively low-frequency sounds in frog calls, and they use the calls to localize the male. Like female túngara frogs, these bats are attracted to simple, whine-only calls, and also like female túngara frogs, they are more attracted to whines with chucks than to whines alone. A group of flies in the genus *Corethrella* shows analogous reactions to túngara frog calls. These flies take a blood meal from frogs; they use the frog's call for localization; and although the flies can locate males producing simple calls, they are preferentially attracted to complex calls. These cases of eavesdropping illustrate nicely the conflict often seen in communication systems between sexual and natural selection. The former favors males that make conspicuous signals that are more attractive to females, but these more attractive calls are simultaneously selected against because of their low survival probabilities.

Communication in Terrestrial Animals

Introduction

Research on vocal communication in terrestrial mammals had until recently lagged behind work on birds and anurans (frogs and toads), perhaps because of the greater difficulty of recording, analyzing, and playing back acoustically more complex signals to animals that are usually free-ranging and difficult to confine for experimental purposes. One exception is the nonhuman primates, which have received intense scrutiny because of their shared ancestry with humans. Although primates can be classified as terrestrial mammals, we do not attempt to comprehensively cover research on this group here but, rather, focus on other terrestrial mammals, where advances in research techniques (enabled by the revolution in digital technology) are beginning to yield interesting results. Research on these mammals integrates study at several levels of investigation, including the functional anatomy of the vocal apparatus, the acoustic structure of the calls, the context of their emission, and their relationship and coevolution with the social structures and reproductive strategies of the animals that give them. As a consequence, research in this area uses a range of methods and tools, including anatomical investigation, sound analyses, and resynthesis and playback experiments. Although mammalian vocal communication is qualitatively different from human speech, humans are also mammals and our mechanisms of vocal production are largely shared. This means that a common framework for understanding the structure and evolution of mammal vocalizations already exists – the source–filter theory of voice production. The realization that this is the case has led to major advances in our scientific understanding of terrestrial mammal calls.

How Mammal Calls Are Produced

The Source and the Filter

In most terrestrial mammals, a vocalization is the product of a source signal, generated by vibration of the vocal folds in the larynx, that is subsequently filtered in the cavities of the vocal tract. This source signal is typically a periodical wave with a fundamental frequency and harmonic overtones that are integer multiples of it (Figure 1). The fundamental frequency (F_0), sometimes called the glottal pulse rate, is determined by the rate of vibration of the vocal folds and is responsible for the pitch of the vocalization: the higher the rate of vibration, the higher pitched the vocalization is perceived to be. However, after being generated at the larynx, the source signal must pass through the cavities of the vocal tract before radiating out through the mouth and nostrils into the environment. During this process, the vocal tract acts as a tube of air with natural resonances and selectively amplifies certain frequencies in the source spectrum. This filtering process shapes the spectral envelope of the signal, producing peaks called 'formants.' The perceptual correlate of formant frequencies is more difficult to characterize, but it is often referred to as the timbre of the vocalization.

One of the important consequences of the source–filter theory of vocal production is that characteristics of vocalizations that arise from inherent properties of the filter can vary independently from those that arise from the source, and either or both may provide receivers with important information. In particular, two key sender characteristics are likely to be coded in mammal calls: information on individual identity, which in large terrestrial mammals usually results from random variation in the shape of the vocal apparatus or the way in which it is operated by individuals, and information on fitness (including size, condition, and age), usually a consequence of physical or physiological constraints that affect the range of variation of acoustic features or the rate of calling.

In principle, pitch should be inversely related to the length and mass of the vocal folds: therefore, smaller animals generally produce higher calls. However, although this is broadly the case across species (mice have higher pitched calls than elephants), empirical data show that within species, pitch is a relatively poor indicator of sender physical attributes, mostly reflecting large-scale, age-related variation (in most species the calls of juvenile individuals are higher pitched than those of adult females, which are in turn higher than those of adult males). However, pitch does not accurately reflect finer scale differences between individuals of the same age/sex classes. In contrast, pitch varies within individuals, and its range, variation, and quality are likely to convey information on motivational state. For example, it is predicted that pitch should rise with increasing levels of fear and stress since vocal folds are likely to become stiffer in more tense animals. Another characteristic of the source that may convey information on motivational state is its periodicity. Many mammalian calls are characterized by a lack of periodicity, caused by irregular vibration of the vocal folds, which confers a harsh quality on the

Figure 1 Waveforms and spectrogram of a common roar from a red deer stag showing the key acoustic features. Common roars are complex calls with modulated source (fundamental frequency) and filter (formants). The narrow, evenly spaced frequency bands rising in the first half of the roar and decreasing toward the end represent the fundamental frequency and harmonics. The vocal tract resonances, or formants, are represented by the darker, less regularly spaced energy bands (F_1–F_8) that decrease during calling as the stag lengthens his vocal tract. Harmonics and formants move independently due to source–filter independence.

resulting vocalizations. This quality tends to be associated with cries indicative of pain (e.g., distress calls) or intensely aggressive vocalizations (e.g., harsh roars in red deer).

Variation in the shape of the vocal tract affects the position of the formants relative to one another and contributes to the individual quality of different voices, as studies of deer (e.g., reindeer, fallow deer, and red deer) and some primate species have shown. More important, there is a direct inverse relationship between the length of the vocal tract and the spacing of formants that results in the presence of size-related information in the calls of many mammalian species (e.g., primates, canids, and deer). Both between and within species, the larger the animal, the lower its resonance frequencies, and consequently the closer the spacing of these resonances (formants) in the frequency domain.

Finally, physiological costs associated with the production of sequences of calls are likely to limit the rate at which individuals can call, and this characteristic potentially provides receivers with an honest indication of the physical condition of the caller, as has been shown in red deer.

The ability of individuals to determine each other's identity, physical status, or internal state from vocalizations dramatically increases the level of functionally relevant information that can be exchanged. Whereas in some cases identity may be inferred from the location of the caller or by using visual or olfactory signals, acoustic cues are likely to be of primary importance when individuals range widely. Such cues can provide receivers with instantaneous information on the location and attributes of the caller and may represent the only effective signaling modality in nocturnal or forest-dwelling species. There is a considerable body of evidence indicating that the vocalizations of terrestrial mammals contain information on the identity and physical attributes of the caller.

Contexts in Which Terrestrial Mammals Call

Intraspecific

Social communication Functionally, vocal communication underlies and facilitates social behavior in terrestrial mammals, allowing individuals to stay in contact with others in their own group (including offsprings) even when widely separated, to defend territories, to interact with others of differing rank without constantly getting into costly fights, and to communicate about certain external events. Individual differences in vocalizations, arising from variation in source and filter characteristics, encode individual identity in a range of large mammals, enabling the social recognition that is at the basis of more complex social behavior. Differences in the fundamental frequency contour have been identified as important in broadcasting information on identity in wolves and elephants, whereas individuality in formant frequencies has been demonstrated in fallow deer, roe deer, red deer, elephants, and rhesus macaques.

In order to study vocal recognition, researchers use playback experiments in which vocalizations from specific individuals are recorded and broadcast back to receivers through a loudspeaker. For example, playback experiments have been used to assess whether animals can discriminate the calls of particular close associates (e.g., mother or offspring) from those of other individuals. Such studies have shown that mother–young recognition can be at least partially mediated by voice cues in a range of species (pinnipeds, sheep, deer, bats, and primates) and that vocal recognition occurs between adult individuals in, for example, red deer, red squirrels, African elephants, and several nonhuman primates. In certain species, the number of individuals that listeners can discriminate by voice can be quite large: playback experiments have demonstrated that female elephants are familiar with the calls of approximately 100 others

in the population and social recognition is possible over distances of up to 2.5 km. Memory for the calls of social companions can also persist for very long periods. For example, there is evidence that fur seals and African elephants can still recognize the calls of particular individuals months and sometimes years after these individuals have separated from them.

Calling and territoriality There is abundant evidence that terrestrial mammals use loud calls to advertise ownership of a territory and defend it against rivals in the vicinity. Territorial defense may be carried out by single individuals calling alone (e.g., a male roe deer barking to delineate a breeding territory) or by groups of individuals (often relatives) cooperating to defend a joint territory or range (e.g., howler monkeys). In the latter case, individuals call in chorus, engaging in vocal battles with neighboring groups that involve howling back and forth. Howling in wolves is used in a similar manner, but empirical evidence suggests that calling serves an intergroup spacing function rather than explicitly representing a territorial advertisement. Much of the work on wolves has been conducted using human simulations of wolf howling (rather than playback) to elicit replies from the study animals. Where playbacks were conducted, wolves called back at the loudspeaker and gave lower pitched howls as they got closer. This could suggest that wolves vocalize with a lower pitch as they get closer to ritualistically advertise a stronger motivation to attack, although the lower pitch could also simply be a by-product of softer calling when the wolves perceive their attacker to be close.

Vocalizations used in territorial defense can be quite complex. Gibbons deliver their territorial vocalizations in songs that are highly structured, and these appear to function in intrasexual competition, with the complexity of songs increasing as the interaction proceeds and more complex songs eliciting faster approaches to playback. This is supported by comparative evidence indicating that singing performance in males is also reduced when energy reserves are limited.

Finally, when groups of individuals cooperate to defend shared resources such as territories and young (e.g., lions and many nonhuman primates), the number of individuals per group can often be more important than interindividual differences in determining the outcome of a contest. Assessment of resource-holding potential would be expected to vary accordingly, and playback experiments on lions, chimpanzees, and black howler monkeys have demonstrated that groups assess one another on the basis of relative group size, with vocalizations providing an important cue to this.

Communication within the social group We have focused on examining communication between groups; however, communication also plays a key role in coordinating activities within groups, with the ability to discriminate the calls of group members from those of other individuals obviously providing the crucial basis for this. Among large terrestrial mammals, female lions have been shown to use roaring to recruit members of their own pride if some individuals are absent when simulated intruders' roaring is played to them. In some species, there is evidence that during within-group communication, callers may direct their calls at specific individuals. Thus, male chimpanzees have been observed to pant-hoot more when particular allies are nearby than when they are absent, and in African elephants affiliated females preferentially respond to each other's rumbles and often call in sequence when approached by dominant individuals. Specific vocal signals between dominants and subordinates within stable social groups also play a key role in allowing individuals of different ranks to interact with minimal aggression and in reconciling opponents after fights. Moreover, within the social group, mammals also use vocalizations to signal to one another about certain external events (e.g., predators, food, and social events). These calls can be functionally referential (denoting objects or events external to the caller) as well as emotional (reflecting the internal state or subsequent behavior of the caller).

Sexual Communication

In addition to their social function, mammal vocalizations are also crucial to sexual behavior, influencing the outcome of contests between males as they compete for females, affecting mate attraction and patterns of mate choice, and sometimes directly influencing reproductive physiology.

Loud calls and sexual behavior Many large mammals have evolved loud calls specific to the reproductive season that function to attract individuals of the opposite sex and advertise resource-holding potential to competitors in the vicinity. These calls are often very conspicuous and seem specifically adapted for attracting the attention of a wide audience. The loud reproductive calls of polygynous deer, which typically serve several functions, provide some of the best examples.

Calling rate and male–male contests A long-term study of a free-ranging population of red deer on the Island of Rum identified roaring rate as an assessment cue that determines the outcome of roaring contests

between red deer stags. When one red deer stag is challenging another for the possession of a harem, he typically approaches his opponent and the two start to exchange roars directly. After this roaring conversation, the stags may or may not escalate to either a parallel walk, in which they parade tensely up and down in parallel (usually roaring as they do so), or a full-blown fight. Fights are more often preceded by roaring contests in which the challenger roars more frequently than his rival. Moreover, roaring rates in contests are well correlated with fighting ability. When roars are played back from a loudspeaker to simulate the presence of a rival stag, stags increase their roaring rate to match that of the challenger unless the challenger is roaring so fast that they are apparently unable to do so. This provides experimental evidence that stags only continue with a challenge if they can outroar their opponent. As a result of roaring contests, and the further visual and vocal assessment possible in parallel walks, relatively few challenges end in costly fights. In the closely related fallow deer, harem-holding bucks groan at higher rates in the presence of nearby vocal males, suggesting that the signal conveyed by groaning rates in this species is primarily a threat aimed at rival males. Bucks achieve their highest call rates immediately after copulating, thereby transmitting information to nearby males on their condition and motivational state. In line with the hypothesis that groaning rate acts as a signal between males, immature males decrease their rates of groaning in response to playbacks of groans from mature males, whereas mature males increase their groaning rates in this situation. Overall, these results suggest that fallow deer bucks vary their groaning rate in relation to the presence and quality of competitors, including the indirect costs of inviting contests with surrounding and potentially stronger males.

Effects of calling on females In both fallow and red deer, there is evidence that rutting calls do not function solely to mediate competition between males. In playbacks conducted under controlled conditions on deer farms, red deer females exposed to male roars during the pre-rut period conceived earlier than females who were not, providing evidence that calling can advance ovulation. Moreover, red deer roaring appears to influence mate choice decisions. Hinds are more likely to look at and move toward a speaker simulating a stag roaring at a higher rate, even at points in the roaring sequence when both are delivering the same number of roars. They even appear to prefer callers that initiate bouts of roaring. High levels of roaring activity may thus confer advantages in intersexual choice as well as intrasexual competition.

Red deer females also appear to attend to the particular roaring characteristics associated with the stag whose roars they hear most often. Hinds are able to discriminate between the roars of their current harem holder and those of other neighboring stags, in accordance with previous findings that red deer roars contain sufficient acoustic cues to identify the caller. Estrous females could benefit by choosing to mate with males that are most familiar to them (i.e., those that are able to spend more time and effort in retaining them within a harem and in roaring at them). It is thought that over the course of the breeding period, red deer hinds progressively become familiar with the vocalizations of the stag in whose harem they spend the most time. The degree of familiarity that a given female has with a particular stag's roars should result from the cumulative extent of her exposure to his roars. A combination of factors is likely to affect this, including the duration of exposure, the rate of roaring during exposure, and the loudness of the roars (harem holders' roars will be received at a higher amplitude simply because of proximity). Studies of long-term groaning rates in fallow deer also indicate that the amount of calling is correlated with reproductive success, therefore providing support for the familiarization hypothesis.

Alternative routes to honest signaling in mammal calls As discussed previously, males and females use rate of calling as an indicator of the quality or resource-holding potential of particular males. In red deer, roaring rate is believed to be an honest indicator of fighting ability (and an evolutionarily stable assessment cue) because of the direct and indirect energetic costs associated with maintaining high roaring rates. Beyond the usual costs associated with phonation, roaring involves strenuous muscular activity related to tilting the head back and retracting the larynx toward the sternum each time a roar is given. However, although roaring rate provides a reasonable indication of a stag's condition, it does not give direct information about a stag's body size – a crucial parameter in predicting the outcome of fights and a good indicator of reproductive success. Studies of the detailed acoustic structure of roars indicate that formant frequencies given when the vocal tract is fully extended are inversely related to body weight and that stags attend to these acoustic features when assessing opponents. Research on the responses of hinds to playbacks of roaring also shows that females prefer roars in which lower formants indicate larger individuals. As discussed at the beginning of the chapter, formant frequencies are inversely related to the length of the vocal tract, which in red deer is constrained by the length of the neck. This provides an example of how physical

constraints can generate honesty in mammal calls independently of any costs linked to their production.

Loud mating calls in other mammals Males from polygynous pinniped species characterized by extreme sexual dimorphism also have loud sexual advertisement calls (e.g., northern elephant seals and common seals) and calling interactions between males on land or under water may be attended to by rival males, potential mates, or both. It remains to be seen whether receivers alter their subsequent behavior on the basis of which male dominates in a calling interaction. In elephant seals, females are unusual in also producing loud calls during matings (copulation calls) that attract other males in the vicinity and indirectly result in the caller being mated by the most dominant male.

Interspecific Communication

We previously discussed the use of terrestrial mammal calls that are directed primarily at other members of the same species. There are also cases of terrestrial mammals producing calls that function in the context of interspecific interactions. One such example is that of pursuit-deterrence calls, typically given by ungulates. A study of roe deer revealed that barks, previously identified as 'alarm calls,' in fact function to elucidate the cause of disturbance. In this communication system, calls inform any predator that might be present that it has been detected. The likelihood of barking in response to a predator-like disturbance is independent of the presence of (related or unrelated) conspecifics in close vicinity, demonstrating that it is not an alarm call. In other cases, animals appear to have developed the ability to listen to the calls of predators and extract sophisticated information that enables them to adjust their defensive behavior according to the specific threat. Work on harbor seals has shown that this species has learned to actively avoid dangerous 'mammal–eating' killer whales in comparison with the local fish-eating ones that pose no threat, and that this discrimination is based on acoustic recognition.

Finally, there is a growing body of research on the impact of domestication and artificial selection on vocal communication between companion animals (particularly domestic cats and dogs) and their human keepers. Within this literature, there is plentiful evidence that vocal signals may be used by pets to specifically alter the behavior of their owners.

Communication in the Honeybee

The Life of Honeybees

Honeybees are social insects and live in colonies of up to about 70 000 individuals. There are three types of bees: workers, drones, and queens. The social cooperation in insect colonies, which is unparalleled in the animal kingdom, ensures that a large number of jobs are done. The jobs include activities as diverse as collecting food, defending the colony, building the nest, feeding larvae, cleaning cells, keeping a constant temperature in the nest, and so on. The probability that an individual does a particular job depends on its age and genetic disposition (which varies in honeybee colonies because the queen has mated with many drones), but each individual decides which job to do and for how long. Obviously, much communication among the individuals is needed in order to coordinate the work that needs to be done.

The in-nest jobs are performed by young individuals, whereas the outside tasks are performed by older bees. Visual communication is not possible inside the dark nest, where the bees have to use chemical and mechanical signals. Vision plays a role in outdoor orientation, but the spatial resolution of the eyes limits the use of visual signals. For example, the swarming bees are kept together by odor from the queen and not by vision when a swarm is flying to a new nest.

Chemical Communication

Modern instrumentation has made it possible to sample and identify small amounts of chemical substances, as well as to measure the responses of olfactory sense organs. Nevertheless, chemical communication in honeybees remains largely unexplored. About 20 pheromones have been identified, but a similar number probably remain to be discovered. The effects of the pheromones on the receiving bees vary from strong physiological responses to minor modifications of behavior.

Most pheromones are volatile, but the main queen pheromones are probably transported from bee to bee during antennal contacts. Examples of volatile pheromones are the orientation odors from the Nasonov gland (at the tip of the abdomen), which workers disperse by fanning when they attract bees to the entrance of a new nest, during swarming, and when marking a source of water (which itself is relatively odorless). Another example is the alarm odors released from the sting, which remains in the skin when mammals are stung. These substances alert the workers to danger, release the attack reaction, and guide the workers to the previously stung spot (when stung, it is therefore wise for mammals, including humans, to remove the sting as soon as possible).

The pheromones produced by the mandibular glands of queens inhibit ovary development in workers (who are females), inhibit the rearing of new queens (and thus swarming), and also seem to calm the workers in the colony and improve their cooperation. Some of these effects are also caused by the footprint pheromone from the queen's tarsal glands. A release of inhibition occurs after the death of the queen, and the workers begin to treat some young larvae as queen larvae. After some weeks without the queen, some of the workers begin to lay eggs (which develop into drones because the workers have not mated). These 'drone mothers' may produce so much queen pheromone that the doomed colony returns to almost normal behavior before the last workers die.

In passing, it should be mentioned that the sense of olfaction is located in the pore plates on the antennae. The antennae are mobile and often far apart, and bees are therefore able to detect the direction to sources of odor by comparing the responses from the two antennae.

Communication by Tactile and Vibration Signals

By observing the behavior of bees inside the hive in dark-red light, which is invisible to the bees, one finds that most bees pass each other without touching. Somehow the bees must be able to sense the presence of other bees and keep a short distance from them. Some cases of touching are known to involve communication. A very common activity is mouth-to-mouth exchange of food (trophallaxis), in which the bees touch each other with their antennae and tongues (Figure 1). The extent of food exchange in a colony can be studied by feeding a few bees radioactively marked food. Within a couple of hours the radioactivity spreads to a large fraction of the bees in the colony. The purpose of trophallaxis is not simple, because food does not always flow from bees with plenty of food to bees with very little food. The opposite also occurs. In the dorsoventral abdominal vibration (DVAV) signal (also known as the shaking signal), vibrations are often combined with touching: a worker vibrates its abdomen up and down,

Figure 1 Two bees (upper left) begging food from another bee (center). Magnification 1.6×. Photo copyright Axel Michelsen.

frequently while grasping another worker or a queen. These signals are very common, and their occurrence is temporally correlated with swarming and foraging activities.

During swarming, the colony is divided into two, and repeated swarming may result in several colonies. The process begins with the construction of queen egg cups, in which the queen deposits eggs. The queen receives an increasing number of DVAVs until the cups are sealed and then a diminishing number until she leaves the nest with about half the bees. The swarm settles not far from the nest, and the shaking workers now perform DVAVs on both queen and workers while other workers engage in house hunting. When the house hunting has been finished, the number of DVAVs received by the queen again diminishes before the swarm takes off for the new nest. The message of the DVAVs to the queen probably is "Reduce your activity." Despite a very convincing correlation between DVAVs and foraging, the message of the DVAVs to the workers is not so obvious. A peak of DVAV activity in the morning may mean "Wake up and go to work," whereas at other times, the message may be "Change your course and do something else." More research is obviously needed.

Several other signals involve vigorous body motion and in some cases also vibrations. The exit of a swarm (both from the nest and from the swarm's temporary position outdoors) is signaled by workers performing buzzing runs. The workers run very fast through the colony or swarm and increase the activity of the other workers, and just before takeoff, all the bees are on the move. During shaking dances (not to be confused with shaking signals), the workers shake their bodies from side to side and invite nearby workers to groom them. On their return to the nest, the nectar foragers transfer the nectar to food-storing bees. If the foragers are not able to find a food-storing bee, the foragers may perform tremble dances, which seem to increase the recruitment of the food-storing bees. Still other dances (jostling, spasmodic) have been described. All these dances look different to human observers, but it is not obvious how the bees distinguish them in the darkness of the nest.

The bees performing tremble dances also emit substrate-borne vibration signals, that is, body vibrations that cause bending wave vibrations in the wax comb. This requires close contact between the vibrating body and the substrate, for example, between the vibrating thorax of the bee and the comb. The most powerful bending waves are made by queens during the preparation for swarming, and these signals may travel up to 20 cm before decaying below the threshold of the receiving bees' perception. Tooting signals last some seconds and are made by the old queen during the days before she leaves with a swarm. During this time, the young queens are still confined to their queen cup cells by workers, who resist the young queens' attempts to leave the cell. The confined queens respond to the toots with quacking vibrations, which are emitted as a long series of short (about 0.1–0.2 s) vibrations separated by pauses of a similar duration. Although these signals travel as bending waves and are perceived by the bees as substrate vibrations, they can be heard by humans as airborne sound because the vibrating comb acts as a loudspeaker. Tooting may be heard meters away from a hive and tell the beekeeper that the colony is about to swarm.

The concert of tooting and quacking goes on for days. Because of the limited range of the signals, the queen is constantly walking from comb to comb through the nest. About every 10 cm, she stops and toots. It is obvious that the confined queens respond to the toots by quacking, but the primary receivers of the toots may be the workers guarding the confined queens. They perform DVAV signals on the queen cells. A large rate of DVAVs on the queen cell is correlated with a delay of emergence of the confined queen and also with the later behavior of the confined queen when she leaves the queen cell. She may either begin to toot and later leave with a new swarm (many DVAVs), or she may kill the other (still confined) queens and not swarm (few DVAVs).

Dance Language

The zoologist Karl von Frisch (Nobel laureate, 1973) is mainly known for discovering that honeybees can recruit other bees to visit a food source by performing a dance in which information on the distance and direction from the hive to the food is codified. The dance language communication about remote events is an exception to the general rule that animals tend to communicate about immediate events connected with

the actor and its surrounds. Furthermore, in the dance language, a symbolic code is used to transmit an impressive amount of information.

The dances are normally performed on the vertical wax combs in the hive. In the waggle dance, the dancer moves in a straight line (the waggle run) and circles back, alternating between a left and a right return path so that the entire dance path takes on a figure-eight shape. During the waggle run, the dancer wags her body from side to side 13–15 times per second and emits 280 Hz sounds by vibrating her wings. The angle between the direction of the waggle run and the vertical indicates the angle which the recruits should later maintain between their flight path to the food and the direction to the projection of the sun on the horizon (known as the sun's azimuth). The distance to the food is indicated by the duration of the waggle run.

A few bees (called follower bees) keep close contact with the dancer during most of the dance, and these bees may be recruited to search for the food at the position indicated in the dance. The dancer carries the odor of the flowers visited, and this information makes it easier for the followers to find the food. This is understandable since the dance does not contain any information about the shape or color of the flowers. The dance language is also used by the bees for indicating the position of resin, water, and suitable new nests (during swarming). At short distances, the presence of the food is signaled by round dances. These dances have a circular dance path but contain the same elements as the waggle dances. The average direction of the waggle run points to the direction to food, but the correlation is weak. The information is therefore not available to the follower bees in limited number of dances followed.

Karl von Frisch and his students made several other discoveries when investigating the dance language. For example, their experiments showed that bees have an internal clock, which allows the dancer and followers to compensate for the rapid changes in the sun's azimuth as the sun is moving over the sky. It was also shown that the vision of honeybees is sensitive to the plane of polarization of light. The polarization of the sky depends on the time of the day and the position of the sun. The bees can therefore use this sensory capacity for determining the position of the sun on cloudy days, provided that they can see a small patch of blue sky. It has also been found that the preferred orientation for polarized light in about 150 single eyes in the bee's composite eye forms a map of the average polarization of the sky.

For many years after the discovery of the dance language, most biologists intuitively believed that it made the bees' collection of food more efficient. Very recently, this question has been investigated in experiments in which the effects of dances with and without indication of direction were compared. One can cause the dancers to become disoriented by forcing the bees to dance on a horizontal surface in diffuse light. The results show that the direction information increases food collection when food sources are scarce, whereas it does not matter when there is plenty of food.

Several parameters of the dance vary with the distance and direction of the food, so this information is redundant. Therefore, one cannot be sure which part of the dance is perceived by the follower bees. This problem has been studied by means of manipulated dances performed by a mechanical robot deployed on the dance floor of an observation hive (Figure 2). The robot was made of brass, and the wings were simulated by a single piece of razor blade, which was vibrated by an electromagnet. A step motor rotated the model and caused it to waggle during the waggle runs. Other motors moved the model in a figure-eight path. All motors were controlled by a computer, which made it possible for the investigators to create dances that differed from the normal waggle dance.

The experiments showed that although the follower bees can obtain the specific information from the movements of the robot, live dancers are more efficient (which was not surprising!). With the computer, the investigators could manipulate dances to provide the bees with conflicting information about distance or direction. For example, the position of the waggle run in the figure eight could be shifted so that opposite directions were indicated by the waggle run and the '8.' The bees now followed the instructions given by the waggle run and ignored the information given by the dance figure. The waggle run appears

Figure 2 A mechanical robot model of a dancing honeybee during its performance of a waggle dance among the bees on the dance floor of an opened observation hive. A number of bees are facing the robot and running along with it, and some of these bees later appear at the location indicated by the robot's dance. Magnification 3×. Photo copyright Axel Michelsen.

to be the 'master parameter' for the transfer of information about both direction and distance.

The follower bees thus obtain information about distance and direction to the food mainly by 'observing' the waggle run. The follower bees can obtain the information in total darkness, so the observation does not have to include vision. Karl von Frisch suggested that the dance sounds might travel as vibrations from the dancer, through the wax comb, to the follower bees, and that the followers might touch the dancer. Some evidence supports these suggestions, but the vibrations seem to be to attract followers rather than to transmit specific information about the direction and distance to food. Studies using high-speed video have shown that follower bees have a chance of touching the dancer with one or both antennae during each waggle. The most obvious information to be obtained from touching is whether the follower bee is facing the dancer's abdomen laterally or from behind, but this information is not sufficient for perceiving the direction of the waggle run.

The problem of how the bees determine the direction of the waggle run is complicated by the waggle motion: the body of the dancer moves from side to side like a pendulum (fixed 1 mm in front of the head) 13–15 times per second. The direction of the waggle run is defined from the position of the head and the average position of the tip of the abdomen. It is difficult to imagine how this average position can be determined when the body makes such rapid lateral movements. One hypothesis focused on the finding that the complicated motion of the dancer during the waggle run gives rise to two three-dimensional fields of intense airflows, oscillating with the frequencies of waggle (13–15 Hz) and wing vibration (280 Hz), respectively. This discovery suggested a third strategy: the follower bees might keep a small distance from the dancer and estimate her dance path by means of receptor organs sensitive to such air flows. However, studies of air flows around models showed that the patterns of oscillatory air flows were much too complicated, especially lateral to the dancer, to provide the follower bees with reliable information about the direction of the waggle run.

Recent studies, in which the positions of the follower bees around the dancers were correlated with their later success in finding the food, have shown that the specific information about the location of the food is available only to the follower bees located behind the dancer, within the angle of the waggle motion. Measurements with tiny anemometers (instruments for detecting air flows) have shown that the passing of the tip of the abdomen of the waggle dancer is associated with a distinct maximum of air flow. The temporal pattern of the maxima of air flows experienced by the follower bees behind the dancer depends on the position of the follower bee relative to the direction of the waggle run. One may therefore speculate that the temporal pattern is used as a cue for calculating the direction to the food. Two mechanisms contribute to the maximum of air flow associated with the passing of the tip of the dancer's abdomen. The oscillatory waggling air flow makes a minor contribution. Most of the air flow hitting follower bees behind the dancer is generated by the vibrating wings and travels away from the dancer as a jet air flow (Figure 3). In contrast to the oscillatory air flows, in which the masses of air flow to and fro, the air in the jet flows in only one direction (away from the dancer).

