This result was extended in the Woodruff-Pak laboratory to demonstrate that the effects of normal aging in eyeblink conditioning appear in humans in the age decade of the 40s and increase in the 50s but that there is no further statistically significant impairment in the age decades of the 60s through the 80s.

Brain Substrates of Eyeblink Classical Conditioning

The essential site of the plasticity for learning resides in the ipsilateral cerebellum, and the hippocampus, while not essential, can affect the rate of conditioning. Significant changes occur in the cerebellum and in the hippocampus during normal aging. It may now be possible to identify and characterize the critical age-related changes in the brain underlying the age-associated decline in eyeblink classical conditioning.

Involvement of the Cerebellum in Associative Learning

A variety of techniques, including electrophysiological recording of multiple and single units, electrolytic and chemical lesions, physical and chemical reversible lesions, neural stimulation, genetic mutations, and pharmacological manipulation, have been used to demonstrate that the cerebellum is essential for all forms of eyeblink classical conditioning. More specifically, the dorsolateral cerebellar interpositus nucleus ipsilateral to the conditioned eye is the essential site for acquisition and retention of conditioned eyeblink responses. The cerebellar cortex is also of demonstrated involvement during normal acquisition. Rabbits with aspirations of cerebellar cortex or mutant mice that lose all Purkinje neurons acquire conditioned responses at a dramatically slowed rate and to a lower maximal performance level than do intact organisms. Tests of patients with lesions in various parts of the cerebellum, along with functional imaging studies of the brain during eyeblink conditioning, have demonstrated that the cerebellum's role in eyeblink conditioning is essential in humans as well as in rabbits and other nonhuman mammals.

Involvement of the Hippocampus in Eyeblink Classical Conditioning

The hippocampus and septohippocampal acetylcholine system are involved in basic associative learning of the sort represented by eyeblink conditioning. In a series of studies using delay eyeblink classical conditioning in rabbits, it was observed that activity recorded in the CA1 pyramidal cell region of the hippocampus forms a predictive 'model' of the amplitude–time course of the learned behavioral response, but only under conditions in which behavioral learning occurs. This response is generated largely by pyramidal neurons. The role of the hippocampus in classical conditioning of the eyeblink response is called 'modulatory' because manipulations of the hippocampus can impair or enhance the rate of acquisition. The memory trace itself is not in the hippocampus, but the hippocampus can markedly influence the storage process.

Although the hippocampus is not necessary for normal acquisition in the delay procedure, it is necessary for trace conditioning. A long-lasting neuronal plasticity is formed in the hippocampus following eyeblink conditioning. This change is essential for learning to occur in the trace eyeblink conditioning procedure, at least until the learning is consolidated. Age-related electrophysiological changes in the hippocampus have been associated with age-related impairment in trace eyeblink conditioning.

Normal Aging in the Hippocampus and Cerebellum

Neuron numbers vary widely among individuals, in part as a consequence of chance developmental variations. The neuron cell loss required for functional impact appears to differ widely among brain regions, and the magnitude of neuron loss in normal aging also varies among brain regions. Until recently, it was widely accepted that neuron death in most brain regions was an inevitable result of normal aging. With the development of stereological methods for counting neurons and the application of these techniques to research on aging, it has become apparent that in the neocortex and hippocampus of humans and many other species, there is little age-related decline in neuron number.

Although there is stability of neuron number in the older hippocampus, electrophysiological investigations of aging in the mammalian hippocampus have revealed that some aspects are compromised. In learning-impaired older rabbits, single-unit records of clusters of pyramidal neurons in CA1 showed diminished responding. Age-related impairments in trace eyeblink conditioning involve an increased after-hyperpolarization in hippocampal pyramidal neurons due in turn to an increased calcium-activated potassium current.

Whereas neuron number is maintained in neocortex and hippocampus, there is significant Purkinje neuron loss associated with aging in the cerebellar cortex. For example, we used unbiased stereology to assess the total number of Purkinje neurons in cerebellar cortex over the life span of C57BL/6 mice. Statistically significant age differences in Purkinje neuron number were observed beginning at 18 months. Similar Purkinje neuron loss in late middle age has been reported in other mammalian species. In addition to significant neuronal loss, functional capacity of older Purkinje neurons is also impaired. Purkinje neuron number has been associated with the rate and magnitude of delay eyeblink classical conditioning in young as well as older organisms. The normal age-related impairment and loss of Purkinje neurons is associated with age-related deficits in delay eyeblink classical conditioning.

Resolution in humans using techniques such as magnetic resonance imaging (MRI) is not fine enough to reveal presence or absence of individual neurons – not even the largest neurons in the brain – Purkinje neurons. Anatomical MRI studies of cerebellar volume over the adult life span indicated significantly smaller cerebellar volume by the age of 50 years. Assessment of cerebellar volume with MRI in humans tested with eyeblink classical conditioning demonstrated that age-related changes in cerebellar volume are highly correlated with age-related deficits in eyeblink classical conditioning.

Amelioration of Eyeblink Classical Conditioning in Older Organisms

A successful means of ameliorating impaired eyeblink conditioning in older rabbits is the use of cognition-enhancing drugs. Several types of drugs are of documented efficacy in this model system. Drugs that promote the availability of acetylcholine, such as acetylcholinesterase inhibitors, are effective in facilitating eyeblink conditioning. In particular, drugs that target nicotinic acetylcholine receptors have shown great efficacy in eyeblink conditioning in young as well as older rabbits. Another drug mechanism that has ameliorated impaired eyeblink conditioning in older rabbits is the blockade of calcium channels. Older organisms have increases in calcium influx in hippocampal pyramidal neurons that apparently impair learning, and drugs that block calcium channels can improve the function of these neurons.

Conditioned Taste Aversion

M R Foy and J G Foy, Loyola Marymount University, Los Angeles, CA, USA

Introduction

Conditioned taste aversion (CTA) is a learned association of taste and visceral distress. CTA occurs when an animal learns to avoid a newly encountered taste after suffering adverse postingestive effects from a noxious substance. From an evolutionary perspective, CTA is thought to prevent animals from eating poisonous substances. From an experimental perspective, CTA has long been considered an important learning paradigm in which neural events have been correlated with different phases of learning, including acquisition, retention, and extinction. Recent advances have been made in understanding the neural pathways involved in CTA learning, and how this learned behavior is affected by the normal aging process. The aim of this article is to provide a brief review of the major components of the CTA paradigm, the neural pathways, the biochemical and genetic factors implicated in CTA, and the effects of aging related to CTA.

The Conditioned Taste Aversion Paradigm

CTA has been known by zoologists and others since the late 1800s and was introduced into the laboratory for intensive investigation in the mid-1950s. The CTA protocol is highly reproducible, and the memory of associations made by the pairing of relevant stimuli in CTA conditioning is long-lasting, which permits analysis of multiple memory phases and systems. In a typical CTA experiment, animals are originally exposed to tap water for drinking, and are adapted to a shortened fluid session (e.g., 30 min per day). During the conditioning phase, a novel taste (saccharin- or sucrose-flavored water) becomes the conditioned stimulus (CS), the substance that produces adverse effects (lithium chloride, LiCl) is the unconditioned stimulus (US), and the behavior following exposure to the US (nausea or behavioral malaise) is the unconditioned response (UR). Thirty minutes of sodium saccharin (0.1% solution) drinking, followed by an intraperitoneal injection of LiCl (0.15 M, 2% body weight) from minutes to hours after exposure to the CS, elicits in rats severe gastrointestinal distress that is followed by strong aversion to saccharin on the next day. In a two-bottle preference test, the animal is given the opportunity to choose between the familiar (water) and novel (saccharin) fluid over an extended period of time (20-day test period) following the single CS–US conditioning procedure. The benefit of using a two-bottle preference test is that the animal is not forced to drink the novel fluid (as opposed to a single-bottle technique, wherein the thirsty animal is offered only the novel fluid, and thus its consumption is dependent upon its motivation and how palatable it finds the novel fluid). Furthermore, the neophobic avoidance of novel stimuli (calculated as the ratio of the volume of the novel fluid to total fluid intake) can be identified more readily in a two-bottle test. In Figure 1(a), a schematic diagram of a typical CTA learning paradigm is shown.

Studies using CTA have found that some animals show less preference for the novel substance prior to poisoning (taste neophobia) than do others. The length of the interval between exposure to the novel CS substance and the noxious US agent (delay) can be manipulated, with longer delays associated with stronger CTA in some animals than in others. Also, the number of trials required to extinguish the aversive behavior shows variability: extinction rates are faster under conditions of deprivation and previous exposure to the preferred substance (familiarity). Furthermore, researchers have identified significant sex, strain, and species differences in CTA conditioning, with several of these aspects of CTA learning having relevance to aging.

Although often considered a form of classical conditioning, CTA does not fit neatly into this classification, nor does it share all of the characteristics of instrumental learning, suggesting that CTA may actually be a unique type of learning. Several critical temporal properties that distinguish CTA from other forms of associative learning include the fact that CTA learning can be acquired following a single pairing of the CS and US stimuli. In other forms of associative learning, multiple CS–US presentations are necessary for conditioning to occur. Some have argued this to be a 'biological preparedness' component of CTA learning, since illness is most easily associated with taste and the association can be made in one trial.

A second parameter unique to CTA is the wide range of interstimulus intervals (ISIs) used in CTA experiments. During CTA training, a CS–US interval of several hours can be tolerated, whereas in other forms of associative learning (e.g., classical and instrumental conditioning), ISIs longer than several seconds become ineffective in establishing conditioned responses. However, like other forms of learning, CTA shows a delay of reinforcement gradient, and conditioning strength can be decreased when the US is presented much longer (e.g., >12 h) after the CS.

Figure 1 (a) Schematic diagram of a typical conditioned taste aversion learning paradigm. In this design, rats are adapted to a 30 min tap water drinking schedule over 7 days. On the conditioning day, all rats are administered the conditioning stimulus (CS; 0.1% sodium saccharin solution) during the normal 30 min water session, followed 4 h later by a single unconditioned stimulus (US; 0.15 M LiCl, 20 ml kg^{-1}, intraperitoneal injection). For 20 days, the rats are then given daily two-bottle preference tests: familiar tap water and novel sodium saccharin solution during the 30 min fluid sessions. (b) Saccharin preference scores for adult (3 months old) male and female rat groups, along with aged (24 months) male and female rat groups. Two-bottle saccharin preference scores for adult male and female rats treated with LiCl after a 4 h delay show a significant sex difference across the 20-day test period between the two groups. Adult males had a slower extinction rate (stronger conditioned taste aversion as measured by lower saccharin preference) compared to adult females (faster extinction rate and higher saccharin preference). This sex difference is very pronounced in the aged group; aged male rats show a much slower extinction rate compared to aged females. Adapted from Foy MR and Foy JG (2003) Reversal of long-delay conditioned taste aversion learning in rats by sex hormone manipulation. *Integrative Physiological and Behavioral Science* 38: 203–213, and Foy MR, Foy JG, and Thompson RF (2005) Aging and delayed conditioned taste aversion learning in rats. *Pavlovian Society Meeting.* Anaheim, CA, 29 September 2005.

Several theories have been proposed to suggest that associative learning mechanisms are responsible for the formation of immediate taste aversions, in which animals are made ill soon (e.g., within minutes) after consuming a novel substance. However, for long-delay learning in which the CS–US interval is quite long (e.g., hours), a nonassociative theory has been proposed to employ the nonassociative learning mechanisms of habituation and sensitization (dishabituation) in combination with neophobic avoidance of novel stimuli.

The use of the CTA paradigm has provided significant advantages for investigating the phenomena and mechanisms of simple associative learning. Single-trial acquisition facilitates the correlation of neural events with learning, and targeted interventions using anatomical and pharmacological procedures can be readily examined in CTA. For example, one promising line of CTA research in rats has identified a sexual dimorphism found in long-delay (4 h) CTA learning. Figure 1(b) illustrates the sex differences in long-delay CTA learning in adult and aged male and female rats that have been correlated with the presence of circulating sex hormones.

Neural Circuitry Implicated in CTA

Research on neural circuitry and related structures involved in CTA learning originates largely from studies of the effects of reversible and irreversible brain lesions, and disruptions of protein synthesis within specific structures during the acquisition and retention of CTA. Generally, these studies reveal that as many as ten sites are relevant for CTA learning and memory to occur. Brief synopses of the major circuitry and structures involved in CTA are delineated in the following sections.

Area Postrema

The small region known as the area postrema (AP), which lacks a blood–brain barrier, lies on the floor of the fourth ventricle. It is presumed to be the site for

the detection of toxins, and the reflexive action to produce illness. Lesions of the AP before conditioning obliterate avoidance responses in CTA. Lesions of the AP after acquisition of LiCl-induced CTA have no effect on retention of the sucrose aversion, suggesting that the AP is not necessary for long-term aspects of CTA. Evidence thus far supports the view that the area postrema is necessary for the acquisition of CTA induced by LiCl, scopolamine, gamma radiation, and histamine, but not for other noxious agents such as amphetamine, nicotine, ethanol, and rotation-induced illness, for which the sites of action are not yet established. CTAs induced by different unconditioned stimuli may be mediated by different neural mechanisms.

Nucleus Tractus Solitarius

Gustatory information from the facial, glossopharyngeal, and vagus nerves (cranial nerves VII, IX, and X, respectively) converge in the brain stem, within the nucleus tractus solitarius (NTS). Neurons in the NTS project to the pontine parabrachial nucleus (PBN). Lesions within the NTS do not always markedly impair CTA, and rats can learn to avoid noxious substances with lesions to this area. The primary deficit observed with NTS lesions appears to be sensory rather than associative; animals with NTS lesions do not show the typical preference for sweet taste and aversion to unpleasant taste seen in intact animals.

Pontine Parabrachial Nucleus

The pontine parabrachial nucleus (PBN) is involved in the initial integration of gustatory with visceral information. Lesions to the PBN are more disruptive to CTA acquisition and retention than are lesions to any other site. PBN-lesioned rats become incapable of acquiring CTA under conditions of delay between CS and US stimuli. However, if conditioning occurs prior to PBN lesioning, CTA expression is unimpaired. It is strongly suspected that the PBN is necessary for CTA acquisition, but not CTA expression, and that the PBN is involved in associating the taste with illness.

Thalamus

Lesion studies involving the thalamus have produced equivocal effects on CTA. Lesions that spare structures providing olfactory cues may confound the results, suggesting that further research is needed. The general finding is that thalamic lesions, especially those of the medial ventrobasal thalamic complex that include the thalamic gustatory nuclei, are sufficient to prevent CTA learning.

Hypothalamus

Hypothalamic neurons are closely related to the influence of motivational state on behavioral responsiveness to gustatory stimuli. Lesions of hypothalamic nuclei responsible for regulating feeding feedback (feeding center or lateral hypothalamic area, satiety center, or ventromedial hypothalamic nucleus) have facilitatory effects on CTA (slower extinction rates) when rats are maintained at normal weights. Obese rats with ventromedial hypothalamic (VMH) lesions and water-deprived rats also have slower extinction rates.

Globus Pallidus

The globus pallidus (GP) plays an important role in the regulation of feeding behavior. Lesions of the ventromedial region of the GP impair acquisition and retention of CTA and are responsible for stronger and more persistent neophobia. These findings suggest that GP neurons are critical in CTA acquisition and retention and also play a role in the attenuation of neophobia.

Amygdala

In the limbic system, parts of the amygdala appear to be involved in the assessment of taste, as well as in the acquisition of CTA. The effects of amygdala lesions on CTA may be determined by the extent of damage to fibers from the insular cortex to amygdala and some key nuclei. Lesions of the basolateral nucleus prevent CTA acquisition, whereas lesions of the central nucleus appear to have no effect on CTA.

Hippocampus

Hippocampal lesions attenuate, but do not abolish, CTA acquisition. Hippocampectomized animals also have slower extinction rates than do intact animals. It has been proposed that the hippocampus is involved in the evaluation of the novelty or safety of the stimulus.

Prefrontal Cortex

The prefrontal cortex (PFC) is involved, generally, in the organization of goal-directed, adaptive behaviors, and more specifically in neural control of feeding. Studies mostly show that deficits in CTA acquisition and retention are associated with PFC lesions, especially marked when lesions are located in the dorsomedial PFC. The number of cells showing c-Fos protein expression is increased in the prefrontal cortex during extinction. These results suggest that the medial PFC may play a substantial role in the formation, retrieval, and extinction of CTA, although further study is necessary.

Table 1 Summary of neural structures and putative relations to conditioned taste aversion learning and memory

Learning/memory feature	*Neural structures*
Taste detection and assessment	Area postrema; nucleus of the solitary tract; amygdala via facial, glossopharyngeal, and vagal nerves
Neophobia	Hippocampus, globus pallidus
Acquisition of CTA	Pontine parabrachial nucleus, thalamus, globus pallidus, amygdala, prefrontal cortex
Strength of CTA	Insular cortex, amygdala, hippocampus, prefrontal cortex
Retention of CTA	Pontine parabrachial nucleus, globus pallidus, amygdala, prefrontal cortex
Extinction of CTA	Hypothalamus, hippocampus, insular cortex, prefrontal cortex

Insular Cortex

The insular cortex (IC) may play a role in the integration of visceral reactions and stress. Whereas lesions of both the IC and the amygdala abolish CTA acquisition, lesions of the IC alone tend to attenuate acquisition and retention of CTA, not because the animals are incapable of aversive responses, but because they retain this ability. The difficulty caused by IC lesions appears to stem from their inability to associate aversive qualities to previously pleasant tastes. Lesions in the anterior IC are more likely to correspond with CTA deficits than are regions of the posterior IC. Studies have confirmed that the IC is involved in taste processing and memory formation and, particularly, mediation of associative aspects of taste responses. Long-term extinction of CTA is eliminated when new protein synthesis and β-adrenergic transmission in the IC is blocked in the late post-retrieval period. The IC may be involved in the consolidation of memory for CTA and require intact noradrenergic activity into the basolateral amygdala.