The honeybee waggle dances have, until recently, been considered a very stereotyped behavior, in which the main variation was the duration and direction of the waggle run, although the duration of dancing and the tendency to vibrate the wings were known to depend on the motivation of the dancer. It is now known that the duration of the return run (between consecutive waggle runs) varies with the profitability of the food source. Furthermore, the dancers may generate two kinds of jet air flows, spatially narrow jets and broad jets, and both may be switched on and off by an adjustment of the position of the wings. A similar flexibility is found in the dance following. The patterns of following dances are related to the foraging experiences of the follower bees and to the presence, on the dance floor, of dancers announcing other targets. Finally, the patterns in which the followers move

Figure 3 A jet air flow caused by wing vibration in a model. The tip of the abdomen and of a metal wing were photographed when the wing was moving up. The air flow is visualized by means of a laser technique, and the air velocities are indicated as vectors (arrows). The largest vectors correspond to approximately 300 mm s^{-1}. Such jet air flows can also be measured (by means of hot wire probes) behind live dancers. Scale bar = 100 mm s^{-1}. Photo copyright Axel Michelsen.

with the dancer also show much flexibility. It seems fair to conclude that the dance language will keep investigators busy for many years to come.

Communication Networks and Eavesdropping in Animals

P K McGregor, Duchy College, Cornwall, UK

© 2009 Elsevier Ltd. All rights reserved.

Communication Networks

A communication network is a group of several animals within signaling and receiving range of each other. Such networks are likely to be ubiquitous because most signals travel farther than the average spacing between individuals. Indeed, a network will exist unless a signal can never be received by more than one receiver or unless a receiver can never receive more than one signal simultaneously. Communication networks can be based on signals of any modality and over any distance, from the ocean-spanning songs of the great whales to the crowded hives of social insects. Therefore, the social environment in which communication has evolved and in which signals are now produced and received is best thought of as a network.

Given such arguments, it is surprising that a network perspective has not been more widely adopted in studies of animal communication. Communication was, and in many instances still is, treated as occurring between two individuals – the signaler–receiver dyad. Notable exceptions are studies of chorusing animals, in particular insects and anuran amphibians, which have long adopted a network perspective and demonstrated the value of doing so.

While a dyad is the simplest relationship possible between the three basic components that characterize communication (the signaler, the signal, and the receiver), there are two important reasons to adopt a network, rather than a dyadic, perspective. First, there are communication behaviors that occur in a network but cannot occur in a dyad. Second, a network perspective better explains some striking signaling behaviors that are not adequately explained by a dyadic view.

Communication Behaviors Specific to Networks

A range of communication behaviors involve more than a signaler–receiver dyad. A good example is eavesdropping, and for this reason it is considered at length later in this article. Eavesdropping involves a least three individuals (signaler, intended or target receiver, and eavesdropper). The term 'bystander' is often used for individuals that are present during an interaction (including signaling interactions) but which do not take part in the interaction – therefore, eavesdroppers are an example of bystanders. The presence of bystanders can affect the nature of signaling interactions, and the effects of such an audience are another example of an aspect of communication behavior that is revealed by adopting a network perspective (and is therefore discussed more fully below).

Victory displays are signals produced by the winner (but not the loser) after an aggressive interaction and are a form of signaling that seems likely to function in a network context. Such displays were first described in waterfowl but also occur in other bird groups (parrots, penguins, divers, shrike, and a songbird), other vertebrates (including an amphibian, a reptile, and mammals), and some invertebrates (such as spiders and crickets). There is little evidence for or against a network function of victory displays, but even if such signals are directed within the winner–loser dyad, their conspicuous nature will ensure that information can travel considerably more widely.

Signaling Behavior Best Explained by Networks

There are two signaling behaviors that are commonly cited as being best explained by a network perspective: signal timing in choruses and the high level of signals used at close range. The widely broadcast nature of many signals also raises the possibility that some aspects of signaling behavior are associated with attempts to direct signals in a network.

Signal synchrony in choruses Choruses are collections of signaling individuals, from groups of several vocalizing mammals (e.g., howling wolves), through thousands of frogs in breeding aggregations, to many tens of thousands of flashing fireflies. Often there is a high degree of signal synchrony in the chorus, but such synchrony is not universal. In anuran amphibians, patterns such as call alternation, following, and overlapping have been described, as having a degree of flexibility in the pattern. Similar variation may exist in the visual waving signals of fiddler crabs. Regardless of the particular pattern of signaling in a chorus, it seems likely to result from the effect of the signals of neighboring conspecifics on the timing of signal production. The number of such influential neighbors varies and is usually only a part of the chorus. However, usually more than one neighbor influences signal timing; therefore, chorus synchrony cannot be explained adequately by considering communication as a dyad.

While several advantages of synchrony have been suggested, such as enhancing group detection or confusing predators, recent studies have focused on competition for receiver attention as the driving force behind the exact timing of signal production. Synchrony could result from individuals each trying

to ensure that their signal is the first to be detected, as females of many species prefer the leading call in a group of calls.

High level of close-range signals From a dyadic perspective, a puzzling aspect of signaling in close-range aggressive encounters is the high amplitude or level employed – human antagonists nose to nose, yet shouting at each other, for example. Such high signal levels seem unnecessary when the individuals are so close to one another. Considered from a network perspective, such high levels are more explicable – there may be more-distant intended receivers in addition to the opponent.

Most studies of parent–offspring communication have adopted a dyadic perspective. In order to do so, these studies treat groups of young being provisioned by adults (e.g., a brood of nestlings) as a unit. However, recognizing that such a system is in fact a network allows explicit consideration of features of begging such as the high amplitude of calls and the role of competition between nest mates.

Directing signals in a network The observation that many signals are widely broadcast leads to the idea of communication networks (see above). However, it is easy to imagine advantages to directing signals to particular individuals in a network in both aggressive and mate attraction contexts. Several features of signaling could achieve such targeting of one particular receiver among many. One suggestion is that songbirds match song types (also termed 'matched countersinging'), that is, they select songs from their repertoire that are most similar to those being sung by the individual to which they seek to direct signals. In many taxonomic groups, the relative timing of signals could be used in the same way, with close temporal association indicating signals directed between particular individuals.

Eavesdropping

Eavesdropping is best defined as the use of information in signals by individuals other than the primary target. It is therefore a receiving behavior that is found only in networks as it requires a minimum of three individuals: a signaler, a target receiver, and the eavesdropper. This definition encompasses most of the ways the term 'eavesdropping' has been used in the animal communication literature without obscuring interesting aspects of the behavior. Eavesdropping is also a word in everyday use in the English language, and dictionary definitions emphasize that eavesdropping refers to acoustic signals and that the behavior is carried out secretly. These two features unnecessarily restrict the use of eavesdropping as a technical term in animal communication. However, whether information gathered without the source's knowledge has particular value or salience (as it seems to have in humans) is an interesting subsidiary question.

Networks and Eavesdropping

The value of the communication network perspective does not depend solely on a demonstration of eavesdropping. While eavesdropping is a communication behavior that can occur only in a network context, there are other communication behaviors and aspects of communication that are best explained from a network perspective. The current degree of prominence of eavesdropping in the literature simply reflects the fact that it was one of the first communication network behaviors to be clearly identified as such and for which experimental paradigms were developed. There is considerable scope to develop experimental investigations of other network behaviors as well as key influences of the network environment on communication behavior.

Two Categories of Eavesdropping

There are two ways in which individuals who are not the primary target of signals can use information in those signals, that is, there are two categories of eavesdropper: interceptive and social. Interceptive eavesdroppers intercept signals intended (in an evolutionary sense) for another individual, whereas social eavesdroppers gather information by attending to the signaling interactions of other individuals. The reason for making this distinction is that the nature of information transfer differs between the two, with resulting differences in the selection pressures they impose.

The two categories of eavesdropping often differ in several other aspects. Interceptive eavesdroppers are usually different species from the signaler; there is commonly a cost of eavesdropping to the signaler; and most often, absolute information is gathered from broadcast signals. Social eavesdroppers are usually the same species as the signaler; the payoff to the signaler can be zero, negative, or positive; and both absolute and relative information can be gathered from directed signaling interactions. While such differences may be common, they are not universal, and they are not necessary or sufficient conditions for distinguishing between interceptive and social eavesdropping. Therefore, such differences do not constitute a sound basis for a working definition of eavesdropping in general or for the two categories of eavesdropping, despite the fact that they have been so used. The definitions used in this article are considerably less likely to result in exceptions or to

generate confusion and will not obscure important characteristics of this behavior.

Interceptive Eavesdropping

Some of the clearest examples of interceptive eavesdropping involve widely broadcast signals, such as the signals designed (in an evolutionary sense) to attract potential mates. Predatory interceptive eavesdroppers can locate potential prey from the prey's mate-attraction signals; an example is the bats that prey on calling male frogs. Parasites can locate potential hosts in a similar way, with parasitic flies attracted to the chemical or acoustic mate attraction signals of their hosts.

An elaboration of this basic pattern is shown by the geckos that prey on female crickets attracted by the calls of male crickets rather than preying directly on the calling males. The effect of the presence of predatory interceptive eavesdroppers is shown by the stream by stream variation in male guppy *Poecilia reticulata* courtship coloration, variation that is explained by differences in the predator guild between streams and the differing abilities of these predators to detect, and therefore intercept, guppy courtship colors.

It is also possible for prey to intercept predators' signals and thereby become aware of the presence of predators. An example is the seals that can discriminate between the calls of transient, mammal-eating killer whale *Orcinus orca* pods and those of resident, fish-eating pods.

Examples involving predator–prey and host–parasite relationships illustrate the costs interceptive eavesdroppers impose on signalers. However, there are examples in which the presence of interceptive eavesdroppers has no cost or possibly even a benefit. One instance is the tendency of individuals to respond to the alarm calls warning of an approaching predator, even if the call is given by a different species. For example, primates respond to the alarm calls of birds and ground foragers in mixed-species bird flocks in forests when these birds are alerted by 'sentinel' species in the canopy. The possible benefit of interceptive eavesdroppers reacting to the alarm call is greater confusion in which to escape. Such examples demonstrate that interceptive eavesdropping should not be defined on the basis of costs and benefits, although clearly costs and benefits are crucial to understanding evolution of the behavior.

Within a species, interceptive eavesdropping has been noted in the contexts of mate attraction and detecting the presence of predators. Signals designed to attract mates from afar have to travel widely and therefore are particularly likely to be intercepted by potential competitors for mates. For example, male fiddler crabs *Uca tangeri* wave in a distinctive fashion (high-intensity waving) when they have detected an approaching female. Experimental studies have shown that other males respond to high-intensity waving by males near them by increasing their own high-intensity waving even when they cannot see the female – such males are interceptive eavesdroppers.

We saw above that interceptive eavesdropping on signals designed to warn others of the presence of predators occurs between species. The same behavior occurs within a species. Convict cichlids *Cichlasoma nigrofasciatum* guarding their young produce a visual signal – fin flicking – to alert young to the approach of a potential predator. Parents were shown to fin-flick in response to fin-flicking models in the absence of predators. Such interceptive eavesdropping is likely to result in their young being alerted to a predator more quickly than if they relied solely on their own vigilance to detect predators. The primary targets of the signal are likely to be relatives of the signaler (i.e., the signaler's young); however, there is no obvious cost to the signaler of interceptive eavesdropping by unrelated adults.

The term 'eavesdropping' has been used in the context of autocommunication, that is, when an animal broadcasts a signal that it also receives in order to investigate the environment. Well-known examples of autocommunication are the biosonar of cetaceans, the bioradar of bats, and the use of electric impulses by electric fish. The use of information in the autocommunication of others could be considered a variant of interceptive eavesdropping: the eavesdropper intercepts a message whose intended receiver is the same individual as the signaler. For example, dolphins can identify objects from the echolocation clicks directed at the object by another dolphin. Similarly, bats can increase their foraging efficiency by paying attention to the echolocation calls of other foraging bats and using information from conspecifics to identify areas of high prey density – and in some instances, to identify suitable individuals of other bat species from which to steal captured prey.

Social Eavesdropping

The defining feature of social eavesdropping is that information is gathered from signaling interactions between others. Therefore, attempts to demonstrate social eavesdropping experimentally have concentrated on ensuring that information likely to elicit a difference in response is contained only in the interaction. A realistic simulation of the presence of a signaler can be achieved by playback of signals alone in acoustic and electric signaling modalities. Playback

can then present subjects with an eavesdropping opportunity – a simulated signaling interaction – in which potentially confounding features (e.g., the amount of song) can be held constant. Achieving a comparable degree of control with visual signals is theoretically possible with video playback but requires a degree of coherence between the perceptual abilities of the subjects and the signal output of the playback system that is yet to be achieved in nonhuman animals. There is now experimental evidence for social eavesdropping in two taxa employing different signal modalities: territorial birds interacting acoustically and fish interacting with visual signals.

Acoustic Interactions in Songbirds

Experimental investigations of social eavesdropping in songbirds have used playback to simulate the presence of rival territorial males. Often playback is interactive in the sense that details of the playback stimulus are determined by the response of the rival male song by song, achieving a realistic interaction.

The earliest experiments involved interactions between playback and a territorial neighbor of the subject. Neighbors were presented either with a more aggressive simulated intruder (signaled by overlapping songs of increasing length) or a less aggressive intruder (alternating songs of decreasing length). When subsequently presented with noninteractive playback of the simulated intruder, male great tits *Parus major* responded to previously aggressive intruders by keeping their distance and overlapping song, while less aggressive intruders were approached quickly. A similar experiment investigated the extra-pair behavior of females in relation to their mate's ability to respond to a simulated intruder. Female great tits were more likely to visit neighboring territories if their mates had responded less vigorously to the simulated intruder than a neighbor had, and females tended to visit the territory of the neighbor who had performed well during playback. In this study, female visits were not translated into extra-pair young. However, a comparable study in black-capped chickadees *Poecile atricapilla* did find an effect of playback treatment on brood paternity.

Interpretation of interactions between playback and a real male could be complicated by changes in behavior of the live male. In the experiments with black-capped chickadees, the behavior of males after each playback treatment was noted, and no effect on subsequent behavior was detected.

This potential problem can be avoided by simulating dyadic interactions with two loudspeakers. Such experiments with nightingales *Luscinia megarhynchos* showed that subjects could associate roles during an interaction with the location of the interactant.

The simulation can be further refined by placing the interacting loudspeakers outside the territory boundary of the subject (ensuring the subject does not approach the loudspeakers during playback), then simulating an intrusion by one of the interactants by playback from within the boundary. This design presented playback treatments that differed only in relative song timing during the interaction, thereby demonstrating that the male great tit subjects had eavesdropped on the interaction as a whole and associated the role of each interactant with features of his song. This approach has been extended to show that great tits combine information from an interaction they took part in with information from an interaction they could eavesdrop on. They have also been shown to combine information on relative features of an interaction with absolute information on singing behavior of each interactant.

Visual Interactions in Fish

Two approaches have been used with visually signaling fish to demonstrate social eavesdropping. In both, the subjects were encouraged to behave as eavesdroppers because they could see the interaction without being seen themselves (achieved by using one-way glass and different light levels between compartments) and could not join the interaction because they were in an adjacent aquarium.

The first approach controlled changes that occur in interacting fish (winner and loser effects) and that might give information on the outcome of interactions rather than (or as well as) information from the dynamics of the interaction. In experiments with male Siamese fighting fish *Betta splendens*, two interactions were staged between similarly sized males displaying across a transparent barrier. However, the subjects could see only one interaction, and the other acted as a control. The staged interactions were allowed to proceed for 15 min, a time that was long enough for a difference in display activity to be detected by subjects but too short for losing males to adopt submissive coloration. Each of the four interacting males (two seen and two unseen) was then introduced into the subject's compartment in turn and the response measured. The male subjects responded to individuals they had seen lose by approaching and displaying sooner than they did to individuals they had seen win. No such differences were seen in response to the unseen males, even though they too had won or lost displays, suggesting that the information used by subjects when responding

was gathered by social eavesdropping. Similar experiments with green swordtails *Xiphophorus helleri* have found comparable evidence for social eavesdropping in aggressive contests between males. Experiments with female fighting fish as subjects followed a protocol similar to that of the experiments with males. The main differences were that the seen and unseen interactions were separated by some days rather than being concurrent and that the females were allowed to move freely so as to exhibit a proximity preference for either male. Females visited seen winners first and more often and spent more time near and displaying to seen winners than to seen losers. Unseen losers were visited first more often than unseen winners, with no difference in the time spent near or displaying to either male. These results are consistent with females' eavesdropping on male–male interactions.

The second approach used to experimentally establish the importance of observed interactions in the future aggressive behavior of male fighting fish has been to decouple the experience of interacting fish from the experience of the subject. This was achieved by placing a small compartment between interacting fish into which the subject could not see. This compartment was filled with water, allowing the males to interact across the gap between them and allowing the subject to see both males involved in a real interaction. However, the compartment could also contain two fish separated by an opaque partition, allowing each of the males seen by the subject to interact with a fish that could not be seen. In this 'apparent' interaction, the subject's interpretation of the aggressive signals given by each visible male is decoupled from that male's actual experience with a hidden fish. Another experiment replaced the two males in the separating compartment with a mirror; therefore, in the apparent interaction, the males were interacting with their own reflection, again decoupling the subject's interpretation from the interactants' experiences. The results showed that the subjects' subsequent response was based on information from interactions, providing support for social eavesdropping.

Effects of an Audience

In communication networks, signaling interactions are likely to be within receiving range of other receivers that do not take part in the interaction. The effect of the presence of such an audience is likely to influence the features of signaling interactions, either because it is an apparent audience (i.e., it is currently present and detected by the interactants) or because it has been present in the evolutionary past, despite being absent during any particular interaction.

Both types of audience impose a selection pressure on signalers, and an audience of predatory or parasitic interceptive eavesdroppers can impose severe selection pressures. Evolutionary audiences result in selection to make signals less easy for interceptive eavesdroppers to locate. Apparent audiences may make the cost of signaling too high to be sustained, and a common response to the presence of a predatory or parasitic eavesdropper is for signaling animals to cease signaling.

The selection pressures imposed on signaling interactions by social eavesdroppers are often less clear cut. It has been argued that the low amplitude of song used by birds in particularly aggressive contexts or when mating is about to occur is an adaptation to prevent social eavesdropping. In some cases, similar considerations seem to have produced the opposite outcome, that is, signaling interactions seem more conspicuous than necessary to transmit information between participants (as discussed above in the context of the high level of close-range signals). Here it may be reasonable to assume that high-amplitude signals are, at least partly, 'intended' for eavesdroppers, that is, that signalers are attempting to communicate more widely in the network than their opponent can. An interesting development of such ideas is that the opponents in an interaction may be subject to different selection pressures, with individuals that are winning wishing to advertise the fact widely and those losing perhaps wishing to withhold that information.

Comparative Biology of Invertebrate Neuromuscular Junctions

Invertebrates Investigated

Analyses of synaptic transmission and its alteration have been carried out in many different preparations, and neuromuscular junctions (NMJs) have provided a great deal of our understanding of basic principles. Studies of both vertebrate and invertebrate NMJs have generated important findings, yet relatively few of the many invertebrate phyla have actually been investigated in detail, and our knowledge is effectively confined to a few species of arthropods, mollusks, and nematodes, with occasional cursory observations from other phyla. Major contributions to studies of synaptic transmission have been derived from giant neurons of a few mollusks (the squid giant synapse, and synapses of central neurons of the marine gastropod *Aplysia*). However, at the level of NMJs, arthropod species have proved to be more amenable to physiological analysis. By far the bulk of current information on invertebrate neuromuscular synaptic structure and function derives from selected arthropods – decapod crustaceans, and members of two orders of insects, Orthoptera (grasshoppers, locusts, and crickets) and Diptera (flies; in particular, *Drosophila melanogaster*). However, recent advances have also been made in the nematode *Caenorhabditis elegans*. Thus, we base the present account mainly on arthropods and nematodes, groups which represent more species than in any other invertebrate phyla, and which promise to be of continuing interest due to the recent emphasis on genetic factors affecting synaptic structure and function.

During the past century and a half, several basic features of synaptic physiology applicable to invertebrates and often to vertebrate synapses, both central and peripheral, were worked out primarily in decapod crustaceans, with more recent contributions from insects (which share many features with crustaceans). Decapod crustaceans provided the best access for physiologists due to the advantages of their large motor neurons and the accessibility of their NMJs for physiological experiments. It is worth noting the results of general significance which have emerged. In brief, these include: (1) establishment of the amino acids γ-aminobutyric acid (GABA) and glutamate (Glu) as neurotransmitters, (2) presynaptic inhibition mediated by GABA, (3) short-term facilitation due to increase in the number of quanta released per nerve impulse, (4) long-term facilitation, a form of long-term potentiation, which involves semipermanent recruitment of synapses, (5) differential effectiveness of individual terminals of a single neuron, now known to occur commonly in the mammalian central nervous system (CNS), (6) modification of physiological and structural properties of individual neurons through chronic alteration of their activity levels, referred to as long-term adaptation, and (6) distinctive properties of synaptic transmission in uniquely identified 'phasic' and 'tonic' motor neurons, with consequent emergence of the 'identified neuron' concept for invertebrate nervous systems. All of these features have proved to be widely utilized in other nervous systems. Striking short-term changes in transmission (frequency facilitation, short-term depression, and responses to neuromodulating amines and peptides) are especially prominent at crustacean NMJs. Thus, crustacean motor neurons continue to have advantages for combined physiological, optical, and ultrastructural studies of glutamate-mediated neurotransmission.

Despite the manifest advantages of crustacean neuromuscular junctions, experimental studies during the past two decades have increasingly moved to insects, especially *Drosophila*. There is a good reason for this: the *Drosophila* genome has been sequenced, the many genes and their products are known, and excellent techniques for genetic manipulation have been developed. These advantages are currently missing for the crustaceans and for most other invertebrates. Insect and crustacean NMJs have much in common, both in structure and function, so findings are often applicable to both groups. The *Drosophila* larval neuromuscular junction has proved to be amenable to electrophysiological and optophysiological investigations, and currently is the most heavily studied invertebrate neuromuscular junction.

Advantages of genetics and molecular information also attach to the nematode *C. elegans*, and thus NMJs of that organism are also of increasing interest to neurobiologists. However, the small size and difficulty of obtaining electrophysiological recordings have so far largely impeded the types of physiological experimentation that have been successful in arthropods. A much larger nematode, *Ascaris*, has been investigated electrophysiologically, but lacks other features that would make it a favorite of neurobiologists. Limited descriptive studies are also available for a few mollusks and annelids, but their NMJs are less easily accessed for experimentation and also are generally smaller and less visible than those of arthropods. Thus, our account of invertebrate NMJs will of necessity emphasize those of arthropods.

Confusion about synaptic terminology currently exists in the scientific literature, especially that concerned with the *Drosophila* larval neuromuscular junction; therefore, we present our preferred definitions here. 'Neuromuscular junction' is the innervation supplied to a muscle fiber by a motor neuron, and may include several ramifications on the muscle fiber's surface (Figure 1). In the CNS, the equivalent is often referred to as a 'synaptic connection' (the collection of synapses supplied by one neuron to another). 'Synapse' is the specialized contact between pre- and postsynaptic membranes, characterized in electron micrographs by uniform separation and often by conspicuous electron density of the adhering membranes. The contact region is rich in adhesion molecules and is physically very robust; it can be isolated from preparations of the CNS by methods which destroy most cell-to-cell contacts.

Figure 1 Morphological features of neuromuscular junctions in different phyla. (a) Muscle arms from each muscle cell travel to a motor nerve: each arm expands into a head section that synapses with a few motor axons. Widespread: found in platyhelminths, nematodes, echinoderms, onychophorans, and protochordates. (b) Short pillars extend outward from the muscle cells to receive branches from motor axons. Present in some annelids, mollusks, and insects. (c) Motor axon terminals fit into grooves in the surface of the muscle cells. Synapses occur along the entire length of the axon terminal. Common in arthropods, mollusks, annelids, and fish. (d) Motor axon terminals make varicosities that contact the surface of the cell either with or without shallow indentations at each varicosity. Common in crustaceans, insects, some mollusks, and fish. (e) Compact cluster of varicosities present in some slow vertebrate skeletal muscles, especially those of reptiles, birds, and mammals. (f) Groove with transverse infoldings in which a single motor axon terminal makes functional juxtapositions with each ridge. Characteristic of amphibia. (g) Groove with both longitudinal and transverse infoldings. Seen in some reptilian fast muscle cells. (h) Groove highly infolded both longitudinally and transversely. Seen in fast mammalian muscles. Adapted from Hoyle G (1983) *Muscles and Their Neural Control*. New York: Wiley.

Within the synapse, various specializations for transmission occur. Electrical synapses of the CNS possess gap junctions in which numerous ion-conducting channels (connexons) link pre- and postsynaptic membranes; chemical synapses of the CNS and NMJs are endowed with arrays of postsynaptic transmitter receptors (typically distributed over most of the postsynaptic membrane) and with presynaptic calcium channels and additional structural features that provide for rapid release of neurotransmitter from synaptic vesicles.

An 'active zone' is a specialized region of the presynaptic membrane of chemical synapses functionally adapted for preferential vesicle exocytosis during neurotransmission. The active zone of many synapses of the CNS typically occupies the entire presynaptic membrane, whereas large central synapses and NMJs often have a more localized active zone, and sometimes more than one for an individual synapse. The essential feature of the active zone is the juxtaposition of voltage-gated calcium channels and synaptic vesicles 'docked' at the presynaptic membrane. This association must be spatially tight in order for neurotransmission to occur in the time observed for synaptic delay.

Muscle Innervation

Diversity across Phyla

Invertebrate NMJs are generally quite different from the well-studied amphibian and mammalian counterparts. In different phyla, morphological arrangements vary, as illustrated in Figure 1. In some invertebrates, muscle extensions innervate motor neurons, while in the more 'advanced' phyla (arthropods, mollusks, and most chordates), motor axons travel to muscles in peripheral nerves to form NMJs. Although NMJs of skeletal muscles in mammals usually exhibit compact 'end-plate' structures and complexly contoured postsynaptic folds not found among invertebrates, simpler varicosities are often found in some vertebrate classes. Invertebrate NMJs have a variety of forms, commonly varicose or filiform, with numerous small synapses.

In the arthropod groups best known physiologically – insects and crustaceans – major muscles for locomotion are innervated by peripheral nerves which convey a small complement of motor axons to target muscles. Typically, an entire muscle is innervated by only one to six motor axons, which branch

within the muscle to supply each muscle fiber with many branches and synaptic contacts (multiterminal innervation). Individual muscle fibers often receive more than one motor axon, each physiologically distinct (polyneuronal innervation). The presynaptic nerve terminals are often varicose, with many small synaptic contacts concentrated on the varicosities (sometimes loosely termed 'boutons'). To illustrate general features of innervation in arthropods, we have selected two examples: crustacean limb muscles and insect (*Drosophila*) larval abdominal muscles. In addition, brief comparative overviews of motor innervation in nematodes, and in selected muscles of mollusks, are included.

Crustacean Limb Muscles

An illustrative example (Figure 2) is the well-studied musculature of crayfish claws and walking legs. Individual muscles are innervated by one to four excitatory motor neurons (all glutamatergic), and by one or two inhibitory neurons (GABAergic). Each neuron typically provides synapses to hundreds or thousands of muscle fibers in one or more muscles. In decapods generally, several muscles receive two motor axons, traditionally termed 'fast' and 'slow,' after the types of contraction they evoke when separately stimulated. More recently, they have often been termed 'phasic' and 'tonic,' based on the nature of their normal nerve impulse discharges. The types of contractions evoked by these axons depend in part on their selective innervation of fast and slow muscle fibers, respectively, but also on their radically different modes of synaptic transmission (to be considered later).

Peripheral inhibitory innervation is a common (but not invariant) feature of arthropod muscles. For decapod leg muscles, there are generally three inhibitory neurons, two of which innervate primarily the 'opener' and 'stretcher' muscles which share an excitatory neuron. These muscles can contract independently only when one of the two specific inhibitory neurons is also active. The third inhibitory neuron, termed the 'common inhibitor,' innervates all of the leg muscles (with the possible exception of the claw opener muscle). Its likely function is to speed up the locomotor response through selective inhibition of slowly contracting muscle fibers in all leg muscles. In many decapod limb muscles, inhibitory axons act directly on their target muscle fibers, generating inhibitory postsynaptic potentials (Figure 2). In some instances, the inhibitory axons also act on presynaptic terminals of motor axons, producing presynaptic inhibition.

Variations in innervation occur in other decapod muscles. Abdominal muscles of crayfish and lobsters receive excitatory and inhibitory innervation, but the

Figure 2 Innervation of crayfish limb muscles. Limb segments containing the muscles are indicated. The paired muscles of the claws and walking legs (w.l.) are each supplied by one to four excitatory axons (red and green 'T' connections) and by one or two inhibitory axons. Paired excitatory axons of the closer (Cls), bender (Bnd), and main extensor (Ext) muscles are differentiated as phasic (green) and tonic (red) subtypes. The opener (Opn) and stretcher (Str) muscles share a single excitatory motor axon. Representative synaptic potentials recorded from the opener muscle with an intracellular microelectrode in response to stimulation of isolated axons illustrate facilitating depolarizing excitatory junction potentials for the opener excitor (OE) axon, and facilitating hyperpolarizing inhibitory junction potentials for the OI and CI axons. The OI axon generates a larger potential than does the CI axon. In the claw, CI innervation is vestigial. Other muscles of the limb are the main flexor muscle (Flx), with quadruple excitatory innervation (one axon exhibits phasic properties); the accessory flexor muscle (AFI), with a single excitatory axon; and the reductor of the meropodite (Red), with undefined excitatory innervation. OI, opener muscle inhibitor; CI, common inhibitory; SI, stretcher muscle inhibitor. Adapted from Wiens TJ (1993) The closer muscle is a second target for the stretcher inhibitor motoneuron of the crayfish's thoracic limbs. *Journal of Comparative Physiology A* 173: 435–444.

inhibitory effects are entirely postsynaptic. In addition, fast and slow contractions are generated by separate sets of muscles arranged in parallel and separately innervated by phasic and tonic motor neurons. In stomach muscles, there is no peripheral inhibitory innervation. At least one of these muscles receives cholinergic

excitatory innervation, while the majority receive glutamatergic innervation. It would seem that the complex physiological scenario of the limb muscles reflects the more refined uses of these appendages, although the means of achieving the required control would probably not have been arrived at by a human engineer.

Drosophila Larval Abdominal Muscles

The second example is an important one because of the large number of recent studies pertaining to it. The *Drosophila* larval abdomen, which accounts for most of the animal's mass at that stage of development, is segmentally arranged; each hemisegment is supplied by its own nerve (Figure 3). A simple dissection exposes all of the musculature and its innervation. In the well-characterized abdominal segments 2–7, each hemisegment has 30 individual muscles (each actually a single muscle fiber) innervated by 31 well-characterized motor neurons, all uniquely identified. Muscle identification is based on position, orientation, and shape, in addition to molecular expression patterns, while motor neuron nomenclature is based on either the origin of the axon or its target, determined by way of retrograde or anterograde single-cell dye labeling. Each muscle receives innervation from one or two glutamatergic excitatory motor neurons supplying prominent boutons, on each of which a number of small neuromuscular synapses occur (Figure 4). Two types of these terminals can be distinguished: type 1b ('big') and type 1s ('small'). Each muscle receives innervation from type 1b terminals, and some receive in addition type 1s terminals. The neurons supplying the latter innervate several different muscle fibers (a type of common excitatory innervation). The type 1 neurons provide the primary locomotor drive for this system. Type 1b terminals produce on average smaller synaptic potential amplitudes while type 1s (smaller bouton size) terminals generally produce larger amplitudes. Small clear synaptic vesicles containing glutamate are found in these boutons along with a small number of dense-core vesicles containing, in many cases, pituitary adenylyl cyclase-activating peptide (PACAP)-like neuropeptide. Other modulatory peptides are found; for example, in muscle 8, dense-core vesicles reveal leukokinin immunoreactivity. Thus, peptidergic cotransmission likely occurs at the glutamate-releasing synapses; its physiological role is not well defined.

No peripheral inhibitory neurons have been found, but two additional types of innervation occur on some muscle fibers. Type 2 innervation consists of long strings of small boutons, each forming one or two neuromuscular synapses (Figure 4). These neurons contain both glutamate and octopamine. Additional innervation, type 3, occurs on only a few muscle fibers and is neurosecretory: type 3 terminals of muscle 12 show insulin-like immunoreactivity and contain other peptides as well. Electrical excitation of type 2 and

Figure 3 *Drosophila* larval muscle innervation. Neuromuscular junctions are shown in an immunostained specimen expressing green fluorescent protein and treated with a fluorescent antibody for the endocytotic enabler protein dynamin (produced by the *shibire* gene). Segmental nerves (SN), appearing red, descend from the central nervous system (CNS), to supply each abdominal segment (numbered) with motor and sensory innervation. Each abdominal hemisegment has 30 muscle fibers ('muscles'), each supplied by 1–4 efferent axons (see Table 1). Inset shows an enlargement of exposed neuromuscular junctions in part of one segment; here, brighter staining indicates a relatively high level of dynamin in synapse-bearing boutons. The specimen is from a D42-Gal4 strain containing one copy of the transgene *UAS-shibire*^{ts1} and one copy of transgene *UAS-gfp* (green fluorescent protein). Specimen prepared and photographed by Dr. Balaji Iyengar, University of Toronto.

Figure 4 Neuromuscular junctions and synapses of larval *Drosophila*. Three types of innervation are illustrated, together with staining of individual synapses. (a) Low-power view of the neuromuscular junctions on abdominal muscles 6 and 7 formed by two parallel motor axons which supply type 1 (1b and 1s) innervation. Three other panels (b–d) show enlargements of two types of varicosities, type 1b (large varicosity) and type 1s (smaller varicosity), belonging to the two different motor axons. The varicosities are stained with anti-horseradish peroxidase antibody (b, green) and antibody nc82, against the active zone structural protein bruchpilot (c, red), to illustrate multiple synapses on each bouton; the merged image is shown in panel (d). Type 1s boutons have higher emission rates per synapse compared to type 1b boutons. Note the variable number of synapses per bouton for both axon types. (e) A third type of innervation (type 2) observed on a few of the abdominal muscle fibers, and characterized by long strings of numerous small varicosities. The merged image of anti-horseradish peroxidase and nc82 staining demonstrates only one or two synapses on each varicosity. (a–d) Prepared and photographed by J Dason, University of Toronto. (e) Prepared and photographed by Dr. G Macleod, University of Texas at San Antonio.

type 3 terminals reveals no prominent fast postsynaptic electrical responses, but small postsynaptic currents (probably caused by glutamate release) have been detected at type 2 boutons. Thus, type 1 terminals are responsible for fast neuromuscular transmission, while type 2 and type 3 terminals play mainly modulatory roles, as yet not well defined.

Significant innervation features are summarized in Table 1. Although up to four different motor neurons can innervate a single muscle cell, only one neuron supplying each type of bouton (1b, 1s, 2, or 3) innervates a given muscle (bouton-type specific exclusion). The most common scenario is triple innervation (1b, 1s, and 2) as seen on muscles 1–4, 8–10, 13, 14, 20–24, and 30.

Other Arthropod Muscles

Insect muscles show a variety of innervation patterns, some simpler than that of the *Drosophila* larva, and others more complex. Simplicity of innervation is exemplified by longitudinal flight muscles of adult *Drosophila*; the six individual muscle fibers ('muscles') of this group each receive unineuronal excitatory innervation. Each motor neuron impulse leads to a large excitatory junction potential (EJP) and muscle spike, eliciting oscillatory myogenic contractions at a high frequency, necessary for flight. Examples of more complex innervation are found in the much-studied locust leg tibial extensor and flexor muscles. The extensor muscle has 'fast' and 'slow' excitatory axons (analogous to those of crustacean limb muscles), and receives a branch of a common inhibitory axon as well as modulatory octopaminergic innervation. The antagonistic flexor muscle is innervated by nine excitatory motor neurons which are selectively, but not exclusively, distributed to subsections of the muscle, and by two inhibitory neurons. Many fibers are innervated by four or more axons. This innervation pattern is the most complex discovered to date for an insect muscle.

Other arthropod groups have been investigated sparsely. Limb muscles of the primitive arachnid horseshoe crab *Limulus* and a tarantula spider show less differentiation of muscle fibers and their attendant NMJs than observed in insects and crustaceans. Muscles are polyneuronally innervated, often by two or three motor axons which generate EJPs of different amplitudes. The main flexor muscle of the *Limulus* leg has as many as 12 excitatory axons. Peripheral inhibition may also occur, since the muscle responds to GABA. In general, the neuromuscular properties found so far in arachnids are functionally less specialized than in crustaceans and insects.

Nematodes

The general features of multiterminal and polyneuronal innervation occur in most other invertebrate groups, including annelids, mollusks, and nematodes. In the latter group, efferent muscle nerves are replaced by

Table 1 Innervation of *Drosophila* larval abdominal muscles

Property	*Type 1b innervation*	*Type 1s innervation*	*Type 2 innervation*	*Type 3 innervation*
Muscles innervated	1–24, 28, 30[1]	1–4, 6–10, 12–16, 18–24, 30[1]	1–5, 8–24, 30[1]	12 (15, 16)[1]
Terminal length	Short[2–4]	Longer[2–4]	Very long[2–4]	
Terminal shape	Minimal terminal branching[2–4]	More elaborate branching[2–4]	Most elaborate branching[2–4]	
Bouton size	Big, 2–6 μm[5]	Small, 1–4 μm[5]	Smallest, 1–2 μm	Small, 1–3 μm
Synapses/bouton	Many (20–40)[2]	Fewer (3–15)[2]	Least (1 or 2)	
T-bars/synapse	0–4[2]	0–3[2]		
Neuroactive substances	Glu[6]/PACAP-like peptide[7]/leukokinin[8]	Glu[6]/PACAP-like peptide[7]/leukokinin[8]	Glu[6]/octopamine[9,10]/proctolin[11]	Insulin-like peptide, other peptides[12]
Dense-core vesicles	Few[4]	Intermediate[4]	Many, elliptical[13]	Many, spherical[13]
Clear vesicles	Numerous, smaller (39-nm diameter)[14]	Fewer, larger (45 nm diameter)[14]		
Readily releasable pool fraction	Low proportion of vesicle pool is readily releasable[15]	High proportion of vesicle pool is readily releasable[15]		
Ca^{2+} sensitivity of release	Low[15]	High[15]

arms of muscle fibers which extend to the major nerve cords to receive synaptic contacts (Figure 1). This mode of innervation is also found in echinoderms, platyhelminth worms, and the onychophoran *Peripatus*.

The success of genetic approaches in *C. elegans* has led to use of its neuromuscular system for discovery of synaptically important molecular pathways. Both excitatory (cholinergic) and inhibitory (GABAergic) motor neurons supply all of the longitudinal locomotory muscle cells. The complete wiring diagrams for the nervous system of both *C. elegans* and the larger parasitic nematode *Ascaris* have been worked out through painstaking serial sectioning. The structural similarities between the two species are remarkable. In *C. elegans*, which has about 20 000 genes, there are 302 neurons, 95 muscle-cells, about 7000 synapses, and 2000 neuromuscular junctions altogether. All cells are specified and identified. The neurons and their distributions are much the same in *Ascaris*. Physiological research is a much easier task in the latter, and it is likely that physiological features in the two species (and in other nematodes) are basically the same.

Motor neurons are confined to the longitudinal nerve cords and connecting commissures, and have relatively few processes. In fact, complex neuropile

structures like those of arthropods and mollusks do not occur in nematodes. Physiological investigations in *Ascaris* have shown that the electrical length constants are very long (centimeters) for nematode motor neurons, and that these neurons do not produce action potentials. Instead, electrical activity and resultant synaptic transmission are graded. Probably tonic release of neurotransmitter at the NMJs accounts for maintained muscular contraction. Stimuli applied to neuronal processes in nerve cords and commissures do evoke synaptic potentials, either depolarizing or hyperpolarizing, in the muscle fibers, sometimes with graded muscle spikes superimposed. The connections of the excitatory and inhibitory motor neurons to different longitudinally arranged muscle groups produce the typical oscillatory waves responsible for locomotion.

Mollusks

Muscle innervation in the mollusks is very diverse, but generally follows the organizational scheme of polyneuronal, multiterminal innervation seen in other major invertebrate groups. Motor axons may be sent to muscles from central ganglia, but often arise instead from local small ganglia within the muscle, a feature which creates semiautonomous muscular activity. Unlike arthropods, the molluscan groups employ acetylcholine as the major excitatory neurotransmitter. Peripheral inhibition has been found in a few molluscan muscles, but is apparently less utilized than in arthropods and nematodes. On the other hand, numerous modulatory neuropeptides occur in molluscan muscles; many of them are likely cotransmitters. They may exert potentiating effects on the muscle, probably through activation of membrane calcium channels, or inhibitory effects through activation of potassium channels; such dual, concentration-dependent effects are outlined for one class of peptides, the myomodulins. Another class (buccalins) acts presynaptically, modulating neurotransmitter release.

Intracellular recordings from muscle cells in a variety of different muscles show EJPs of different amplitudes (polyneuronal innervation). Accompanying contractions in the muscle are usually graded in accordance with the depolarization produced by EJPs and are stronger when muscle action potentials are initiated. However, an unusual form of regulation is present in certain muscles of bivalve mollusks. The anterior byssal retractor muscle (ABRM) of the mussel *Mytilus* develops an extremely prolonged, powerful contraction ('catch' contraction) in response to application of acetylcholine, the major excitatory transmitter substance. Application of serotonin, contained in a second set of nerves, relaxes the catch. Thus, the serotonergic nerves are referred to as 'relaxing nerves.' Serotonin may produce its effect by promoting sequestration of Ca^{2+} within the muscle cells.

Fast and slow contractions are often elicited in molluscan muscles participating in swimming or escape responses. A particularly good example has been described in the pteropod mollusk *Clione limacine*, which is specialized for swimming at variable speeds. Swimming muscles contain slow-twitch and fast-twitch muscle fibers, which are recruited for slow and rapid swimming, respectively. The former are innervated by small motor neurons which have small innervation fields. A second type of input is produced by large motor neurons which have widespread innervation fields, including both fast- and slow-twitch muscle fibers. These 'general excitor' neurons become active when fast swimming is required, and their activity generates spikelike electrical events and strong contractions in muscle cells throughout the innervation field. This system represents a counterpart to the specialized phasic and tonic neuromuscular systems of crustaceans, in which differences in speed of response are accomplished through activation of motor neurons with appropriate synaptic properties and distributions.

Structural Features of Invertebrate Neuromuscular Junctions

Synapses

NMJs typically are formed by varicose terminals or linear filiform branches of motor axons, although in nematodes muscle processes reach the motor neurons in the nerve cords to form the junctions. Invariably, small synapses, often numerous, are found at invertebrate NMJs (Figure 4). A single varicosity on an arthropod muscle fiber typically bears 5–40 individual synapses. At higher resolution in electron micrographs, synapses are characterized by rigidly aligned, electron-dense pre- and postsynaptic membranes uniformly separated by 10–20 nm (Figures 5 and 6). On the postsynaptic (muscle) side, a complex reticular structure (subsynaptic reticulum) extending from the muscle fiber receives the synapses; the postsynaptic membrane exhibits regular arrays of particles in freeze-fracture replicas, and these are thought to be the receptors for the major neurotransmitter. On the presynaptic side, prominent presynaptic densities (typically 0–4 per synapse) are associated with clusters of clear synaptic vesicles, some of which appear to be attached to the presynaptic density by microfilaments. The general arrangement of synapses differs from that generally seen in skeletal muscles of mammals, in which a single localized large consolidated end-plate is often found on each muscle fiber.

Figure 5 Specializations of *Drosophila* neuromuscular junctions. (a) Overview of two presynaptic boutons illustrating variable T-bar (arrowheads) morphology. In the right-hand example, two dense pillars share a single T-projection. In the middle example, very fine filaments emanate from the T-bar. In the left-hand example, a clear separation appears between the dense pillar and the presynaptic membrane. (b) Enlarged view of a single T-bar (arrow) with clustered synaptic vesicles, and a docked vesicle under one arm of the T-bar. (c) Diagram of the active zone, illustrating the relationship between the T-bar, synaptic vesicles, calcium channels, and a structural protein Bruchpilot which surrounds and is closely associated with the active zone. Antibody (nc82) labeling of this protein reveals the presence of a synapse endowed with one or more active zones. SSR, subsynaptic reticulum; S, synaptic; m, mitochondrion. Electron micrographs taken by Dr. L Marin, University of Toronto. From Atwood HL (2006) Gatekeeper at the synapse. *Science* 312: 1008–1009.

Figure 6 Active zone of the American lobster, *Homarus americanus*. (a) Freeze-fracture replicas (left image) of an excitatory synaptic bouton's P-face, showing three synaptic contacts (raised plateaus), with active zones (arrowheads) consisting of variably shaped collections of large intramembranous particles surrounded by images of vesicular fusion (shown at higher magnification in right top image). Transmission electron micrograph (lower right) shows a presynaptic dense body (arrowhead) with an adjacent image of vesicular fusion, and additional nearby synaptic vesicles. (b) Diagrams based on the transmission electron micrographs and freeze fracture replicas. Face view (left) and orthogonal (transverse) view (right) are drawn to scale. Presynaptic Ca^{2+} channels (black circles) appear in apparently random arrangement throughout the presynaptic membrane region occupied by the dense bar (yellow). The latter appears to be tethered just above the presynaptic membrane, as seen in transmission electron micrographs. Synaptic vesicles (red) are typically 'docked' around the edges of the dense bar, and exocytosis occurs preferentially at that location, as illustrated (scale in nanometers). (a) Reproduced from Atwood HL and Govind CK (1990) Activity-dependent and age-dependent recruitment and regulation of synapses in identified crustacean neurones. *Journal of Experimental Biology* 153: 105–107, with permission from the company of Biologists. (b) Reprinted from Pearce J, Govind CK, and Shivers RR (1986) Intramembranous organization of lobster excitatory neuromuscular synapses. *Journal of Neurocytology* 15: 241–252, with kind permission of Springer Science and Business Media.

Active Zones

The synaptic specialization termed the 'presynaptic active zone,' denoting a small region specialized for intense secretory activity, was originally recognized at amphibian NMJs, but similar features have been

characterized at invertebrate NMJs and at central synapses. In transmission electron micrographs of arthropods (Figures 5 and 6) and nematodes (Figure 7), the 'signpost' of the active zone is an electron-dense adhesion on the presynaptic membrane, variable in appearance. In crustaceans it is often hemispherical (Figure 6), while in *Drosophila* and some other insects it has a typical T-shaped appearance, and is referred to as a 'T-bar' (Figure 5). In all cases, the electron-dense structure appears to be

Figure 7 Neuromuscular junctions of nematodes. (a, b) Drawings of the neuromuscular arrangements in *Ascaris*. Muscle cells with contractile regions (MF) and large noncontractile cell bodies (CB) extend 'muscle arms' (MA) to dorsal and ventral nerve cords (DNC and VNC, respectively). Synapses are made between muscle arms and motor neurons (MN) in the nerve cords. (c) Neuromuscular junction in *Caenorhabditis elegans*. Cross section of a neuromuscular junction obtained after high-pressure freezing to preserve synaptic components. The nerve terminal contains numerous clear synaptic vesicles and four dense-cored vesicles (open arrowheads); a dense projection (closed arrowhead) has a clear synaptic vesicle docked beside it. The granular process of the postsynaptic muscle fiber (m) receives the synapse and appears to possess closely associated laminar subdivisions. (a, b) From Hoyle G (1983) *Muscles and Their Neural Control*. New York: Wiley. (c) From Weimer RM, Gracheva EO, Meyrignac O, Miller KG, Richmond JE, and Bessereau JL (2006) UNC-13 and UNC-10/rim localize synaptic vesicles to specific membrane domains. *Journal of Neuroscience* 26: 8040–8047; image courtesy of Drs. J-L Bessereau and R Weimer.

slightly detached from the presynaptic membrane, but tethered to it (Figure 6). In this respect, it bears similarity to some vertebrate sensory synapses which have large electron-dense structures, either round or ribbon-shaped, attached at the active zone. The presynaptic density appears to be the focal point within the synapse for synaptic vesicle accumulation at the presynaptic membrane; most of the vesicles that adhere to the presynaptic membrane ('docked' vesicles) are found around the presynaptic density and some are attached to it by fine filaments (Figures 5 and 6). Thus, cytoskeletal proteins are thought to promote the arrangement and movement of synaptic vesicles.

Evidence from freeze-fracture replicas and immunostaining strongly supports the view that presynaptic voltage-gated calcium channels are closely associated with the presynaptic density, and that the clear synaptic vesicles are preferentially released along its sides, close to the presynaptic calcium channels (Figure 6). Prominent intramembranous particles visible in freeze-fracture replicas are thought to be mainly synaptic calcium channels. In many arthropods, these are not regularly arrayed, as at vertebrate NMJs. Many occur on the membrane surface under the dense projection, but the small gap between the latter and the presynaptic membrane may facilitate diffusion of Ca^{2+} to the edges of the active zone, where vesicle fusion occurs. The active zone provides the necessary spatial arrangement for fast neurosecretion; vesicles to be released must be very close to presynaptic calcium channels in order to be activated in 200 μs or less by the calcium trigger that is known to precipitate vesicle fusion with the presynaptic membrane.

The presynaptic voltage-gated Ca^{2+} channels (VGCCs) responsible for exocytosis have been partially characterized in *Drosophila* and can be compared with known vertebrate counterparts. Combined studies using selective pharmacological disruption of calcium channels and immunocytochemical characterization of calcium channel distribution suggest that N-type and P/Q-type voltage-gated calcium channels are the main players of vertebrate synaptic transmission. Both are high-voltage activated and they are sensitive to ω-conotoxin GVIA and ω-agatoxin VIA, respectively. At least 10 vertebrate α1 subunits (the pore-forming components) and at least 4 β subunits (supplementary modulatory components) have been cloned. In contrast, *Drosophila* has only three genes encoding pore-forming α1 subunits. *DmCa1D* encodes an α1 subunit homologous to that of vertebrate Cav1 VGCCs, *DmCa1A* (*cacophony*) encodes an α1 subunit homologous to that of Cav2 VGCCs, and cDNA has been cloned for a homolog of the α1 subunit of vertebrate Cav3 VGCCs. Only one gene coding for a β subunit has been identified in *Drosophila*. The *Drosophila* presynaptic calcium channels, while homologous to N- and P/Q-type channels in location and function, are not highly sensitive to either ω-conotoxin GVIA or ω-agatoxin VIA.

The *Drosophila* neuromuscular junction contains several distinct calcium channels; three have been described for the presynaptic terminal. A *cacophony*-based calcium channel, sensitive to the spider toxin *Plectreurys* toxin II (PLTXII), is confined to the active zone, and is solely responsible for fast synchronized transmitter release. A La^{3+} and flunarizine-sensitive Ca^{2+} channel, likely more diffusely distributed, is involved in endocytosis. A third type, a non-*cacophony* PLTX-sensitive calcium channel thought to be involved in endocytosis, is likely also diffusely distributed.

Other differences between invertebrate and vertebrate calcium channels involve the synaptic protein-interacting ('synprint') site. In vertebrates, key docking proteins (syntaxin 1, SNAP25, and synaptotagmin 1) bind to an intracellular domain of the II–III linker region of the α1 subunit of mammalian N-type and P/Q-type calcium channels. Injection of rat synprint peptide to competitively dissociate interaction of the synprint site with synaptic proteins diminishes synaptic transmission, supporting the hypothesis that a physical association is necessary for fast synaptic transmission. However, the invertebrate homologs neither appear to require such a region nor a physical interaction with synaptic proteins for fast transmission. Work done on *Lymnaea* has revealed that despite lack of direct interaction between synaptic proteins and calcium channels, synprint peptide injection disrupts synaptic transmission as it does in vertebrate preparations. This supports the hypothesis that neurotransmitter release is blocked downstream of calcium entry, and suggests that earlier results may need to be reexamined.

Several additional synaptic active zone molecules have recently come to light in studies of *Drosophila* and *C. elegans*. As yet, the coordinating roles of these molecules are not well understood, but many are important for synapse formation and optimal release of neurotransmitter. As an example, the *Drosophila* anchoring protein Bruchpilot, a structural protein with coiled-coil domains and homologies to a mammalian active zone protein, is essential for localizing the T-bar to the presynaptic membrane. *Drosophila* mutants lacking this protein also do not exhibit the normal T-shaped presynaptic density or normal presynaptic calcium channel distribution. Although they can maintain evoked neurotransmission, its effectiveness is reduced to about one-fourth of normal, and the timing of exocytosis is less precise. An antibody to Bruchpilot (nc82) is now used extensively to reveal the number and distribution of active zones

(or synapses with active zones) at the *Drosophila* neuromuscular junction (Figures 4 and 5).

Several examples of active zone-associated molecules have been discovered in *C. elegans*, using screens for mutants with abnormal locomotion and defective presynaptic morphology. Among these are RPM-1 (regulator of presynaptic morphology), which regulates formation and spacing of active zones in motor neurons. This protein possesses guanine nucleotide exchange factor and zinc finger domains, suggesting a role in regulating formation of protein complexes. Similar proteins are found in *Drosophila* presynaptic terminals (Highwire) and at mammalian synapses (Pam), indicating conservation of function. As yet, a general model of invertebrate active zones that would account for the roles of all of the structural and regulatory proteins has not emerged.

Neuroactive Substances and Receptors

General Features

The majority of invertebrate neurons communicate via chemical synapses, which employ several major neurotransmitters. Complete definition of these neuroactive substances involves the characterization of their biosynthetic pathways, their receptors, and their second-messenger pathways. Glutamate is the primary excitatory neurotransmitter of arthropod NMJs, while acetycholine is a major excitatory transmitter of NMJs in nematodes, annelids, mollusks, and a few crustacean stomach muscles. The primary transmitter of invertebrate inhibitory NMJs is GABA, though glutamate can also activate inhibitory receptors in certain cases.

In the presynaptic terminal, glutamate is synthesized from α-ketoglutarate by way of glutamate dehydrogenase and is taken up into vesicles to be mobilized for release. In inhibitory terminals, glutamate is further metabolized by glutamate decarboxylase into GABA. Both GABA and glutamate are actively removed from the synaptic cleft by transporters in adjacent cell membranes.

Primary neurotransmitters acting directly at invertebrate NMJs are often co-released with agents that can exert effects elsewhere. Proctolin, a pentapeptide unique to arthropods, is released as a cotransmitter at some NMJs, but exerts its effects on the extrasynaptic muscle membrane. Some neuroactive substances are released at locations remote from the neuromuscular junction upon which they act, and access their targets either by diffusing to nearby NMJs (neuromodulator) or by entering into the circulation and targeting distant sites (neurohormone). Neuromodulatory neurons of insects often contain octopamine (OCT), while peripheral endings of some neurosecretory cells contain several neuropeptides. In fact, all of the glutamatergic and GABA-containing neurons contain variable numbers of dense-core vesicles, most of which are probably loaded with neuropeptides. A few cases of peptidergic cotransmission with glutamate have been investigated. Representative neurotransmitters released at invertebrate NMJs as well as some of the better-known neuroactive substances that can modulate transmission are presented in Table 2.

Numerous receptors, both pre- and postsynaptic, are present in and around invertebrate NMJs. The sum of activity of excitatory and inhibitory ionotropic synaptic receptors determines the ultimate effect of transmission on electrical responses of the postsynaptic target. Additional receptors, including extrasynaptic, metabotropic, neuromodulatory, and neurohormonal receptors, modulate the effects of primary neurotransmission.

Several excitatory and inhibitory receptors were initially identified in crustacean and insect neuromuscular synapses through dose–response experiments using several analogs of the endogenous transmitters. Receptors have been historically categorized by their preferred agonist, a substance that potently activates the receptor in a way similar to the endogenous transmitter. Further classification is based on antagonist pharmacology, location (pre/post and synaptic/extrasynaptic), and biophysical characteristics (desensitization, conductance, current and ion selectivity).

Postsynaptic Ionotropic Glutamate Receptors

Ionotropic glutamate receptors are the main transducers of excitatory neuromuscular activity in arthropods and they are also essential for rapid neuronal signaling in the vertebrate CNS. Vertebrate glutamate receptors, classified by the agonist of highest potency, include α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, which have fast kinetics and are typically impermeable to calcium, and *N*-methyl-D-aspartate (NMDA) receptors, which are slower and do conduct calcium. Invertebrate ionotropic glutamate receptors show a mixture of the vertebrate characteristics, having fast kinetics and calcium permeability. They are not very responsive to the major vertebrate agonists. Early studies in *Drosophila*, locust, and crayfish neuromuscular preparations found quisqualate to be the most potent agonist of excitatory ionotropic receptors at the neuromuscular junction. The quisqualate-type invertebrate receptors are inhibited by antagonists such as the polyamine-containing toxins from the venoms of spiders (argiotoxins) and wasps (philanthotoxins). Interestingly, NMDA has been found to induce presynaptic effects through a metabotropic receptor in the crayfish NMJ. Other glutamate

Other neuroactive subsatances can act as neuromodulators or neurohormes to modulate the effects of a primary transmitter (denoted by Δ); parentheses indicate cursory observations from a few muscles. A role for NO in modulating neuromuscular transmission has been suggested but not fully substantiated in some systems (denoted by ?), including the locust slow extensor tibiae preparation. Data based on the following sources: Brezina V, Bank B, Cropper EC, et al. (1995) *Journal of Neurophysiology* 74: 54–72; Osborne RH (1996) *Pharmacology and Therapeutics* 69: 117–142; Nistri A and Constanti A (1979) *Progress in Neurobiology* 13: 117–235; Muneoka Y, Fujisawa Y, Matsuura M, et al. (1991) *Comparative Biochemistry and Physiology C* 98: 105–114.

receptors found postsynaptically on the muscle membranes of locusts and crayfish pass chloride ions and are therefore inhibitory. It is uncertain whether these receptors occur directly at the synapse.

Glutamate released into the synaptic cleft binds to receptors located primarily, if not entirely, at the postsynaptic density (PSD), causing an increase in the channel open probability. Binding of several glutamate molecules is required for a single channel to open. Once open, channels are permeable to Na^+, K^+, and Ca^{2+}. Biophysical characterization of ionotropic quisqualate-sensitive receptors reveals a high degree of similarity between several species of arthropods in most categories (Table 3). Application of a high concentration of agonist (10 mM) activates these nonselective excitatory receptors, revealing a high conductance level (100–150 pS) and a current of 7–9 pA (in single-channel muscle patches held at –70 mV). This steplike change in channel conductance contributes to the rapid change in muscle membrane potential typically preceding muscle contraction. The probability of a channel being open is dependent upon the concentration of glutamate in the cleft. Bursts of channel openings quickly reach a peak and then decay over the duration of glutamate's presence. Prolonged exposure to glutamate causes channel desensitization. Although the time constant of desensitization is concentration dependent, recovery is not.