The gustatory cortex (GC), a small region of the IC, appears to be involved in the processing, encoding, and storage of motivation-independent taste familiarity information. Lesion studies indicate that the GC is involved in CTA with delay between the taste exposure and the illness, but not under no-delay conditions. Other studies indicate that while the gustatory cortex is involved in the acquisition of CTA, it is not essential for acquisition, but rather for the retention, of the aversion.

Figure 2 Gustatory afferent pathways in the rat. VII, facial nerve, including the chorda tympani and greater superficial petrosal nerve; IX, glossopharyngeal nerve; X, superior laryngeal nerve belonging to the vagal nerve; NTS, nucleus tractus solitarius; PBN, parabrachial nucleus; VPM, ventral posteromedial nucleus of the thalamus; CGA, insular cortical gustatory area; BNST, bed nucleus of the stria terminalis; LH, lateral hypothalamus; Am, amygdala. Anatomical Summary

A cautionary approach to eating or drinking novel substances, even when they taste good, seems prudent and evolutionarily advantageous. Likewise, avoiding substances that have caused illness but which would normally be considered pleasant to taste is adaptive, but only if the substance continues to cause illness. Thus some degree of neophobia, aversion, and extinction constitutes critical features of CTA in the normal individual, beyond, of course, being able to detect tastes and to assess these tastes along pleasant–unpleasant dimensions. Delineating the neural pathways implicated in CTA thus must account for these elements (Table 1), which clearly involve gustatory afferent pathways (Figure 2), as well as pathways involving visceromotor integration with higher-order learning.

In order for CTA to occur, the individual must be able to taste and to assess that taste. CTA thus requires sensory coding and taste discrimination, subserved by neural pathways involving the facial, glossopharyngeal, and vagal nerves to the area postrema, NTS, and amygdala, three areas where the taste is detected and evaluated. Both novelty of taste and how to respond to it require accessing memories

corresponding to the taste and regulating subsequent feeding behavior accordingly. The hippocampus and globus pallidus appear to be involved when the individual evaluates a novel taste and, although finding it pleasant, exhibits cautionary feeding behavior. When a substance makes an individual ill, the substance must be associated with the illness and remembered as being associated, and feeding behavior must be regulated on the basis of these cognitive processes in order for there to be acquisition of a conditioned taste aversion. Neural structures involved in acquisition of CTA include the PBN, thalamus, globus pallidus, amygdala, and prefrontal cortex.

Once a CTA has been established, how much avoidance of the substance the individual engages in appears to be subserved by the insular cortex, amygdala, hippocampus, and prefrontal cortex. There is strong consensus that the processes of retention of a learned response and extinction are distinct, both cognitively and behaviorally. They also appear to involve distinct neural substrates. Retention of CTA appears to involve the PBN, globus pallidus, amygdala, and prefrontal cortex. The hypothalamus, hippocampus, IC, and PFC have been linked with extinction in CTA.

Effects of Aging on CTA Learning

An extensive literature associates normal aging with mild, but significant, changes in learning and memory function. Many of these studies employ techniques that examine molecular, cellular, and behavioral changes associated with the aging process. It remains unclear, however, whether these age-dependent declines are related to an increasing deficit in learning, to reduced influences of contextual cues, or to whether the performance on learned tasks deteriorates with age and thereby obscures a relatively unimpaired ability to learn.

The CTA paradigm has been employed in developmental studies of learning because it minimizes performance factors that may confound age comparisons on learning ability, while providing an opportunity for demonstrating an ability to associate different types and qualities of stimuli. Parameters within the CTA protocol, such as the intensity of the CS, intensity of the US, interval between the CS and US, and effects of preexposure can all be systematically modified in order to study the effects of aging. The behavioral measures that can be studied include acquisition of CTA (indicated by a reduced preference for sweet taste compared to preference scores in unconditioned subjects), strength of conditioning (relative preference for the sweet taste over the nonsweet taste), and extinction rates (magnitude or frequency of preference scores relative to a time unit, usually measured in days).

The effects of aging as revealed in the CTA paradigm can be summarized as follows: parameter changes that weaken conditioning tend to highlight age differences. For example, a long CS–US delay (several hours) typically weakens the strength of the conditioned aversion. Aged rats show stronger conditioned aversion differences than do young rats when the CS–US delay is long (e.g., 3 and 6 h); age differences are not as apparent in short-delay paradigms. This effect also appears to be mediated by the strength of the US, which is typically correlated with the strength of the conditioned response. With long delays, age differences are eliminated when the US is relatively intense (e.g., 0.4 M LiCl). Aged rats develop stronger CTAs than do young rats at both short and long delays when the US is relatively weak (e.g., 0.15 M LiCl).

Aged individuals show markedly slower CTA extinction rates compared to younger individuals. The ability to acquire a CTA is not diminished in rats as old as 24 months. In fact, compared to younger rats, aged rats show an early and strong aversion to the novel CS following CS–US conditioning, and a much stronger resistance to extinction to the CS during extinction trials. This superiority is independent of learned safety ability, exposure to relevant contextual cues, physical characteristics associated with aging (such as body weight), and ability to metabolize the US. Referring back to Figure 1(b), typical extinction rates over 20 days in a 4 h delay CTA paradigm are illustrated comparing adult and aged rats. The finding of an age-related increase in resistance to extinction is consistent with those of other aging studies that used instrumental learning tasks, such as shuttle avoidance, maze learning, or operant bar pressing.

Another parameter known to affect CTA learning is preexposure to the CS. Daily preconditioning reduces CTA acquisition in young rats, but not aged rats, whereas a single US preexposure 1 h prior to conditioning reduces CTA acquisition in both young and aged animals. In summary, aged individuals appear to form a strong initial trace in the CTA paradigm that lasts considerably longer, compared to younger individuals.

Mechanisms underlying age differences in CTA learning are not yet well defined or understood. Some authors have speculated that aged rats may be less sensitive to contextual cues, rendering them less vulnerable to interference effects. Another line of research suggests that slowed metabolic processes known to be associated with aging may slow a hypothetical biochemical clock, making stimuli disparate in time subjectively more contiguous, and more

strongly associated in aged rats, compared to young rats in whom long CS–US delays are typically associated with weak CTA traces.

Biochemical and Metabolic Factors Related to Aging and CTA

Aging is associated with decreased adrenal androgen sensitivity to adrenocorticotropin hormone (ACTH), and with decreased concentrations of adrenal androgens and steroids in both men and women. In adult rats, water deprivation and preexposure to the preferred substance (familiarity) typically decrease the rate of extinction independent of acquisition of the CTA, whereas ACTH and testosterone are associated with prolonged extinction rates. Male rats are more neophobic and require more extinction trials than females. These sex differences can be reversed by gonadectomy and restored in gonadectomized animals by hormone replacement. Animals implanted with a testosterone metabolite (e.g., 5α-dihydrotestostoerone) show slower CTA extinction rates, regardless of sex, than do animals implanted with estrogen (17β-estradiol). Elevated testosterone levels in water-deprived male rats (e.g., following injection with corticotropin) are also linked with slower extinction rates.

Genetic Factors Related to Aging and CTA

Long-term memory is dependent on the production of new proteins in the brain via the regulation of gene expression, transcription, and translation mechanisms. By blocking protein synthesis with specific drugs at different time points, it is possible to determine when new proteins are required for long-term taste aversion learning. Blockade of protein synthesis impairs CTA learning and is associated with at least three specific proteins: c-Fos, inducible cAMP element repressor (ICER), and spinophilin. In the CTA paradigm, the antimetabolites 1β-D-arabinofuranosylcystosine (ara-CTP), cytosine arabinoside (ara-C), and the protein synthesis inhibitor anisomycin impaired CTA at long-delay time intervals but not short-delay time intervals (e.g., 1 h).

Substances that interfere with the formation of cAMP response element-binding protein (CREB) transiently reduce the level of CREB protein during training and impaired CTA memory when tested 3–5 days later when injected into the amygdala several hours before CTA training. These substances had no effect on CTA retrieval when administered after CTA memory formation, and did not affect short-term CTA memory.

The central nucleus, which is connected to the IC, has been proposed to be critical for the establishment of long-term CTA memory in the behaving rat. This process involves long-term changes subserved by CRE-regulated gene expression in amygdala neurons, and the amygdala may retain some CTA-relevant information over time, rather than merely modulating the gustatory trace during acquisition of CTA.

Clinical Features of Aging Relevant to the CTA Paradigm

Aging is associated with structural, physiological, and genetic changes that could be involved in CTA learning and memory function. Aging typically reduces sensitivity to taste, with greater quantities of the taste substance required; however, aged rats are more neophobic than are young rats, suggesting that the typical quantities of the US used in CTA paradigms are sufficient for taste detection. Conflicting findings have been reported as to whether aging significantly affects the vagus nerve. Aging is also associated with changes (usually cell loss) to many of the pathways involved in CTA: gastric mucosa and the NST, volume of the prefrontal cortex, insula, anterior cingulate gyrus, superior temporal gyrus, inferior parietal lobule, medial nucleus of the stria terminalis, hippocampus, and precuneus. Aging appears to have little effect on the volume of the amygdala, although impaired amygdala–hippocampus interactions have been found in aged rats with cognitive impairments. Shrinkage of the globus pallidus only occurs in men. The number of neurons in some regions of the hypothalamus (e.g., corticotropin-releasing neurons of the paraventricular nucleus) increases whereas oxytocin neurons in the paraventricular nucleus remain intact during aging. The hypothalamic–pituitary–adrenal (HPA) axis shows reduced responsiveness to glucocorticoid feedback inhibition in human aging.

Conclusions

The neural processes and behaviors associated with CTA learning have been delineated. Aging is linked with strong aversion responses under conditions in which these aversions are weakened in younger individuals. Aging is also associated with slower extinction rates, compared to younger individuals. Aging-associated biochemical and metabolic factors that affect key areas of neural pathways in CTA might be responsible for these results. Systematic investigations of the role that neural structures, hormones, and genes play in behavioral changes associated with CTA

hold promise for elucidating the neural mechanisms associated with behavior, understanding specific processes associated with aging, and developing interventions for age-related cognitive decline.

The Antennal Lobe and the Mushroom Body Are Sequentially Involved in the Olfactory Memory Trace

In honeybee olfactory learning, the pathways for the conditioned stimulus (CS, odor) and the unconditioned stimulus (US, sucrose) are well defined. The US pathway is implemented in a single identified neuron, the VUMmx1 neuron. The olfactory pathway (the CS pathway) consists of the olfactory receptor neurons projecting through the antennal nerve to the antennal lobe (AL); the first-order integration neuropil; the olfactory projection neurons (PNs), which connect the AL with the mushroom body (MB); the lateral horn (also called lateral protocerebrum); and other higher-order brain regions. CS and US pathways converge anatomically at three sites: the AL, the lip region of the MB, and the lateral horn. For two of these regions, the AL and the MB, it has been shown with local injections of the putative transmitter of the first ventral unpaired median neuron of the maxillary segment (VUMmx1) as a substitute for the reward stimulus that olfactory memory induces learning by forward pairing (but not by backward pairing). These findings corroborate earlier observations using local cooling as a retrograde amnestic treatment, which documented a cooling-sensitive memory phase for the AL during the first 1–2 min after a single learning trial and such a phase for the MB for the first 5–6 min. The early and late short-term-memory phases after single-trial olfactory conditioning were related to the AL and MB, respectively, on the basis of such findings.

Single Neuron Activity Correlate with Olfactory Learning

The reward neuron VUMmx1 responds to sucrose with long-lasting spike activity and to various visual, olfactory, and mechanosensory stimuli with low-frequency spike activity. Depolarizing VUMmx1 immediately after CS presentation (forward-pairing, CS^+) leads to learning, but backward-pairing does not (CS^-). Thus VUMmx1 constitutes the neural correlate of the US in associative olfactory learning. After differential conditioning in which an odor CS^+ is forward paired with sucrose reward (US) and another odor CS is backward paired with US, presentation of the CS^+ alone activates and CS^- inhibits VUMmx1, indicating that the reward pathway learns about the stimuli, a property that may be the neural substrate of second-order conditioning. In addition, VUMmx1's response to the US after presentation of the CS^+ is greatly reduced, but the response to CS^- remains normal, indicating that the response of VUMmx1 to US after conditioning depends on US expectation. This property of VUMmx1 is sufficient to explain the behavioral phenomenon of blocking and may thus reflect its neural substrate. These results demonstrate that the single identified neuron VUMmx1 is a sufficient neural substrate for the reinforcing function of the US sucrose in olfactory conditioning and has properties that allow explaining second-order conditioning and blocking.

Many other neurons belonging to different tracts leading from the AL toward the MB, or which are extrinsic to the MB, have been tested for associative plasticity by means of the differential conditioning paradigm. PNs connecting the AL with the MB calyx were less clear in CS^+-specific plasticity when intracellular recordings were applied, but recent extracellular multiunit recordings provided compelling evidence for associative plasticity in the minute range after conditioning. Most interesting, particular PNs specifically enhance or reduce their responses to CS^+ in about equal proportions, and a CS^+-specific shift in the power spectrum of local field potentials indicates an increase of precise spike timing for the CS^+ but not for the CS^-. This property may explain findings from optical imaging experiments in which Ca^{2+} activity of the postsynaptic sites of lateral PN neurons in the AL glomeruli was monitored during differential olfactory conditioning. No specific CS^+ and CS^- effects were seen. It appears that the glomerulus as a whole reliably codes odors in a combinatorial pattern together with other glomeruli, whereas single PNs undergo specific associative plasticity. In the case of a balance between associative rise and fall of activity in PNs originating in the same glomerulus, no learning effect will be seen when the whole glomerulus is imaged. It will have to be elucidated in the future whether the associative rise and fall in the rate responses of particular PNs or the precise timing of spikes in particular subsets of PNs represents the learning-related signature in the AL-MB network.

Two other observations support the conclusion that the AL network is indeed involved in an early and short-lasting memory trace. First, Ca^{2+} imaging of glomerular activity after bath application of the Ca^{2+} indicator (Ca-green FM ester) gave consistently higher responses to CS^+ than to CS^-. The fluorescence signal in such a situation may come predominantly from the presynaptic terminals of olfactory receptor

neurons (and possibly also from local interneurons and glia cells), indicating that synaptic processing inside the glomerulus converts CS^+-specific plasticity into both enhancement and reduction of odor responses. Second, the postsynaptic sites of lateral PN neurons within the glomeruli show spontaneous Ca^{2+} fluctuations. After stimulation with an odor, these spontaneous activity fluctuations are more strongly correlated between the glomeruli that had been activated simultaneously by the odor, and the correlations between the spontaneous activity fluctuations suffice to reconstruct the stimulus. It is concluded that these modifiable fluctuations could provide an ideal substrate for Hebbian reverberations and sensory memory in a neural system. It is important to note that all these associative and nonassociative changes seen in the AL glomeruli and PNs last only for a few minutes, corroborating the conclusion that the AL may be involved in the establishment of an olfactory memory trace only shortly after the learning trial.

Two kinds of MB-extrinsic neurons have been studied with respect to associative plasticity, a single identified neuron, the pedunculus-extrinsic neuron 1 (PE1), and neurons in the protocerebral-calycal tract (PCT). The PE1 neuron leaves the alpha lobe of the MB and receives its input across the peduncle of the MB at two bands of putative postsynaptic specializations. PE1 responds to a large range of odors. Differential conditioning leads to a CS^+-specific reduction of odor responses, whereas US-only presentations (sensitization) cause an increase of odor responses. Since the CS^+-specific responses – as recorded intracellularly from isolated bee heads – were lost after a few minutes, it was initially concluded that PE1 may be related to short-term memory. However, recent extracellular recordings from the intact animal lasting many hours have shown that the CS^+-specific response reduction is stable over the lifetime of the recording (several hours). Furthermore, the synapses between the MB-intrinsic neurons (Kenyon cells) and the PE1 were found to undergo long-term potentiation if PE1 was depolarized during the tetanic electric stimulation of the Kenyon cells. It is not yet clear how learning-related response reduction and associative long-term potentiation in PE1 can be reconciled.

CS^+-specific effects – as compared with CS^- or US-only effects – were seen in neurons of the PCT. Many of these neurons are γ-aminobutyric acid immunoreactive and project back from the alpha lobe of the MB to its input site, the calyx. They terminate both at the presynaptic sites of the PNs and the postsynaptic sites of the MB intrinsic neurons, the Kenyon cells. It is conceivable that PCT neurons provide an adapted inhibitory feedback from the output site of the MB to its input. Since PCT neurons also cross between the sensory domains of the MB, they could also be involved in context-specific forms of learning.