Unlike the interspecies similarities that exist in conductance levels and pharmacology, desensitization characteristics are quite different among the arthropods. Postsynaptic receptor populations in *Drosophila* desensitize more slowly than in crayfish and recover from desensitization much more slowly than in crayfish or locust. Desensitization kinetics also differentiate subtypes of the quisqualate receptors within species. Outside-out patches from crayfish muscle revealed several types of ionotropic glutamate receptors, which differ mainly in desensitization kinetics. One type of glutamate receptor completely desensitizes, another partially desensitizes, while a third does not desensitize. The time constant of desensitization of both the completely and partially desensitizing crayfish channels are very similar, while they differ in the different locust (25 and 5 ms) and *Drosophila* (19 and 2 ms) channels.

Quantal currents (produced by release of glutamate from single synaptic vesicles) can be explained from the observed channel kinetics under certain assumptions. The rapid rise time of quantal currents at the crayfish NMJ indicates that glutamate concentration in the cleft should be approximately 1 mM, to open channels rapidly. At this concentration, the time constant of desensitization is similar to the decay constant of the quantal current. Assuming that responding postsynaptic receptors are not the nondesensitizing type, desensitization may terminate the quantal current. However, most of these data come from recordings

of individual or small groups of receptors isolated from the muscle, without any indication of the full composition or relative contribution of receptor types located at the PSD. How individual receptors contribute to the synaptic currents evoked during neuromuscular transmission is best documented at the *Drosophila* larval neuromuscular junction. Genetic studies, supported by immunocytochemistry, have been employed to assess the relative contributions of individual receptor subtypes to synaptic responses.

Determining the full complement of receptors of an organism requires the integration of molecular and genetic studies, which in *Drosophila* and *C. elegans* have allowed a more complete elucidation of these receptors. The *Drosophila* model is presently ideal since it allows for combined pharmacological, kinetic, and genetic studies to examine the physiological mechanisms of synaptic transmission. Over 30 glutamate receptor genes have been identified in the *Drosophila* genome (15 in *C. elegans*), several of which are ionotropic, including *DGluRI* (kainite), *DNMDAR* (NMDA), and *DGluRIIA*, *B*, *C*, *D*, and *E*. Five muscle-specific subunits have been identified: DGluRIIA, DGluRIIB, DGluRIIC, DGluRIID, and DGluRIIE. DGluRIIA and DGluRIIB subunits are found in all somatic muscles but not in the CNS. The two genes are adjacent in the genome, have similar genomic organization, and are closely related, though their products share only 44% amino acid identity. In the putative pore region, critical for Ca^{2+} permeability, the sequence of the DGluRIIA is identical to that for vertebrate channels, while the sequence of DGluRIIB is divergent.

The postsynaptic excitatory ionotropic glutamate receptor in *Drosophila* muscles consists of four subunits. The GluRIIC, GluRIID, and GluRIIE subunits are required, in addition to either the GluRIIA or GluRIIB subunit. Immunocytochemistry reveals GluRIIB-containing receptors are abundant at both type 1b and type 1s boutons, while GluRIIA-containing receptors are most abundant at type 1b boutons. This suggests that postsynaptic sensitivity is determined by a mixture of both types. Genetic deletion of one or the other receptor subunits allowed characterization of the biophysical characteristics of each receptor type (see Table 3). In GluRIIA-containing mutants, postsynaptic sensitivity was greater than in GluRIIB-containing mutants. Increased levels of DGluRIIA increase quantal size, while decreased levels decrease quantal size. Conversely, overexpressing DGluRIIB decreases quantal size. These data also suggest that postsynaptic sensitivity is determined by a combination of both GluRIIA and GluRIIIB receptors. However, evidence from single-channel recordings of receptors on the muscle membrane and relative sensitivity to argiotoxin suggests that DGluRIIA receptors contribute more to normal (wild-type) EJP amplitude and time course than do DGluRIIB receptors. The slow recovery from desensitization of *Drosophila* receptors may in part explain decreased amplitude of EJPs during fictive locomotion, when a high rate of nerve impulse activity (50–100 Hz) is often attained. Functionally, this may serve as a negative feedback control of muscle contraction.

Other Invertebrate Neuromuscular Receptors

Features of other receptors found at invertebrate NMJs are summarized in Table 4. Biophysical studies have been confined mainly to those of arthropods. Ionotropic GABA receptors (GABA-A type) are found in postsynaptic muscle membranes of many arthropods and in presynaptic terminals of crustacean NMJs. Both in the muscle and in the presynaptic nerve terminals, GABA opens chloride channels, effectively counteracting the depolarizing effects of concurrent inward current flow. In muscle membranes, this is sufficient to attenuate or diminish action potential amplitude in muscle fibers that produce electrogenic responses (Figure 8). In nerve terminals, the presynaptic action potential is reduced in amplitude, and consequently the nerve terminal's transmitter output decreases (presynaptic inhibition).

Three different ionotropic GABA channels have been characterized in crayfish. In the opener muscle, a GABA channel exhibits a conductance of 29 pS, with a rise time of about 1 ms (50 mM GABA) and a 0.12 mM K_d (agonist concentration at half maximal binding). In the deep abdominal extensor muscle the conductance is greater, the rise time is slower, and the K_d is higher. When the deep abdominal extensor muscle is denervated, conductance drops from 35 to 31 pS, rise time increases from 5 to 10 ms, and the sensitivity to GABA increases slightly from 1 to 0.8 mM. These changes following denervation are attributed to an alteration in subunit composition, analogous to that seen in vertebrate nicotinic receptors following denervation.

In *Drosophila*, 10 genes appear to code for ionotropic GABA receptor subunits, while *C. elegans* possesses 37 genes. Single-channel recordings from *Drosophila* muscle reveal GABA receptors with conductance substates of 40, 80, and 110 pS. The 40 and 80 pS conductances were also elicited by application of glutamate. Nothing is known about the role of GABA receptors in *Drosophila* neuromuscular transmission, but in *C. elegans* GABAergic neuromuscular transmission is of major importance for locomotion.

Several other presynaptic receptors have the potential to modulate transmitter release at invertebrate NMJs. At the lobster stretcher muscle in the

Figure 8 Excitatory and inhibitory electrical responses at crustacean neuromuscular junctions. (a) Simultaneous intracellular records of the presynaptic action potential (AP) and the excitatory junction potential (PSP, postsynaptic potential) from a muscle fiber in the leg opener muscle of the crayfish, *Procambarus clarkii*. Stimulus artifact is indicated by an arrow before the AP's occurrence. (b) Examples of excitatory and inhibitory potentials from two different muscle fibers of the leg stretcher muscle of a crab, *Grapsus grapsus*. In fiber 1 (F1), a single stimulus to the excitor axon (1) produces an excitatory junction potential (EJP), which triggers a muscle action potential (AP). A single stimulus to the stretcher inhibitor axon (4) generates a hyperpolarizing inhibitory junction potential (IJP). Stimulating the inhibitor 8 ms before the excitor leads to disappearance of the AP (2). When the inhibitory stimulus leads the excitatory stimulus by 2 ms, the EJP is drastically reduced, indicating strong presynaptic inhibition (3). In fiber 2 (F2), a large EJP (1) is shortened when the IJP occurs synchronously (2), and is drastically reduced (indicating presynaptic inhibition) when the inhibitory stimulus arrives 2 ms in advance. (a) Recording by Dr. M Wojtowicz, University of Toronto; (b) recordings by Dr. H L Atwood, University of Toronto.

carpopodite joint, three presynaptic receptors may contribute, in varying degrees under differing conditions, to the modulation of transmitter release: an ionotropic GABA receptor (GABA-A type) that activates a chloride channel, a metabotropic GABA receptor (GABA-B type) that activates potassium channels, and a metabotropic glutamate receptor that also activates potassium channels. Metabotropic receptors coupled to G-proteins can modulate release of transmitter directly or indirectly. Both Ca^{2+} and K^{+} channels can be modulated by metabotropic receptors through phosphorylation mediated by second-messenger pathways. Opening of K^{+} channels by metabotropic receptors hyperpolarizes the nerve terminal, altering membrane excitability over a prolonged period of time (several hundred milliseconds or more). Duration of presynaptic inhibition can be influenced by activity of metabotropic receptors, although its major component is attributed to ionotropic GABA-A receptors.

The *Drosophila* genome encodes three putative metabotropic glutamate receptors and three putative metabotropic GABA receptors. One of the former is located in the periactive zones of neuromuscular synapses and is sensitive to glutamate. It regulates activity-dependent synaptic facilitation in addition to sculpting or fine-tuning synaptic morphology.

Presynaptic ryanodine receptors are also involved in regulating transmitter release. In *C. elegans*, loss-of-function mutations of the ryanodine receptor (UNC-68) cause a large reduction in amplitude of excitatory postsynaptic currents and a loss of large-amplitude mini postsynaptic currents. At these synapses, ryanodine receptors likely affect quantal size through presynaptic mechanisms involving regulation of intraterminal calcium stores. The generality of these effects has yet to be determined.

Retrograde Modulation of Synaptic Strength

Although the predominant operation of neuromuscular junctions and other synapses is to convey signals anterogradely from the presynaptic neuron to its postsynaptic targets, there is evidence for retrograde signaling that determines the morphology and response properties of the presynaptic nerve terminals. Two types of evidence have recently been gathered from *Drosophila* NMJs. First, retrograde signaling pathways involving receptors and ligands of the transforming growth factor-β (TGF-β) superfamily of secreted trophic molecules have been implicated as determinants of presynaptic morphology and performance. Second, an acute secretory mechanism involving an isoform of the calcium receptor synaptotagmin, known to be a key partner in calcium-mediated vesicle fusion, has been demonstrated in the postsynaptic region.

Evidence for synaptic retrograde signaling in *Drosophila* was initially derived from observations on effects of manipulating postsynaptic glutamate receptors. Genetic deletion of the GluRIIA subunit, which chronically reduces quantal size (due to reduced postsynaptic receptor sensitivity) leads to an increase in quantal content (number of transmitter-filled vesicles

presynaptically released per nerve impulse), resulting in a postsynaptic recording equal in amplitude to wild type. This indicates a compensatory adjustment of transmitter release in the presynaptic terminal to maintain the functional effectiveness of transmission. Thus, synaptic strength (amplitude of postsynaptic potentials) is influenced by retrograde signaling, which modulates transmitter release to compensate for changes in postsynaptic sensitivity.

Further searches for the mechanism of this effect demonstrated that postsynaptic calcium/calmodulin-dependent protein kinase II (CaMKII) can control retrograde modulation of synaptic strength in *Drosophila*. Chronic increase of postsynaptic CaMKII activity decreases transmitter release, while chronic decrease of postsynaptic CaMKII activity has the opposite effect. Increased quantal content in CaMKII mutants occurs without a decrease in quantal size and is accompanied by an increase in presynaptic T-bars at the active zone.

An additional component of the retrograde signaling pathway came to light with the finding that the complex presynaptic protein Highwire (Hiw), a putative E3 ubiquitin ligase and structural regulator, controls synaptic growth of the neuromuscular junction through negative regulation of effects of bone morphogenetic protein (BMP), a member of the TGF-β superfamily. The presynaptic BMP receptor gene *wishful thinking* (*wit*) is required for the retrograde signal-induced alteration in presynaptic form and function. Thus, a *Drosophila* version of BMP is thought to be a ligand secreted postsynaptically and acting on a presynaptic receptor (which is in turn regulated by Hiw). A presynaptic signal is then received and transduced by the motor neuron's nucleus, leading to modifications of the presynaptic terminal. There is an overlap in mechanisms regulating developmental, structural, and activity-dependent plasticity.

Evidence for a postsynaptic secretory mechanism comes from additional studies of acute alterations in transmitter release, which apparently can occur through retrograde signaling. Postsynaptic calcium influx through glutamate receptors is sensed by an isoform of the calcium-binding protein synaptotagmin (Syt4), triggering vesicle fusion. The contents of the postsynaptic vesicles initiate a large increase of quantal release from the presynaptic terminal (spontaneous calcium-independent vesicle release). In this case, the unknown retrograde signal stimulates the presynaptic cAMP-dependent protein kinase pathway, leading to increased transmitter release. Chronic decreases in many of the proteins involved in this pathway also produce structural alterations to the synaptic areas, suggesting that this pathway may also be involved in longer term changes in synaptic function.

Physiological Features

The numerous distributed synapses provided to a muscle fiber each typically release on average small amounts of neurotransmitter in response to a single presynaptic action potential (sometimes less than 1 quantum per 100–1000 trials in some crustacean tonic axons). In this, they resemble the majority of vertebrate and invertebrate central synapses more closely than NMJs of skeletal muscles in higher vertebrates. The resulting electrical response (postsynaptic potential) of the muscle fiber is often called a junctional potential, either excitatory (EJP) or inhibitory (IJP), according to the type of postsynaptic receptor and ionophore engaged (**Figure 8**). EJPs are capable of eliciting contraction in the responding muscle fiber without provoking a muscle action potential, since the muscle fiber's resting membrane potential is often close to the threshold potential for excitation–contraction coupling. In fact, many invertebrate muscle fibers lack the appropriate mix of ion channels for excitability, and thus do not produce action potentials even when the EJP is large. When a muscle action potential does occur, its amplitude is often variable, depending on the rate of rise and amplitude of the EJP. In contrast, IJPs are usually of small amplitude and act to reduce the depolarization of the EJP, since the IJP's reversal potential is usually close to the muscle fiber's resting potential. The speed and force of the contraction are governed by the rate of rise and amplitude of the electrical events produced by the combined effects of EJPs and IJPs. In addition, the contractile properties of the muscle fiber (which range widely in arthropods and mollusks) play an important role in the ultimate performance of the neuromuscular system.

Representative electrical responses recorded at crustacean (**Figures 8–10**), *Drosophila* (**Figure 11**), and nematode (**Figure 12**) NMJs illustrate typical features and range of invertebrate signaling. In crustaceans, the presynaptic action potential can be recorded intracellularly together with the evoked EJP or IJP (**Figure 8(a)**). The synaptic delay is brief (0.5–1 ms, depending on temperature), and at many junctions the EJP is small at low frequencies of activation. Inhibitory transmission may decrease the amplitude and speed up the decay of the EJP, and eliminate graded muscle action potentials (**Figure 8(b)**). In many limb muscles, drastic attenuation of EJP amplitude indicates presynaptic inhibition mediated by axo-axonal synapses. The *Drosophila* larval preparation shows no sign of peripheral inhibition; two EJPs mediated by different axons can be readily detected (**Figure 11**). In nematodes, EJPs (sometimes accompanied by muscle action potentials) and IJPs (sometimes

Figure 9 Variation in electrical responses at crustacean neuromuscular junctions. Intracellular records of excitatory junction potentials were taken from eight identified muscle fibers in the closer muscle of the walking leg of the crab *Eriphia spinifrons*. Five stimuli were delivered at a frequency of 16 Hz to either the slow (tonic) excitor (SCE) or the fast (phasic) excitor (FCE). A wide range of excitatory junction potentials, differing in amplitude, time course, and facilitation, was found. Some fibers in this sample (fibers 1, 6, 7, and 8) appeared to be innervated by only one of the two excitors (FCE). From Rathmayer W and Erxleben C (1983) Identified muscle fibers in a crab. I. Characteristics of excitatory and inhibitory neuromuscular transmission. *Journal of Comparative Physiology* 152: 411–420.

Figure 10 Physiological features of crustacean phasic and tonic neuromuscular transmission. (a) Nerve terminals of phasic and tonic axons supplying the claw closer muscle of the crayfish *Procambarus clarkii* differ in morphology and physiology. Boutons of tonic terminals are considerably larger and generate an excitatory junction potential which is initially small, but facilitates dramatically with 20 Hz stimulation, and does not show depression. Phasic terminals are filiform, and produce an excitatory junction potential which is relatively large, but which shows only moderate transient facilitation at 20 Hz, and soon depresses. (b) Demonstration of inverse relationship between facilitation and depression in phasic axon 3 and tonic axon 6 supplying abdominal extensor muscles of the crayfish, *Procambarus clarkii*. Stimulation at the indicated frequencies was sustained for 20 min, leading to depression and facilitation, respectively, of the phasic and tonic excitatory junction potentials. (a) From Lnenicka GA and Morley EJ (2002) Activity-dependent development and plasticity of crustacean motor terminals. In: Wiese K (ed.) *The Crustacean Nervous System*, pp. 266–282. in combination with EJPs) are elicited by appropriate nerve stimulation (Figure 12). These events are often superimposed on a background of depolarization attributed to tonic release of neurotransmitter.

Synaptic Diversity of Single Neurons

Characteristically, in response to trains of action potentials, both EJPs and IJPs exhibit short-term facilitation and depression, but the manifestations of these processes vary enormously at different terminals of individual neurons. Diversity of terminal physiology is best known in crustaceans (Figure 9). Individual muscle fibers, which differ in physiological and biochemical features, are thought to specify the physiological properties and also the structural features of the innervating terminals. In particular, the probability of transmitter release per synapse and the extent of short-term facilitation and depression are variable features which are characteristically different for terminals innervating specific muscle fibers. Experimental manipulation of muscle fibers to alter their electrical properties leads to compensatory adjustments in physiological responses evoked by the innervating terminals on the affected muscle fiber. This line of evidence indicates a retrograde influence from the muscle fiber to the presynaptic nerve terminal.

Figure 11 Electrical responses at *Drosophila* neuromuscular junctions. (a) Spontaneously occurring excitatory junction potentials (EJPs) of muscle 6, recorded with an intracellular electrode during fictive locomotion. Two motor neurons are active, producing different patterns of excitatory potentials. Large and small EJPs occur in bursts; bursts of small EJPs are more prolonged. (b) Spontaneously occurring EJPs averaged to illustrate their relative amplitudes. In a different preparation, direct stimulation of the motor axons produces small EJPs and compound EJPs (at higher stimulus strength and recruitment of the second motor axon). (c) Extracellular recording from small and large boutons (type 1s and 1b, respectively) with a 'macropatch' electrode. Recordings were made in HL3 solution (20 mM Mg^{2+}, 1.5 mM Ca^{2+}). Responses of type 1s boutons typically showed little or no facilitation during repeated stimulation; those of type 1b boutons were initially smaller, but often showed short-term facilitation in this physiological solution. From Kurdyak P, Atwood HL, Stewart BA, et al. (1994) Differential physiology and morphology of motor axons to ventral longitudinal muscles in larval *Drosophila*. *Journal of Comparative Neurology* 350: 463–472.

Retrograde signals like those described in *Drosophila* could be partly responsible for muscle cell specification of presynaptic terminal properties. But the general effects on growth and transmitter release ascribed to the BMP pathway may not be enough to account for the wide range of response properties observed in crustaceans (Figure 9). Additional refinements, which may include other retrograde signals, quantitative regulation of signaling effectiveness, and regulation of local protein synthesis in or near the presynaptic terminal, are very likely involved and have yet to be elucidated.

Proximate factors responsible for variation in release properties are in part structural – terminals with higher output have on average more active zones per synapse, and the individual active zones are on average larger – and in part physiological, possibly related to higher impulse-linked calcium entry per synapse in high-output boutons. Biochemical or immunohistochemical observations have not been made to determine molecular differences among boutons.

Synaptic Specialization of Different Motor Neurons

Synaptic differentiation among motor neurons is best known in crustaceans, where large differences between phasic and tonic motor neuron subtypes are strikingly apparent. Very similar neurons are found also in insects. Phasic neurons, normally silent but active for brief episodes of intense activity, produce EJPs of large amplitude which fatigue rapidly on repeated stimulation, whereas tonic neurons, active continuously during normal activity, produce smaller EJPs which often facilitate dramatically and are very resistant to depression during sustained activity (Figure 10). The physiological differences are linked to morphological ones: tonic axons have larger terminal varicosities which contain more mitochondria (Figure 10(a)). These very different types of motor neurons often innervate the same muscle fibers in crustacean limb muscles. Muscles innervated exclusively by either phasic or tonic motor neurons

Figure 12 Electrical responses at nematode neuromuscular junctions. Intracellular recordings from muscle fibers of *Ascaris lumbricoides* with stimulation of identified neurons in transverse commissures. (a) Stimulation of dorsal excitatory (DE) neurons produces slow depolarizations, which evoke action potentials in medial muscle fibers. (b) Stimulation of a dorsal inhibitory (DI) neuron generates a hyperpolarizing response in dorsal muscle fibers. (c) Biphasic responses (combined depolarization and hyperpolarization) produced by stimulation of DE and ventral inhibitory (VI) neurons. From Walrond JP, Kass IS, Stretton AO, et al. (1985) Identification of excitatory and inhibitory motoneurons in the nematode *Ascaris* by electrophysiological techniques. *Journal of Neuroscience* 5: 1–8.

are also prevalent; abdominal muscles of crayfish and lobsters provide the best known examples.

At the physiological level, explanations for the phasic–tonic differences have become available. The large differences in synaptic fatigue are linked to a smaller store of docked and releasable synaptic vesicles, and a larger fractional release of available vesicles, in phasic neurons. In addition, smaller and less active mitochondria in these terminals are less effective in maintaining intracellular ion homeostasis, vesicle recycling, and transmitter supply. The larger fractional release in phasic terminals, which ensures a much higher probability of release per synapse, is due to higher Ca^{2+} sensitivity and more rapid kinetics of intracellular Ca^{2+} receptors governing synaptic vesicle exocytosis, rather than to larger Ca^{2+} entry at each synapse during an action potential. This feature was demonstrated in experiments with 'caged' Ca^{2+} injected into the terminals. Photolysis of the caging compound produced about tenfold more release in phasic than in tonic terminals at the same final intracellular Ca^{2+} concentration. In combination with slower Ca^{2+}-binding kinetics of the intracellular Ca^{2+} receptors at the active zone in tonic nerve terminals, this differentiating feature accounts for most of the phasic–tonic phenotypic peculiarities.

Molecular differences that could account for these remarkable features of performance remain sparse. A regulatory Ca^{2+}-binding protein, frequenin, that affects transmitter release in *Drosophila*, is more strongly expressed in crustacean phasic neurons, but it is not clear that this can account for the observed physiological differences. Very likely, many molecular differences are responsible.

In other invertebrates, phasic–tonic differentiation also occurs, though usually less strikingly than in crustaceans. For example, in the *Drosophila* larva, type 1s boutons fire less often during locomotion, have a higher output per bouton, and facilitate less than do type 1b boutons (Figure 11). Compared to type 1b terminals, they are more 'phasic' in their response properties and roles in locomotion. The quantal output per synapse is larger in type 1s boutons, but only by a factor of 2–3, rather than 100–1000 as in crayfish phasic and tonic terminals. Thus, the *Drosophila* larval preparation does not provide a clear-cut model for investigating this aspect of synaptic differentiation.

Conclusion

This brief survey of invertebrate NMJs brings out general features of our current knowledge. Physiological and biophysical findings on details of synaptic transmission, relevant receptors, and ion channels are based largely on experimentally amenable NMJs of a few species of arthropods. On the other hand, modern genetic and molecular information relevant to synaptic structure and function has been built up using small organisms (*Drosophila* and *C. elegans*)

which lend themselves less well to physiological analysis. The *Drosophila* larval preparation, although small, can be used for physiological analyses and there are many recent studies on the effects of various mutations and genetic manipulations on synaptic performance. In *C. elegans*, physiological work is an order of magnitude more difficult, and most of what we know by direct measurement about nematode neurophysiology has been obtained from the much larger *Ascaris*.

Considering known invertebrate systems in total, it is clear that the major invertebrate phyla share a few common features, but differ in detail greatly from each other and from vertebrates. Conserved features in the invertebrates which distinguish their NMJs from those of higher vertebrates are the prevalence of numerous small neuromuscular synapses and active zones, generally widely distributed on the muscle fiber's surface; the common occurrence of polyneuronal innervation, often including peripheral inhibitory neurons; and, frequently, striking exploitation of short-term synaptic plasticity (facilitation and depression). But there are great differences among the major invertebrate phyla. Arthropods use glutamate and GABA, major central neurotransmitters of vertebrates, as their neuromuscular transmitters, and acetylcholine as their major central transmitter; mollusks and nematodes use acetylcholine as their major peripheral excitatory transmitter. Arthropods and mollusks innervate their muscles with branches of motor axons that conduct action potentials to the neuromuscular junction; nematodes have motor neurons that do not conduct action potentials, release transmitter tonically, and synapse with muscle arms that travel directly to the longitudinal nerve cords. A combination of these styles of innervation is found in onychophorans.

Several solutions to the problem of obtaining maximum range of motor activity from a limited set of neurons and muscle fibers have been developed in arthropods and mollusks. Synaptic differentiation at different terminals of a single motor axon permits variable recruitment of muscle fibers in the innervation field according to functional demand. In contrast, synaptic differentiation of specialized phasic (fast) and tonic (slow) neurons, often innervating the same muscle fibers, has evolved as a method of generating different modes of locomotion. These neurons are fundamentally different in their physiology. While retrograde signaling from the muscle fiber may account for differentiation of terminals associated with a single neuron, it cannot explain the differences between phasic and tonic neurons innervating the same muscle fiber. Further analysis will be needed to uncover the root causes of phasic–tonic presynaptic neuromuscular differentiation.

Comparative Neurobiology: History

R L Reep, University of Florida, Gainesville, FL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Three interrelated conceptual threads run through the history of comparative neurobiology: understanding the relationship between nervous system activity and behavior, reconstructing the evolution of the nervous system, and uncovering the mechanisms that generate the patterns and transformations seen during development of the nervous system. These three themes were regular points of departure during the nineteenth and early twentieth centuries, but technical limitations often resulted in long periods of little or no progress beyond certain limits. Since the 1930s, the development of ever more refined techniques for electrophysiological study of the nervous system has led to detailed analyses of the patterns of neuronal activity that underlie sensory and motor functions and behavior, and has provided maps of the localization of these processes in the brains of vertebrates. The development of sensitive axonal tracing techniques in the 1960s, together with the formulation of systematic methods by which to compare phenotypic characters, led to combination of the two approaches in efforts to understand homologies among vertebrate nervous systems. Since the 1980s, the explosion of molecular data on gene expression has begun to provide a framework by which to understand themes and variations in development and evolution, including that of the nervous system. In invertebrates, the combination of electrophysiology, characterization of the architecture of single neurons, and analysis of gene expression patterns is enabling dynamic descriptions of the operation of small neural networks having defined functions.

Origins

Recognition of the brain as the organ which is responsible for organizing sensation, movement, cognition, emotions, and behavior has many origins in antiquity, but it became firmly established in the nineteenth century. Along the way came the recognition that brains in animals perform many of these same functions. In the third century AD, Galen performed dissections on the nervous systems of many mammals, described the sympathetic chain, distinguished between sensory and motor nerves, and concluded that cerebral convolutions could not be the seat of intelligence, since they were well developed in donkeys. He also focused on the ventricles as a storage place for animal spirits, and thus the seat of the soul. Based upon wounds suffered by soldiers, Galen proposed that the brain substance was the site of intellect. Fascination with the role of the ventricles in higher functions persisted into the Renaissance and beyond. Leonardo da Vinci performed wax casts of the ventricles in cattle. Vesalius commented that animals had ventricles that were similar to those in humans. Descartes chose the pineal as the seat of the soul, partly because it was surrounded by cerebrospinal fluid that he also believed to contain the animal spirits. In the seventeenth century, Thomas Willis developed the first modern theory of functional localization when he ascribed different functions to the cerebral cortex and corpus striatum. In the eighteenth century, it was discovered that the medulla contained centers for cardiovascular and respiratory functions, through experiments on dogs and rabbits. Studies on dogs also showed that dorsal spinal roots conveyed sensory signals whereas ventral roots were motor. One of the most important findings of the nineteenth century was the localization of the dog motor cortex by Fritsch and Hitzig in 1870.

The history of comparative neurobiology is inextricably linked to several major trends in biological thought, revolving around comparative anatomy, embryology, and evolution. In the early nineteenth century, Cuvier and others who embraced Naturphilosophie conceived of species as being immutable, each one being the perfect design product of a creator who had particular functional needs in mind. Interestingly, Cuvier gave priority to the nervous system in establishing his system of animal taxonomy, arguing that all other systems were subordinate to it. In contrast, his contemporary and former friend, Étienne Geoffroy Saint-Hilaire, emphasized that function follows form, and that final causes cannot serve as explanatory principles. Geoffroy suggested that philosophically there is only a single animal. He emphasized the existence of a unity of plan for vertebrates, and thought that archetypal structures could be modified in many ways and that each of these allows a certain range of functional capacity (this is an early example of the concept of developmental constraint). However, these modifications were not conceived to occur within the framework of descent with modification later articulated by Darwin. Homology (Geoffroy's analogy) was properly recognized by the principle of connections – relative position and spatial relationships rather than simply shape. This presages the use of relative position of nuclei and their patterns of neuronal connections as

modern criteria for homology. Geoffroy Saint-Hilaire's proposal to extend the vertebrate archetype to arthropods was generally viewed skeptically and contains many fanciful, erroneous elements. However, since the 1980s, molecular biological studies have revealed deeply conserved genes and gene expression patterns across phyla, including segmental and dorsoventral patterning. Now it is commonplace to expect to find ever more intricate similarities in developmental mechanisms, because the acceptance of a common tree of life is firmly embedded in biological thinking.

Biologists of Geoffroy Saint-Hilaire's time knew nothing about genes, yet they realized that some as yet undiscovered portion of the cell was directing transformations such as differentiation. It then became possible to imagine realistic (but then unknown) scenarios by which transformations had created the extensive diversity of biological forms coming to light through nineteenth century study of fossils and extant organisms. Darwin's revolutionary synthesis firmly established descent from common ancestry as the guiding principle in studies of relatedness of form, rather than Cuvier's functional morphology or Geoffroy's unity of plan. Darwin also emphasized that a true theory of inheritance must include a mode of transmission and a mode of development. He emphasized the modular nature of individual body parts, which evolved with a degree of independence, thus glimpsing one of the current preoccupations of evolutionary developmental biology.

Neuroanatomy in an Evolutionary Context

Comparative neurobiology began to flourish in the latter half of the nineteenth century, at a time when naturalists traveled the world collecting specimens of previously undescribed life forms, fossil discoveries were providing an ever expanding record of diversity in the past, geologists were finding evidence that the Earth was much older than had been thought, and Darwin's theory of evolution was being expounded and digested. The practice of sectioning brains and staining sections began in the mid-nineteenth century, shortly after the exposition of the cell theory by Schleiden and Schwann in 1837. Degeneration methods began in 1852 with Waller. Weigert developed myelin staining in 1881, around the same time that Nissl developed a method for staining cell bodies and Cajal began his intense study of neurons using the Golgi stain. Cajal championed the view that the nervous system is composed of separate cells (neurons) rather than a continuous reticulum as envisioned by Golgi. Toward the close of the century, Sherrington formalized the concept of the synapse. Around this time, several centers devoted to comparative neuroanatomy were being established in Europe and North America. Even Sigmund Freud joined the fray, investigating crayfish neurons.

Comparative neurobiology naturally embraced an evolutionary context for its discoveries. However, in spite of Darwin's emphasis on the use of actual genealogies to define taxonomic relatedness, another dominant tendency of the day was adopted, the ancient belief in scala naturae – a phylogenetic scale of nature that viewed evolution as progressive and linear, with increases in complexity and intelligence from fish to amphibians, reptiles, birds, and mammals, culminating with humans. This viewpoint was to dominate comparative neurobiology until the 1980s. For Cajal there was a discernible increasing complexity in behavior and elaboration of nervous system elements as one progressed from unicellular organisms, which lack a nervous system and exhibit rudimentary responses to stimuli, through coelenterates, with sensory and motor neurons, to worms, in which the primitive scheme of sensory and motor neurons only is embellished by the appearance of the interneuron or association neuron. Cajal even stated that with the advent of the association neuron, multicellular organisms became true animals. This qualitative leap was, of course, due to the integrative richness made possible by the interposition of interneurons between sensory and motor neurons. Although we now know that the situation is not so simple (e.g., coelenterates have integrative capacities), these first glimpses of the neural machinery, which undoubtedly was at the heart of generating complex sensory impressions and coordinated movement expressed as behavior, sparked a new era in comparative brain studies that continues to the present. As important as association neurons were, Cajal felt that an even greater step was taken when the psychomotor neuron appeared. These, too, were association neurons but were farther removed from sensory and motor elements, and were organized into concentrated masses, such as the cerebral ganglia of arthropods and the cerebral hemispheres of vertebrates.

Cajal enumerated several ways in which the general organizational structure of vertebrate nervous systems resembled the ganglionic nervous systems of invertebrates: axons of spinal cord motor neurons innervate striated muscles, primary sensory neurons originate outside the central nervous system (CNS) and terminate in the spinal cord, second-order association neurons lie within the cord, higher order neurons transmit neural activity to the cerebral cortex, and corticospinal neurons run the length of the CNS. Cajal envisioned the transformation from the invertebrate to the vertebrate plan to be driven by proliferation of neurons and their processes, elaboration of

neural morphology to increase capacity for information processing, and progressive unification of neural tissue into a continuous mass to increase conduction speed and conserve neuronal cytoplasm.

In 1906, JB Johnston viewed gross features of the vertebrate brain and patterns of neuronal connections as having evolved through adaptation to particular modes of life, and by embryonic development, whereby important roles are played by special structures adapted to the embryonic mode of life and inherited structures adapted to ancestral modes of life. Similarly, Cajal emphasized the limited range of stimuli provided to the CNS by the sense organs, and this limitation led him to speak of a substance of which we would remain forever ignorant, whose essence would inevitably escape our understanding. Johnston and Cajal both viewed cerebral cortex as responsible for organizing the most complex functions.

One aspect of scala naturae thinking was the concept that some brain traits were older than others. For Edinger, Herrick, Ariëns Kappers, and others, olfaction seemed to be the most primitive sense; therefore, the olfactory areas of the brain were viewed as the most ancient. The telencephalon in Agnathans was believed to receive only olfactory projections, hence it was said to consist of a paleopallium and paleostriatum. Fish were believed to have evolved higher olfactory centers, represented by the hippocampus or archipallium. Thalamic projections to the striatum were thought to have originated in amphibians, whereas those to the neopallium were believed to have appeared first in reptiles. With mammals the neopallium and neostriatum became predominant. Thus in mammals olfactory cortex was named paleocortex, hippocampus was archicortex, and the six-layered isocortex became neocortex. (Ironically, according to ancient usage, the prefix 'archi-' should have been used for the most ancient region.)

The application of purely architectonic methods, together with names derived from the scala naturae mindset, led to erroneous designations that only became clarified much later, with the advent of histochemistry, axon tracing techniques, and methods to trace developmental lineages. Thus, histochemical staining for acetylcholinesterase revealed that the avian striatum comprised a small ventral region, compared to the voluminous territory that had been designated paleostriatum, archistriatum, neostriatum, and hyperstriatum. An overhaul of this terminology has been made recently for avian brains, and it also includes corrections for telencephalic pallial regions erroneously designated as belonging to the striatum. Another case involves ray-finned fishes, in which the telencephalon exhibits eversion during development. This produces reversed locations of the medial and lateral pallium, compared to other fishes. Proper interpretation of axonal labeling patterns was required to correctly identify these regions.

The architectural parcellations of human brains by Brodmann and the Vogts were mirrored by similarly detailed studies of a wide variety of other animals. These descriptive anatomical studies culminated in the 1930s with the publication of the Kappers, Huber, and Crosby volumes. Anatomical comparative neurobiology had temporarily run its course until revived in the 1960s by the advent of more refined techniques for tracing axonal pathways. However, these early descriptive anatomical studies set the stage for a profusion of electrophysiological studies that were soon to come.

Functional Mapping

The tradition of functional localization began with the discovery of excitable motor cortex in dogs by Fritsch and Hitzig in 1870. In the twentieth century, study of functional localization was ignited by the development of microelectrode recordings in anesthetized animals. Woolsey's group set out to map sensory and motor areas of the cerebral cortex in a wide variety of mammals, as a way of gaining insight into the neural events that underlay known variations in behavior and anatomy. This tradition has resulted in many fundamental findings, including detailed studies of topographic maps within the visual, auditory, somatosensory, and motor systems, including subcortical areas of the brain stem and thalamus. A key insight has been the presence of expanded representations in the cortex that reflect specializations of the sensory periphery. Functional mapping has also revealed cortical fields that are common to all mammalian species. These include primary and secondary sensory areas for vision, audition, and somatic sensation, and primary motor cortex. This work provides a basis for hypotheses concerning the elaboration of new cortical areas (e.g., multiple visual areas in primates), and for defining the developmental processes by which they originate.

Specializations are important because they represent the boundaries of known evolutionary potential, and because they represent the neural underpinnings of specialized behaviors. The sensory periphery exerts a powerful influence on the development and organization of the central regions that process this information. This is vividly illustrated in the range of variation in sensory specializations exhibited among vertebrates. These include electroreceptors, which appear to have evolved several times; eyes, including four-eyed fish and reductions in blind cave fish; hearing, including echolocation in bats and odontocete cetaceans; tactile

specializations, including body-wide distribution of sensory hairs in naked mole rats, sirenians, and hyraxes; lateral line detectors in fishes and amphibians; and dense mechanoreceptors on catfish barbels, alligator domes, the platypus bill, and the nasal appendages of the star-nosed mole. Among the many striking central elaborations associated with sensory systems are the vagal lobes of certain teleosts. These are voluminous spiral outgrowths of the visceral sensory column in the medulla which process gustatory information from similarly spiraled epibranchial organs located in the oral cavity. Catfish have enlarged medullary facial lobes which process gustatory information originating from the perioral barbels. Electroreceptive fish exhibit an enlarged region of the medulla which receives inputs from an electrosensory lateral line. Mormyrid electric fish possess a hugely enlarged region of the rostral cerebellum. Mammalian examples of central specializations associated with sensory input include neuronal aggregations in the brain stem, thalamus, and cerebral cortex for vibrissal input; multiple visual areas in primate cerebral cortex; expanded central representations in the platypus for tactile receptors and electroreceptors that reside on the bill; expanded cerebral cortical representations in star-nosed moles to accommodate tactile input from elaborate nasal appendages; expanded representations of the forepaw digits in raccoon cerebral cortex; and expanded auditory processing regions in echolocating bats and cetaceans. The cortical neuron aggregates known as barrels, which are associated with vibrissal input, are curious because some species exhibit solid aggregations whereas others have hollow barrels. The developmental determinants of these two types of morphology are not well understood, but appear to involve factors including the distribution of thalamocortical afferents. Understanding how such factors influence the development of particular adult morphologies will illuminate the basis of species-typical neural variation.

Simpler Systems

At the mid twentieth century, Herrick noted that much of the early research in neuroanatomy was motivated by the idea that the simpler brains of nonmammalian vertebrates present fundamental features of the human brain, without the complexities seen in humans and other mammals. Herrick's approach was to study the brain of the tiger salamander, chosen due to its simple behaviors, rapid development, and small brain. His primary interest was the study of the brain as the organ which regulates behavior.

Herrick's approach – to use a simpler vertebrate to understand the human brain – was taken a step further by Wiersma and others in the 1950s, who argued that general principles of the neural control of behavior could be derived from studying and modeling invertebrate systems. This view, that particular systems could reveal general principles of neural function, had precedent in the studies of axon conduction by Hodgkin and Huxley in the 1930s, using the squid giant axon, and those of neurotransmission by Katz and Miledi using the frog neuromuscular junction. Wiersma discovered giant interneurons in the crayfish that are constant in location across individuals, have characteristic firing properties, and produce characteristic movements upon stimulation (thus presaging the later discovery of many other identified neurons). Command neurons have been found to initiate, gate, or terminate patterned neural activity generated by pacemaker networks intrinsic to specific ganglia, in a variety of invertebrate systems, including crayfish swimmerets, insect walking, *Aplysia* feeding, and cricket stridulation. The same command neuron may trigger different movement sequences, depending upon environmental variables. Another striking example of behavioral organization in an invertebrate was Roeder's discovery that mating behavior in the male praying mantis was programmed in the thoracic and abdominal ganglia. This patterned behavior was released upon disconnection from the brain (either experimentally or by having the head bitten off by a female), apparently through cessation of tonic descending inhibition.

The development of microelectrode recording techniques had a major impact on the long-standing goal of understanding the relationship between brain activity and behavior. On the one hand, it was now possible to examine the firing patterns of single neurons. On the other hand, there were vast numbers of neurons in vertebrate brains. The complexity of studying vertebrate systems presented three approaches to the problem, outlined by Don Maynard: (1) shift the focus from single neurons to single brain regions, each consisting of many neurons; (2) examine a few single neurons in great detail, in the hope that general principles will emerge; and (3) explore simpler systems in great detail. In the 1970s, the third strategy led to an intensive focus on invertebrates, which presented the following advantages: fewer nerve cells arranged in discrete aggregations (ganglia), large cell bodies superficially located and thus accessible for recordings, and interesting behaviors. Furthermore, significant aspects of behavior and plasticity could be studied in isolated preparations, such as one thoracic ganglion and its associated legs or wings, the lobster stomatogastric ganglion, or *Aplysia* gill withdrawal. Those in this new field of neuroethology sought to understand the relationship between patterns of activity in single neurons and behavior. A major

advance in invertebrate neuroethology was the discovery that invertebrates possess identified neurons – neurons that have the same cell body location, neurite branching pattern, and basic physiological properties across individuals. Similarly, within an individual there are serially homologous neurons, wherein identified neurons in different ganglia have similar locations and morphologies (but may have different functions). In 1965, Bullock and Horridge summarized the voluminous literature on invertebrate nervous systems. Interestingly, this was the same year that Cohen and Jacklet reported the existence of identified neurons in insects. With the increasing use of microelectrodes to perform intracellular recording and staining, it became possible to correlate cell body location, neurite branching pattern, and firing properties. As a harbinger of the complexity present in even simpler systems, it became apparent that single invertebrate neurons may have extensive neuritic fields, often with several functional compartments that are electrotonically isolated from each other. This raised important issues, still unanswered, concerning the degree to which single invertebrate neurons may sometimes function as several neurons in one. Thus, although invertebrates have many fewer neurons than do vertebrates, the functional properties of their individual neurons may sometimes be greater in complexity.

The discovery of identified neurons and the development of intracellular recording and staining techniques led to a profusion of fruitful studies of the neural networks mediating behavior, mostly in arthropods and mollusks. Recording from several identified neurons simultaneously allows one to investigate network properties in great detail. For specific behavioral sequences, especially those exhibiting repetitive movements, it was found that the pattern of motor neuron output is closely associated with the pattern of movement (e.g., repeating sequences of flexion and extension in limb-based locomotion). Fundamental features of these patterns were often found to persist in isolated preparations lacking sensory input or connections of motor neurons to the muscles they normally innervate. Thus, centrally generated patterns could be studied independent of the actual behavior, and free from the modifying influence of sensory input. By 1966, such isolated systems included cicada song, crustacean heart rhythm, insect flight, crayfish swimmeret beating, insect respiration, insect copulation, and cricket song. There was a general feeling of optimism that the relatively simple nature of the neural components, together with the freedom to study them independent of sensory or motor output, held the promise of understanding the underlying basis for central pattern generation. This view was held not only with respect to the neuroethology of particular systems of interest, but with the aim of deriving general principles of information flow in neural networks. Throughout the 1970s–90s, this resulted in studies of the neural networks mediating behaviors such as walking, flying, escape, stridulation, and digestion. It became clear that the membrane properties of neurons play a key role in pattern generation. Pacemakers that drive the intrinsic rhythm can consist of one or a few neurons with intrinsic bursting oscillatory firing patterns that are either endogenous or are triggered by extraneous factors such as neuromodulators or descending input, as in the crustacean stomatogastric ganglion. More frequently, the rhythm is generated synaptically by a distributed group of interconnected neurons that collectively exhibit oscillatory firing, even though none of the units alone does so, as in locust flight. Reciprocal inhibition, plateau potentials, adaptation, and postinhibitory rebound are other features of these neuron networks that shape the output of central pattern generators (CPGs) in complex ways. However, the details of central integration that produce and modulate such output have proved daunting to unravel, even in the case of rhythmic behaviors. For example, it has proved difficult to specify the cellular basis for observed properties of the frequency and phase of motor output patterns. Intersegmental coordination of movement patterns is mediated by sensory feedback in some cases, and by central interneurons in others. It has also become apparent that groups of neurons may participate in more than one CPG, switching from one to the other under the influence of factors such as neuromodulators. Thus, one outcome of these findings is the striking complexity present in what were initially thought to be simple systems.

The organization of behavior into coherent modules (e.g., feeding, mating, escape) was noted by early neurobiologists, including Charles Sherrington. Later neuroethological studies, particularly those carried out in mollusks, established the neural bases for producing the singleness of action noted by Sherrington. In some cases hormones act as neuromodulatory signals that inhibit certain behaviors during the performance of others. Suppression of one behavior can also occur via synaptically mediated signaling that occurs during another behavior. These mechanisms produce a network of behavioral hierarchies, demonstrating plasticity under certain conditions and thus representing a neural substrate for interpreting concepts such as drive and motivation. In addition to their usefulness for neuroethology, invertebrates have also provided insights into the cellular mechanisms of nerve conduction, synaptic transmission, and synaptic plasticity. In 2000, Eric Kandel was awarded the

Nobel Prize in Physiology or Medicine for his group's work on synaptic plasticity involved in learning and memory in *Aplysia*.

Known vertebrate central pattern generators include those that generate characteristic output for respiration, locomotion, chewing, swallowing, coughing, crying, laughing, sneezing, fear responses, saccadic eye movements, and the hippocampal gamma and theta rhythms. As with invertebrate CPGs, these networks are viewed as providing a basic output pattern that is then modified by a variety of local, ascending, and descending inputs. Swimming in fish, lampreys, tadpoles, and salamanders involves segmental CPGs, on the right and left sides of the spinal cord, that exhibit reciprocal inhibition. Spinal CPGs are controlled by descending input from the brain stem. The basal ganglia play a major role in selecting which CPGs are activated by release from tonic inhibition, and dopaminergic influences are an important factor in all vertebrates. Mammalian limb-based locomotion appears to involve spinal CPGs for each portion of the limb (hip, knee, ankle, foot), and more proximal CPGs entrain those located more distally.

Among vertebrates, one of the best studied examples of neuroethology is birdsong. The modular nature of birdsong has been fundamental to success in analyzing the influence of environmental manipulations, brain lesions, and hormones on song learning, song production, and song perception. This rich subject includes detailed studies of the brain circuitry involved in these functions, comparisons among many species, and investigations of sexual dimorphism, development, and seasonal changes. Another well-studied system is echolocation in bats. The neural representations of specific components of ultrasonic-frequency modulated signals and constant-frequency signals in the inferior colliculus and auditory cortex have been precisely correlated with their behavioral significance. These findings have revealed species-typical neural specializations associated with different signaling patterns and environments, and have also demonstrated specializations at the level of individuals in some species. The coevolution of some bats and their ultrasound-detecting moth prey is a fascinating example of ongoing interspecific neurobehavioral competition, and this has a counterpart in the similar coevolution of echolocating odontocete cetaceans and their clupeid fish prey.

Brain Size

One of the simplest comparisons to make among vertebrates is that of brain size. Comparisons among humans have a long tradition including divining (often in a *post hoc* manner) the moral and intellectual merits of famous individuals based upon the size of their brain. In the mid-nineteenth century this was added to by the burgeoning popularity of phrenology, examining the external bumps of the skull as a window into the soul, due to their close proximity to the brain. Although these speculations may seem laughable now, they illustrate the magnitude of importance that had come to be placed upon the brain as the organ most centrally responsible for human 'identity.' Close behind considerations of brain size have been speculations concerning the significance of gyral patterns in the cerebral cortex. These have been with us since Galen, and until recently have centered on an imagined correspondence between gyral complexity and intelligence. Theories of the past 30 years have focused instead on mechanistic models that take into account the following observations: (1) gyral patterns are lineage-specific; (2) within a lineage, larger brains tend to be more gyrated; (3) gyral crowns exhibit thicker gray matter and greater axon density; and (4) sulcal boundaries between adjacent gyri are often also the site of functional boundaries. Thus, physical features involving relative thickness of gray matter versus underlying white matter, mechanical tension inherent in axon bundles, and sequences of developmental events are given primacy.

Harry Jerison championed the use of relative rather than absolute brain size, reasoning that because larger animals require larger brains, one should compare the excess brain volume present in order to get at issues of intelligence. Sophisticated quantitative procedures have been brought to bear, and there has been an enduring desire to find the basis of intelligence in its many manifestations, represented in brain anatomy. Thus, in a fundamental sense the twentieth century school of thought championed most vigorously by Jerison has its roots in the nineteenth century craniometry of Broca and others. This has raised countless questions within humans alone, not to mention the question of comparing measures of intelligence across taxa. In the late 1970s, the focus shifted from intelligence to more readily defined biological variables. Thus, relative brain size in bats was found to correlate with feeding strategy. Manatees appear to have relatively small brains because dietary and energetic factors drive selection for large body size, perhaps independently of large brain size. Large dinosaurs appear to have small brains simply because they follow the general negative allometric trend for reptiles. The brain case of *Archaeopteryx* suggests that its brain exhibited some traits associated with

flight, characteristic of modern birds. Primates may have relatively large brains due in part to energetic trade-offs between gut and brain.

Total brain size is likely to be a crude measure of intelligence or any other functional variable. Increased understanding of functional localization has resulted in attempts to use allometric analysis to examine the relative enlargement or diminishment of brain regions rather than whole brains. Thus, the ratio of superior to inferior colliculus volume provides a rough index of visual versus auditory dominance, and correlates surprisingly well with known behavioral specializations (e.g., visually dominant frugivorous bats vs. echolocating aerial insectivorous bats). One of the problems with this approach is that most volumetric data exist for major brain divisions rather than for the specific nuclei that comprise functional systems. Nevertheless, recent findings by Barbara Finlay and colleagues have shown significant developmental linkages between the sizes of brain regions in mammals. Because regions differ with respect to important factors like duration of neurogenesis, they scale with each other in a nonlinear fashion. Thus, for example, larger brains will exhibit disproportionately large cerebral hemispheres. Models of brain scaling based upon schedules of neurogenesis explain much of the observed variation in adult brain composition across taxa. An important conclusion from this work is that developmental plasticity allows for specific regions to increase in size, but this is balanced by constraints that produce compensatory changes in other regions. These constraints may be related to rhombomeric and prosomeric compartmentalization of the brain during development.

Evolutionary Developmental Neurobiology

Theories of brain evolution that were proposed prior to the flood of new information on neural connections tended to be based on a scala naturae view of evolution. Phrases such as the 'phylogenetic scale' and terms like 'higher' and 'lower' were regularly used. Paul McLean's triune brain theory posited that the mammalian brain consists of a core that is dominant in reptiles, an intermediate limbic system, and a neopallial cerebral cortex. The popularized notion that there exists a reptilian brain inside each human brain has proved to be a powerful metaphor, but this cultural cooptation has distorted the theory, so that its biological essence has been overshadowed. Thus, in discussions of the triune brain theory, humans often stand in for mammals generally, ignoring the astounding range of perceptual and behavioral diversity among mammals. McLean's theory is in essence a combination of scala naturae thinking with functional localization that focuses on three collections of regions within the brain, ascribes functional properties to each of these three collections, and then uses this as a framework by which to compare taxa. However, we now know that brain regions and collections of regions do not evolve independently. Rather, functional circuits involve multiple brain regions and portions of each of the three systems recognized in the triune brain theory. The scala naturae viewpoint persisted until the 1980s, as neurobiologists were slow to realize the significance of the modern evolutionary synthesis, with its implications that (1) there is no chain of being – rather, evolutionary changes occur independently in each radiations and (2) there are no primitive extant animals – rather, living forms display a mixture of primitive and derived phenotypic traits.

Like other soft tissue characters, most brain traits do not fossilize. Therefore, they can be compared only among extant taxa. Thus, reconstructing brain evolution has been analogized to finding fruit on the ground beneath a tree and trying to reconstruct which fruit fell from which branch. This reality necessitates use of the comparative method, whereby one gathers information about the status of a suite of characters (in this case, neural) in a number of living taxa, then infers the status of the traits in a common ancestor by reference to known evolutionary trees derived from the fossil record or molecular data, together with outgroup analysis and the principle of parsimony (Occam's razor). The result is a pattern of the degree and direction of transformation from the ancestral state among the taxa examined. This leads to working hypotheses concerning which traits are likely to be homologous (similar due to derivation from a common ancestor) or homoplastic (similar due to parallel or convergent evolution). Glenn Northcutt (see **Figure 1**) has led the way in these kinds of studies, and has been a major influence in helping comparative neurobiologists make the transition from scala naturae thinking to an outlook that is congruent with the modern evolutionary synthesis. (He was also instrumental in forming the JB Johnston Club in 1980. This organization's annual meeting provides an important venue for presentations on comparative neurobiology, and the club's official journal, *Brain, Behavior and Evolution*, is an important outlet for publications.)

Of fundamental importance for comparative neurobiologists is the notion of a common plan for the vertebrate nervous system, first suggested by nineteenth century embryologists and anatomists, and

Figure 1 A fanciful chinoiserie scroll, showing Glenn Northcutt and Ted Bullock exploring the wonders of animal nervous system. Presented to Ted on his 80th birthday.

elaborated upon in the past 50 years through studies of gene expression, neurochemistry, and neural connections. Features common to all vertebrates include (1) a dorsally located ectodermal neural tube that exhibits segmental structure and contains the following major divisions: telencephalon, diencephalon, mesencephalon, pons, cerebellum, medulla, and spinal cord; (2) longitudinally oriented functional zones for somatic, visceral, and special sensory and motor regions; (3) cranial nerves associated with specific functional systems, brain regions, and central nuclei; (4) sensory ganglia of cranial nerves derived from ectodermal placodes and neural crest; (5) autonomic and spinal ganglia derived from neural crest; (6) major divisions of the brain with characteristic nuclear groups having particular patterns of connections with other brain regions; and (7) common location of particular groups of neurons identifiable based upon neurotransmitter or other biochemical markers (e.g., dopaminergic projections from the midbrain).

Through the work of von Baer in the early nineteenth century, it was recognized that during vertebrate embryogenesis (1) features common to a group of animals (e.g., medial and lateral nasal processes in mammals) appear earlier than do specialized features present in particular species (e.g., multiple nasal appendages in star-nosed moles), (2) specialized features develop from more general ones (e.g., expanded vagal lobes present in some teleosts develop from the visceral sensory column of the medulla), and (3) embryos of one species do not pass through the adult stage of any other species; rather, divergent adult morphologies result from divergent development. Thus, Darwin proposed that commonality of embryonic features was a key indicator of common descent. Experimental embryology of the late nineteenth century and early twentieth century defined the germ layers and explored the processes of cell lineages, induction, restriction, determination, and differentiation. Diffusible morphogens were suspected to be important factors in inductive interactions and embryonic patterning.

The rise of molecular biology and methods for analyzing complex networks has made possible the long-awaited marriage of evolutionary theory and developmental biology. Garstang, among other biologists of the nineteenth and early twentieth centuries, emphasized that evolutionary changes (new heritable adult traits) can only arise as a result of alterations in development. However, it was not until the 1980s that evolutionary developmental biology came of age. Some of the most stunning findings have involved the deeply conserved nature of genes and gene expression patterns, exemplified by the Hox genes and other genes involved in segmentation and patterning of the body (including the nervous system) in invertebrates and vertebrates. Thus, the notion of a common plan in the vertebrate nervous system must be extended to encompass a common plan for early developmental patterning of the nervous system in invertebrates and vertebrates. This naturally puts a primacy on variation in developmental characters and processes when attempting to reconstruct phylogenetic changes in the brain. Modern thinking about the relationship between ontogeny and phylogeny was reinvigorated in 1977 upon the publication of Stephen Jay Gould's book of the same name. Coming as it did at the beginning of the explosion of studies of the molecular genetics that underlies developing morphologies, this work not only clarified much of the older thinking but also set the stage for understanding phenomena such as heterochrony and homoplasy. Comparative

neurobiologists came to realize that the key to understanding homologies was to analyze developing nervous systems in addition to their adult endpoints.

The development of phylogenetic systematics (cladistics) provided comparative neurobiologists with a method by which to make strong inferences about the evolution of neural characters. These schemes often relied on existing phylogenies derived from paleontological data, together with the principles of parsimony and outgroup comparisons applied to the distribution of the neural character in question. Another approach was to develop the phylogenetic tree *de novo*, based upon the status of multiple neural characters. One of the most scientifically charged applications of this approach was the contention by John Pettigrew that megachiropteran bats were more closely related to primates than to the microchiropteran bats, based primarily upon their patterns of retinotectal connections. This finding provoked a long and lively debate that involved bat biologists as well as neuroscientists. Argument pivoted upon issues familiar from interpretations of character data in many other systems: the relative weight which should be given to various neural and nonneural characters, the independence of characters, and ability to infer the developmental trajectory of a character by observing its organization in the adult. Similar considerations apply to the question of the role of the reptilian dorsal ventricular ridge in mammalian brain evolution. Current debate related to that issue centers on the relative primacy of neural connections versus developmental data.

The analysis of the developmental processes rather than the adult characters that represent their endpoints is providing a rich basis upon which to make comparisons. Stuart Kauffman and others have developed methods for modeling complex networks consisting of many interacting units. This has facilitated understanding the dynamics of adaptive evolution on fitness landscapes, building on the earlier work of Sewall Wright, RA Fisher, and JBS Haldane. (This viewpoint, that evolution explores the functional possibilities inherent in various architectural combinations, would undoubtedly please Geoffroy Saint-Hilaire to no end.) Eric Davidson and others have emphasized that alterations in gene expression in developing systems often occur because of changes in the *cis*-regulatory elements that modulate spatiotemporal patterns of gene expression. These perspectives, together with the deeply conserved aspect of many developmental genes, suggest that under certain conditions genetic regulatory networks exhibit self-organization into ordered states, and that changes in the structure and expression patterns of genetic regulatory networks become the means by which evolution explores fitness landscapes through phenotypic change, subject to general constraints such as the laws of physics and metabolic possibility, and subject to local constraints such as the current habitat and climate. One of the most interesting constraints is the current state of the genetic regulatory network. This biases the direction of change and the basins of attraction (stable states) which the network is likely to find. Thus, as noted by Gould in his magnum opus, *The Structure of Evolutionary Theory*, the random mutation scheme inherited from Darwin is being supplemented with the view that complex evolving networks are biased and generate some of their own order. A central issue is the extent to which this occurs. If developmental constraints in complex gene networks make some transformations more likely to occur, then much of what has been considered parallel evolution (one kind of homoplasy) may be explained as basins of attraction that represent recurrent stable states for complex gene networks. This may have occurred in megachiropteran bat retinotectal connections and vertebrate electroreception, among other cases.