Neural Circuits Underlying Olfactory Conditioning: Signaling Cascades Mediating CS and US Stimuli

The different contributions of AL and MB in associative learning are also evident at the level of the molecular machinery implicated in learning and memory formation. Processing CS and US stimuli – even as early as during training – activates different signaling cascades *in vivo*. Stimulation of the antenna with sucrose, the US, induces a short transient activation of the cyclic adenosine monophosphate (cAMP)-dependent protein kinase A (PKA) in the AL, whereas odor stimulation (CS) or mechanical stimulation of the antennae does not affect PKA activity in the ALs. This US-induced PKA activation in the AL is mediated by octopamine, the putative transmitter of the reward neuron VUMmx1. The dense innervation of the VUMmx1 in the AL, the main localization of the PKA in AL interneurons, and the biochemical measurements support a general modulatory function of US-induced processes mediated via the cAMP/PKA cascades in the AL. The specific reinforcing function of octopamine during learning in the AL was supported by silencing the expression of the octopamine receptor which impairs olfactory acquisition but not odor discrimination.

Although the calyces, the olfactory input area of the MB, are also densely innervated by the octopaminergic VUMmx1 neuron, stimulation with sucrose (US) does not lead to PKA activation in the MB calyces *in vivo*. This, and the fact that octopamine can, in principle, stimulate PKA in cultured Kenyon cells of the MBs, supports the idea that octopamine receptors that receive input from VUMmx1 in the MB are most likely coupled to Ca^{2+}-regulated pathways. The signaling cascade mediating the US function in olfactory conditioning in the MB has not yet been identified.

Molecular Signaling Cascades in the ALs Are Critical for the Induction of Olfactory Memory Traces

Direct *in vivo* measurements demonstrate that the temporal characteristics of the US-induced PKA activation in the AL is critically influenced by its pairing with CS stimuli during olfactory conditioning. A single CS/US forward pairing, which induces a weak olfactory memory, leads to a transient increase in PKA activity that returns to basal levels 60 s after

the conditioning trial. Three CS/US forward-pairings in succession, which induce a long-term memory (LTM), prolong PKA activation in the AL up to more than 3 min. In contrast, US stimulation alone and, independent of the number, US/CS backward pairings induce a significantly shorter PKA activation. This close correlation between training parameters on the one hand and the temporal relation between US and CS stimulation, the number of conditioning trials, and the dynamic properties of PKA activation in the AL on the other hand leads to the hypothesis that prolonged PKA activation in the AL is involved in LTM formation. The hypothesis was tested by photolytic release of caged cAMP in the AL to artificially prolong PKA activation during olfactory conditioning. A local replay of the prolonged PKA activation in the AL *in vivo*, combined with a single conditioning trial, is sufficient to induce long-lasting memory. This provides direct functional evidence for a link between conditioning parameters, PKA activation in the AL, and its contribution to LTM formation in intact animals.

The use of the uncaging technique allowed further identification of the molecular processes underlying the prolonged PKA activation in the AL and thus the mechanisms contributing to induction of LTM in the AL. Nitric oxide, which is required for LTM formation in the honeybee, mediates the prolongation of the PKA activity by activation of the soluble guanylate cyclase and increase of cyclic guanosine monophosphate (cGMP). Inhibition of the soluble guanylate cyclase impairs both the prolonged PKA activation in the AL and LTM formation. Similar to the uncaging of cAMP, photorelease of caged cGMP in the AL – in combination with single-trial conditioning – induces long-lasting memory. Although the target of cGMP has not yet been identified *in vivo*, the synergistic activation of honeybee PKAII by cAMP and cGMP points to a direct function of cGMP in the prolonged increase in PKA activity ($\approx$25%) in the AL.

These findings demonstrate that molecular processes localized in the neural circuit of the AL critically contribute to LTM formation. Prolongation of PKA activation in the AL in conjunction with single-trial conditioning, however, does not reach the level of conditioned responses after multiple-trial conditioning, and thus it seems feasible that additional molecular processes or neural circuits may contribute to the prolongation. The molecular and neural targets of the early events in the AL that finally lead to LTM are yet unknown.

The signaling cascade that involves the Ca^{2+}-phospholipid-dependent protein kinase C (PKC) is implicated in a parallel-acting system contributing to olfactory memory at the AL level. In contrast to US-specific activation of the PKA in the AL, PKC is activated by both the US and the CS. The temporal pattern of PKC activation is independent of the sequence of CS and US stimulation or the number of conditioning trials. Since inhibition of PKC activation during the conditioning phase affects neither acquisition nor memory formation, conditioning-induced PKC activation in the AL seems not to be required for memory induction. The analysis of the learning-induced changes in PKC activity in the AL hours and days after training revealed a function of PKC in memory maintenance. In contrast to a single conditioning trial, repeated conditioning trials that induce LTM cause an increase in PKC activity beginning 1 h after conditioning and lasting up to 3 days. This long-lasting PKC activation can be dissected into two mechanistically independent phases. In the early phase (1–16 h), a constitutively active PKC, the PKM, contributes to the elevated activity. PKM is formed by cleavage of the activated PKC by the Ca^{2+}-dependent protease calpain. Blocking calpain activity during conditioning prevents PKM formation in the AL and impairs memory in a time window between 1 and 16 h. This treatment does not affect acquisition, the early memory phase up to 30 min, and memory after 1 day. The late phase of the training-induced increase in PKC activity (1–3 days) in the AL is unaffected by calpain blockers but requires protein and RNA synthesis. Thus, PKM formation in the AL is an independent parallel process required for maintaining a midterm memory phase. The function of the late phase (1–3 days) is still unclear but is probably one of several parallel mechanisms occurring in different brain circuits required for the formation of the late phase of LTM.

In summary, currently evidence exists for a function of the AL circuitry only in early processes of learning and memory formation, like the nitric oxide-mediated PKA activation involved in LTM induction and the early PKM formation required for maintaining a memory phase in the hours range.

Glutamate-Mediated Signaling Cascades in the MBs Contribute to LTM Formation

Glutamate is the major excitatory transmitter in mammals and plays a central role in neuronal plasticity in vertebrates. Its function in the insect brain, however, is only poorly understood. Although glutamate receptors have been identified in honeybees and manipulation of glutamate function using pharmacological tools supports a function in learning processes, the results are a matter of controversial discussion.

Photolytic uncaging of glutamate in the honeybee MB revealed direct evidence for a defined spatial and temporal contribution of glutamate in LTM formation. Uncaging glutamate immediately after a weak training protocol (single-trial training) in the MB improves the formation of a late memory phase (2 days) and thus mimics the effect of a strong training protocol. Uncaging shortly before the weak training has no effect, pointing to a defined function of glutamate with respect to early memory processing rather than learning. This function of glutamate is restricted to the MB circuitry, since glutamate release in the AL does not improve learning or retention. Taken together, glutamate action is restricted to the MBs, where it contributes to induction of a late memory phase in a time window shortly after training. Although it is still unclear whether this late memory phase is mechanistically identical with the LTM induced by a strong training (three-trial conditioning), the findings provide an example for parallel molecular processes underlying learning and memory formation *in vivo* occurring in different neural circuits.

Parallel Molecular Processes Contribute to LTM Memory Formation

As in other systems, LTM in honeybees can be divided into an early phase (eLTM, 1–2 days), which requires protein synthesis, and a transcription-dependent late phase (lLTM, $\geq$3 days). In all model systems investigated so far, inhibition of PKA activity during the training period results in a loss of both eLTM and lLTM. Although this suggests a single PKA-triggered process, experiments considering the impact of the satiation level in appetitive learning and memory formation in the honeybee provided evidence of a more complex function of the cAMP/PKA cascade in LTM induction. Three-trial conditioning in hungry animals leads to perfect acquisition and induction of midterm memory and both LTM phases. However, feeding bees 4 h before olfactory conditioning impairs acquisition and memory formation. This, and the different basal PKA-activity in honeybee brains at different satiation levels, points to a contribution of the cAMP/PKA cascade. Elevating the low basal PKA-activity levels in animals fed 4 h before conditioning specifically rescues the transcription-dependent lLTM. Acquisition, midterm memory, and eLTM are still impaired. The fact that both eLTM and lLTM require PKA for their induction, but PKA rescue in fed animals improves only lLTM but not eLTM, points to the existence of two parallel cAMP/PKA pathways implicated in memory formation: one process appears to trigger events leading to translation-dependent eLTM; the other is involved in inducing cascades required for transcription-dependent lLTM. Localization of the neural circuits related to these independent cAMP/PKA pathways will provide important information on the organization of the neural network involved in LTM formation.

Background

Notions Received from Pavlov

Much of the progress in understanding the basic mechanisms of learning is due to research conducted with Pavlovian (i.e., classical) conditioning, a paradigm in which animals change their response to a target stimulus, referred to as a conditioned stimulus (CS), as a function of the pairings of a CS with another stimulus, designated as an unconditioned stimulus (US). In the simplest Pavlovian conditioning procedure, one CS is paired with one US. As the result of one or more of these pairings or trials, the animal progressively changes its response to the CS, acquiring a conditioned response (CR). Subsequently, presentation of the CS without the US leads to a progressive diminution in the amplitude and frequency of the CR, in a process known as extinction.

The foundations of acquisition and extinction of the CR, as well as two related phenomena of generalization and discrimination, were intensively investigated by Pavlov and his followers more than a century ago. In generalization, it is seen that the strength of the CR is an increasing function of the similarity between the tested stimulus and the originally trained CS. In discrimination, acquisition trials with a given CS (i.e., A+) are intermixed with nonreinforced trials with another CS (B−). At first, this A+/B− training may result in responding to B as well as A (presumably due to generalization from A to B), but as training continues the animals progressively lose their response to B. In a special type of discrimination training in which A is followed by the US when alone, but not when presented in compound with B (i.e., A+/AB−), B acquires the capacity to inhibit the response elicited by other CSs, which is referred to as an instance of 'conditioned inhibition.'

The predominant explanation of all of these phenomena has been associative. That is, it is assumed that acquisition of the CR results from the strengthening of CS–US excitatory associations, that conditioned inhibition results from the development of inhibitory CS−US associations, and that extinction results from the weakening of excitatory CS−US associations or the suppressing effects of inhibitory associations.

Figure 1 depicts a prototypical network that can be used to describe the associative approach. It is assumed that environmental events, CSs and USs, activate their respective sensory processing units, represented by circles, which, by means of a net of interconnections (of strengths V and λ), influence the activity of a special 'adaptive' unit, which is responsible for the generation of the response. Pavlovian conditioning takes place because the adaptive unit, which prior to training is activated only by the US, can also, with training, come to be activated by the CS unit via its excitatory connection. Generalization is understood as the capability of similar CSs to partially activate the sensory unit of a trained CS. Likewise, conditioned inhibition is understood as the development of a negative connection between a CS and the adaptive unit. Extinction can be understood as either the weakening of the excitatory connection or as the superimposing of a new inhibitory connection (see the section titled 'Inhibitory learning during extinction').

The Linear Rule

The same computational learning rule was proposed within two major theoretical traditions, the Hull–Spence approach and the so-called stochastic models. This rule, known as the 'linear rule,' consists of the computation of the change in the strength of a habit (in the case of Hull–Spence theory) or the probability of a response (in the case of stochastic models) controlled by a CS, as a function of the discrepancy between a maximal or asymptotic associative level and the current associative level of the CS. This can be expressed formally by the equation $\Delta V_i = \theta(\lambda - V_i)$, where ΔV_i is the change in the excitatory associative strength of CS_i, θ is a learning rate parameter, and λ is the maximal associative strength supported by the US that occurred. According to this equation, changes in associative strength accrue to all stimuli for which internal representation is active on the occasions of reinforcement or nonreinforcement, regardless of any other stimuli present in the trial.

Contingency Effects and the Delta *P* Rule

In the late 1960s several lines of converging evidence suggested that the linear rule was not sufficient to explain conditioning. The first set of observations, concerning what are known as contingency effects, demonstrated that conditioned responding depends not only on the probability of the US given a CS, but also on the probability of the US in the absence

Figure 1 A network representation of Pavlovian conditioning (CS, conditioned stimulus; US, unconditioned stimulus). The circles represent processing units and the lines ending in arrows represent links among units. Continuous and discontinuous lines represent modifiable (V_i) and unmodifiable (λ) connections, respectively. The letters X_i and Y, represent the activity of the stimuli and adaptive units, respectively.

of the CS. In the typical contingency experiment several groups of animals receive the same number of CS–US pairings, but receive a different number of occurrences of the US in the absence of the CS. The outcome is that CR frequency or amplitude is negatively correlated with the probability of the US in absence of the CS.

The earliest account of contingency effects posited that animals must compute the correlation between the CS and US. Consider the contingency table shown in Table 1, containing the frequency of occurrence of the CS and the US in the presence and absence of each other. Excitatory conditioning takes place when the probability of the US in the presence of the CS (P(US/CS) = a/a + b) is greater than the probability of the US in the absence of the CS (P(US/no CS) = c/c + d). Inhibitory learning occurs when the probability of the US in the presence of the CS is smaller than the probability of the US in the absence of the CS, and no learning occurs when the two probabilities are equal. This idea has been summarized in what is known as the ΔP rule, which posits that the CR is a function of P(US/CS) − P(US/no CS), which, like a correlation coefficient, can vary between +1.0 (maximal excitation) and –1.0 (maximal inhibition).

Table 1 Contingency table

	US present	US absent
CS present	a	b
CS absent	c	d

The Rescorla–Wagner Rule

Another challenge to the linear rule came from a series of experiments that demonstrated that in conditioning involving a compound of cues, what is learned from one of the cues on a trial appears to depend not only upon its own current associative value, but also upon the associative value of the other cues present. The most influential observation is known as 'blocking.' If some CS, X, is reinforced in compound with another CS, A, the prior reinforcement of A alone reduces (blocks) the acquisition of conditioned responding to X. The phenomenon of conditioned inhibition, when subjected to careful analysis, revealed a similar dependence. That is, it was observed that training with AX, nonreinforced, causes X to become inhibitory only to the degree that A has been reinforced to be excitatory.

The Rescorla–Wagner model was designed to account for such effects. Formally, the model posits that the amount of change in the strength of the CS–US association for each CS present on a trial is a function of the error of the prediction of the US by all the CSs that are present in the trial – that is, that $\Delta V_i = \theta\ (\lambda - \sum V_i)$. This departs from the linear operator rule by introducing the aggregate associative strength in the computation of the learning to each CS. That is, when a CS is paired with a US or is nonreinforced, the change in the associative value of that CS does not depend only upon its own associative value, but also upon the aggregate value of all CSs present on that trial. In terms of Figure 1, the learning rule states that the more the adaptive unit is activated by all the CSs present on a trial, the less the associative strength will be increased if the US is presented, but the more the associative strength will be decreased if the US is not presented.

A major appeal of the Rescorla–Wagner rule was that it could account for contingency effects. It could do so by assuming that the experimental context can function like other stimuli in isolation and in compound with the training CS. Thus, US-alone trials can be seen as context-US trials, and CS–US trials can be seen as CS plus context-US trials. Application of the model with different frequencies of such assumed trials in the manner of Table 1 leads to quantities that co-vary with ΔP. In this regard, the Rescorla–Wagner rule, can be regarded as an approximate

heuristic for judging correlational relationships, as seen in contingency effects, without appealing to any complex computational capacity in the animals. Of course, the model has several limitations and these have stimulated theorizing during the past 30 years. Indeed, the history of associative learning theory after 1972 can be traced, in part, as the attempt of subsequent theorists to overcome presumed shortcomings of this model. The following sections introduce several current issues and discuss how they relate to the Rescorla–Wagner model.

Current Issues

Inhibitory Learning during Extinction

The term 'extinction' is commonly used to refer to a procedure in which a well-trained CS is presented repeatedly without reinforcement. The term also refers to the typical outcome of this procedure, which is a progressive decrease in the strength and frequency of the CR as a function of the number of nonreinforced presentations of the CS. The Rescorla–Wagner model construes the strength of a CS–US association as falling on a simple continuum from excitation to inhibition. During extinction the association becomes less excitatory and closer to being inhibitory. By this account there should be no difference between a CS that is mildly excitatory, because of modest CS–US training or because of extensive CS–US training, and some CS-alone extinction.

This unicontinuum account has been challenged as not easily accounting for the fact that an extinguished CR tends to reappear after extinction – that is, to show an increase not seen with a simple, modestly trained CS. This postextinction recovery of the CR happens under a number of circumstances including (a) when unsignaled USs are introduced after extinction (reinstatement), (b) when extinction is carried out in a context different from the one used in training and a subsequent test is carried out in the original context (renewal), and (c) after the mere passage of time (spontaneous recovery).

The demonstrations of reinstatement, renewal, and spontaneous recovery have encouraged the idea that extinction involves the development of a separate inhibitory CS–US association, which counteracts the intact excitatory tendency. In order to account for the postextinction recovery effects, it is further assumed that the inhibitory association construed during extinction is more susceptible to disruption by events like the passage of time or contextual changes than is the excitatory association. Although several descendants of the Rescorla–Wagner model have included separate excitatory and inhibitory CS–US connections during extinction, there is not yet a satisfactory theoretical rationalization of the presumed greater 'fragility' of the inhibitory learning.

Elementistic versus Configural Stimulus Representation

One of the major issues that separates current theories of associative learning is whether the associated stimuli are basically coded in elemental or configural fashion. Elementistic theories emphasize separate processing and representation of stimuli, no matter whether they are presented independently or in compound with other cues. By contrast, 'configural' accounts propose that compound stimuli are processed as unique exemplars and form associations independent of those formed by component elements. Thus, the cognitive representation of a compound is qualitatively different from the representation of its elements, although some of the associative strength acquired by a configuration can generalize to similar cues.

Although elemental and configural theories are often pitted against each other, it is important to appreciate that all existing theories recognize both elemental and configural processes. This can be seen in Figure 2, which depicts the general features of the Rescorla–Wagner model and Pearce's configural model. The Rescorla–Wagner model supposes that association develops for each element of a compound AB, but these include a context-dependent configural element X_{AB} as well as the context-independent elements X_A and X_B. The usual assertion is that the configural element X_{AB} is less salient than are the context-independent elements in learning situations involving compounds. On the other hand, configural models suppose that associations develop to experienced compounds, rather than to the elements of the compounds, but allow that association generalizes from one compound to another according to the distance that separates them along their elemental dimensions (denoted by the similarities links ${}_iS_j$ that connect the stimulus units in Figure 2). The usual assertion is that the generalization leaves much that is not shared from one configuration to others, even in cases of separable compounds.

Some phenomena are more intuitive from an elemental perspective. For example, when individuals are trained with two stimuli, A and B, each paired separately with the US, it can be anticipated that more responding will be seen in response to the novel compound, AB, than to either of the training stimuli. Other phenomena are more intuitive from a configural perspective. For example, it can be anticipated that the individuals can learn nonlinear

Figure 2 A network representation of elementistic (left panel) and configural (right panel) models of Pavlovian conditioning (CS, conditioned stimulus; US, unconditioned stimulus). In the elementistic model, the representational unit of A is equally activated by the A and AB stimuli, and the representational unit of B is equally activated by the B and AB stimuli. In the configural model, the AB stimulus activates directly its own representational unit AB and exerts an indirect influence over the A and B units via generalization links ($_{AB}S_A$ and $_{AB}S_B$). In the configural model, the A and B stimuli also influence the activity of the AB unit via their respective generalization links ($_AS_{AB}$ and $_BS_{AB}$).

discriminations, such as 'negative patterning,' in which A and B are separately paired with the US, but AB is not. But, all existing theories recognize both elemental and configural influences in order to provide some reasonable approach to these well-demonstrated phenomena. Advocates of the different theory types have nominated numerous additional phenomena as being more or less congenial to the different theories, or have come to different conclusions about their integrative usefulness. It is as possible, however, that the essential need is to understand better the variable influence of elemental versus configural processing in different circumstances.

Representation of Time in Conditioning

In the models that have been mentioned, the basic unit of analysis is the trial. For example, in the Rescorla–Wagner model the parameters, θ and λ, for the occurring stimuli, are specified constants on each trial, and ΔV_i is computed trial by trial. Such models are not equipped, without modification, to address important within-trial temporal phenomena. The most notable phenomenon is the tendency for the CR to be initiated and to peak at a time after CS onset that increases with the delay between the CS and US during training. The timing of the CR appears to become discriminated so as to occur at about the time at which the US has been presented. A striking instance of this can be seen when conditioning involves training with two different CS–US intervals on intermixed occasions. With sufficient training the result is a bimodal CR, with peaks at the two intervals at which the US was experienced.

The general approach to such phenomena has been to assume that the CS initiates a stimulus trace that is composed of a number of temporally differentiated components, and that ΔV is computed for each of the components on a moment-to-moment basis. In this case, just those components that are relatively active at the moment of the US are strengthened and become capable of eliciting the CR, whereas those that are relatively more active at moments of non-reinforcement are extinguished.

The notion of a componential CS representation was anticipated by Pavlov, who hypothesized that the timing of the CR was the result of discrimination learning that takes place among the many components that comprise the CS during its duration, some of which could be reinforced, nonreinforced, or partially reinforced. Modern models frequently employ a moment-by-moment application of the Rescorla–Wagner rule in computing how the temporal discrimination is formed, but differ in the pattern of activation of the components that the CS is assumed to initiate. Figure 3 presents three examples of the pattern of CS-component activity used in different componential models. The top plot depicts a so-called tap delay line, in which the CS onset initiates a sequential activation of elements in series. Each element activates the next element in the line but may have a period of activity that overlaps a number of the subsequent elements. Another possibility shown in

Figure 3 Time courses of three examples of componential conditioned stimulus (CS) representations. The black rectangle at the bottom of each plot represents the duration of the CS. The top plot represents a tap delay line, in which the CS activates a sequence of elements (the circles connected by arrows), which in turn give rise to identical nonmonotonic courses of activity. The middle plot represents the gamma functions, in which the CS gives rise to successive patterns of activity of varied shapes. The bottom plot presents a raster plot, with the activation of binary elements, in which each of the elements is represented on the ordinate and its state of activity varies over the duration of the CS. Superimposed on the raster plot is a summary function describing the aggregate number of elements that are active at each moment.

the middle plot is to assume that the CS generates a population of signals that vary in rise and decay parameters. These functions, known as gamma functions, are different from the delay line in that they are initiated at the same time, but nonetheless have different distinctive courses of activity. Finally, the bottom plot shows another example in which the CS influences the pattern of activity of a population of binary elements, each of which has 'on' and 'off' states that vary according to some characteristic stochastic process. One alternative or another may be defended on some formal grounds, as consistent with some sense of neurobiological plausibility, or as shadowing some particular data pattern in some conditioning preparation. Beyond such differences, the need for a componential representation of the CS has become relatively uncontroversial in the past 20 years.

Stimuli Trained in Compound Do Not Have a Fully Common Fate

One of the most straightforward implications of the Rescorla–Wagner rule is that there is a common fate for all stimuli that are trained in compound. Because a common error term is used to compute the learning that accrues to all of the stimuli present in a trial, equally salient stimuli should experience equal associative change. In fact, in many situations one can be most impressed with the way in which cues of different excitatory and inhibitory value, when trained in compound, appear to be commonly moved by reinforcement or nonreinforcement, as the model assumes. However, the results of a very clever experimental design recently employed by Robert Rescorla suggest that the change in associative strength of CSs trained in a compound do not have a fully common fate, as each is constrained to a degree by its own starting associative level.

The experiment proceeded as follows. Two stimuli, A and B, were originally trained to be equally excitatory by simple reinforced trials (A+ and B+). Two additional stimuli, C and D, were trained to be equally inhibitory by being nonreinforced in compound with an otherwise reinforced stimulus X (X+, CX−, and DX−). It could be assumed (without testing) that the compounds AC, AD, BC, and BD would all have equal total strength, since each contained one excitatory and one inhibitory element. Then one of these compounds, AC, was selected and further reinforced, so that it could be expected that both A and C would be incremented. The question posed was whether the increments to A and C were equal. If learning was determined by the error term in the Rescorla–Wagner rule ($\lambda - \sum V_i$), A and C should have gained exactly the same amount of associative strength at the end of the second phase. Whether they did, or not, was tested by comparing responding to the AD and BC compounds, each of which contained one of the originally reinforced CSs, one of the originally nonreinforced CSs, one of the additionally incremented CSs, and one nonincremented CS. The data clearly showed more responding to BC than to AD, indicating that the originally inhibitory C must

have been increased more than the originally excitatory A by the AC+ treatment.

This differential learning about elements of compounds can be handled by various modifications of the Rescorla–Wagner rule. One approach begins with a componential representation of the CSs, as described in the previous section. Assume that the associative strength of each of the nominal stimuli is determined by the summed strength of a large number of components of varying strengths. Assume further that whereas the total strengths are relatively unbounded, there is a limited excitatory or inhibitory strength that can be acquired by each individual component. Following this reasoning, it may be that when the excitatory A and the inhibitory C were reinforced in compound, although acted upon by a common error term, a greater proportion of the A components than the C components reached asymptote and were prevented from further increment. It remains to be seen whether this or some other modification in the learning rule will prove more useful, but the Rescorla data clearly imply that some constrained rule is necessary.

Priming Phenomena

The Rescorla–Wagner rule embodies the assumption that the more predicted is a US by the aggregation of CSs that precede it (i.e., the greater is $\sum V_i$), the less effective that US will be in producing excitatory learning. A substantial body of data indicate (a) that diminished learning is but one of the behavioral measures by which a predicted stimulus may be seen to be less effective than it otherwise would be, and (b) that prediction by a preceding CS is but one of the prestimulus manipulations by which diminished processing can be brought about. The larger pattern of data has encouraged a theoretical approach that has more general scope than does the Rescorla–Wagner model.

Among the other ways by which a predicted stimulus may be seen to be less effective than it otherwise would be, one that has been central to theoretical development, is the 'conditioned diminution of the UR.' This refers to the fact that a US that is preceded by an excitatory CS with which it has previously been paired elicits a UR that is of diminished amplitude, in comparison to when it is unannounced or is preceded by the same CS after it is extinguished. This phenomenon of conditioned diminution is not peculiar to the stimuli customarily employed as USs in Pavlovian conditioning, but has been demonstrated as well, using a measure of the orienting response, with stimuli that would more commonly be used as CSs. For example, a light that has been repeatedly preceded by a distinctive tone produces less of an orienting response when it is preceded by the tone than when not, and this diminution depends on the integrity of the tone–light association.

Another prestimulus manipulation by which diminished processing of a stimulus can be brought about is by a shortly preceding exposure to the same stimulus. The phenomenon of short-term habituation is well known, whereby the UR to a stimulus is decremented on the second of two exposures, depending on the interval of time between the two. Studies in eyeblink conditioning of the rabbit with a paraorbital US have demonstrated that application of the US shortly before a CS–US pairing diminishes the UR observed to the US in the pairing and decreases the amount of excitatory learning that it produces. Studies have similarly shown that application of the CS shortly before a CS–US pairing decreases the amount of conditioning that accrues to the CS.

The general pattern that emerges from these observations is that a training stimulus, whether CS or US, is rendered less effective than it otherwise would be, if on the occasion of its occurrence if it is preactivated or 'primed' in the memory system. This can be accomplished by presentation of the stimulus itself, or by presentation of a stimulus that can retrieve the training stimulus as a result of prior associative learning. A formal model that incorporates these notions was formulated by Allan Wagner and his colleagues, and given the acronym, SOP (for 'sometimes opponent process').

Detailed exposition of the quantitative features of SOP is beyond the scope of the present treatment, but the essence of the formulation can be appreciated through the network depicted in Figure 4. Stimuli are assumed to activate a sequence of nodes, Al followed by A2. The central assumption by which the priming effects are addressed is that activity of the secondary node recurrently inhibits the primary node, making it transiently less susceptible to activation by its initiating stimulus. The assumption is further made that, of the activity sequence that is occasioned by any stimulus, it is the A2 node that is the adaptive node that can come to be activated by a formally neutral stimulus. By this reasoning, if the A2 node of a US is activated either by a recent instance of that stimulus or by the precedence of an associated CS, the A1 node of that US will be less susceptible to activation, so as to produce a diminished UR and less associative learning. The same reasoning would apply if the A2 node of a CS is activated by a recent instance of that stimulus or the precedence of an associated stimulus. In this case the CS should show diminished associability.

Applications of the SOP model, like the Rescorla–Wagner model, have often imputed associative

Figure 4 A network representation of the SOP model (see text for discussion). Each stimulus is represented by a primary ($A1_i$) and a secondary unit ($A2_i$) unit. The conditioned stimulus (CS) and the unconditioned stimulus (US) activate their respective primary units, which in turn activate the corresponding secondary units. The CS influences the activity of the US-secondary unit by means of its associative value, V_{CS}. The links ending in a vertical line represent inhibitory feedback from each secondary unit to its corresponding primary unit. The activity in the $A1_{US}$ units is responsible for the generation of the primary unconditioned response, whereas the activity in $A2_{US}$ is responsible for the generation of the secondary unconditioned response and the conditioned response.

influence to the experimental context in which Pavlovian conditioning occurs. US preexposure in one context diminishes the associative learning produced by the US in that context. Similarly, CS preexposure in one context diminishes the associability of the CS in that context. Both these effects can be rationalized as being due to the preexposure context acquiring, through associative learning, the ability to activate the representation of the preexposed stimulus to the A2 state. Such a context-specific associative effect may be implicated in many observations of long-term habituation, but at the moment there is not clear understanding of why the habituation decrement observed in some URs (e.g., freezing) is more context specific than is that of others (e.g., startle) elicited by the same stimulus.

One feature of SOP pointed to in Figure 4 is that the CR and the UR supported by a US are not assumed to be identical. The UR is assumed to involve a primary response to the A1 activity, followed by a secondary response to the A2 activity, whereas the CR is assumed to involve only the latter response. In some conditioning preparations, such as the rabbit eyeblink reinforced by paraorbital shock, the CR and UR are separable eyelid closures are similar. In other preparations, such as the conditioned emotional response reinforced by a shock US, the two responses may appear antagonistic, as the CR (and secondary UR) is freezing, whereas the prominent initial UR is increased activity.

Divergence of Response Measures

Much of the diversity among current theories of Pavlovian conditioning stems from differences regarding the manner in which the CS is represented. By contrast, there has been relatively less attention paid to the manner in which the US is assumed to be represented. There is, however, reason to suppose that the US is represented by dissociable elements, just as is the CS. The most obvious call for such an assumption comes from the substantial data showing that different Pavlovian conditioning responses reinforced by the same nominal US may fail to be well correlated.

The term 'divergence of response measures' was first coined in reference to the finding with rabbits, conditioned with a paraorbital shock US, that over a portion of the CS–US interval function, evidence of conditioning with the eyeblink CR decreased while evidence of conditioning with a heart rate CR increased. In a more striking example in the same preparation, it has been shown that the same backward pairings, of a paraorbital shock US followed by a CS, produced evidence of net inhibitory associative learning to the CS when assessed through conditioned eyeblink responding, but produced evidence of net excitatory associative learning when assessed through conditioned suppression of drinking. One possible interpretation of this phenomenon is that the conditioned eyeblink and the conditioned emotional response may be reinforced by different aspects of the US, and that the different aspects engage differential temporal processing.

Figure 5 is intended to hint at this frequently assumed notion of separable processing of two US components, one representing the sensory–perceptual aspect of the US and the other representing its emotional attributes. Association of the CS with the sensory–perceptual aspect of the US is assumed to be responsible for the CR, whereas the association of the CS with the emotional attribute is thought to be responsible for the conditioned emotional response (CER). This is consistent with findings suggesting that the rabbit eyeblink is controlled by a US processing center in the cerebellum, whereas the CER is controlled by a center in the amygdala. Different centers in the amygdala activated by the US appear to similarly produce variation in common measures of the CER, such as freezing, startle, heart rate changes, and defecation. Included in Figure 5 is the supposition

Figure 5 A network representation of a modulatory model of Pavlovian conditioning. It is assumed that the presentation of the unconditioned stimulus (US) produces activation of a sensory unit (Y) and an emotive unit (Z) via its $\lambda_{sensory}$ and $\lambda_{emotive}$ links, respectively. The sensory unit controls the conditioned response (CR) and can be associatively activated by the conditioned stimulus (CS) via the link $V_{sensory}$. The emotive unit controls the conditioned emotional response (CER), modulates the sensory unit, and can be associatively activated by the CS via $V_{emotive}$.

that a consequence of the CER is also a modulation of the motor CR occasioned by the same CS.

Learning Occurring with Absent Stimuli

The Rescorla–Wagner model and the elaborations and alternatives that have been mentioned are alike in assuming that CS–US association and CS extinction occur only via episodes in which the designated stimuli occur. There are a number of phenomena that challenge this restriction, some of which have been given ready interpretation, but others which remain problematic and in search of explanation. 'Second-order conditioning' occurs when CSl–US pairing leads CS1 to elicit a CR, and subsequent CS2–CSl pairings cause CS2 to acquire similar responding. This well-documented phenomenon might be entertained as suggesting that, during the CS2–CS1 training, CS2 was paired with a representation of the absent US retrieved by CS1 to establish an effective CS2–US association. However, analysis of the learning that occurs favors the interpretation that the CS2–CS1 pairing establishes an association between CS2 and the CR produced by CS1 during this training. 'Sensory preconditioning' occurs when CS2–CS1 pairing precedes CS1–US pairing and subsequent CS2 presentation evokes the CR previously acquired to CS1. Again, this might be interpreted as evidence that CS1 retrieved representation of CS2 on the occasions of the CS1–US pairings, so that the absent CS2, as well as CS1, formed associations with the US. However, analysis of the learning that occurs favors the interpretation that only CS2–CS1 and CS1–US associations are involved – that is, that upon testing, CS2 retrieves the representation of CS1, which then evokes the CR. This supposes that an absent stimulus may mediate responding but does not necessarily mediate associative learning.

There are two conditioning phenomena that are related to the previous examples but about which interpretation is less secure. In one case, a CS is paired with a food US in phase 1 of training and with a malaise-inducing agent in phase 2. The test in this instance is not with the responding to the CS, but rather with the response to the food US that had been employed in phase 1. The finding was that, as a result of the phase 2 training, the food was less accepted. The 'absent cue' interpretation is that during phase 2 the CS retrieved representation of the food US during the pairings with malaise, thereby strengthening a food–malaise association that made the food less attractive.

A second interesting case that has been reported is an instance of apparent retrospective revaluation termed 'unovershadowing.' In initial training, a compound CS, AB, was paired with a US, so that A acquired a tendency to elicit a CR, but less than if it had been trained in isolation (i.e., without the overshadowing influence of B). In phase 2, cue B was extensively extinguished, after which cue A was tested. The challenging observation has been that cue A is more responded to as a result of the extinction of B. The 'absent cue' interpretation is that on trials in which B is extinguished, it retrieves representation of A, the association of which with the US is not extinguished but, rather is enhanced.