Because brains play a major role in the generation of behavior, and some behavior is adaptive, it follows that if environmental influences alter the brain they can alter behavior, and thus fitness (defined as reproductive success). Therefore, phenotypic plasticity becomes another significant variable to consider in theories of brain evolution. This is particularly true for brains because of their role as a dynamic interface between the organism and the environment, through sensory inputs and motor outputs organized as behavior. Furthermore, nervous systems exhibit a wide range of physiological plasticity, as occurs during learning. Cichlid fish are proving very useful in this endeavor because of their wide range of adaptive phenotypes and rapidity of change. Songbirds have also been an important example due to hormonally driven seasonal changes in brain structure related to song production and learning and song perception. Future research will explore the range of such plasticity, which is found in phenotypes involving factors such as the regulation of receptors and action of hormones and neuromodulators, but also in more conserved traits such as patterns of neuronal connectivity.

Complexins

J Tang, University of Texas Southwestern Medical Center, Dallas, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Complexins (also called synaphins) are small synaptic proteins. They form a small protein family with four isoforms, I–IV. Complexins I (synaphin II) and II (synaphin I) were first identified as co-binding proteins with SNARE complex in the immunoprecipitates by syntaxin antibody. Their name derives from the feature that they preferentially bind to SNARE complex, but not SNARE monomer or heterodimer. Composed of 134 amino acids, both complexin I and complexin II are highly negative charged proteins. The amino acid sequence identity of complexins I and II can reach 84%. The homology is also high for complexin I and II orthologs in different species, especially for complexin II, which is 100% identical among mouse, rat, and human. Complexins III and IV were discovered by protein profile search in a genomic database (CELERA). They have a higher molecular weight, containing 158 and 160 amino acids, respectively. Protein sequence alignment of complexins III and IV revealed that these two isoforms are homologous (58% identity) to each other, and their orthologs in human, mouse, and rat are also very similar. However, there is only limited homology between complexins III/IV and complexins I/II (24–28% identity), indicating that these four isoforms can be further divided into two subfamilies.

All complexins have an evolutionary conserved central region, which is responsible for SNARE complex binding. Outside this region, the similarity is only limited to certain species or one of the two subfamilies. The most striking difference between vertebrate subfamilies is that complexins III/IV contain a CAAX consensus sequence at their C-terminus for posttranslational prenylation that is not present in complexins I/II but is found in some invertebrate complexins. With the exception of this CAAX motif, most invertebrate complexins (with only one or two known isoforms) are more similar to complexins I/II. These data suggest that complexins I/II and some other complexins may lose this CAAX sequence after separation from complexins III/IV.

Expression and Localization

Complexins I–III appear late in brain development on postnatal day 6 (P6), and their levels increase and reach a plateau at approximately P20, a period of synaptogenesis. Complexins I and II are highly enriched in the brain, with much less in retina. In addition, low levels of complexin II were found ubiquitously expressed in peripheral tissues, such as kidney, muscle, and lung. Immunostaining revealed that complexins I/II were neuron specific, with no immunoreactivity detected in glia. The distribution of complexins I and II in the brain and retina, as well as their subcellular localization, has been extensively studied using immunohistochemistry and immunocytochemistry. Both complexins are widely expressed in the brain but with distinct distribution patterns. Complexin I is present in a subpopulation of neurons in cortical layers III–VI, with characteristic punctuate labeling around neuron soma. Cortical layers II, III, V, and VI are the main regions for complexin II, but there are additional granular or stringlike signals scattered over these layers. In hippocampus, complexin I staining is mainly concentrated in the cell soma in dentate gyrus, the CA1–3 region, and some scattered neurons, whereas complexin II covers both cell bodies and synaptic layers of these neurons. Complexin II also highlights the granule cells of cerebellum (complexin I has weaker staining), with ubiquitous granular staining in the molecular layer. Basket and stellate cells are only immunoreactive to complexin I. In Purkinje cell soma, neither complexin I nor complexin II is present. Many other regions, including the spinal cord, contain both complexin I and complexin II, but the pattern is quite different.

Within neurons, complexin immunoreactivity is observed primarily in somas, axons, and presynaptic terminals. Electron microscopy results of complexin labeling have shown signals in both axosomatic and axodendritic synapses, usually associated with synaptic vesicles and plasma membrane. Postsynaptic labeling has also been detected in some dendrites and dendritic spines with much lower intensity. Interestingly, complexin I is remarkably localized in the axosomatic synapses, and complexin II is preferentially present in terminals of axodendritic synapses. The small degree of overlap indicates that they might work mainly in different synapses. The accumulation of complexins in synapses is time dependent. In the early stage (P14), complexin staining of pyramidal neurons is limited to cell somas on hippocampus slice. In comparison, synaptic vesicle proteins already exhibit a punctate distribution. After maturation, the intensity of labeling in the hippocampus is remarkably increased in synaptic layers. These *in vivo* findings of the differential distribution of complexins I and II, as well as the enrichment in synapses during maturation,

are consistent with observations of *in vitro* cultured hippocampal neurons.

In retina, complexin I and II antibodies stain GABAergic amacrine cells. Whether glycinergic amacrine cells contain complexins I/II is controversial since there is supportive evidence for both. Small amounts of complexins I and II have been detected in horizontal cells and the soma of amacrine cells in the inner nuclear layer (INL), whereas they are much more widely distributed in the inner plexiform layer (IPL), as well as ganglion cells in the ganglion cell layer (GCL). Both complexins are absent in photoreceptors and bipolar cells since their staining does not overlap with vesicular glutamate transporter 1 (VGLUT1)-labeled synaptic terminals of these cells.

Unlike complexins I and II, complexin IV is exclusively expressed in retina, whereas complexin III is preferentially located in retina but also may be found in certain areas of the brain, mainly cortex, hippocampus, inferior colliculus, and striatum. Only trace amounts of complexins are detected in other tissues. In retina, complexin III immunoreactivity is present in both the outer plexiform layer and the IPL. Double labeling with VGLUT1 indicated that complexin III is expressed in photoreceptors and bipolar cells. In the IPL, complexin III antibody also labels glycinergic amacrine cells. Similar to the distribution of complexin III, both photoreceptor and bipolar cell terminals contain complexin IV. However, complexin IV-stained terminals in IPL are located in the middle of this layer, which is different from complexin III-containing terminals (in IPL), which are next to the INL and GCL. Moreover, within photoreceptors, complexin III is present in both cone and rod photoreceptor terminals, whereas complexin IV exists only in rod photoreceptor terminals.

Similar to the subcellular localization of complexins I/II, complexins III and IV exhibit a characteristic presynaptic distribution in primary hippocampal neurons. The distribution is dependent on the prenylation modification of the CAAX motif at the C-terminus since cysteine-to-serine mutation in both complexin III and complexin IV altered their localization (like soluble protein). *In vivo* assay with HEK293 cells has confirmed that they can be farnesylated at cysteine within the CAAX motif. Farnesylation enabled complexins III/IV to associate with membrane, which may account for the accelerated accumulation of complexins III/IV in presynaptic terminals as early as D14 in *in vitro* cultured neurons.

Structure and Biochemical Features

Nuclear magnetic resonance and circular dichroism studies have revealed that complexin has no tertiary structure except a stable α helix at the N-terminus of the central region (residues 29–64). Binding of the second half of this α helix to the SNARE complex might induce the extension of the helix to the C-terminal half of the central region and result in the complete interaction with the SNARE complex. Complexin binding did not cause major conformational changes to SNARE complex. Based on fluorescence resonance energy transfer measurement and the crystal structure of the complexin/SNARE complex, it is clear that complexin binds to the four-helix bundle of SNARE complex in an antiparallel manner with a 1:1 stoichiometry (Figure 1). Within this complex, complexin is located in the groove between syntaxin and synaptobrevin and has no direct contact with SNAP-25. This is in agreement with the biochemical result that the substitution of SNAP-25 has the least effect on complexin binding.

The binding of complexin to SNARE complex is mediated by the combination of hydrogen bonding and hydrophobic and ionic interactions in the central region from residues 48 to 70: three arginines (R48/R59/R63) of complexin form salt bridges with three aspartate residues (D57/D65/D68) from synaptobrevin, tyrosine 52 has extensive contact with synaptobrevin by hydrogen bond and lysine 69 and tyrosine 70 respectively contribute to the ionic interaction and hydrogen bonding with syntaxin aspartate D218. These residues are conserved in all complexin isoforms from various species. The substitution of them by alanine completely abolishes binding to the SNARE complex.

Figure 1 Three-dimensional structure of the complexin/SNARE complex. Complexin is shown in pink and binds antiparallel to the mini SNARE complex, which is composed of syntaxin C-terminal SNARE motif (yellow), and corresponding SNARE motifs from synaptobrevin (red) and SNAP-25 (green and blue). The approximate locations of the membranes and the N-terminal domain of syntaxin are indicated. From Rizo J and Südhof TC (2002) Snares and Munc18 in synaptic vesicle fusion. *Nature Reviews Neuroscience* 3: 641–653.

The high conservation of the primary protein sequence within this binding region among all complexins indicates that SNARE complex binding represents the most fundamental function of complexin. As expected, even complexins III/IV maintain the SNARE complex binding ability, although the affinity of complexin IV is much lower compared to that of the other three isoforms. The similarity of the general structure between rat and squid SNARE/complexin complex further confirms this conservation at the tertiary structure level, suggesting an essential physiological function for this interaction.

Although complexin binding does not induce major changes in the four-helix bundles of the SNARE complex, it promotes an extremely tight contact between synaptobrevin and syntaxin/SNAP-25 at the C-terminus of the SNARE complex. The stabilization of the SNARE complex at the C-terminus may help overcome the repulsive forces from the two opposing membrane structures and hold them in close association.

Biochemically, the characteristic feature of complexins is that they can selectively bind to the SNARE complex. The interaction is rapid ($k_{on} \sim 5 \times 10^7$ m s^{-1}) and with high affinity (K_D of approximately 10–36 nM by independent methods). However, this binding does not affect the rate and kinetics of the SNARE complex assembly. In contrast, the extent of SNARE complex formation might determine the affinity of complexin binding. In addition, calcium has little effect on this interaction.

The relationship between complexin and other SNARE complex binding proteins, such as synaptotagmin 1 and α-SNAP, has also been investigated. Experiments using both recombinant and native proteins have confirmed some of the previously discussed results and uncovered a striking finding that there is competition between complexin I, synaptotagmin 1, and α-SNAP for SNARE complex binding. In the hydrophilic environment, α-SNAP has the highest affinity to the SNARE complex. It can easily replace complexin from the immobilized SNARE complex, but the reverse competition fails under the same conditions. Similarly, complexin I is more efficient than synaptotagmin 1 for SNARE complex binding. Mutation (R48/R59/K69/Y70A) of complexin I completely abolishes its SNARE complex binding ability, as well as the inhibitory effect on synaptotagmin 1 for SNARE complex binding, indicating that the competition is specific. However, when SNARE complex is embedded in the phospholipid bilayer to mimic its physiological status, the binding affinity for complexin I decreases dramatically (~70 times lower) compared to that in solution using stopped-flow fluorescence. The major difference results from slower k_{on} and faster k_{off} values produced in the membraneous environment. This change directly leads to the result that synaptotagmin 1 can replace complexin from the SNARE complex more efficiently than the reverse competition in a strictly calcium-dependent manner. The EC_{50} of free calcium concentration for this competition is 50 μM, which is within the physiological calcium concentration range, supporting the physiological relevance of this replacement. Structural studies indicate that complexin binding is able to stabilize the SNARE complex. However, this effect does not block SNARE complex disassembly because NSF can still easily take the SNARE complex apart in the presence of complexin with the help of α-SNAP and ATP, which is consistent with the idea that α-SNAP binds tighter than complexin to the SNARE complex.

As an important presynaptic protein involved in synaptic transmission, complexin can be regulated. Serine 93 of complexin II has been found to be phosphorylated in okadaic acid (OA)-treated primary cortical neurons by mass spectrometry. Since OA is thought to be a selective inhibitor of protein phosphatase 2A (PP2A), complexin II is a potential target of PP2A. It is unknown why complexin I is not detected for the same phosphorylation since residues 91–102 are identical for complexins I and II. Either residues outside this region determine the specificity of the modification or the phosphorylation on complexin I is very transient and weak. In addition, sequence ^{115}SILD^{118} matches the consensus motif of S/T-x-x-D/E for protein kinase CK2 phosphorylation, and *in vitro* assay has confirmed that serine 115 can be phosphorylated. Interestingly, the phosphorylated complexins I/II exhibit higher affinity for SNARE complex binding, suggesting that this modification could potentially regulate SNARE function. However, phosphorylation-specific antibody can only detect complexin II in the immunoprecipitates by complexin antibody, but not in whole brain lysate in the presence of protein phosphatase inhibitors, indicating that only a small fraction of complexin II is phosphorylated *in vivo*. The absence of complexin I signal suggests that either it is not phosphorylated by CK2 *in vivo* or the phosphorylation is very transient or very sensitive to protein phosphatase.

Mechanism of Complexin Function

Microinjection of complexin II-specific antibody into *Aplysia* buccal ganglia induces a transient increase in IPSC amplitude. Application of complexin II recombinant protein causes a sustained depression of IPSC, which can be reversed by further addition of recombinant α-SNAP. Overexpression of complexins I/II in PC12 cells suppresses the exocytosis of both large dense core vesicles and small synaptic vesicles.

These results suggest that complexins have a negative regulatory role in synaptic transmission.

Injection of competitive complexin fragment for SNARE complex binding into squid axons inhibits synaptic transmission. A similar reduction is also observed by knocking down complexin expression in mast cells and pancreatic β cells by RNAi. These results indicate that complexin is required for vesicle fusion. Complexin has been found to be able to promote the oligomerization of the SNARE complex, which is medicated by the incorporation of two individual SNARE motifs of SNAP-25 into different SNARE complexes. However, neither biochemical nor biophysical (CD and fluorescence spectroscopy) data from another research group support this function of complexin. Regardless of the controversial explanation, oligomerization of the SNARE complex has been detected and confirmed. The formation of the ring structures of the SNARE complex might bring the two membrane structures in close association and provide a scaffold for other protein binding, and it may be essential for efficient transmitter release.

Mouse genetic studies may provide the evidence for the physiological function of complexin *in vivo*. Complexin I knockout mice have strong ataxia and die within 2–4 weeks, although with an enhanced feeding regime they have a normal life span (>2 years). Complexin II null mice show no obvious phenotype, indicating that complexins I and II are partially redundant. Deletion of both complexin I and II causes the mice to die within a few hours after birth. Complexins have no effect on brain development and synaptogenesis since no abnormality is found in brain structure, cytoarchitecture, or synapse numbers and density. At the molecular level, the expression of critical synaptic proteins, including SNAREs and synaptotagmin 1, is unaffected in complexin single and double knockout mice. Excitatory postsynaptic currents (EPSCs) of neurons in hippocampal autapic culture from either complexin I or complexin II single knockout mice are indistinguishable from those of control littermates, whereas double knockout neurons exhibit a 66% reduction, which further confirms the redundancy of complexin and also indicates that complexins are necessary for exocytosis. Normal sucrose response and unchanged miniature amplitude and frequency rule out the possibilities of presynaptic readily releasable pool size reduction and postsynaptic dysfunction. Together with indistinguishable vesicle refilling rate and synaptic ultrastructures (active zone length, vesicle number, and docked vesicles) between double mutant and control, results strongly indicate that neurons without complexins I/II are capable of translocation, docking, and priming of synaptic vesicles. The defect in synaptic transmission must occur following vesicle priming and before final fusion. In agreement with these results, both vesicular and synaptic release probabilities are reduced. As expected, facilitation of transmitter release is observed in the early phase of train stimulation in double mutant neurons, whereas consistent depression of EPSC amplitude is detected in control neurons. Titration of external calcium concentration has revealed that the reduction of release probability is due to the impaired calcium sensitivity of evoked vesicle release. Insufficient calcium entry caused by changes of calcium channels can be ruled out since bypassing calcium channels with calcimycin does not eliminate the difference between mutant and control neurons. The dysfunction at the level of the SNARE complex and its associated proteins (including calcium sensor) during the last calcium-triggering step is more likely a reasonable explanation.

Calcium-dependent synaptic transmission can be divided into two components: fast synchronous and slower asynchronous release. In complexin double knockout mice, only the synchronous part is impaired, with the asynchronous part unchanged. This selective decrease of the fast component of vesicle release is very similar to the phenotype of synaptotagmin 1 knockout neurons, which has a more complete abolishment of synchronous release. However, the specific disturbance of the last step of calcium-dependent exocytosis in complexin deletion mice remains unsolved since all known biochemical characteristics of complexins are calcium independent. The similarity between synaptotagmin 1 null and complexin double knockout mice, together with the fact that synaptotagmin 1 has calcium-dependent SNARE complex binding, raises the possibility to explain the phenotype in association with the effects from other SNARE binding proteins.

Discoveries from three groups raise new hypotheses for complexin functions in exocytosis. Using *in vitro* liposome-based fusion assays or a cell fusion system with flipped SNARE proteins on plasma membrane, two groups have shown that synaptotagmin 1 can reverse the inhibitory effect of complexin on liposome and cell fusion, and the release of this clamp is strictly calcium dependent. The function of complexin here was contradictory to the results using complexin double knockout mice. One of the groups provided data on the calcium-dependent co-binding of synaptotagmin 1 and complexin with SNARE complex in liposomes as molecular evidence to explain the relief effect of synaptotagmin 1. However, their results did not indicate whether the co-binding was due to synaptotagmin 1 and complexin binding to the SNARE complex together or only by synaptotagmin 1 binding to liposomes (synaptotagmin 1 has calcium-dependent phospholipids binding). An unanswered question is how the formation of the larger complex (complexin,

synaptotagmin 1, and SNARE complex) resulted in clamp relief.

Another hypothesis is based on the finding that complexin competes with synaptotagmin 1 for SNARE complex binding. As mentioned previously, with the SNARE complex embedded in membrane, synaptotagmin 1 can efficiently replace complexin from the SNARE complex in a strict calcium-dependent manner within the physiological concentration range. This hypothesis emphasizes the function of complexin as an activator to stabilize the SNARE complex after its formation in the absence of calcium. Energetically, the primary effect of complexin binding to the SNARE complex is to overcome repulsive forces and catalyze the SNARE complex to a 'metastable' status for further fusion reactions; with a secondary effect to prevent fusion before calcium entry. Calcium-induced simultaneous binding of synaptotagmin 1 to the SNARE complex and phospholipids removes complexin clamp and triggers vesicle fusion. This hypothesis suggests that primed vesicles containing a partly assembled SNARE complex are either substrates for asynchronous Ca^{2+}-triggered release or activated by complexin binding to SNARE complexes, which transforms them into a substrate for Ca^{2+}-triggered synchronous release. This hypothesis includes a 'clamp' function for complexins that is secondary to their role in activating SNARE complexes and only clamping of activated SNARE complexes produced by complexin binding (Figure 2). In this model, complexin and synaptotagmin 1 function in the same pathway for synchronous release but are not involved in the other asynchronous process, which explains the similarity in phenotype between knockout mice.

To test the hypothesis *in vivo*, a complexin 1/synaptobrevin 2/Venus fusion protein was introduced

Figure 2 Model for complexin and synaptotagmin 1 function in Ca^{2+}-triggered release. Docked vesicles containing unassembled SNARE complexes (top) are primed for release by partial SNARE complex assembly catalyzed by Munc18, Munc13, and RIM (step 1). The resulting primed vesicles form the substrates for two release pathways: asynchronous release, in which full assembly of the SNARE complexes leads to fusion-pore opening followed by complete fusion (steps 2 and 3), or synchronous release, in which 'superpriming' by binding of complexins to assembled SNARE complexes (step 4) activates and freezes SNARE complexes in a metastable state (referred to as priming stage 2). This stage is substrate for fast Ca^{2+}-triggered release when Ca^{2+} binding to synaptotagmin 1 induces its binding to phospholipids and SNARE complexes, with the latter reaction displacing complexin and resulting in fusion pore opening (step 5). Again, opened fusion pores can then dilate to complete fusion (step 6). Fused vesicles undergo endocytosis and the *cis*-SNARE complex is dissembled by α-SNAP and NSF and ready for the next cycle (step 7). From Tang J, Maximov A, Shin OH, Dai H, Rizo J, and Südhof TC (2006) A complexin/synaptotagmin 1 switch controls fast synaptic vesicle endocystosis. *Cell* 126: 1175–1187.

into cortical neurons by lentivirus infection. With a flexible linker at the C-terminus, exogenous complexin folded back and bound to the assembled SNARE complex into which the fused synaptobrevin 2 was incorporated. The high affinity of intramolecular complexin binding to the SNARE complex did counteract the effect of synaptotagmin 1 and inhibit its binding to the SNARE complex, but not α-SNAP binding. Thus, the expression of this fusion protein in wild-type neurons produced a phenotype similar to synaptotagmin 1 knockout mice without a significant change in vesicle pool size. Mutations (R48/R59/K69/Y70A) on complexin could eliminate this effect, indicating that the effect was specific.

Although complexin II knockout mice appeared normal and their hippocampal neurons had no significant difference in EPSC amplitude and paired-pulse facilitation (PPF), titanic stimulation-induced long-term potentiation (LTP) in both CA1 and CA3 regions was impaired. The decrease of LTP in CA1 was frequency dependent, and the difference was significant only at 100 Hz and not at 10 and 30 Hz. Mossy fiber-CA3 LTP was expressed presynaptically, so the reduction of LTP could be directly caused by presynaptic depletion of complexin II. However, Schaffer collateral fiber-CA1 LTP was mediated mainly by the postsynaptic activation and insertion of AMPA receptors. Direct application of NMDA induced the same potentiation of EPSC, suggesting that the postsynaptic machinery was presumably intact. One possibility was that complexin acted downstream of the retrograde signals from the postsynaptic machinery at a later stage of LTP. Another was that complexin may be involved in postsynaptic function, although its expression level was very low. In agreement with the electrophysiological finding, additional behavior studies of complexin II-deficient mice showed a severe impairment in Morris water maze, suggesting that complexin II plays an essential role in synaptic plasticity, even learning and memory.

The conservation of all complexin isoforms for SNARE complex binding suggested that complexins III/IV may have similar functions. Expression of complexins III and IV fully rescued the reduction of EPSC amplitude in complexin I/II double knockout neurons. Although the farnesylation of complexin III had little effect on rescue, it did regulate complexin IV function, with the mutant (C158S) having much less rescue activity.

Pathological Function of Complexin

Huntington's disease (HD) is a neuronal degenerative disorder characterized by motor, emotion, and cognitive dysfunction. It is caused by an expanded CAG repeat in the huntingtin gene, which results in a polyglutamine repeat expansion in protein. A selective and progressive depletion of complexin II has been detected in brains of HD model mice (R6/2), which expresses the first axon of the huntingtin gene with an expanded CAG repeat. Measurement of protein samples from postmortem brains of HD cases has confirmed the decrease of complexin II in striatum, which is accompanied by a significant reduction of synaptobrevin 2 and Rab3A. Unexpectedly, in contrast to the results from striatum, the protein levels of all three proteins are remarkably elevated in samples from hippocampus. The selective depletion or increase of limited synaptic proteins indicates that this is not due to progressive neuronal degeneration since most synaptic proteins are unaffected. Moreover, complexin II knockout mice and R6/2 mice have a common impairment of LTP in the CA3 region, suggesting that the depletion of complexin II may contribute to the LTP reduction in R6/2 mice. Cross of R6/2 mice with complexin II knockout mice does not cause additional deteriorative effects on the phenotype of R6/2 mice, indicating that loss of complexin II shares the same mechanism underlying R6/2 phenotype. However, whether complexin II has a causal effect and how complexin II is involved in the pathological process of HD are unknown.

Complexins have also been widely employed as an indicator in many mental disorders, such as schizophrenia, bipolar disorder, and major depression. Studies in this field have provided very controversial results: both an increase and a reduction of complexin II:complexin I ratios have been reported for schizophrenia from different groups. Furthermore, genetic association analysis in Japanese schizophrenia patients found a very weak linkage between complexin and schizophrenia. All these inconsistencies indicate that the issues of complexin functions in these disorders and the responses to different drugs are quite open.

Future Directions

Much progress has been achieved in the past few years, but more questions are still open and need to be addressed. Complexins are in a pool with various proteins within the presynaptic terminals; the relationship between them needs to be reevaluated and explored. One example is Munc18. Studies have demonstrated that Munc18 is incompatible with SNAP-25 for syntaxin binding, implying that Munc18 functions as a binding partner for the closed form of syntaxin but not for the open form of syntaxin within the SNARE complex. However, data have demonstrated the existence of a SNARE/Munc18 complex. In addition, unpublished results from GST-complexin pull-down

assay indicate an efficient co-binding of Munc18. Thus, whether complexin and Munc18 bind together with the same SNARE complex or not is a very interesting question. This can be further expanded for other proteins. As another example, in complexin double knockout mice, there is approximately 34% EPSC left. It is known that complexin III is also expressed in hippocampus. By making triple knockout mice or performing complexin III knockdown on the background of complexin I/II double knockout neurons, we can answer the question of whether the remaining response is due to the existence of complexin III.

Introduction

There are an infinite number of movements that we can do at any given moment. How do we select what kind of movement to perform? We perform actions to acquire rewarding states. For example, we may reach in order to pick up a cup of tea and bring it to our mouth. The drinking of the tea is the rewarding state that we have chosen as our goal, and the reach is the action that allows us to experience that rewarding state. The problem of what to do begins with a catalog of all potential rewarding states and proceeds with an evaluation of these possibilities to decide on one that is most valuable.

Our ability to choose from among the infinite number of potentially rewarding states depends on our brain's ability to assign value to those states. This value includes a measure of cost and a measure of reward. The basal ganglia play a fundamental role in this ability to assign value to potentially rewarding states and help in choosing the goal. However, once the goal has been chosen, the problem of how to perform it remains. The cerebellum plays a fundamental role in this ability to control the process of performing actions.

The problem of motor control is summarized in Figure 1. Through our belief about costs and rewards of various states, we choose a goal state. We use the cost and rewards associated with our goal to generate motor commands that we believe will bring us closer to the goal state. Our motor commands cause states of our body to change. We sense these state changes through our sensory system. However, we also predict what the sensory changes should be through internal models (called forward models). We combine what we predicted with what we actually sensed to form beliefs about the state of our body. We compare our belief about our current state with our goal state and continue to produce further motor commands until either the goal state is achieved or we abandon that goal and consider another one.

The Problem of What to Do

We select actions based on cues that are available to us. Some of these cues tell us about the position of our body and objects in the environment with respect to a spatial map. For example, suppose that a rat is released into a pool of water from some random starting point. A platform is positioned in a specific location just below the waterline and cannot be seen. The platform is always at the same location in the pool. Rats dislike being wet and will try to find a way to elevate themselves. The normal rat can learn to locate the platform position by paying attention to the visual cues that surround the pool. For example, the rat might learn that the platform is near the wall with a particular feature. This requires learning a spatial map of where the platform is located with respect to the surrounding visual cues. With repeated swims, the animal learns a spatial map. This spatial map is analogous to a reward function that associates places in the pool with the likelihood of the platform (and therefore the likelihood of not having to be wet). Once they learn the map, rats can find the platform regardless of where they are released into the water because the map is related to the cues on the walls. If the platform is removed, the normal animal will spend most of its time searching in the region where the platform used to be.

Learning of a spatial map depends on the hippocampus. If a genetically altered rat with a malfunctioning hippocampus is given the same training, he will not learn the spatial map and will spend equal time in each quadrant. Therefore, selecting an action based on a spatial map likely relies on the hippocampus. Sometimes, certain cues are rewarding no matter where they are located. Consider a pool where there are two hidden platforms: one that is large enough for the rat to mount and one that is too small. Both have a distinct visual cue associated with them: a little flag attached to each platform, each of a different color, sticking out of the water. Suppose that the flag attached to the large platform is red, and the flag attached to the small platform is green. The platforms may be positioned in any part of the pool, and their locations will change from trial to trial. Therefore, in this experiment, the animal needs to learn that the red flag indicates the location of the suitable platform and is a rewarding object.

In another version of the experiment, the large platform will always be located in a particular spatial location, but the flag atop it will be a random color. In this version of the experiment, the animal needs to learn that it is not the color of the flag that is important but the spatial location. The two versions of the experiment are depicted in Figures 2(a) and 2(b). There is a natural competition between the learning systems that might be involved in these two conditions: Is the platform the same 'place' as before (where place refers to a location in the spatial map), or is the platform always where the red flag is located? After a few trials in which the flags

Figure 1 Schematic of motor control for voluntary movements.

move around, in the first experiment the animal should learn that the spatial map is not a good indicator of the platform and that therefore the values associated with places in the spatial map should be near zero. However, the value associated with the red flag should rise. In the second experiment, the animal should learn that it is the spatial location that is of value and that the flag colors are irrelevant.

Packard and McGaugh performed both experiments by having their animals swim eight times per day for a number of days. They recorded the number of times the animals mounted the small platform and labeled these as errors. In the first experiment, where reward was associated with the red flag, healthy animals gradually learned to swim to the red flag (Figure 2(a)). It is interesting that animals with damage to the medial temporal lobe (which includes the hippocampus and the fornix, a major afferent–efferent pathway of the hippocampus) learned the task just as well as the healthy controls. However, animals with damage to the caudate nucleus (a part of the basal ganglia) were much slower in learning the association. After days of training, they continued to attempt to mount the platform under the green flag. Therefore, it appears that the ability to associate reward to stimuli regardless of spatial location depends on the basal ganglia.

In the second experiment, where reward was associated with a spatial location, healthy animals gradually learned to swim to that location and ignore the color of the flag (Figure 2(b)). Animals with damage to the caudate nucleus performed similarly to the healthy controls. However, animals with damage to the medial temporal lobe were much slower in learning the association. Therefore, the ability to associate reward to a spatial location depends on the medial temporal lobe.