The two challenging phenomena have sometimes been interpreted via modification to the SOP model. The model explicitly assumes that $A1_{CS}$–$A1_{US}$ conjunctions are necessary for excitatory learning and that $A1_{CS}$–$A2_{US}$ conjunctions are necessary for inhibitory learning. The data from the first example might be accounted for if it were assumed that $A2_{food}$–$A1_{malaise}$ conjunctions strengthened the food–malaise association. The data from the unovershadowing example might be accounted for by assuming that $A2_{A}$–$A2_{US}$ conjunctions strengthened the A–US association. Whatever the virtues of the separate modifications of SOP might be, it should be apparent that the two appear incompatible: pairing of a retrieved A2 state of a stimulus with the A1 state or the A2 state of another stimulus cannot be similarly strengthening of an association, at least within the usual understandings of the model.

There is yet another theoretical approach that may account for several of the reported effects of learning with absent cues. This is the 'comparator theory' proposed by Ralph Miller and his colleagues. This approach assumes that learning occurs by mere CS–US contiguity (like the linear operator rule) and that responding to a given CS is a function of the comparison of the CS's associative strength with the associative strengths of any other cues with which the CS has become associated. Thus, for instance, the low level of responding initially seen in response to the overshadowed cue A would not be due to the low associative strength of the cue, but to the comparison with the similar or greater associative strength of the overshadowing cue B, with which A was associated. After extinction of B, performance in response to A can be assumed to increase thanks to a more advantageous comparison with B.

The comparator theory deals well with phenomena like unovershadowing, in which the target cue (e.g., the overshadowed cue A) is transparently affected by a comparator cue (e.g., the overshadowing cue B). However, the theory at this time is necessarily complicated by extensions which appeal to mechanisms that regulate when target and comparator cues sustain a competitive or facilitative relationship. The issue of learning with absent cues clearly begs further empirical and theoretical clarifications.

Cone Photopigment Evolution

G H Jacobs, University of California, Santa Barbara, CA, USA

Essential Features of Cone Photopigments

Cones are delicate, elongated cells located at the outermost portion of the neural retina (Figure 1(a)). Along with rods, they constitute the two types of vertebrate photoreceptors. These receptors contain photopigments that convert photon energy into neural signals, thus serving as the essential first stage in the complex process that culminates in vision. Rods and cones in all vertebrates have different distribution patterns across the retina, different patterns of connectivity to downstream neurons, and inherent differences in sensitivity and temporal responsivity. These differences condition the manner in which rod and cone operation is linked to vision. Cones are traditionally conceived as supporting daylight vision by providing the information required for high spatial acuity and good temporal resolution. Subpopulations of cones in the retina of any given species typically contain different types of photopigments. This latter feature allows cones to also provide the signals that can be used to support color vision. In general, there are predictive relationships between the number of cone pigment types and the dimensionality of color vision: those retinas that contain only a single pigment are linked to an absence of color vision (a condition referred to as 'monochromatic'), those with two pigment types yield a single dimension of color vision (dichromatic), those with three types support two dimensions (trichromatic), etc.

Cone pigment is packed in a stack of parallel membranes that make up the distal portion of cone receptors, a region called the outer segment (Figure 1(a)). The physical arrangement is such as to increase the total pigment density in each receptor, thus maximizing the likelihood that incoming light will be absorbed by the pigment. Cone pigments are members of a family of G-protein-linked receptor molecules in which a chain of amino acids is embedded in a lipid membrane. The folding of the amino acid chain of the visual pigment is such that it traverses the membrane in seven helical palisades (Figure 1(b)). This protein, called opsin, has an accessory group – a chromophore – that is covalently linked to the opsin in the seventh of the transmembrane segments of the molecule (at position 312 in Figure 1(b)). The chromophore is a derivative of vitamin A and all vertebrate cone pigments are made from one of two chromophores: retinal or 3-dehydroretinal. The chromophore used in the manufacture of the cone pigments of birds and mammals is retinal; cone pigments of fishes, reptiles, and amphibians are constructed from either retinal or 3-dehydroretinal. Absorption of a photon of light by the pigment causes a conformational change (an isomerization) in the chromophore. The isomerization of the chromophore from an 11-*cis* to an all-*trans* configuration initiates a cascade of molecular events that produces a change in the flow of ionic current across the membrane of the cone outer segment. Characteristic features of this cascade include considerable speed and a large amplification of signal strength. Once initiated, the signal can spread along the extent of the receptor membrane and so trigger a change in the rate of release of neurotransmitter from the synaptic terminal of the cone, in turn informing second-order cells about receptor activation.

As for all other pigments, an absorbance spectrum provides an essential characterization of a visual pigment. Such spectra plot the probability that absorption will occur as a function of the wavelength of the light (Figure 1(c)). Opsin itself absorbs maximally in the ultraviolet (UV) wavelengths, below 300 nm. When it is bound to the chromophore, the absorbance spectrum shifts toward the longer wavelengths. The exact spectral positioning of the resultant pigment depends on the structure of the particular opsin. Although there are well-documented exceptions, generally each cone contains only a single type of photopigment. When they are properly scaled, the shapes of the absorbance spectra of all photopigments are very similar. Consequently, it is convenient and conventional to specify photopigments by the wavelength value to which they are most sensitive (λ_{max}).

Linking Opsin Genes and Cone Opsins

The genes specifying the opsins of the three types of human cone photopigment were first isolated and sequenced about 20 years ago. This achievement served as a catalytic event in the quest to understand the evolution of photopigments. As had long been inferred from early work on the inheritance of the common color vision defects, the genes for two of these opsins are located on the q-arm of the X-chromosome, where they lay in a head-to-tail tandem array. Because of the relative positioning of their absorption spectra, the two products are conventionally termed M (middle-wavelength-sensitive)

Figure 1 (a) Sketch of a vertebrate cone photoreceptor. The normal pathway followed by incoming light is indicated by the arrow. The outer segment (OS) at the top consists of a stack of photopigment-rich disks. The synaptic terminal of the photoreceptor where signal transmission to other retinal cells occurs is located at the bottom. (b) Schematic representation of the M/L primate cone opsin molecule. The 364 amino acids in this molecule are shown as small circles. The three residues that are responsible for the spectral tuning of these pigments in New World monkeys are located at numbered locations (see text). The chromophore attachment site is at residue 312. (c) Absorption curve for a typical cone photopigment.

and L (long-wavelength-sensitive) pigments. As shown in the schematic drawing (Figure 1(b)), each of these genes specifies an opsin consisting of 364 amino acids. Reflective of their common evolutionary history, the structures of these two genes are very similar, yielding proteins that have amino acid sequences that are ~96% identical. The gene for the third type of human cone pigment, the S (short-wavelength-sensitive) pigment, is located on chromosome 7. It specifies an opsin consisting of approximately 350 amino acids. The sequence of this gene is considerably divergent from the other two, producing an amino acid sequence for the S opsin that is only about 40–45% identical to that of the M and L opsins.

This early work on the structure of opsin genes inspired two lines of research. First, the availability of opsin clones led to the isolation of other opsin genes, and over the past two decades hundreds of

opsin sequences derived for many different species have been resolved. These sequences are deposited at the website of the National Center for Biotechnology Information (NCBI). Second, it quickly became possible to correlate opsin sequences with photopigment spectra, thus providing a critical link between gene structure and visual function. This was accomplished in two different ways. The first was to compare opsin sequence variations in animals whose cone pigments were known from other types of measurements to have different absorption spectra. Another was to directly produce opsins in artificial expression systems and then make *in vitro* measurements of the pigment product. The latter proved to be a particularly powerful approach because it could be pursued in opsins with engineered sequence variations, including both those having targeted mutations and those that were constructed as opsin gene chimeras. These approaches eventually made possible an understanding of the linkages between gene structure variations and variations in cone absorption spectra.

Changes at only a few critical locations in opsin genes are associated with shifts in the spectral absorption properties of the photopigment. For example, the M/L photopigments of New World (platyrrhine) monkeys occupy any one of five discrete spectral locations having λ_{max} values in the range from about 530 to 560 nm. This variation is controlled by changes at only three locations in opsin molecule (these are indicated in Figure 1(b)). Dimorphic amino acid substitutions at these three locations – alanine/serine at position 180, tyrosine/phenylalanine at 277, and alanine/threonine at 285 – yield pigments at the five locations. In other primates, substitutions at these same locations plus an additional two sites are involved in the spectral tuning of M/L cone pigments. This very conservative mechanism for spectral tuning allows inferences to be drawn about M/L pigments in animals where direct pigment measurements are not available. Cone opsin gene sequence information in turn can then be used to directly infer some features of visual experience, particularly about the nature of color vision.

Opsin Gene Families and Their Evolutionary Histories

Comparisons of the amino acid sequences of photopigment opsins from a variety of species has led to the consensus conclusion that all vertebrate visual pigments can be classified into five groups. These groups are considered to be paralogous, that is, they share a common evolutionary ancestry. An opsin family tree for these five groups appears in Figure 2,

Figure 2 Opsin gene family tree. Shown are representative contemporary species that draw their pigments from the five families. The ranges of λ_{max} values characteristic of the pigments from each of the families are indicated to the right of the brackets. The tree construction is derived from Hisatomi O and Tokunaga F (2002) Molecular evolution of proteins involved in vertebrate phototransduction. *Comparative and Biochemical Physiology B* 133: 509–522.

where results from a number of species representing different vertebrate groups are illustrated and the spectral locations of pigments characteristic of each group are noted. In total, vertebrate opsin genes produce photopigments whose λ_{max} values cover the spectrum from about 360 to 620 nm. The spectral diversity of pigments specified by some of these gene families is restricted – pigments from the SWS2 (short-wavelength-sensitive) group have peak values extending across a range of only about 20 nm – whereas pigments from other groups spread over a much more expansive range; for example, the pigments from the LWS (long-wavelength-sensitive) family cover a peak range of some 130 nm. Of the five groups, pigments from the Rh1 family are typically expressed in rods while the other four are usually cone pigments.

Although the general relationships among the opsin genes seem to be reasonably settled, it is much less clear as to the timing of important evolutionary changes. One suggestion is that photopigments arose very early in the evolution of life, perhaps in motile microorganisms similar to green algae. The divergence of a single type of opsin gene into two

separate families was apparently also an ancient event, variously estimated as having occurred 800–1100 Ma. The products of this divergence would have permitted animals to have two types of photopigments with respective maximum sensitivities in the short and long wavelengths. In understanding subsequent changes that may have occurred, recent work on the opsin genes of the lamprey, an agnathan (jawless) fish, has been particularly informative. This animal has predominantly cone-based vision that originates from the activation of four types of cone photopigments. Each type of pigment is drawn from one of the four classes of cone opsin genes. That fact provides strong evidence that four of the five classes of vertebrate opsin genes arose prior to the evolution of jawed vertebrates, that is, by the early Cambrian period (~540 Ma). Rod pigments then appeared only after all the cone opsin gene families were in place. These facts imply that, at least potentially, a relatively elaborate capacity for daylight vision, including color vision, has been characteristic of the entire history of vertebrates, with rod-mediated (dim light) vision a relatively more recent invention. That scenario also receives support from examinations of the structure of mammalian retinas, which show that there is much more elaborate neural circuitry for the analysis of cone as opposed to rod signals. All of these observations suggest that rods and their associated neural circuitry were superimposed on an organization originally evolved to support cone-based vision.

From Figure 2, it can be seen that all four classes of cone opsin genes are present in some contemporary birds, fish, and reptiles. Note however that the only mammal represented in Figure 2, *Homo sapiens*, has pigments drawn from only two of the four gene families, LWS and SWS1. That example, and many others, indicates that although four opsin gene families have been maintained throughout the history of vertebrates, that arrangement is not uniformly true for all contemporary vertebrates. The particular exceptions offered by mammals are the focus of the following sections.

Mammalian Cone Pigment Evolution

Paleontological evidence suggests that the early mammals were mostly strongly nocturnal, and that is believed to have had a strong impact on mammalian visual adaptations. This photic history may have led to three types of changes in the visual system: average increases in rod/cone ratios, loss of colored oil droplets from mammalian photoreceptors that have been retained in many other vertebrates, and the disappearance of any representation of cone pigments from two gene families, namely Rh2 and SWS2 (see Figure 2). The latter fact implies that the retinas of ancestral mammals were limited to two types of cone pigments, one absorbing in the short wavelengths and one in the middle to long wavelengths. Based on evidence that a total of only five amino acid sites in LWS opsins are involved in the spectral tuning of all mammalian LWS cone pigments, it is possible to infer the evolution of spectral change in these pigments. Figure 3 shows a tree typology for mammalian LWS pigments for a number of representative mammals. By this accounting, the original mammalian LWS pigment had a spectral peak close to 530 nm. Divergences since then have yielded cone pigments that span a spectral range from about 510 to 560 nm. Note that among the contemporary mammals shown in Figure 3, only the human has acquired a second type of LWS pigment. That addition is also characteristic of some other primates, as described in the next section.

An interesting exception to the rule that mammals have retained only two of the four cone opsin gene families occurs in some Australian marsupials. At least four species from this group have recently been found to have a total of three types of cone photopigments. In addition to pigments drawn from the SWS1 and LWS gene families, these animals have a pigment from the Rh2 family. Recent behavioral experiments indicate that this third cone pigment does support trichromatic color vision in these marsupials. Why some marsupials have retained pigments derived from the Rh2 opsin gene family, while all other mammals seem to have lost them, remains at present a mystery.

Figure 3 A proposed tree of mammalian LWS pigments. The numbers on the branches are λ_{max} values for the pigments as obtained from a model of spectral tuning; those in parentheses represent direct measurements. These inferences were derived from Yokoyama S and Radlwimmer FB (1999) The molecular genetics of red and green color vision in mammals. *Genetics* 153: 919–932.

Primate Cone Pigment Evolution

The number of cone pigments and the dimensionality in color vision this allows are summarized for the various groupings of extant primates in Table 1. A major point is that, among eutherian mammals, only primates have been able to move beyond two classes of cone photopigment and the visual confines this creates. But not all of them have done this, and the ones who have done it have accomplished it in two quite distinct ways. In one instance, the single LWS X-chromosome opsin gene duplicated at a point close to the base of the radiation leading to contemporary catarrhine primates (Old World monkeys, apes, and humans), perhaps 30–35 Ma. This led, through subsequent changes that are still matters of speculation, to the presence of two genes coding for spectrally distinct M and L pigments (Figure 3). This arrangement provides routine trichromatic color vision to all members of these species. There are some exceptions to this, notably among humans (see later).

Some New World monkeys have been able to achieve the same trichromatic end by following a quite separate pathway. In these primates, there are alleles of the X-chromosome opsin gene, usually three, each coding for a spectrally distinct M/L cone pigment. This allows heterozygous females, those getting different versions of the gene on their two X-chromosomes, to produce two spectrally distinct M and L pigments. Because they lack a second X-chromosome, male New World monkeys do not have a second M/L pigment and neither do homozygous females. The consequence is that among these New World species there is significant polymorphism of cone photopigments and color vision. There are two lineages of New World monkeys that do not follow this plan – one has routinely trichromatic color vision like the catarrhines, the other has lost color vision entirely due to gene mutation.

Among the species in the third major branch of the primate order, the more primitive strepsirrhines (lemurs, bushbabies, etc.), there is considerable variation in M/L pigment arrangements. Some species are like nonprimate mammals in routinely having only two classes of cone photopigments; others have only a single cone pigment and must therefore be monochromatic, while still others resemble the majority of New World monkeys, that is, they are polymorphic, with some females having a total of three types of cone photopigment while all other individuals have only two.

There are a number of clear instances of evolutionary change having occurred in primate cone opsin genes. As the preceding summary documents, these would include (1) loss of S-opsin gene function in some platyrrhine and strepsirrhine lineages, (2) the appearance of opsin gene polymorphisms in most platyrrhines and in a few of the strepsirrhines, and (3) the addition of a third opsin gene in all catarrhines and in some female platyrrhine and strepsirrhines. Finally, there are the intriguing polymorphisms of X-chromosome opsin genes found in humans. These include the much-studied variations classically associated with color vision defects, found mostly in males, and more subtle variations detected among both males and females. Evolutionary change of this kind is believed to be virtually absent in other catarrhines and so must have arisen in human history. There are clear variations in the incidence of these polymorphisms among human populations. The meaning of that fact has led to much speculation, but relatively little real insight.

Evolution of SWS1 Cone Pigments

Cone pigments derived from genes in the SWS1 family fall into two spectral classes having respective peaks in the UV, with λ_{max} of ~360–390 nm, and at

Table 1 Cone photopigments and color vision in primates

Suborder[a]	*Infraorder*[a]	*Exemplars*	*Cone pigments and color vision*[b]
Strepsirrhini	Lemuriformes Chiromyiformes Loriformes	Lemur, loris, galago	Monochromatic; dichromatic; polymorphic
Haplorhini	Tarisiformes	Tarsier	Dichromatic
Haplorhini	Eusimiiformes Platyrrhini	New World monkeys	Majority polymorphic; one genus is monochromatic; one genus is routinely trichromatic
Haplorhini	Eusimiiformes Catarrhini	Old World monkeys, apes, humans	Routinely trichromatic (with notable polymorphism in humans that is not seen in other catarrhines)

longer wavelengths (λ_{max} of ~395–435 nm). The latter are identified as S pigments in Figure 2, although elsewhere they have alternatively been referred to as VS (violet-sensitive) pigments. The picture relating gene sequence changes and spectral tuning for the pigments in this group is less clear-cut than for the LWS pigments. Comparative examinations of opsin gene sequences have led to the conclusion that the ancestral pigments in this group were UV pigments. In different lineages, these have been converted to S pigments and, sometimes, then reconverted back to UV pigments. The amino acid substitutions associated with tuning changes may involve as many as eight residues, with perhaps three that are key to spectral shifting.