The Major Reward System in the Brain Is the Neurotransmitter Dopamine

How does reward get associated with a stimulus? That is, how do we learn the value of a location on a spatial map or the color of a flag? This issue is still poorly understood, but a major piece of the puzzle appears to be the neurotransmitter dopamine. Neurons that release dopamine have their cell bodies in the midbrain area (an area called the substantia nigra) of the brain stem. They project to three main areas: the striatum (encompassing the caudate and putamen nuclei of the basal ganglia), the hippocampus, and the prefrontal cortex. About 80% of the dopamine in the brain is in the basal ganglia.

The earliest studies of neuronal activity in the dopaminergic cells of the midbrain led to few published reports. The investigators conducting those experiments often reported frustration because the neurons never seemed to 'do anything.' For example, the dopaminergic cells discharged at about 2–4 Hz, but this rate never seemed to change. Although they did not recognize it at the time, the people who made these observations had actually stumbled on a crucial and important property of dopaminergic cells. The earliest recordings were made in monkeys that performed highly overlearned movements – a simple flexion and extension of the arm – in a highly stereotyped and repetitive manner. The monkeys performed the task perfectly and learned nothing during the recording sessions.

When Wolfram Schultz and his colleagues reexamined the activity of midbrain dopaminergic cells years later, they placed their monkeys in a situation involving learning, and the cells showed significant modulation in their activity level. They found that these cells carried a signal that conveyed a measure of the predicted reward: when an unexpected reward occurred, the dopaminergic cells increased their discharge rates. After repeated experience, the cells became unresponsive to rewards *per se* but discharged after signals that predicted reward. The omission of expected reward led to a decrease in the firing rate of dopaminergic neurons. Thus, dopaminergic cells seemed to encode both errors in predicted reward and stimuli that predicted reward.

Figure 2 Learning to associate reward to locations on a spatial map depends on the hippocampus, while learning to associate reward to arbitrary visual cues depends on the striatum. (a) Two hidden platforms, one small and one large, are positioned in a constant position with respect to the colored walls. A flag is attached to each platform. On each trial, the flag is randomly changed, but the position of the platforms remains constant with respect to the walls. Each trial block is eight trials. Errors refer to the number of times the animal attempted to mount the small platform. (b) The position of the platforms randomly changes on each trial, but the colors of the flags atop each platform remain constant. Error bars are standard errors of the mean (SEM). Data from Packard MG and McGaugh JL (1992) Double dissociation of fornix and caudate nucleus lesions on acquisition of two water maze tasks: Further evidence for multiple memory systems. *Behavioral Neuroscience* 106: 439–446.

Okihide Hikosaka and his colleagues have studied the prediction of reward by neurons in the caudate nucleus. In their experiment, the monkey had to make either a left or a right saccadic eye movement, cued by a light spot, in order to keep the trials coming. However, for a block of consecutive trials, only movements to the left target would produce a reward. Then the experimenters reversed that contingency, and after the reversal, only movements to the right target produced reward. The activity of striatal neurons related to leftward saccades increased after just one trial when a leftward target became associated

with reward. In conjunction with that increase in activity, the monkeys responded faster to that cue. Then, after the experimenters switched the reward contingency so that rightward, not leftward, movements produced rewards, the cell slowly returned to its original, lower level of activity as the monkey responded more slowly to the leftward target. Therefore, rewarding behaviors are performed faster, which is certainly quite familiar to parents who request that their child do something. It is important to note that this reduced reaction time is associated with increased activity in the caudate nucleus of the basal ganglia. The basal ganglia seem to be crucial for associating reward to stimuli.

Balancing Expected Rewards with Motor Costs

Associating reward to sensory states is important, but there is another crucial piece of the puzzle: costs of motor commands. Although drinking a cup of tea may provide us with a pleasant sensory state, if that were the only constraint, then we should reach as fast as possible. But people do not reach as fast as possible. Why do we reach with a specific trajectory and speed? What is the cost that prevents us from moving at maximum speed?

The obvious cost is a metabolic cost of the motor commands. Therefore, in choosing how we should move, we need to consider how much reward we might get when we achieve our goal state and the costs associated with the motor commands that we would produce to get to that state. However, for something as simple as an eye movement, it is hard to imagine that the metabolic costs are very high. Is there some cost other than metabolic cost that constrains our movements?

It turns out that a more compelling motor cost is noise. Large motor commands produce noisy, variable movements. That is, if our objective is to reliably achieve a rewarding state, then large motor commands are a bad idea because they will increase the variance of our movements. These ideas were first described by Harris and Wolpert in a theoretical paper that showed that the cost of minimizing variance of our movements nicely explains the trajectories that animals choose for their eye and arm movements. At the heart of the theory is the assumption that large motor commands make our movements more variable and therefore difficult to control. An experiment by Jones and colleagues has demonstrated this idea (Figure 3). In this experiment, participants produced a given force with their thumb flexors (Figure 3(a)). To guide force production, the participants viewed a cursor that displayed thumb force, but the experimenters analyzed the data during a 4-s period in which this feedback had disappeared. They observed that variance of force was larger when the force magnitude was larger: standard deviation of the force grew linearly with the size of the force

Figure 3 The standard deviation of noise grows with mean force in an isometric task. Participants produced a given force with their thumb flexors. In one condition (labeled 'voluntary'), the participants generated the force, whereas in another condition (labeled neuromuscular electrical stimulation (NMES)), the experimenters stimulated their muscles artificially to produce force. To guide force production, the participants viewed a cursor that displayed thumb force, but the experimenters analyzed the data during a 4 s period in which this feedback had disappeared. (a) Force produced by a typical subject. The period without visual feedback is marked by the horizontal bar on top (4 s), and is expanded in the second column. (b) When participants generated force, noise (measured as the standard deviation (SD)) increased linearly with force magnitude. MVC, maximum voluntary contraction. From Jones KE, Hamilton AF, and Wolpert DM (2002) Sources of signal-dependent noise during isometric force production. *Journal of Neurophysiology* 88: 1533–1544.

(Figure 3(b)). Therefore, large motor commands produce inaccurate movements because the standard deviation of the noise in the signal grows with the size of the signal.

The Problem of How to Do It: Minimizing Costs to Find a Control Policy

Todorov and Jordan have suggested that the movements we make are a reflection of a cost that includes both a measure of expected rewards and a measure of motor costs. They suggested that our movements are optimal with respect to a cost function that includes both motor costs and expected rewards. For example, if we use the vector **y** to represent our belief about our current state, vector **r** to represent our goal state, and vector **u** to represent the motor commands, the objective is to find the motor commands **u** that minimize the cost:

$$\sum_{t=1}^{N}(\mathrm{y}^{(t)}-\mathrm{r})^{T}T^{(t)}(\mathrm{y}^{(t)}-\mathrm{r})+\mathrm{u}^{(t)T}L^{(t)}\mathrm{u}^{(t)} \qquad [1]$$

where matrices T and L are measures of the weighted costs associated with achieving the rewarding state and producing the motor commands.

To get to the rewarding state, we need to find the motor commands that will minimize this cost (eqn [1]). To find the motor commands, we need to understand how our motor commands produce changes in our states. For example, if we intend to make a reaching movement, we need to know how the motor commands to our arm muscles are expected to produce sensory feedback. The term 'internal model' (or forward model) refers to this ability of the brain to predict the sensory consequences of motor commands. In a gross simplification of the problem, these predicted consequences may be written as a linear function of our motor commands:

$$\begin{aligned}\hat{\mathbf{x}}^{(t+1|t)} &= \hat{A}\hat{\mathbf{x}}^{(t)}+\hat{B}\mathbf{u}^{(t)}\\ \hat{\mathbf{y}}^{(t)} &= \hat{C}\hat{\mathbf{x}}^{(t)}\end{aligned} \qquad [2]$$

where $\hat{\mathbf{x}}^{(t)}$ represents the state of the body and the world that we interact with, $\mathbf{u}^{(t)}$ is our motor command, $\hat{\mathbf{y}}^{(t)}$ is our expected sensory feedback, and $\hat{\mathbf{x}}^{(n+1|n)}$ is our predicted state at time $t+1$, given our previous predictions and observations at time t.

Now our body and the world that we interact with have their own dynamics, represented as follows:

$$\begin{aligned}\mathbf{x}^{(t+1)} &= A\mathbf{x}^{(t)}+B\mathbf{u}^{(t)}+\varepsilon_{u}^{(t)}\\ \mathbf{y}^{(t)} &= C\mathbf{x}^{(t)}+\varepsilon_{y}^{(t)}\end{aligned} \qquad [3]$$

These dynamics are affected by noise: $\varepsilon_{u}^{(n)}$ is a stochastic variable representing motor noise, and $\varepsilon_{y}^{(n)}$ is a stochastic variable representing sensory noise. As we send motor commands, we receive a continuous stream of sensory feedback **y**. We combine what we predicted with what we observed to update our estimate of the state of our body and the world:

$$\hat{\mathbf{x}}^{(t+1|t+1)}=\hat{\mathbf{x}}^{(t+1|t)}+K^{(t)}(\mathbf{y}^{(t)}-\hat{\mathbf{y}}^{(t)}) \qquad [4]$$

In this equation, the term $K^{(t)}$ is a mixing gain (or a Kalman gain) that determines how much we should change our belief based on the errors between what we predicted and what we observed. Therefore, eqn [2] describes how we make predictions about sensory feedback, and eqn [4] describes how we combine the actual sensory observations with our predictions to update our beliefs.

Our problem is to try to get as much reward as possible for as little cost as possible. How do we generate motor commands that produce the greatest amount of reward? If eqn [2] is an accurate model of how motor commands produce changes in the state of the body and the state of the cursor that we are observing on the screen, then we can use it as a set of constraints with which to minimize eqn [1]. This is the classic linear quadratic problem in optimal control. Solving this problem yields a linear feedback control law that specifies the motor commands as a function of our belief about our state with respect to our goal:

$$\mathbf{u}^{(t)}=G^{(t)}\hat{\mathbf{x}}^{(t|t-1)} \qquad [5]$$

This feedback control law is called a control policy. The new variable G in a time-dependent matrix that represents the gain of the sensorimotor pathway. This way of formulating the problem of motor control is extremely powerful because, in principle, it can account for behavior whether we look at a single act, like a reaching movement, or our actions over the course of a day.

The theory states that our aim is specified as a long-term goal, and our actions try to achieve that goal by implementing a control policy that relies on expected costs and rewards and on our belief about where we are at any given time with respect to that goal. Therefore, the computational problem of motor control may be described as having four components:

1. We live in a world where, at any given time, many actions are possible. For any possible action, we need to know the costs associated with it as well as the sensory states that are rewarding (eqn [1]). We choose to perform an action because we believe it will be more rewarding than other potential actions. The way that we perform that action will depend on our internal estimates of costs and rewards.

2. Once we choose to acquire a rewarding state, we need to know how our motor commands produce changes in things that we can observe (eqn [2]). This is a system identification problem associated with our body or tool that we may be trying to control. Learning of this map is called forming a forward model.

3. We must learn how to actually produce the motor commands that are needed so that we minimize the costs and maximize the reward. That is, we need to figure out the 'best' motor commands that bring the cursor to the target and get it to explode. This is the constrained minimization problem (minimize eqn [1] under the constraints of eqn [3]). The result of the minimization is a feedback control law, or a control policy, that specifies our motor response to the sensory states that we observe in our body and the environment (eqn [5]). Learning of this feedback control law is sometimes called forming an inverse model.

4. As we generate motor commands, we make predictions about the sensory consequences (eqn [2]). When actual sensory feedback arrives, we integrate our observations with our predictions and form a belief about how our motor commands have affected the state of our body and the world around us (eqn [4]). Combining predictions with observations is sometimes referred to as Bayesian integration.

At the heart of the approach is the idea that we make movements to acquire rewards. The way that we make a movement, that is, how quickly we move, what trajectory we choose to execute, and how we respond to sensory feedback, depends on our control policy, which itself depends on our belief about the costs and rewards associated with that movement.

Effects of Damage to the Basal Ganglia on Representation of the Cost Function

Writing instruments are one of the most common tools that we use in our daily lives. One of the striking features of damage to the human striatum is micrographia, an impairment of writing characteristics in which letter sizes become very small and writing speed becomes slow. This condition is most common in degenerative diseases of the basal ganglia such as Parkinson's disease. However, it can also occur in the case of focal lesions. For example, consider patient FF, an individual who suffered an ischemic stroke in the left basal ganglia, in the head of the caudate nucleus and the anterior part of the putamen. When FF was asked to copy a four- or an eight-letter string of letters, the writing with the right hand was much smaller than with the left hand.

Micrographia can be a complex disorder, manifesting itself sometimes in self-generated writing and not in copying of sentences or present in copying letters but not copying geometric shapes. However, the basic observation of smallness of writing size and slowness of writing speed has been puzzling. Current theories suggest that the disorder may be related to a function of the striatum in forming complex repetitive and sequential motor actions. But if we assume that a fundamental role of the striatum is to associate sensory states with their expected reward properties, then the optimal control formulation of motor control provides a different perspective.

In the optimal control framework, there are no desired trajectories for our movements. That is, we do not move our hand along a particular path because that path is somehow hardwired in our brain. Rather, the path is a result of a control policy (eqn [5]), which itself is a result of minimization of a cost function (eqn [1]). The cost function depends on two quantities: an expected reward and a motor cost. What matters is the ratio between these two costs. In theory, movements become small and slow if the cost associated with the motor commands becomes large compared with expected rewards. Therefore, micrographia may be a reflection of a relative loss of expected reward, or increased motor costs, associated with the use of the writing instrument.

If we assume that the control policies that govern our movements (eqn [5]) require an internal measure of costs and rewards (eqn [1]), and if we further assume that the striatum is a crucial node where the brain forms associations between visual cues and expected rewards, then perhaps we can understand bradykinesia (slowness of movements) in Parkinson's disease as a reflection of a disorder in this implicit measure of costs and rewards. Mazzoni and colleagues recently reported that although patients with Parkinson's disease reach more slowly than age-matched controls, they are nevertheless able to make fast movements without a loss in accuracy if forced to move fast by the experimental task. However, the patients take longer (require more trials) to accumulate a set number of movements at the required speed. Thus bradykinesia (slowness of movements), one of the hallmarks of Parkinson's disease, may represent decreased intrinsic value of a given motor task because of an imbalance between an estimate of an implicitly determined cost for making a fast movement and the expected rewards.

Cerebellar Damage and the Ability to Predict Sensory Consequences of Motor Commands

In the optimal control framework, control policies generate motor commands on the basis of beliefs

about the state of the body and the environment (eqn [5]). In eqn [4], we see that the state estimate $\hat{\mathbf{x}}^{(t)}$ depends on two quantities: a prediction $\hat{\mathbf{y}}^{(t)}$ and an observation $\mathbf{y}^{(t)}$. The prediction comes from an internal model that uses a copy of the motor commands to estimate the state change that is expected to occur (eqn [2]). The observation comes from the sensory system. The predicted value acts as a prior belief that 'colors' the observed value. That is, our beliefs are not based on our observations alone. Rather, our beliefs are a combination of what we predicted and what we observed.

An important part of the optimal control framework is that motor commands continuously depend on predictions about state, which in turn continuously depend on predictions about sensory consequences of motor commands (the internal feedback pathway that relies on the forward model in **Figure 2**). Some movements are so fast that there is no time for the sensory system to play a role. A prominent example is control of saccades, rapid eye movements that move the eyes to a new location, typically within 50–80 ms. Such movements are too brief for visual feedback to influence saccade trajectory. In fact, the brain actively suppresses visual processing during saccades to reduce the perception of motion. Furthermore, proprioceptive signals from the eyes do not play any significant role in controlling saccade trajectories. Thus, the brain must guide saccade trajectories in the absence of sensory feedback. How is this accomplished? A plausible solution is for the brain to use an internal estimate of the state of the eye, derived from a copy of ongoing motor commands. This idea is supported by the observation that both natural and drug-induced variability of saccade velocity and duration have little influence on saccade amplitude. That is, variability of the saccade's trajectory is partially corrected as the saccade progresses.

What are the neural substrates of this internal feedback? The cerebellum is known to be critical for many aspects of saccade control and adaptation. The projections from the superior colliculus to the cerebellum may provide the efference copy. Indeed, Takeichi and colleagues have shown that adaptive changes in saccade amplitude are already reflected in the nucleus reticularis tegmenti pontis, a major source of input to the cerebellum. Together, the superior colliculus–cerebellar–brain stem side loop seems important for steering saccade trajectories midflight. This side loop is a likely candidate for the role of forward model of the plant to produce midflight corrective feedback.

A simple experiment can test whether the brain has the capacity to predict consequences of self-generated motor commands. In an experiment described by Nowakand colleagues, the participant holds a force transducer that measures grip forces (participant's right hand in **Figure 4**). Attached to the transducer is a basket. The experimenter drops a ball into the basket. When the ball drops, it exerts a downward

Figure 4 The cerebellum participates in predicting the sensory consequences of motor commands. In an experiment described by Nowak and colleagues, the subject holds a force transducer that measures grip forces. Attached to the transducer is a basket. When a healthy individual drops the ball, the brain predicts the consequences: on impact, the ball will exert a downward force. The traces indicate the grip force of the hand holding the transducer (right hand in the picture), rate of change in the grip force, and acceleration of that hand along the vertical dimension. The first vertical line indicates time of ball impact on the basket. The second vertical line is time of maximum hand acceleration. The third vertical line is time of maximum grip force. To maintain grip, in the healthy subject the right hand exerts a greater force right before the ball hits the basket (blue and red arrows, 50 ms before ball impact). Patient HD, who does not have a cerebellum, does not show this predictive response. Rather, she responds to the sensory feedback from the ball impact by increasing the grip force. From Nowak DA, Timmann D, and Hermsdorfer J (2007) Dexterity in cerebellar agenesis. *Neuropsychologia* 45: 696–703.

load force on the hand. The participant responds by squeezing the transducer so that it will not slip out of the hand. Because there are delays in sensing the drop of the ball, the grip response by the participant is delayed with respect to the drop of the ball (about 100 ms after ball hits the basket, the grip force increases).

Nowak and colleagues have described patient HK, who did not have a cerebellum because of a very rare developmental condition. When the experimenter dropped the ball into the basket, both the healthy individual and HK showed the delayed response. Therefore, the sensory feedback pathways appeared intact in HK. In a subsequent trial, the participant (rather than the experimenter) dropped the ball (**Figure 4**). In a healthy individual, the cerebellum predicts that release of the ball will result in an increased downward load when the ball hits the basket. In anticipation of this event, the healthy individual squeezes harder (with the right hand holding the force transducer) around the time that the ball is released. HK, however, could not make this prediction. Rather, she responded to the perturbation the same way that she responded when the ball was dropped by the experimenter. Therefore, the cerebellum appears to be required for the ability to predict the sensory consequences of motor commands; that is, it participates in representing a forward model.

Individuals with cerebellar damage are often profoundly impaired in learning to control tools. If the cerebellum is the crucial site for learning forward models (eqn [2]), then it probably makes its contribution to control of reaching via its outputs to the thalamus, which in turn projects to the cerebral cortex. Indeed, artificial stimulation of the ventrolateral thalamus impairs the ability of essential tremor patients to learn the reach adaptation task, even though the stimulation improves the patient's tremor. These results suggest that a crucial function of the cerebellum is to learn forward models that predict sensory consequences of motor commands.

Introduction

Computational neuroscience uses techniques from computer science and applied mathematics to simulate and analyze computational models of neurons and neural systems at many levels of investigation. Digital computers have continued to increase in speed, making it possible to approach more complex neural systems. The number of investigators using computational tools is expanding, and a variety of new journals, summer schools, and scientific conferences that focus on computational neuroscience have proliferated (Table 1). The second edition of a comprehensive handbook on brain theory is available, and there are 33 specialized articles covering many aspects of computational neuroscience in this encyclopedia. Comprehensive introductions to the methods used to develop computational models are also available. This article provides an overview and a discussion of the major methods and techniques in computational and theoretical neuroscience.

The brain regulates behavior by gathering, storing, and accessing information. The brain solves computational problems with specialized circuits, which evolved to process information rapidly and efficiently, in contrast with digital computers, which can be programmed to solve many different types of algorithms inefficiently. For example, the retina is dedicated to visual transduction and image processing and cannot be reprogrammed to process sounds. Because of the close coupling between structure and function in a dedicated system, the anatomy and physiology of a brain region provide important clues to its function. The connectivity between neurons and their properties is shaped by the environment during development and remain plastic even in adulthood. Thus, as the brain processes information, it changes its own structure in response to the information. This plasticity is important in allowing brains to respond flexibly to a changing world through adaptation and learning.

One of the major constraints on the evolution of brains has been their high energy cost. In humans, 20% of the energy budget is consumed by the brain, which constitutes 2% of the body weight. The energy constraint has consequences for coding strategies and communications protocols.

Brain Models

Brain models used as an adjunct to experimental techniques have several advantages: (1) models provide intuition about the possible behaviors of complex, dynamical brain systems, especially when they are nonlinear and have feedback loops; (2) the predictions of a model make explicit the consequences of the underlying assumptions, and comparison with experimental results can lead to new insights and discoveries; and (3) the results of difficult experiments can be simulated with a model, such as reversible lesions of selected channels or neurons, to optimize the design of the experiment for distinguishing between competing explanations.

There are three different types of brain models. The first type, called an interpretive model, is used to analyze experimental data in order to determine whether they are consistent with a particular computational assumption. For example, Apostolos Georgopoulos has used a vector-averaging technique to compute the direction of arm motion from the responses of a population of cortical neurons, and William Newsome and his colleagues have used signal detection theory to analyze the information from single cortical neurons responding to visual motion stimuli. In these examples, the computational model was used to explore the information in the data but was not meant to be a model for the actual cortical mechanisms. Nonetheless, these models were highly influential and have provided new ideas for how the cortex may represent sensory information and motor commands. These models in turn have affected experimental design, which has then led to improved models.

A second type of model, called a confirmatory model, has been used extensively to test whether a set of data can account for the phenomena being studied. In many biophysical experiments, such as the classic Hodgkin–Huxley studies of the squid action potential, sets of data are collected under a variety of conditions, and a model is later constructed to integrate the data into a unified framework. A highly realistic Monte Carlo model of synaptic transmission in the chick ciliary ganglion recently predicted that the majority of vesicles in the nerve terminal were not released at active zones, identified by presynaptic and postsynaptic specializations, but ectopically where they stimulated extrasynaptic receptors; this surprising prediction was subsequently confirmed experimentally. This type of model is most effective when most of the variables in the model have been measured experimentally and

only a few unknown parameters need to be fit to the experimental data. One danger with this approach is that even if the model fits the data, the resulting model may not be unique. However, automated techniques have been developed for systematically exploring large parameter spaces to determine all combinations of parameters that fit the data. As the number of experiments increases, the number of possible solutions that fit all the data should converge to a unique set.

Finally, a third type of model starts with a general principle and produces an abstract model that implements the principle within known biological constraints. These models can be quite fruitful in helping to motivate experiments that might not have been otherwise undertaken. An example of this approach is the model of coupled nonlinear oscillators analyzed by Nancy Kopell, Bard Ermentrout, and others, which has led to new experiments on fictive swimming in the lamprey spinal cord. One of the strengths of this type of model is that it can be used to identify the critical variables that determine the qualitative behavior of a system. One corresponding weakness is that because much of the fine detail is often absent, it may not be possible to make detailed comparisons with data.

Dynamical systems theory provides a global analysis of neural systems, but is mainly applicable when the numbers of parameters and variables are small. Most models of neural networks involve a large number of variables, such as membrane potentials, firing rates, and concentrations of ions, with an even greater number of unknown parameters such as synaptic strengths, time constants, and conductances. In the limit that the number of neurons and parameters is very large, techniques from condensed matter physics become applicable in predicting the average behavior of large networks. There is a midrange of systems where neither type of limiting analysis is possible, but where simulations can be performed. One danger of relying solely on computer simulations is that they may be as complex and difficult to interpret as the biological system itself.

Compartmental Models

At the cellular and molecular levels, significant advances have taken place in modeling specific neurons and synapses based on biophysical measurements of ionic mechanisms. Markov models that are used to model ionic channels can be applied to every aspect of synaptic signaling, including transmitter release and the intracellular second messenger systems that modulate synaptic transmission. The original Hodgkin–Huxley models for the fast sodium and delayed rectifier potassium channels are special cases of a Markov model, as are the detailed biophysical models of receptor kinetics.

The pioneering work of Wilfrid Rall on the electrical properties of dendrites was based on the analysis of simplified dendritic geometries. It is now possible to simulate multicompartment models of dendrites from the geometries of reconstructed neurons. Voltage-dependent sodium and calcium channels have been observed in the dendrites of cortical neurons, which greatly increases the complexity of synaptic integration. The experimental confirmation first predicted by compartmental models that active currents can carry information in a retrograde direction from the cell body up to the distal synapses also has theoretical significance for Hebbian forms of synaptic plasticity. Another intriguing observation made with modeling techniques is that the wide variety of spiking patterns in cortical neurons can be reproduced from the same distribution of ionic channels by varying only the geometry of the dendritic tree.

Network Models

Realistic models with several thousand cortical neurons can be explored on the current generation of workstation, which allows the dynamics of cortical columns to be explored in detail. The first model for the orientation specificity of neurons in the visual cortex was the feedforward model proposed by Hubel and Wiesel, which assumed that the orientation preference of cortical cells was determined primarily by converging inputs from thalamic relay neurons. Experimental evidence now favors this model over other models in which the orientation specificity was determined by local cortical circuits. Simulations of orientation columns have shown that the intrinsic circuits in the cortex could be used to increase feature selectivity, amplify weak signals, and suppress noise as well as to perform gain control to extend its dynamic range. This is an important step forward in understanding the function of visual cortex.

A good example of an abstract model that provided a conceptual framework for understanding experimental results is the strongly nonlinear Hopfield network, which exhibits attractor dynamics. This model can be analyzed and convergence proven from any initial state to one of several possible attractor states. Realistic network models of spiking neurons with similar self-sustaining dynamics are now used to study delay-period activity in prefrontal cortical areas and head direction cells in the hippocampus.

Although thalamic neurons that project to the cortex are called relay cells, they almost surely have additional functions since the visual cortex makes massive feedback projections back to them. As an example of a speculative model that has led to a new computational hypothesis for the thalamus, Crick has proposed that the relay cells in the thalamus may be involved in visual attention, and has provided an explanation for how this could be accomplished based on the anatomy of the thalamus. This searchlight model of attention and other hypotheses for the function of the thalamus are being explored with computational models, and new experimental techniques are being used to test these models. Detailed models of thalamic networks can reproduce the low-frequency oscillations observed during sleep states, when feedback connections to the thalamus affect the spatial organization of the rhythms.

Learning Models

The precise timing of single spikes carries information about the locations of objects for echolocating bats and electric fish and for visual motion in invertebrates. Pyramidal neurons are capable of initiating spikes with high precision, and spike-timing-dependent synaptic plasticity (STDP) has been found in the hippocampus and cerebral cortex to be sensitive to timing difference between pre- and postsynaptic events in the millisecond range. Although spike timing has also been suggested as an information code for the cerebral cortex, experimental evidence instead points toward a role for temporal patterns of spikes in regulating the flow and storage of information in the cortex, such as top-down control of attention and expectation.

Classical conditioning occurs on a timescale of seconds, and recent recordings from dopamine neurons in the ventral tegmental area of monkeys has confirmed the predictions of temporal difference (TD) reinforcement learning, which hypothesizes that the dopamine neurons signal the prediction of future reward. The dopamine neurons project diffusely throughout the cortical mantle and the basal ganglia, where they influence actions and regulate synaptic plasticity. TD learning takes advantage of temporal order to encode causal relationships. It has also been used to model honeybee foraging and is consistent with STDP, which suggests that it may be a general computational principle in nature.

Technology for Brain Modeling

Simulations of large-scale neural systems currently are performed on fast workstations and multiprocessor supercomputers. Computer programs for performing these simulations are freely available (Table 1). New technology, however, is needed to scale up simulations from thousands to millions of neurons. A new approach to massively parallel models has been introduced by Carver Mead, who uses subthreshold complementary metal-oxide semiconductor (cMOS) very large-scale integrated (VLSI) circuits with components that mimic the analog computational operations performed by the brain. For example, silicon chips that model the visual processing found in retinas have been built. Analog VLSI cochleas have also been built that can analyze sound in real time. These chips use analog voltages and currents to represent the signals and are extremely efficient in their use of power compared to digital VLSI chips. A new branch of engineering called neuromorphic engineering has arisen to exploit this technology.

Protocols have been designed for long-distance communication between analog VLSI chips that use the equivalent of all-or-none spikes in the same way that long-distance communication between neurons is accomplished. Many of the design issues that govern the evolution of biological systems also arise in these neuromorphic systems, such as the trade-off in cost between short-range connections and expensive long-range communication. Computational models

that quantify this trade-off and apply a minimization procedure can predict the overall organization of topographical maps and columnar organization of the cortex.

The increase in computer memory capacity and advances in machine learning algorithms have greatly increased our ability to automatically segment serial thin sections from electron microscopy and to reconstruct neural circuits. The goal of connectomics is to produce complete connectivity diagrams. Although connectivity cannot give a complete picture including the temporal dynamics of neural circuits, there are many questions that can be answered, such as whether the neurons in the brain are organized to minimize wire length.

Concluding Remarks

Although brain models are becoming increasingly accepted into neuroscience as tools for interpreting data and generating hypotheses, we are still a long way from having explanatory theories of brain function. For example, despite the relatively stereotyped anatomical structure of the cerebellum, we still do not understand its computational functions. Although the cerebellum is thought to be involved in motor coordination, functional imaging suggests that the cerebellum is also involved in higher cognitive functions such as attention and language. Modeling studies may help in exploring competing hypotheses and suggesting a new type of explanation, such as a common computational operation used in motor coordination, attention, and language. This has already occurred in the oculomotor system, which has a long tradition of using control theory models to guide experimental studies.

At this stage in our understanding of the brain, a model should be considered only a provisional framework for organizing thinking. Many partial models need to be explored at many different levels of investigation, each model focusing on a different scientific question. As computers become faster, and as software tools become more flexible, computational models should become increasingly important in analyzing and interpreting experimental data as well as helping to design critical experiments to test alternative hypotheses.

Computational Neuroethology

Definitions

Ethology is the study of behavior that allows animals to survive and reproduce in natural environments (i.e., adaptive behavior). Neuroethology is the study of the neural basis of adaptive behavior. Computational neuroethology is the use of modeling and simulation to study the neural control of adaptive behavior. In contrast, the broad area of computational neuroscience generally focuses on modeling microscopic properties of neurons (e.g., channel biophysics, dendritic spines), single neurons (e.g., multiple conductance models of complex neurons and their morphology), neural circuits, and the dynamics of neural circuitry, without reference to biomechanics or environmental phenomena.

History

In 1990, both Randall D Beer and Dave Cliff independently called for the creation of a new field, computational neuroethology. Beer succinctly summarized the rationale for the new field:

> The working assumptions of computational neuroethology can be summarized as follows: (1) the ability to flexibly cope with the real world is a defining characteristic of intelligent behavior, and more fundamental than conscious deliberation; (2) adaptive behavior derives from a structural congruency between the dynamics of an intelligent agent's internal mechanisms and the dynamics of its external environment; (3) modeling the neural control of behavior in simpler whole animals will provide insights into the nature of the dynamics required for adaptive behavior, and eventually lead to an understanding of the successive elaborations of these mechanisms which are observed in higher animals.

Recently, Cliff has published a review of this area that provides an excellent overview and a summary of key examples of computational neuroethology, with an emphasis on research that has focused on artificial agents.

Conceptual Framework

The conceptual framework of computational neuroethology draws on classical ethology, ecological psychology, biomechanics, and dynamical systems theory. The first key concept of the framework (see Figure 1) is that behavior is embodied, that is, it is not purely due to neural commands but emerges from the ongoing interaction of the central nervous system with a complex sensory and mechanical system. For example, in response to motion in the periphery of its visual system, a monkey will move both its eyes and head, thus using its motor system to reposition its sensory structures. As another example, the optimal angle for throwing a soccer ball from over the head is determined not simply by Newtonian mechanics but by the mechanical advantage that human arms can generate. More generally, embodiment implies that the central nervous system does not 'stand above' the sensory and motor system in the process of responding to the environment; rather, preprocessing by sensory structures, active perception (movement of sensory structures as part of the perceptual process), and the filtering of motor commands by muscles and body structures are crucial for generating adaptive behavior.

The second key concept of the framework is that behavior is situated within a particular environment. For example, changes in optic flow as a fly approaches a surface allow the fly to trigger a rapid landing response. Recently, investigators used optic flow to control a flying robot. Another example of the situated nature of behavior is provided by studies showing that animals change leg stiffness during running to match the elasticity of the surface. In humans, activation of muscles changes depending on whether pointing movements occur with or against gravity. More generally, the situated nature of behavior implies that it is not solely due to the actions of the agent but emerges from the ongoing interactions of the agent with its environment.

Thus, the third key concept of the framework is that adaptive behavior emerges from the coupling of the nervous system, body, and environment. For example, in a virtual reality environment, it is possible to predict human behavior in response to goals and to obstacles by modeling goals as attractors and obstacles as repellers with a relatively simple damped mass spring model for the heading error relative to each object. Sophisticated routes that avoided obstacles and reached goals emerged from this analysis without explicit path planning. As another example, the behavior of a hexapod robot with insectlike reflexes emerged from its ongoing interaction with soft, irregular surfaces.

The centrality of coupled dynamics for adaptive behavior is not surprising. Evolution cannot select for brains or bodies in isolation. Rather, the likelihood

Figure 1 A schematic illustration of the framework of computational neuroethology. Nervous systems are embodied within the biomechanics of a body, and animals are situated within an environment. Adaptive behavior emerges from the coupling of the dynamics of the nervous system, the body, and the environment.

that an animal will survive or leave more offspring than other competitors depends on that animal's ability to coordinate its nervous system and body effectively within a particular environment. Thus, evolution selects an overall coupling of the dynamics of the components that effectively generates adaptive behavior.

Finally, an implication of the three concepts is that understanding adaptive behavior requires the analysis of the dynamical properties of the coupled system. Within each component – the nervous system, the body, and the environment – are complex processes that unfold over time according to rules, and thus each component is a dynamical system. Since each of the systems is coupled to one another, they are nonautonomous, but the entire coupled system may be viewed as an autonomous dynamical system.

The conceptual framework has several important implications. First, it suggests that stable behavioral patterns can be viewed as attractors within the dynamical system defined by the entire coupled system. Second, given that environments change over time, the conceptual framework suggests that understanding the transient structure of the coupled system may be as important as understanding its possible steady state behaviors. Third, any slow dynamical process that allows an organism to improve its interaction with its environment may be adaptive; thus, learning may not be a distinct process but may simply be these slower dynamical processes.

Goals and Methodology

Computational neuroethology has been pursued with two distinct, albeit complementary, goals. From the perspective of a biologist, computational neuroethology is another approach to understanding the mechanisms of adaptive behavior in animals. Thus, the models and analyses are in the service of understanding general principles that may illuminate the adaptive behavior of a single animal or a particular group of animals. The value of the results will depend on how well they explain behavior in animals, generate testable hypotheses, and suggest general principles for the function of similar organisms. More abstract models may be of great utility if they provide general principles that could apply to many organisms. For example, a theoretical approach for all forms of locomotion – constructal theory – has recently been described that provides very general principles for running, flying, and swimming.

Investigators whose primary focus is in the area of computer science or engineering study computational neuroethology with different goals. For these investigators, computational neuroethology provides a new methodology for developing principles for intelligent behavior, as well as a means of designing adaptive artificial devices that have the flexibility of animals. From this perspective, the models and analyses are in the service of understanding adaptive behavior of any agent, whether it corresponds to a biological organism or not. As a consequence, the value of the results will be the insight they provide into a general understanding of adaptive behavior and intelligence or their utility for artificial devices such as robots to function in complex, open-ended environments.

Distinguishing these two different goals is important. A robot that can avoid obstacles using an algorithm based on studies of the escape response in the cockroach may be of great utility, and thus a success from the point of view of engineering. From a scientific viewpoint, however, the success of the robot demonstrates that the proposed algorithm could actually work in the physical world but does not prove that it does work that way in the biological system. Thus, an engineering success may not be the same as a scientific proof. Conversely, it is important for investigators interested in animals to be willing to develop models that may omit or greatly simplify biological details in the search for general principles. A highly detailed model of insect flight may be so computationally intensive and so complex that the general principles of operation, such as the importance of nonstationary aerodynamics or the relative importance of inertial and viscous forces, may be obscured.

These observations have led investigators to pursue computational neuroethology using a variety of models, ranging from highly abstract to highly realistic. Abstract agents provide the opportunity to confront the most general questions about the mechanisms of adaptive behavior. The study of 'frictionless brains'

can provide insights similar to the study of frictionless planes in physics. All features of the agent are known, unlike a biological organism. Careful choices of models of the environment, the body, and the neural network controlling the agent can generate systems that are tractable to detailed mathematical analysis, providing deep insights into the underlying dynamics of adaptive behavior. For example, a study of evolved neural networks for locomotion elucidated the importance of the mechanics of the body for many features of the evolved pattern generators. However, it may be difficult to make quantitative predictions from abstract agents to any particular animal.

Realistic models provide the ability to directly connect model predictions with experimental results. Quantitative predictions can be made about the effects of specific perturbations. Realistic models have drawbacks, however. In addition to the large number of parameters that must be fit by experimental data, the 'brittleness' of models in response to small errors in parameters, and the high computational cost associated with simulating realistic models, it is often difficult to understand or derive general principles from models if they rival the original biological system in complexity.

Thus, some of the most effective work in computational neuroethology has been done by the use of a bracketing methodology, in which both abstract and highly detailed models are studied, with the goal of developing models of intermediate complexity that retain some analytical tractability but whose predictions can be tested experimentally. For example, studies of the mechanisms of insect locomotion have made use of simplified 'template' models of running or climbing movements, which have then been compared to highly detailed 'anchor' models based on the biology of particular animals (e.g., cockroach or gecko).

Investigators of computational neuroethology also debate the value of simulations versus robotic models. On one hand, simulations can be reconfigured rapidly. Combinations of different parameter values can be systematically explored, and if the model as a whole needs to be restructured, this can also be done relatively quickly. On the other hand, if an investigator wishes to ensure that the agent is interacting with the environment, a robot provides the actual physics of the world for free and ensures that any algorithm that works well in simulation can also work well in the presence of fallible sensors, unreliable actuators, and a complex, changing environment. But robots can be expensive to build and difficult to quickly reconfigure, and if they fail to function properly, the investigator needs to ensure that the failure is relevant to the original hypothesis. For example, if a robot is built to examine a perceptual problem but uses wheels rather than legs to negotiate its environment, the investigator needs to be sure that the question of interest (whether biological or theoretical) is unaffected by this change in the periphery. Once again, combined studies of simulations and robotics are likely to be more effective than a sole reliance on one or the other.

Examples

This section provides an overview of some recent work in computational neuroethology, but it is not exhaustive. Rather, the examples illustrate some of the key aspects of the conceptual framework, as well as the models that have been generated, from highly abstract to highly specific; the animals and behaviors that have been studied, ranging from invertebrates to humans; and the fruitful interplay of simulation and robotics.

Embodiment: Biomechanics and Neural Control

A combined mechanical and neural model of walking in the cat revealed that the mechanics of the body played a crucial role in stabilizing or destabilizing gait, depending on the coordination rule used. To study the role of sensory reflexes in locomotion, investigators created a realistic model of the mechanics of the hindlimbs of the cat and a simplified finite state model of the neural control that was driven by sensory inputs from the model body. One mechanism for triggering the transition of a leg from supporting weight on the ground (the stance phase) to moving forward before initiating the next step on the ground (the swing phase) is the removal of load from the limb as other limbs begin supporting the body's weight. The force in the ankle extensor muscle monitors the unloading of the limb. When this rule was used alone to drive walking gaits, the resulting movements were stable even in response to perturbation. The reason was that if the other limbs were not yet taking up load, the limb that was about to switch from stance to swing was delayed by this mechanical input, and this stabilized the gait. In contrast, when the extension of the hip was used alone as the signal to terminate stance, the resulting gaits were unstable because the mechanical system tended to increase the hip extension independent of whether the body could afford to lift that limb. This model provided strong evidence for mechanical coupling through the body as a stabilizing mechanism for locomotion. Further support for this view is provided by the recent work of investigators who have used a dynamic periphery and a simple neural network to create a fast bipedal

walking robot (RunBot) that takes advantage of peripheral biomechanics to stabilize its gait and can improve its walking with experience.

A neuromechanical model of feeding in the marine mollusk *Aplysia californica* made it possible to predict the roles of mechanical reconfiguration during feeding. Investigators created a kinetic model of the feeding apparatus and showed that the change in shape of the central grasper from spherical to ellipsoidal changed the forces exerted by a separate muscle, a protractor muscle that wraps around the grasper and was stretched by the grasper's change in shape. As a consequence, the protractor muscle became stronger, both because of its position on its length–tension curve, and because of its enhanced mechanical advantage, allowing it to generate stronger protractions. Subsequently, *in vitro* and *in vivo* studies showed that the model predictions were correct. These results have been used to define the concept of neuromechanical modulation – the ability of one set of motor neurons to affect the actions of a different set of motor neurons through the changes in the mechanics of the periphery.

These results emphasize the importance of understanding motor neuronal activity within the context of biomechanics. More generally, it is clear that motor behavior is best understood within an embodied context.

Situatedness: Coupling among the Environment, the Periphery, and the Nervous System

A striking illustration of the importance of the coupling among the environment, the body, and the nervous system was provided by a simulation of lamprey swimming. The neuromechanical model performed well without sensory feedback in water flowing at a constant velocity. In contrast, in the absence of sensory feedback, when the model encountered a barrier consisting of water flowing at a higher velocity, the model lamprey failed to swim across the barrier. When the model lamprey was provided with appropriate sensory feedback but no other changes were made to the neural circuit, the model could swim effectively through the barrier. The faster flowing current induced rapid sensory inputs that induced a faster oscillation of the body, which in turn allowed it to move through the faster water. Thus, a new and effective behavioral pattern emerged from the interaction of all the components.

Another example of the coupling of the environment and the body to generate adaptive behavior is provided by the studies of insect flight. A robotic fly that operated in mineral oil, whose wing dimensions and viscous interactions with the fluid surrounding it were scaled to have similar Reynolds number to those of the fruit fly, was used to demonstrate that delayed stall due to translational motion of the wings was insufficient to account for the ability of *Drosophila* to fly. Rotation of the wings during stroke reversals was also critical, allowing the insect to take advantage of rotational circulation and wake capture. These additional forces not only enhanced lift but also provided the insect with the ability to change direction and steer. Recent studies have focused on the steering mechanisms underlying rapid right-angle turns (body saccades) in fruit flies, using three-dimensional, high-speed infrared video to capture the actual motions of the wings and body of the flies and using the dynamically scaled robot to examine the underlying forces responsible for the turns. Surprisingly, they found that inertial forces dominated turning behavior due to subtle tilts of the stroke plane angle and small changes in stroke amplitude.

These results emphasize the importance of understanding behavior through detailed studies of the interactions of biomechanics and environmental forces, which in turn may both simplify and limit what the nervous system can do at every instant.

Active Perception

Perception within the context of ongoing behavior, or active perception, has been one of the most heavily investigated areas of computational neuroethology. Physical constraints on active sensing systems, as well as the need for appropriate sensorimotor coordination, determine whether systems can simply react to events or can anticipate them. Combining models of electrosensory and mechanosensory stimuli with prey strike trajectories performed by electric fish (recorded using infrared video), investigators demonstrated the relative contributions of different frequency components of the electric sense and mechanosensory inputs on prey capture. Recently, investigators have developed a simple robot capable of underwater localization of targets using electrolocation.

A variety of other active perceptual processes have been studied. Cricket phonotaxis, the ability of a female cricket to locate a male cricket by its calling song, has been studied using a series of increasingly complex and realistic robot and neural network models. Investigators recently demonstrated that a model neural circuit driving a legged robot could successfully detect and locomote to sound sources outdoors. Using a slightly modified model of human navigation, investigators controlled a differential drive robot and showed that it negotiated obstacles

more smoothly than did previous methods. A robotic whisker array demonstrated that moments induced by whisker contact with objects or flows could be used for accurate reconstruction of the inputs.

These results demonstrate that when sensing is both embodied and focused on environmentally relevant features, complex perceptual feats can be accomplished efficiently.

Cognition and Intelligence

Computational neuroethology provides a novel approach for creating intelligent behavior. Rather than relying primarily on an abstract analyzer and manipulator of symbolic representations of the world, it emphasizes that highly complex and adaptive behavior, including behavior that is cognitive, emerges from the interaction of brain, body, and environment. For example, investigators have created a series of models of specific behavioral competencies – frog prey capture, rat spatial navigation, monkey saccades and grasping, and human language – which are inspired by known anatomy and neurophysiology. Investigators have argued that the successive elaboration of functional schemas provides insights into prey capture, predator avoidance, negotiation of obstacles, recognition and categorization of one's location in egocentric space relative to external space, the ability to imitate motor actions, and ultimately the ability to recognize, imitate, and generate 'combinatorially open' abstract motor sequences that can become the basis for language.

A complementary approach is creating agents that have 'minimally cognitive' capabilities, such as the ability to categorize objects, to focus attention, to manipulate objects, or to signal to other agents. By making the agents as simple as possible, but capable of an arguably cognitive behavior, investigators can analyze in detail the mechanisms underlying their behavior. Investigators have pursued this line of inquiry using genetic algorithms as a means of searching for agents that produce cognitive behaviors (e.g., categorical perception, selective attention, associative learning) so that the neural circuits are not hand designed, which could introduce *a priori* biases into their function, and then analyzing how they work. Recent work analyzed an agent evolved to perform categorical perception: the agent could catch circular objects and would avoid diamond-shaped objects. The agent's behavior could be explained in terms of the dynamics of its interaction with the environment and the dynamics of its nervous system, but no 'representations' of either circles or diamonds were found. These results suggest that a dynamical systems approach to embodied and situated agents may well provide insights into the nature of cognition and intelligence in biological organisms, and in artificial devices, without recourse to abstract symbol manipulation.

Summary and Conclusions

Although the field of computational neuroscience is still relatively young, it has become increasingly important for understanding adaptive behavior. As computers become faster and cheaper, it is more feasible to create sophisticated models that incorporate features of the environment, of biomechanics, and of neural control. Successful analyses of complex adaptive behavior using computer simulation and robotics have encouraged investigators to adopt the methodology of computational neuroethology. At the same time, simulated organisms and robots capable of solving challenging real-world problems have emerged from this research, suggesting that it is a fruitful approach for generating artificial devices that have the flexibility of biological organisms.

What is most exciting about recent work in computational neuroethology is both the growing empirical support for the larger conceptual framework and the progress in clarifying general principles for adaptive behavior. Thus, it is clear that many aspects of motor behavior can be understood only by examining neural activity within its appropriate biomechanical and environmental context. Similarly, the process of perception involves active and ongoing engagement of the organism with its environment, so perception must be studied within both a biomechanical and an environmental context. Finally, cognition and intelligence must be understood within a behavioral context and emerge from an embodied and situated agent, not a disembodied pure reasoner.

Conditioned Reflex

D S Woodruff-Pak, Temple University, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

The Discovery of the Conditioned Reflex

The Nobel laureate physiologist Ivan Petrovich Pavlov discovered the conditioned reflex in the first decade of the twentieth century. The initial work involved the autonomic nervous system with Pavlov's use of the salivating reflex in dogs. He discovered that presenting a neutral stimulus such as a bell that never normally elicited salivation could come to elicit salivation if presented repeatedly before giving the dog meat powder. The learned response (called the 'conditioned response') was the dog's salivation to the bell. Presentation of the bell followed by presentation of the meat powder led to the formation of an association. Throughout the century following the discovery of classical (Pavlovian) conditioning, it has become one of the most widely employed paradigms for the investigation of associative learning and memory and its neurobiological substrates. Pavlov was the first scientist to observe that old dogs condition more slowly than young dogs. Thus, research on classical conditioning in normal aging has a long and illustrious history.

Classical Conditioning

The standard format for the presentation of stimuli in classical conditioning is called the delay procedure. A neutral stimulus such as a tone, light, or tactile vibration is called the conditioned stimulus (CS). It is presented for a fixed duration (optimally around half a second) before the presentation of a reflex-eliciting stimulus, called the unconditioned stimulus (US). In the delay procedure, the CS and US overlap and typically end together. Learning occurs when the organism responds with the reflex to the CS before the onset of the US. The learned response is called the conditioned response.

A second format for the presentation of stimuli in classical conditioning is called the trace procedure. In this case, the neutral stimulus that is the CS is presented and then turned off before the US is presented. There is a blank period of time, called the 'trace,' between the CS offset and US onset. Pavlov thought that in the trace conditioning procedure, a 'memory trace' had to be formed in the blank period between CS offset and US onset. The two major classical conditioning procedures, delay and trace, are illustrated in Figure 1. Although there are a number of additional formats for classical conditioning, virtually all the studies of conditioned responses in normal aging have used the delay or trace classical conditioning procedures.

Classical Conditioning of the Eyeblink Response

Whereas Ivan Pavlov discovered the phenomenon of classical conditioning using a conditioned reflex in the autonomic nervous system, the conditioned reflexes used in contemporary studies of classical conditioning, such as the conditioned eyeblink response, are controlled in the central nervous system. Skeletal muscle innervated by the cranial nerves controls the eyeblink. Eyeblink classical conditioning is a common paradigm for investigations of classical conditioning in general and classical conditioning in normal aging in particular. Fear conditioning, in which a neutral CS is paired with a moderately painful US, is another promising model system that has been elaborated extensively on a behavioral and neurobiological level. Studies of aging effects on fear conditioning have been reported, but the results are not consistent. The magnitude of age-related fear responses appears to be small, especially in comparison with age-related changes in eyeblink classical conditioning.

The neural circuitry that supports classical conditioning of the eyeblink response is almost completely mapped, and the behavioral and neurobiological parallels in this form of associative learning extend to all mammals that have been studied, including humans. Processes of normal aging affect eyeblink classical conditioning similarly in all species in which older organisms have been tested – mice, rats, rabbits, cats, and humans.

For several decades, the promise of eyeblink classical conditioning as a model system for the study of learning and memory in aging has been evident. Among the significant advantages of this model system for investigating processes of normal aging are that (1) age differences in the classically conditioned eyeblink responses are large and (2) striking parallels exist between the age differences in eyeblink conditioning in nonhuman mammals and humans. The initial parallels in normal aging and eyeblink conditioning were demonstrated between rabbits and humans. On no other species is there such a large body of parametric data on classical conditioning as on the classically conditioned eyeblink response in the rabbit. Indeed, much of the general literature on classical conditioning is based on data collected in the rabbit with the nictitating membrane (third eyelid of the rabbit) response and in the human with the

Figure 1 (Top) Delay classical conditioning paradigm in which the conditioned stimulus (CS) and unconditioned stimulus (US) overlap. (Bottom) Trace classical conditioning paradigm in which the CS is turned off before the US is turned on. The blank period between CS offset and US onset is called the 'trace' period.

eyeblink. Now techniques for behavioral and electrophysiological testing in rats, including neonatal rats, have been developed, along with techniques to test eyeblink conditioning in normal, mutant, and transgenic mice and rodent slice preparations.

Ernest Hilgard was the first to study eyeblink classical conditioning in animals and did classic studies on human eyeblink conditioning as well. His work established the close correspondence in properties of the conditioned eyeblink response in humans and others animals, suggesting that the underlying neuronal mechanisms of memory storage and retrieval are the same in all mammals, including humans. Here, perhaps more than in any other form of learning, neuronal mechanisms of memory elucidated in infrahuman mammals apply directly to the human condition. Isadore Gormezano was the first to publish eyeblink conditioning studies in the rabbit and to introduce measurement of the nictitating membrane extension response.

Initial research on aging and classical conditioning studied rabbits or humans. However, there are advantages of other species, such as mice and rats, for research on aging. In particular, mice and rats, with their short gestation period, large litter size, relatively small space requirements, and short life spans, are highly desirable for research on development and aging. Neither the genetic controls nor the breeding environments presently available for rabbits equal those in place for the mouse and rat. Consequently, many of the recently published studies on eyeblink classical conditioning, including those on aging, involve rodent subjects.

Eyeblink Conditioning in Aging Mammals

Eyeblink classical conditioning displays natural age-related deficits in all species in which it has been tested, including humans, cats, rabbits, rats, and mice. The generalization first observed in humans, that age-related deficits appear in middle rather than old age, holds for the species that have been tested over the adult life span: mice, rabbits, and humans.

Rodents Mice and rats are a useful species for research on normal aging. They have the advantage of small space requirements and short life spans. Breeding colonies maintained by the National Institute on Aging facilitate research on aging by making a number of strains of rodents, at all points of the life span, available to researchers.

Techniques for rodent eyeblink conditioning were initially developed in rats, and age differences in eyeblink classical conditioning in rats were first document in John Disterhoft's laboratory. Jeansok Kim, Lu Chen, and Shaowen Bao, in Richard F Thompson's laboratory, developed eyeblink conditioning initially in the C57BL/6 mouse. This group demonstrated that the mouse preparation exhibited normal associative learning and memory. The C57BL/6J strain was used to start the C57BL/6NIA barrier-reared strain used extensively for research on aging and also commonly used to build transgenic mouse strains. Research on normal aging and eyeblink conditioning in mice has been carried out exclusively with the C57BL/6 strain. The first published study of eyeblink conditioning in aging C57BL/6 mice was carried out in Kirino's laboratory, and age-related impairment was observed in 20-month-old mice in the delay procedure. The CS was a 1 kHz, 85 dB sound pressure level tone. Interpretation of those results was problematic because C57BL/6 mice have age-related hearing impairment beginning about mid-life, with thresholds at all frequencies greatly elevated in the second year of life. C57BL/6 mice begin to exhibit progressive, high-frequency, sensorineural hearing loss at 3 months of age that extends to middle and lower frequencies by 16 months. Some studies have used a white noise CS so that the frequency spectrum would be covered up to around 15 months of age. This strategy makes the CS clearly audible to C57BL/6 mice in the younger age groups, but severe hearing losses in C57BL/6 mice have been reported between 16 and 23 months of age. CS intensity affects the rate of acquisition, and perceived CS intensity is undoubtedly lower in C57BL/6 mice older than 16 months. Age-related hearing loss accounts for some portion of the observed age-related impairment in eyeblink classical conditioning in the older groups.

In other species, such as rabbits and humans, hearing deficits have been ruled out as the cause of age-related impairment of eyeblink conditioning, but those species do not suffer the magnitude of hearing loss that affects C57BL/6 mice. In future studies of aging in mice, the use of CSs in other sensory

modalities and the use of different mouse strains that do not demonstrate significant age-related hearing loss will clarify normal aging effects on eyeblink conditioning.

Figure 2 Age differences in the 750 ms-delay eyeblink classical conditioning procedure in 110 rabbits ranging in age from 3 to 84 months. There was statistically significant age-related impairment in trials to a learning criterion of eight conditioned responses in nine consecutive trials between the ages of 21 and 30 months with no significant additional decline in the older groups.

Rabbits The rabbit has some major advantages as an animal model in classical conditioning research because of its size and, especially, its docile nature. Rabbits tolerate well the restraint required in classical conditioning studies. In some laboratories, research on eyeblink conditioning and aging has occurred long enough so that hundreds of rabbits of various ages have been run. Using a delay paradigm in which the interval between the CS and US was 750 ms, 110 rabbits ranging in age from 3 to 54 months in Diana Woodruff-Pak's laboratory showed significant age-related impairment in trials to learning criterion between the ages of 21 and 30 months, with no significant additional decline in the older groups (see Figure 2). These results were paralleled closely in John Disterhoft's laboratory using the 600 ms short CS trace paradigm. In 180 rabbits older than the age range of 2–36 months, age-associated learning impairments were seen by 24 months of age. Comparisons of young and older rabbits in 600 ms and 750 ms delay and trace eyeblink classical conditioning paradigms in Woodruff-Pak's laboratory indicated that older rabbits performed significantly worse in the 750 ms than in the 600 ms delay paradigm, but they performed as well as young rabbits in the 600 ms delay paradigm. Both age groups of rabbits were more impaired in the trace paradigm, with older rabbits equally impaired in the 600 ms and 750 ms trace paradigm (Figure 3).

Figure 3 Age differences between 4-month-old and 26-month-old rabbits in delay and trace eyeblink classical conditioning paradigms with a 600 ms or 750 ms interval between the CS and US (called the interstimulus interval, ISI). There were statistically significant effects of age, ISI, paradigm, and training session.

Since rabbits have a life expectancy that has been estimated to be about 8 years, these animals may be useful as animal models for studies of brain and behavior relationships in aging. Assuming that human life expectancy is almost 80 years, it is tempting to make a linear extrapolation from the human to the rabbit life expectancy and equate a human decade with a rabbit year. In this scheme, a 60-year-old human would be equivalent to a 6-year-old rabbit. However, there are a number of reasons that a linear interpolation of human to rabbit life expectancy probably is inappropriate. For example, at birth the rabbit is much more mature than the human, and rabbits reach puberty by 6 months. According to the linear extrapolation between human and rabbit age, a 6-month-old rabbit would be the equivalent of a 5-year-old human. However, since 5-year-old children cannot reproduce, the linear interpolation between human and rabbit age is inaccurate in early life. Using reproductive capacity as a biomarker, a 6-month-old rabbit is roughly comparable to an adolescent aged 12–14 years. The age of 3 years in rabbits might compare to the human age decade of the 50s, and humans in their 60s might correspond in age to 4-year-old rabbits. Age changes in reproductive capacity appear to be a useful means to parallel human and rabbit age, and age differences in learning and memory occur at similar times in the life course of these two species when reproductive capacity is used as a biomarker to assess age.

Humans The first research on aging and human eyeblink conditioning was carried out in the early 1950s by the Russian scientists Gakkel and Zinina and reported in the United States by Jerome in the first *Handbook of the Psychology of Aging* in 1959. Differences between eyeblink classical conditioning in young and older nursing home residents in a single 70–90-trial session were reported. These results were replicated and extended to normal, community-residing older adults. The main and striking result was the relative inability of the older participants to acquire the conditioned eyeblink response.

The early studies of eyeblink conditioning in normal aging in humans involved comparisons of college students and older volunteers. The first study to investigate eyeblink conditioning over the adult life span was carried out in Woodruff-Pak's laboratory in the 400 ms delay eyeblink classical conditioning procedure. The 103 participants represented the adult life span between the ages of 18 and 83 years. Participants received a series of 108 trials; 96 trials were paired presentations of the tone CS and corneal air puff US, and 12 trials were presentations of the tone CS alone. Before the session, neutral instructions were given that were designed neither to facilitate nor to inhibit eyeblinks. Results replicated earlier reports that age differences in acquisition of conditioned eyeblink responses were large. A novel finding was that age differences in eyeblink conditioning occurred early in adulthood, in the age decade of the 40s. These results were replicated almost identically in Paul Solomon's laboratory. Donald Powell's laboratory reported age differences in both eyeblink and heart rate classical conditioning.