Until about 15 years ago, it was believed that, although the locations of their λ_{max} values may vary from species to species, all mammals had S pigments. It is now known that this is not true, that in fact some mammals possess the ancestral UV sensitivity. The evolutionary events that might account for this essential difference among the mammals are unknown. Mammals with UV pigments are mostly rodents (common examples: house mouse and rat), but some rodents have acquired S pigments (e.g., most members of the squirrel family), so the shift from UV to S pigments must have occurred in the more distal branches of rodent phylogeny. The former are nocturnal, the latter diurnal, so it might be thought that a shift to a diurnal lifestyle was somehow linked to a change from a UV to an S pigments. However, there are many mammals possessing S pigments that are classified as nocturnal, and at least one rodent classified as diurnal (the Chilean *Octodon degus*) is known to have a UV photopigment. So there seems to be no completely compulsive relationship between lifestyle and S pigment type. Further clouding this picture is the fact that it is not at all obvious how heightened sensitivity to the UV might particularly benefit a nocturnal animal.

An interesting twist in the story of mammalian SWS1 pigments is that there has been a loss of function of these opsin genes in some lineages. This was first discovered in a search for S pigments in the retinas of two species of nocturnal primates (the owl monkey and the bush baby). No S pigment could be found and, subsequently, it was discovered this was due to the fact that the SWS1 genes in these animals contained fatal mutational changes that obviated the expression of any pigment. This loss seems to be specieswide. That fact carries the implication that the loss of S pigment must be in some way adaptive. Subsequently, a similar loss of S cone function has been documented for some rodents and for some carnivores. Remarkably, this loss of function of the S-cone opsin gene is apparently universal among many species of marine mammal, including all of the pinnipeds and all of the cetaceans. At present, there is no satisfactory explanation of what caused some mammalian lineages to abandon their S cones and, with them, the potential for a dimension of color vision and some additional sensitivity to the short wavelengths.

Cone Pigment and Color Vision Evolution

As the preceding discussion makes clear, considerable progress has been made toward understanding the evolution of cone opsin genes and the cone pigments they specify. Since, as already noted, inferential linkages can be drawn between cone pigments and color vision, it is tempting to suppose that cone pigment evolution is also the evolution of color vision. That equation is too simplistic – there is much more to color vision than just cone pigments. In particular, in order to support color vision, the nervous system must have a means of comparing signals generated in cones containing different types of photopigments. Consequently, adding a new type of photopigment to a retina will broaden the window for spectral absorption (i.e., a larger range of wavelengths will have a probability of being absorbed by the pigment), but it will not automatically add a new dimension of color vision. Since simply capturing more photons may by itself prove advantageous, a new pigment type conceivably could evolve in the absence of any new color vision.

Even assuming that the evolution of a new cone pigment adds new color vision to the perceptual repertoire, the quality of that new capacity will depend on factors quite beyond the mere appearance of a new pigment type. In particular, the total number of cones containing the various pigment types and their spatial distribution across the retina can have a major impact on how acute the color vision capacity will be. For instance, both the domestic cats and humans with deuteranopic color vision (a dichromatic defect) have two photopigment types with respective spectral peaks that are not too greatly different for the two species. However, the acuteness of color discrimination in the color-defective human system is much greater than that in the cat, simply because of vastly greater number of cones in the human retina. Finally, to add color vision, one needs to add a new cone pigment type and assure that this new pigment type gets selectively expressed in cones. Coexpression of cone pigments (i.e., two pigments being present in one photoreceptor) does in fact occur in some rodent retinas, and this arrangement allows, at best, for only a very weak color vision capacity.

Summary

From the current understanding of the relationships between opsin genes and photopigments, it is now possible to discern the stages through which contemporary vertebrates have acquired their cone pigments. Because the linkages between photopigments and visual behavior have been much studied in these species, one can, with appropriate due caution, use ideas about cone pigment evolution to provide predictive insights into the visual capacities of ancestral species and this may, in turn, permit an enhanced understanding of their photic worlds and their visual behaviors.

Congenital Muscular Dystrophy

C G Bonnemann, Children's Hospital of Philadelphia; and University of Pennsylvania School of Medicine, Philadelphia, PA, USA

© 2009 Published by Elsevier Ltd.

Introduction and History of the Concept of Congenital Muscular Dystrophy

Congenital muscular dystrophy (CMD) refers to neuromuscular conditions with clinically apparent muscle weakness at birth or in early infancy, and in which the muscle biopsy reveals a dystrophic or myopathic picture without other diagnostic features suggestive of one of the structural congenital myopathies or of a mitochondrial or denervating disorder. The congenital muscular dystrophies are genetically and clinically quite heterogeneous. However, with the ongoing clarification of the genetic and molecular basis of an increasing number of conditions, new delineations of molecular subgroups and their associated clinical phenotypes have been introduced. The following is a brief historical review of the evolution of the concept of CMD up to the molecular era in CMD research.

The concept of congenital muscular dystrophies was first introduced by Frederick Eustace Batten in 1903, who carefully described patients with a

> disease [that] is congenital or starts in early infancy, and is characterized by smallness, lack of power, and loss of tone in all the muscles of the body without localized atrophy or hypotrophy of individual muscles or groups of muscles.(...) The disease is but slowly progressive for the child may, as development takes place, learn to sit up, and possibly to stand with support. The child usually learns to talk at the normal age, and intellectually is often in advance of his years. As a rule these children never learn to walk but adopt some strange method of getting about.

This phenotype corresponds closely to what today is known as laminin 2 (merosin)-negative CMD. In 1930, Otto Ullrich gave an equally detailed description of a phenotype which he called "scleratonic muscular dystrophy" because of the striking coexistence of low muscle tone and joint laxity as well as contractures. This condition is now is known to be caused by deficiency of collagen VI and is referred to as CMD type Ullrich. In 1960 in Japan, Yukijo Fukuyama published a series of papers describing in great detail a form of CMD with abnormalities of brain formation as well as with mental retardation that was prevalent in Japanese patients. In 1973, Victor Dubowitz recognized the clinical phenotype of rigid spine CMD, a proportion of which is now known to be caused by SEPN1 mutations. Muscle–eye–brain disease was described in 1977 by Pirkko Santavouri in the Finnish population. Arthur Earl Walker in 1942 and Mette Warburg in 1978 described a syndrome of severe eye and brain malformations that was designated as Walker–Warburg syndrome by Roger Williams and Verne Caviness in 1984 who also recognized its relationship to Fukuyama CMD and thereby muscular dystrophy. This was confirmed by William Dobyns in 1989 who proposed diagnostic criteria for Walker–Warburg syndrome and also referred to the cortical malformation as lissencephaly type II. The molecular age of CMD begins with the description of merosin/laminin 2 deficiency by Fernando Tome in 1994 and molecular confirmation of LAMA2 gene mutations by Pascale Guicheney's group in 1995 as the first identification of a gene mutated in CMD. Subsequently, there has been a considerable expansion of genetically defined conditions with the identification of mutations in various genes in the group of α-dystroglycanopathies, in the collagen VI genes, as well as in selenoprotein N. This molecular expansion is likely to continue.

The identification of this expanding number of genes involved in CMD has influenced the classification of the CMDs, which is now based largely on pathophysiolgical principles. However, since some of the defining clinical aspects are in good agreement with the molecular classification, the best approach to this group of disorders will take both the clinical syndrome and its range of underlying possible genetic etiologies into account. It is of interest to note that many disorders that are now classified as CMD affect components of the extracellular matrix as well as the interface between matrix and muscle. These CMDs of the extracellular matrix include those affecting α-dystroglycan glycosylation and α-dystroglycan's ligand merosin/laminin 2 as well as collagen VI. Intracellular molecules involved in causing CMD include selenoprotein N (SEPN1) as well as the inner nuclear matrix component lamin A/C. Thus, there is no single pathophysiological concept that would be applicable for all disorders now subsumed under CMD.

Disorders of α-Dystroglycan Glycosylation

Dystroglycan is a central component of the dystrophin-associated glycoprotein complex. This complex is composed of proteins that co-purify with dystrophin on wheat germ agglutinin columns from muscle membrane preparations. The complex includes an intracellular subcomplex (including syntrophin and dystrobrevin) as well as membrane spanning

molecular components. The membrane spanning part of the complex is composed of α- and β-dystroglycan as well as the sarcoglycan complex. β-Dystroglycan binds to dystrophin's cysteine-rich C-terminal domain and to α-dystroglycan on the extracellular side. α-Dystroglycan in turn binds to laminin 2 (merosin), one of the major components of basement membranes around muscle. Other α-dystroglycan ligands are known, including neurexin in the central nervous system and agrin at the neuromuscular junction. Both α- and β-dystroglycan are transcribed from the same gene DAG1 on chromosome 3p21 and are subsequently cleaved by posttranslational processing. α-Dystroglycan in particular undergoes significant further posttranslational glycosylation, including N-linked glycosylation at one site, but more important, O-linked glycosylation in the serine and threonine-rich region of the peptide, giving it mucin-like characteristics. Thus, the molecular weight of the processed α-dystroglycan is 156 kDa in muscle, whereas the weight of the core peptide is only 74 or 75 kDa. The molecular weight is lower in brain (120 kDa) and in heart (140 kDa), suggesting that there are tissue-specific modifications of this process. The O-linked glycosylation of α-dystroglycan that is of particular relevance for the pathogenesis of the CMDs is of the O-mannose linked type, a rather unusual form of O-linked glycosylation for which only very few targets are known. The enzymatic machinery involved is directly affected in the pathogenesis of an expanding class of CMDs now also referred to as secondary dystroglycanopathies. Mutations in the α-dystroglycan gene are not known to occur and are probably not compatible with life because inactivation of the *dag1* gene in the mouse is lethal in very early embryonic development (at the formation of Reichert's membrane). Some of the genes mutated in the group of disorders of O-linked glycosylation of α-dystroglycan are actual glycosyltransferases with proven enzymatic activities (protein *O*-mannosyl transferase 1 and 2 (POMT1 and POMT2, respectively) and protein *O*-mannose β1,2-*N*-acetylglucosaminyltransferase 1 (POMGnT1)), whereas the roles of others are less clear (Fukutin, Fukutin-related protein/FKRP, and LARGE), although putative functions have been suggested. The end result of mutations in all of these genes is an incomplete *O*-mannose-linked glycosylation of α-dystroglycan with direct effects on its function as a receptor for extracellular matrix components such as laminin 2 (merosin), agrin, neurexin, and presumably others. This impaired binding capacity of α-dystroglycan appears to lie at the basis of both the muscular dystrophy and the associated brain and eye malformations. The resulting muscular dystrophy is associated with membrane fragility, as evidenced by the elevated creatine kinase (CK) levels in affected patients, whereas the typical cortical malformation is a disorder of neuronal migration referred to as lissencephaly type II. This type of lissencephaly is associated with overmigration of neurons beyond the limits of the regular cortical plate, likely because of breaches in the glia limitans, the basement membrane covering the cortical surface of which α-dystroglycan is a crucial component. The result is a very disorganized layer of overmigrated neurons covering the original brain surface with resulting loss of normal gyration and increased thickness of the cortex. Observations in mouse models carrying tissue-specific conditional inactivations of the *dag1* gene to circumvent the early embryonic lethality suggest that most, if not all, of this pathology is directly related to loss of normal α-dystroglycan function. The biochemical and immunohistochemical hallmark of all of these disorders is a reduction of the glycoslyated epitope of α-dystroglycan (evident on Western blotting as well as on immunohistochemistry) while the core protein for α-dystroglycan is unaffected.

Several clinical syndromes are known in this group of disorders; their classification depends on the involvement of muscle, brain, and eyes. Ongoing genotype/phenotype analysis suggests that most of these phenotypes can be caused by mutations in more than one of the genes related to the pathway and that each of the genes in this pathway has a broadening range of phenotypes associated with it.

Walker–Warburg Syndrome

The most severe of the phenotypes is Walker–Warburg syndrome (WWS). Affected infants have extensive lissencephaly type II, hydrocephalus, absence of the corpus callosum, and fusion of the hemispheres due to overmigrating neurons. Rarely, there may be an occipital encephalocele associated with this malformation. There is significant pontocerebellar hypoplasia. Eye abnormalities may be severe and include microphthalmia, malformations of the anterior chamber, cataract, congenital glaucoma, and retinal dysplasias. Mental retardation is profound and epilepsy develops frequently. Life expectancy is limited so that only 5–10% of patients survive beyond 5 years. Genes known to cause WWS include POMT1, mutated in approximately 20% of patients; other genes known to be involved include POMT2, Fukutin, as well as FKRP, but together these do not account for all patients with WWS.

Muscle–Eye–Brain Disease

Muscle–eye–brain disease (MEB) is somewhat milder in that the brain malformation may be less complete, there may be lissencephaly as well as pachygyria, or sometimes there may also be polymicrogyric-appearing cortex. Abnormalities of the white matter

on magnetic resonance imaging (MRI) may be present, even transiently. Most consistently, there is a small pons as well as cerebellar hypoplasia with conspicuous cerebellar cysts on imaging. Eye involvement includes congenital myopia, glaucoma, as well as retinal dysplasias and optic disc abnormalities. The myopia and retinal abnormalities can be progressive. Mental retardation is invariant with a high possibility of the development of epilepsy. Patients may gain the ability to walk; however, there may be loss of ambulation because of increasing spasticity, ataxia, and weakness. This condition was originally described in Finland but is now known to occur worldwide. Mutations in MEB were first found in POMGnT1, located on chromosome 1p32–34, but mutations have also been found in FKRP as well as in POMT1 and -2.

Fukuyama Congenital Muscular Dystrophy

Fukuyama congenital muscular dystrophy (FCMD) is related to MEB but has its highest prevalence in Japan based on a founder mutation in the gene Fukutin (retrotransposon insertion into the gene locus). The spectrum of possible brain malformations in FCMD is very similar to MEB, whereas the eye findings tend to be less severe, mostly consisting of myopia. Profound mental retardation and the development of epilepsy are common. Patients in other countries with a FCMD-like clinical disease have had mutations in other genes along the pathway, whereas mutations in Fukutin outside of Japan have been associated with a more severe WWS-like disease and also with a severe (initially steroid-responsive) LGMD form.

Other Phenotypes

There are also patients with CMD or milder muscular phenotypes associated with mental retardation and brain malformations that may range from substantial to minor brain malformations, such as cerebellar cysts only, or with a normal appearing brain on imaging. These clinical syndromes may be associated with mutations in the same genes that are also responsible for the more severe phenotypes described. Mutations in the gene LARGE are associated with abnormal white matter and other subtle brain abnormalities, mental retardation, and muscular dystrophy but no eye involvement in the initial case, thus not formally qualifying as MEB. This condition is referred to as MDC1D. There is evidence that LARGE interacts with α-dystroglycan in the Golgi apparatus to facilitate subsequent *O*-mannosyl-linked α-dystroglycan glycosylation and in addition functions as glycosyltransferase in its own right. There are also patients with a milder LGMD-like muscular dystrophy, with mental retardation and microcephaly that are caused by mutations in POMT1, the gene originally associated with WWS. This disorder is now also classified among the limb–girdle muscular dystrophies as LGMD2K. Finally, at the mildest end of the spectrum, at least from the perspective of brain involvement, there are patients with muscular dystrophy only, without brain involvement or mental retardation. Mutations in the gene FKRP cover the broadest range of possible severity, ranging from severe WWS to a late adulthood onset form of pure LGMD. The severity of FKRP-associated muscular dystrophy can vary from severe CMD but normal brain imaging and intelligence (referred to as MDC1C) via Duchenne- and Becker-like severities to a milder adult-onset form of LGMD (referred to as LGMD2I). This supports the notion that these disorders should be viewed as a spectrum of a broadness that currently is unique in neuromuscular diseases. From a clinical perspective, it is important to realize that there may be cardiac involvement in addition to the skeletal muscle involvement in FKRP-related disease and also in the other dystroglycanopathies.

It is clear that there must be additional undiscovered genes causing hypoglycosylation of α-dystroglycan because not all patients with biochemical evidence for an α-dystroglycanopathy can be accounted for by mutations in the currently known genes (see Table 1 for additional possible phenotypes associated with biochemical evidence for α-dystroglycan deficiency).

Laminin 2 (Merosin)-Deficient Congenital Muscular Dystrophy

Mutations in a component of the ligand for α-dystroglycan, laminin 2 (also referred to as merosin), cause a CMD that occurs with an estimated frequency of 30–40% of all CMDs in Europe and has been recognized in most countries. It may be less common in North America. This condition is also referred to as MDC1A. Laminin 2 (merosin) is a heterotrimer composed of laminin α_2, laminin β_1, and laminin γ_1. The mutations occur in the LAMA2 gene on chromosome 6q22–23 coding for the heavy chain of laminin 2, laminin α_2. Laminin α_2 is also a component of laminin 4 occurring at the neuromuscular junction, which is therefore also affected by LAMA2 mutations, although the clinical consequences of this are not clear. Laminin 2 is a crucial component of basement membranes around muscle fibers, Schwann cells in the peripheral nervous system, whereas in the brain it is found around capillary blood vessels between the astrocyte foot process and the vessel and as a component of the lamina limitans on the surface of the brain. Laminin 2 also interacts with integrin β_1/α_7 as another receptor on muscle and also with components of the basement membrane, including nidogen, perlecan, and collagen type IV. Mutations in integrin α_7 have been described

Table 1 The congenital muscular dystrophies

Disease entity	*Locus* *protein product* *gene symbol*	*Helpful clinical features*	*CNS involvement*	*Laboratory testing*
Primary merosin/laminin 2 deficiency				
CMD with primary laminin 2 (merosin) deficiency (MDC1A)	6q22–q23 Laminin α_2 LAMA2	Sitting and standing with support as maximal motor ability if complete deficiency; neuropathy; epilepsy in approximately 30%; possible subclinical cardiomyopathy; generally normal mental development	Abnormal white matter signal (T2 MRI); 5% occipital pachy- or agyria; pontocerebellar atrophy (rare)	Mostly complete laminin α_2 deficiency on IH/WB; secondary reduction of integrin α_7 possible; mutation analysis[b]
α-Dystroglycanopathies – secondary merosin/laminin 2 deficiency				
CMD with partial merosin deficiency (MDC1B)	1q42 Not known	Rare; variety of severity; delayed onset possible; limb girdle weakness; generalized muscle hypertrophy; early respiratory failure possible	Abnormal white matter and structural changes possible	Partial deficiency of laminin α_2 on IH/WB; α-DG significantly reduced on IH; linkage analysis
Fukutin-related proteinopathy (MDC1C)	19q13.3 Fukutin-related protein FKRP	Often reminiscent of MDC 1A, but severity more variable, from severe CMD to LGMD; generally normal mental development; cases with structural brain involvement and mental retardation increasingly recognized, including MEB and WWS	Range from normal to significant structural abnormalities, ranging from cerebellar cysts to typical MEB and WWS	α-DG with diminished MW on WB, or reduction of IH using antibodies against glycosylated isotopes; secondary reductions in laminin α_2 on IH/WB; mutation analysis[b]
LARGE-related CMD (MDC1D)	22q12.3 Acetylglucosaminyltransferase-like protein LARGE	Only one patient described; congenital muscular dystrophy with profound mental retardation may eventually blend with the MEB/WWS spectrum	White matter changes; hypoplastic brain stem; mild pachygyria (similar to MEB)	IH/WB comparable to MDC1C; mutation analysis[b]
Fukuyama CMD (FCMD)	9q31 Fukutin FCMD	Frequent in Japanese population; never walk; mental retardation; epilepsy common – clinical overlap with MEB	Lissencephaly type II/ pachygyria; hypoplastic brain stem cerebellar abnormalities	IH/WB comparable to MDC1C; mutation analysis
Muscle–eye–brain disease (MEB)	1q32–q34 Protein-O-linked mannose β1,2-*N*-acetylglucosaminyltranferase 1 POMGnT1, also FKRP, Fukutin	Severe weakness and mental retardation; large head; prominent forehead; flat midface; walking rarely achieved; ocular involvement (e.g., severe myopia, retinal hypoplasia); deterioration because of spasticity	Lissencephaly type II/ pachygyria; eye malformations; brain stem and cerebellar abnormalities	IH/WB comparable to MDC1C; mutation analysis (genetic heterogeneity)
Walker–Warburg syndrome (WWS)	9q34.1 O-Mannosyltranferase 1 POMT1, also POMT2, FKRP, Fukutin	Severe; lethal within first years of life because of severe CNS involvement	Lissencephaly type II/ pachygyria; hydrocephalus; encephalocele; hypoplastic brain stem; cerebellar abnormalities; eye malformations	IH/WB comparable to MDC1C; mutation analysis (genetic heterogeneity)

Other matrix disorders (merosin/laminin 2 positive)				
Ullrich CMD (UCMD)	21q22.3 and 2q37 $\alpha_{1/2}$ and α_3 collagen VI COL6A1, COL6A2, COL6A3	Distal joint hyperextensibility; proximal contractures; motor abilities variable; precludes independent ambulation in severe cases; soft palmar skin	No	IH for collagen VI with severe to mild deficiency; mutation analysis[a]
Integrin α_7	12q13 Integrin α_7 ITGA7	Very rare; delayed motor milestones; walking within 2–3 years of life	No	Absence of integrin α_7 on IH (secondary reduction possible); mutation analysis[b]
Other CMDs				
Rigid spine muscular dystrophy (RSMD)	1p36–p35 Selenoprotein N SEPN1	Delayed walking; predominantly axial weakness with early development of rigidity of the spine; restrictive respiratory syndrome	No	Normal expression of laminin α_2; mutation analysis
CMD merosin-positive	4p16.3	Severe muscle weakness of trunk and shoulder girdle muscles; mild to moderate involvement of facial, neck, and proximal limb muscles; normal intelligence	No	Normal expression of laminins; dystrophin; sarcoglycans and β-dystroglycan
Lamin A/C-related CMD	1 Lamin A/C LMNA	Early motor deterioration; prominent axial weakness with dropped head syndrome; early development of spinal rigidity	No	Lamin A/C IH present
CMD with microcephaly/calf hypertrophy	Not known	Joint contractures associated; severe psychomotor retardation; no walking; striking enlargement of the calf and quadriceps muscles; CK grossly elevated	Megacisterna magna; cerebellar hypoplasia; white matter changes	Mild to moderate partial deficiency of laminin α_2 on IH
CMD with adducted thumbs	Not known	Rare; adducted thumbs; toe contractures; generalized weakness; delayed walking; ptosis; external ophthalmoplegia; mild mental retardation	Mild cerebellar hypoplasia	Normal expression of laminin α_2 and α-DG on IH
CMD with mental retardation and microcephaly	Not known, FKRP not yet excluded	Microcephaly; delayed psychomotor development; generalized muscular wasting and weakness with mild facial involvement; calf pseudohypertrophy; joint contractures; severe mental retardation	Pontocerebellar hypoplasia; focal cortical dysplasia; white matter changes; cerebellar cysts	Normal expression of laminin α_2
CMD with cerebellar atrophy	Not known	Delayed motor milestones; mild intellectual impairment	Moderate to severe cerebellar hypoplasia; no white matter abnormalities	Normal expression of laminin α_2

in three patients with a congenital muscle disease, but this appears to be extremely rare. Of the six domains that are recognized in laminin 2, the C-terminal G-domain is the most important domain for interaction with α-dystroglycan; specifically, the globular subdomains G4 and G5 have been shown to interact with α-dystroglycan. Mutations abolishing the expression of this domain as well as that of domains I and II are usually associated with severe disease. In the typical case, there is a complete deficiency of laminin 2 in the muscle biopsy on the basis of truncating mutations. Partial deficiencies may be caused by compound heterozygosity of a truncating mutation and an in-frame deletion or a missense mutation. The absence of laminin 2 disrupts the lamina dense of the basement membrane, causing dysfunction of the sarcolemma, as evidenced by elevated CK levels in the plasma of patients and in mouse models of laminin 2 deficiency. There is evidence that there may be both membrane instability and an increased rate of apoptosis in mice with laminin 2 deficiency.

Clinically, primary deficiency of laminin 2 is a severe disease with profound hypotonia at birth. Some patients may have distal contractures; however, these are not prominent. Standing with support is frequently the maximal motor achievement, whereas free ambulation typically is not achieved, although rare exceptions exists. Dysphagia and later respiratory compromise are common. Milder clinical courses can be seen with partial deficiency of laminin 2, resembling a milder CMD or a limb–girdle muscular dystrophy, with sometimes prominent contractures. A typical finding in patients with laminin 2 deficiency is abnormal white matter signal on T2-weighted MRI. This abnormal signal spares the more compacted fiber tracks such as the corpus callosum or the internal capsule. The nature of this abnormality is not completely understood but likely does not reflect de- or dysmyelination; however, it may reflect abnormal water content of the white matter. A small but significant percentage of patients with primary laminin 2 deficiency have structural abnormalities of the brain as well, including occipital pachygyria and cerebellar hypoplasia. There is also a higher incidence of epilepsy in patients with primary laminin 2 deficiency (approximately 30%). Thus, there are some clinicopathological features that are common to both the α-dystroglycanopathies and primary laminin 2 deficiency.

Disorders of Collagen VI (CMD Types Ullrich and Bethlem)

Mutations in the extracellular matrix component collagen type VI underlie a CMD known as type Ullrich as well as its milder allelic counterpart Bethlem myopathy. Collagen VI is composed of three α chains encoded by three genes: COL6A1 and COL6A2 on chromosome 21q22 or COL6A3 on chromosome 2q37. The individual chains have relatively short collagenous domains of 335–336 amino acids as well as N-terminals and C-terminal domains, frequently including von Willebrandt factor A domains as the most prominent component. The C-terminal globular domain in the α_3 chain is the largest. Collagen VI undergoes a complex assembly process in which all three α chains are required to form a heterotrimeric monomer, presumably by C-terminal association followed by zipper-like formation of the triple-helical collagenous domain. This monomer then undergoes further intracellular assembly that is stabilized by the formation of disulfide bridges involving cysteine residues that are located at the N-terminal part of the triple-helical domains of all three chains. Tetramers are then secreted and assemble end-to-end in the extracellular matrix to form beaded microfibrils. Collagen VI is a prominent component of most extracellular matrices, in which it forms beaded microfibrils that are found in close connection with cells and basement membranes as well as in the interstitial space in many tissues, including muscle, tendon, skin, cartilage, and intervertebral discs. Thus, collagen VI mutations present as a combination of disorders of both muscle and connective tissue in that joint hyperlaxity and contractures as well as abnormal skin are important aspects of the clinical phenotype in addition to the weakness. It is still unclear how collagen VI links or relates to the DAP complex, if at all. However, the molecular basis and consequences of this disorder appear to be different from those of the α-dystroglycanopathies in that the disease is less overtly 'dystrophic' but still leads to significant weakness and disability. There is evidence from work in a mouse model of collagen deficiency suggesting that apoptosis mediated by mitochondrial dysfunction may play a major role in the pathogenesis of the disease. This process appears to be mediated by a breakdown of the mitochondrial potential because of dysfunction of the mitochondrial permeability transition pore, triggering apoptosis. The transition permeability pore can be blocked by cyclosporine A and some of its derivates, thus providing the potential for treatment for this group of disorders.

CMD Type Ullrich

Clinically, there are two recognized disorders associated with mutations in collagen type VI – the more severe type Ullrich and the milder type Bethlem. In the Ullrich type of CMD (UCMD), there is hypotonia and weakness present at birth in conjunction with striking hyperlaxity of the distal joints. The hyperlaxity in particular is present in the vast majority of

affected infants, it is often associated with a characteristic prominent calcaneus. Typically, there are also contractures present that coexist with the distal laxity, either present at birth, including kyphoscoliosis or torticollis, or developing in early childhood, affecting more proximal joints and the spine. In severe cases, independent ambulation is not achieved or is lost after a variable and delayed period of ambulation. This deterioration is also caused by the progressive nature of the contractures. A prominent but treatable complication is respiratory insufficiency. There are also abnormalities of skin that include abnormal scar formation, peculiar softness of the skin in the hands and soles, and keratosis pilaris over the extensor surfaces of the arms and legs. In contrast to the CMD types associated with abnormalities of α-dystroglycan and laminin 2, there is no excessive elevation of CK, which is frequently normal or only mildly elevated. The immunohistochemical hallmark of this disorder is the absence of collagen VI from the muscle or just from the basement membrane.

Bethlem Myopathy

In the milder phenotype of Bethlem myopathy, there is also early evidence of hypotonia, although the weakness is much less pronounced and walking is achieved at a normal or slightly delayed age. Later contractures set in at the Achilles tendons, elbows, pectoralis, and the long finger flexors. However, the degree of contractures is variable and can be pronounced even with only mild weakness, or there can be minimal contractures in conjunction with much more pronounced weakness. Ambulation is usually preserved until adulthood, although approximately 50% of patients will require assistive devices with ambulation by age 60 years. Restrictive respiratory impairment can be a complication in Bethlem myopathy, as can abnormal scar formation and the formation of keloids.

Mutations causing UCMD occur in all three chains forming collagen VI and are of two types. Autosomal recessive mutations were found initially, often as null mutations, causing complete absence of collagen VI. *De novo* dominant negative mutations have been added as a mutational mechanism in approximately half of patients. Mutations in the latter mechanism are deletions or splice mutations causing in-frame skipping of exons located in the N-terminal part of the triple-helical domains of all three collagen VI chains, allowing for full assembly of the mutant chain into the collagen VI heterotrimer and subsequently into the secreted tetramer so that at the end of the assembly process only 1 of 16 tetrameres will be composed of wild-type chains only. In Bethlem myopathy, mutations have been dominant, causing less severe interference with collagen VI assembly compared to the UCMD mutations. It is becoming increasingly clear that there are phenotypes intermittent between Ullrich and Bethlem, suggesting that there may be a spectrum of severity from severe Ullrich to milder Bethlem disease.

Congenital Muscular Dystrophy with Spinal Rigidity

There are two forms of CMD caused by mutations in intracellular genes that are associated with prominent rigidity of the spine but which are also associated with other phenotypes.

Selenoprotein N-Related CMD

Mutations in selenoprotein N (SEPN1) are associated with CMD with spinal rigidity (RSMD1) and also with other morphological phenotypes, including multi-minicore disease, Mallory body myopathy, and congenital fiber type disproportion, whereas the clinical phenotype is very similar in all of these histologically different conditions. SEPN1 is localized to the endoplasmic reticulum, but its functions there are unknown. Selenoproteins in general incorporate a selenocysteine residue at the position of an in-frame UGA stop codon. For this to occur, the presence of a hairpin structured selenocysteine insertion sequence (SECIS) in the 3′ UTR of the mRNA as well as other protein factors are required. Some selenoproteins of known function are involved in redox systems and in thyroid hormone synthesis, such as in members of the glutathione peroxidase or iodothyronine deiodinase families. Severe nutritional selenium deficiency can cause a form of cardiomyopathy in children referred to as Keshan disease (endemic in certain regions of China where the selenium content in soil is extremely low).

Clinically, patients present with early onset of hypotonia but only mildly delayed motor milestones. There is atrophy of muscles, particularly affecting the inner thigh. Early spinal rigidity can be noted as early as 4 or 5 years of age and is clearly evident by 10 years of age. There may also be scoliosis. Of clinical importance is the early onset of nocturnal respiratory failure, which requires regular careful monitoring of oxygenation in sleep and the timely introduction of assisted ventilation at night. There is no known cardiac involvement.

Lamin A/C-Related CMD

Lamin A/C is an intermediate filament of the inner nuclear matrix with direct interactions with emerin, the protein mutated in X-linked Emery–Dreifuss

muscular dystrophy. Dominant mutations in the gene coding for lamin A/C (LMNA) more frequently cause autosomal dominant Emery–Dreifuss muscular dystrophy, but a number of other and disparate phenotypes are also caused by mutations in this gene, including LGMD1B, arrhythmogenic familial cardiomyopathy, lipodystrophy Dunnigan type, a form of CMT2B, mandibuloacral dysplasia, Hutchinson–Guilford progeria, and variants of Werner syndrome. It has become apparent that there is also an early onset presentation of the disease presenting with significant axial weakness including head drop because of weakness of the neck extensors, as well as early rigidity of the spine, thus making this an important differential diagnosis for patients with CMD and early rigidity of the spine.

Other CMD phenotypes for which genes have not yet been identified are included in Table 1.

Connectionist Models

T T Rogers, University of Wisconsin–Madison, Madison, WI, USA

© 2009 Elsevier Ltd. All rights reserved.

Connectionism is a theoretical framework for cognition whose principal tenets are (1) that all cognitive phenomena arise from the propagation of activation among simple neuronlike processing units and (2) that such propagation is mediated by weighted synapselike connections between units. Connectionist theories are typically instantiated as computer models, that is, computer programs that simulate how activation propagates through the system of interconnected units specified by the theory. Such models have profoundly influenced virtually every subdomain of cognitive science: perception and attention; word recognition, reading, derivational morphology, and other aspects of language; episodic, semantic, and short-term memory; action and other forms of sequential processing; executive function and cognitive control; many aspects of cognitive development; and even emotion. Many researchers, however, consider the connectionist framework to be incommensurable with the mainstream view that the human mind is a symbol-processing system and, for this reason, consider connectionist theories to be fundamentally flawed, or at least insufficient to serve as a general framework for cognition. This article considers the historical roots of connectionism, reviews key aspects of the approach, and addresses some of the criticisms it faces.

History

The roots of connectionism lie in the mid-1940s, when Warren McCullough and Walter Pitts showed how individual neurons could be viewed as simple computing devices, assuming that:

1. Neurons can assume two states (on or off, that is, 1 or 0).
2. Each neuron has a fixed threshold above which it assumes the on state.
3. A given neuron's activation state is influenced by the other neurons from which it receives connections.
4. The influence of a sending neuron on the receiving neuron depends on the value of the synapse or weight connecting them.

McCullough and Pitts demonstrated that individual neurons could compute the basic two-bit logic functions (AND and OR) and that networks of such neurons could compute more complex logic functions (e.g., exclusive-OR (XOR)).

At around the same time, Donald Hebb had become interested in the cellular basis of learning and memory, and he suggested a mechanism for changing the efficacy of a synapse to support a simple form of associative learning. Specifically, he suggested that, "When an axon of cell A is near enough to excite B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased" (Hebb, 1949). This insight – that correlated activity in a system of neurons can produce synaptic change – provided a basis for understanding the neural mechanisms that support learning and memory.

These contributions provided the foundations for the connectionist enterprise. Like other approaches, the connectionist framework assumes that cognitive systems are information processing systems that take in information via sensory organs, transform the information to form internal representations of the environment, and from these representations generate outputs in the form of overt behaviors. In contrast to some other approaches, the connectionist framework posits that the functional elements that support cognitive information processing are something like the abstract neurons described by McCullough and Pitts – units that take on activation states depending on their inputs and transmit these states to other units via weighted connections. It also posits that the principal mechanism for learning and memory is something like that proposed by Hebb – learning is effected through changes to the weights that connect processing units; such weight changes are partly (although not necessarily completely) driven by patterns of correlated activity across units in the system; and such correlated patterns in turn depend on experience.

These foundational ideas were developed in the 1950s and 1960s, largely through the work of Frank Rosenblatt, who introduced the perceptron, a form of neural network similar in some respects to those described by McCullough and Pitts. Rosenblatt derived a learning algorithm (a rule for changing the weights between units) that allowed the perceptron to solve a much wider range of learning problems than the Hebb learning rule. Rather than changing weights in proportion to the correlation between connected units, the perceptron learning rule minimizes the error generated by an input. That is, for each input, the algorithm compares what the network actually produced to the pattern it should have produced (the target pattern) and adjusts the values of each

weight so as to reduce the difference between these (the error, sometimes referred to as delta because it describes a difference between two terms). This delta-rule learning algorithm thus requires a teaching signal (the network must be told what pattern it is to generate in response to each input), but given this signal it can learn input–output mappings that are well beyond the Hebb rule.

Rosenblatt died tragically in a boating accident in 1969 at the age of 41. The same year, in a book called *Perceptrons*, Marvin Minsky and Seymour Papert published a forceful critique of perceptron-based theories of cognitive function. The book showed that networks of simple perceptrons were incapable of learning to compute nonlinearly separable mappings between input and output; for instance, they could not learn second-order logical functions such as XOR. Largely on this basis, the authors argued that perceptrons could not, in principle, provide a basis for understanding human cognition. This book, coupled with the intensive lobbying (by Minsky) of various funding agencies and other scientists, seriously dampened general interest in and funding for neural network modeling for the next 10 years, although important advances were made during this period by a number of scientists working independently.

The Modern Period

The 1980s witnessed a renaissance of interest in connectionism, for three principal reasons. The first was the publication of some landmark papers that set aside the difficult questions about learning raised by Minsky and Papert but that used connectionist principles and implemented computer models to understand a range of cognitive phenomena. Perhaps most influential was the interactive activation and competition model of word recognition, which accounted for a very wide range of behavioral phenomena in the domain and resolved several important puzzles pertaining to lexical processing (see Figure 1). Among other things, this model introduced the notions that the component processes involved in word recognition proceed in parallel and not in serial; that processing is cascaded, so that a later process can begin to operate on the outputs of earlier processes before the earlier processes have themselves completed; and that bottom-up and top-down processes continually interact throughout processing. These notions were antithetical to the then-dominant view that cognitive processes were carried out by informationally encapsulated modules whose operation proceeded largely in serial.

The second major development was the discovery of a solution to the perceptron-learning problems raised by Minsky and Papert. The discovery was made independently by various investigators, but its importance to cognitive science was made clear in an influential article by Rumelhart, Hinton, and Williams. The key insight concerned the nature of the transfer function that governed how a single unit sets its activation state in response to inputs. Previous investigators had, for simplicity's sake, assumed either a linear transfer function or a step function; and the limited the scope of the perceptron-learning rule was a direct consequence of these choices. Rumelhart and colleagues investigated a logistic transfer function which (1) is nonlinear like a step function but (2) varies smoothly with net input so that it is differentiable (and, in fact, has a comparatively simple derivative; see Figure 2(b)). Because the transfer function is nonlinear, groups of units arranged in series are capable of computing the nonlinearly separable mappings that cannot be learned in a multilayered perceptron with linear units. Because

Figure 1 The interactive activation model of word recognition. The model consists of feature detectors organized hierarchically so that those toward the bottom represent simple visual features, those in the middle represent individual letters, and those at the top represent individual words. The visual appearance of an individual word activates basic features at the bottom, which pass their activation up through the hierarchy via weighted connections. Features excite the letters with which they are compatible and inhibit the letters with which they are incompatible. Individual letters inhibit one another, excite word units with which they are compatible, and inhibit word units with which they are incompatible. The activation of word-level units can feed back down to influence letter-level units, inhibiting incompatible letters and further exciting compatible units. Processing of a given input thus depends on the interactive activation of representations at all levels of the hierarchy. From McClelland JL and Rumelhart DE (1981) An interactive activation model of context effects in letter perception, Part 1: An account of basic findings. *Psychological Review* 88: 375–407.

Figure 2 Exclusive- or (XOR) mapping: (a) architecture of a six-unit network for computing the exclusive- or (XOR) mapping; (b) logistic transfer function indicating how a unit's activation state changes with its net input; (c) a model environment containing patterns for the XOR learning problem; (d) one-weight matrix learned by the backpropagation learning rule. In (a), each oval indicates a neuronlike processing unit, and each arrow indicates a synapselike connection between units. In (b), a given receiving unit computes its net input by taking the dot product of the activations of sending units from which it receive projections times the values of the interconnecting weights. The dotted line indicates the derivative of the activation function, which can be used by the backpropagation learning rule to adjust the magnitudes of weights in the network so as to reduce error at the output layer. In (c), to process each pattern, the input units in (a) are set to the values indicated in the table (1 or 0), and this activation spreads forward in the network as determined by the values of the interconnecting weights and the transfer function. The activations of the two output units are then compared to the desired outputs shown in the table; the difference is converted to a measure of error, and the derivative of this error with respect to each weight is computed in a backward pass from outputs toward inputs. Each weight is adjusted by a small amount so as to reduce error at the output. In (d), the gray cells indicate logically possible connections between neurons that are not present in the network architecture, so their values are fixed to zero. The line labeled bias indicates each unit's intrinsic bias, which is a constant added to the unit's net input. When each of the input patterns in (c) is presented to a network with these weight values, outputs closely approximate the desired outputs also listed in (c).

the function is differentiable, it is possible to compute how each weight in such a network should be adjusted to improve performance. It is therefore possible to train a network of such units by (1) presenting an input and computing the forward propagation of activation from inputs toward outputs; (2) computing a measure of error, that is, a measure of the discrepancy between the observed and desired (target) output; and then (3) computing the derivative of the error with respect to each weight in the network in a backward pass from outputs toward inputs, and using these to adjust each weight in the network so as to reduce the error at the output. Networks trained with this backpropagation learning rule can, in principle, learn any input-output mapping, so long as there is an intervening layer of at least two units between inputs and outputs.

The third watershed event was the publication in 1986 of *Parallel Distributed Processing*, a two-volume work that laid out a comprehensive rationale for basing cognitive theories on principles derived from neural computation, reviewed the methodological state of the art, reported models of cognitive function across a remarkably broad variety of cognitive domains, and linked these models to core principles derived from theories of neural information processing. The two volumes highlighted some of the key differences between the then-dominant mind-as-computer approach to cognition and a neurally inspired approach. For instance, whereas computers

employ blindingly fast serial processors to achieve their computational power, individual neurons operate on an orders-of-magnitude slower time scale but are massively parallel. Despite the relatively slow computations achieved by a single neuron, neural systems achieve remarkably rapid and accurate performance in tasks that seriously challenge even the fastest serial computers (e.g., speech recognition). This suggests some fundamental difference in the way that parallel and serial systems process information; and if the mind is a product of a massively parallel processing system, it follows that the endeavor to understand cognition as the product of a serial symbol-processing system may not be optimal.

Basic Properties of Connectionist Networks

Connectionist models have seven general properties: (1) a set of units, (2) an activation state, (3) a weight matrix, (4) an input function, (5) a transfer function, (6) a learning rule, and (7) a model environment.

A Set of Units

Units are abstract neurons, simple processors that set their activation level by combining incoming signals and then transmit their activation state to other units through weighted connections. Some models construe individual units as representing particular theoretical constructs – for instance, explicit stimulus properties (such as colors, shapes, individual letters, or phonemes) or even individual words, objects, or concepts. Other models suggest that such theoretical constructs are best represented as patterns of activity across collections of units, so the activation of any individual unit has no directly interpretable significance. Figure 2 (a) shows the architecture of a feed-forward model for computing the XOR function.

An Activation State

At any given point in time, every unit in a network has a certain activation state. The state of the entire network, then, may be conceived as a one-dimensional vector, with each element corresponding to a single unit and containing that unit's current activation. When processing any given input pattern, the state of the XOR network is represented with a vector of six elements.

A Weight Matrix

Units can influence one another's activation via synapselike connections, or weights. Weights have direction; they project from a sending unit i to a receiving unit j. The weights in a network with n units can thus be conceived as an $n \times n$ matrix, with each element indicating the value of the weight projecting from one neuron to another, elements below the diagonal coding weights projecting in one direction (i.e., from i to j) and elements above the diagonal coding weights projecting in the reverse direction (i.e., from j to i). Most networks also include a vector of bias weights, that is, a vector then includes one constant for each unit in the network that reflects that unit's base activation in the absence of input. The architecture of the network (the arrangement of units into groups or layers) constrains which units project to which other units; where no connection exists between two units, the value in the weight matrix is fixed to zero. Figure 2(d) shows the matrix for a configuration of weights that solve the XOR mapping; gray cells in the matrix indicate values fixed to 0 because no connection exists between the corresponding units (A in Figure 1).

An Input Function

At any given time, a receiving unit j receives input from some set of sending units via the intermediating weight. The input function associated with a network determines how these inputs are combined to provide a net input to the receiving unit. The most frequent input function is simply the dot product of the vector of sending activations and the weight vector; that is, for each sending unit, one computes the product of the unit's activation and the value of the weight projecting to the receiving unit. These products are then summed across all sending units, and the result is the receiving unit's net input.

A Transfer Function

The transfer function determines how a unit's current net input influences its activation state. As previously mentioned, the logistic transfer function (a sigmoid bounded at 0 and 1) is very commonly used due to its desirable computational properties; but linear functions, step functions, radial basis functions, and other choices all appear in the literature. Models can also vary in how the transfer function integrates time. In many models, units update their activation instantaneously, but it is possible to gradually update the unit's state so as to simulate temporally extended network behaviors. Figure 2(b) shows the logistic transfer function and its derivative.

A Learning Rule

Although the weights in a connectionist model can sometimes be set by hand (i.e., specified by the

modeler), a key aspect of their appeal is their ability to discover useful weights as the consequence of applying some learning rule, that is, some rule for determining how weights should change as the consequence of processing an input pattern. There now exist a variety of learning rules, including many variants of the Hebb rule, in which weights are adjusted on the basis of correlated activity between pairs of units; various forms of error-correcting learning, such as the delta rule and backpropagation; and unsupervised learning rules that come to categorize, or cluster, their inputs without any explicit indication of what the desired output should be. There remains considerable controversy regarding the significance or utility of particular learning rules, the principal issue being an apparent trade-off between computational power and biological plausibility. Specifically, backpropagation remains the most powerful learning rule yet discovered, but it makes use of error signals that, at least at first blush, appear to have no analog in real brains. In contrast, variants of the Hebb rule closely reflect changes to synaptic potentiation in real brains; consequently, such rules are sometimes viewed as more biologically plausible, but they are also known to be fairly limited in the kinds of computations they can learn to perform.

A Model Environment

Because, in the connectionist view, all information processing involves the propagation of activation among units, it follows that, in any given task, both the stimulus and the behavior must be represented as patterns of activation across subsets of input and output units. The theorist must explicitly specify how such inputs and outputs are coded; in models of reading, for instance, the modeler must specify how the visual appearance of a word form and the motor act of articulating a word are to be coded as patterns of activity across units. The model environment consists of a collection of input–output pairs that constitute the mappings to be learned. Because a model's behavior is strongly influenced by the structure of its inputs and outputs, decisions about how these are best represented are often key to the theory that a given model is intended to exemplify. The training environment for the XOR problem is shown in Figure 2(c).

Appeal of Connectionist Models

Models with the seven properties just described provide an appealing basis for understanding aspects of cognition that seem especially challenging from traditional mind-as-computer approaches to cognition. For instance, such models exhibit:

1. Content-addressable memory. Connectionist models are good at pattern completion. Given some partial information about a previously learned pattern, the propagation of activation through a connectionist net can reinstantiate the full pattern; and moreover, any part of the full pattern can later be used as the cue for retrieval. This is also clearly true of human memory, but it is not naturally achieved in computer systems, in which a given data record can be retrieved only if one knows the correct address (i.e., the physical location on the storage medium where the record begins).
2. Generalization. In most connectionist networks, all patterns are processed through the same network of units and weights. Consequently, new inputs that share structure with previously learned items tend to generate similar outputs to the previously learned items. This ability to generalize past learning to new situations is critical to connectionist accounts of memory and language.
3. Graceful degradation. As any software engineer knows, computer programs are extremely brittle – tiny flaws in a program can completely destroy its ability to function. In contrast, connectionist networks exhibit graceful degradation. When weights or units are removed from the system, such networks can often generate outputs that are completely or at least partially correct. The human cognitive system also appears to exhibit graceful degradation, in that brain damage rarely if ever produces an all-or-nothing pattern of cognitive impairment. Furthermore, because the elements of a connectionist model can correspond, at least in principle, to particular brain regions, it is possible to investigate how brain damage in a particular locus should influence behavior under a given theory. Thus, connectionist models offer a valuable tool for the development of neuropsychological theories.
4. A mechanism for cognitive change. More traditional information-processing approaches are often used to characterize a child's mental processes at different stages of development, but under such approaches it is often unclear what mechanism subserves the transition from one stage to another. Connectionist models provide explicit hypotheses about mechanisms of change, in the form of the learning rule used to train the model, explicit assumptions about the nature of the developing child's experience, and explicit assumptions about how maturational change affects the architecture of the neural network

supporting the behavior. So, such models also offer a means of generating explicit hypotheses about mechanisms underlying cognitive development.

Symbolic versus Connectionist Approaches

Connectionist theories are sometimes viewed as providing a fundamentally different approach to cognition than the more traditional symbol-processing approach. Symbol-processing theories assume that the mind is a computational system consisting of two basic elements: (1) symbols, that is, structured representations that stand for things in the world, and (2) rules or operations, that is, algorithms for manipulating, combining, and responding to symbols. For instance, to generate the past-tense form of a verb such as 'look' might require, under a symbol-processing view, two symbols – one standing for the word 'look' and one standing for the English past-tense suffix '-ed' – and a rule that says, "'IF the goal is to generate the past tense from the present tense, THEN attach the past-tense suffix to the present-tense form." Applying the rule to the symbols then generates the correct past-tense form, 'looked.' Moreover, such a symbolic approach has a certain generative power; after learning a new present-tense verb (e.g., 'mave'), it is possible to infer the past-tense form ('maved') simply by applying the past-tense rule to the newly learned symbol.

Because symbol-processing systems are generative (i.e., they can produce an infinite variety of new representations and behaviors from a finite set of starting elements), many scientists believe that they must underlie much of human cognition, which is also generative. Connectionist models, in contrast, are thought by some to be capable of showing, at best, only a limited range of generativity. The current debate concerning the merits of connectionist approaches often hinge on these issues, which are best illustrated by an example.

Consider that in English, approximately 80% of verbs have a past tense formed by simply adding '-ed' to the present-tense form. The remaining 20% have past-tense forms that may be somewhat related to the present-tense form (e.g., 'give' → 'gave') or may even be completely unrelated to it (e.g., 'go' → 'went'). How do people come to learn which past-tense forms to produce from a given present-tense verb?

One commonsense hypothesis is that the present- and past-tense forms of familiar verbs are linked together in memory, by virtue of prior learning. Several empirical facts about language appear, however, to challenge this view. For instance, (1) people can reliably generate past-tense forms for novel verbs, and because these have never before been encountered, the behavior cannot depend on simply remembering the correct form; (2) children often generate incorrect forms that they are unlikely ever to have heard (e.g., producing 'goed' as the past tense of 'go'); and (3) a similar kind of behavior is observed following some kinds of brain damage, and it is absurd to imagine that brain damage causes someone to suddenly remember some past-tense form they have never before experienced or produced.

Such phenomena suggest that past-tense formation is subserved by something other than an association in memory between present- and past-tense forms. Symbol-processing theories propose that this something other is a rule like the one articulated earlier. In this view, the rule is used to generate past-tense forms for the majority of verbs, including novel verbs. Exceptions to the rule are stored in a separate lookup system or lexicon; and there may be additional rules for handling such exceptions (e.g., IF the present tense is listed in the lexicon, THEN look up the past-tense form in the lexicon; OTHERWISE use the rule to generate the past-tense form). Such a proposal nicely explains the empirical facts: because novel verbs such as 'mave' are not stored in the lexicon, the rule is used to generate a lawful past-tense form; children, on initially acquiring the rule, may mistakenly overapply it to exception words such as 'go' (thus accounting for their production of forms such as 'goed' that they have never encountered); patients who, after brain damage, generate forms such as 'goed' or 'drived' may have an intact rule system but a degraded exception system and so apply the rule to previously known exceptional forms.

It turns out, however, that the associative-learning account is not as limited, nor is the symbolic approach as powerful, as we might initially suspect. Connectionist networks trained to generate past-tense from present-tense forms (with real English words) actually exhibit all of the behaviors listed. The reason has to do with the remarkable ability of such models to generalize from previous experience. For instance, although such a network is never trained with a nonword such as 'mave', it does, during training, encounter real verbs with a similar structure: 'save', 'pave', 'rave', and so on. Most of these words form their past tense by adding '-ed' to their present-tense forms; and because this is so, new items such as 'mave' tend to produce a similar output. Such systematic tendencies in the language can also produce patterns of overregularization early in network training, as when children produce 'goed' instead of 'went', or when the knowledge in the network is perturbed by removing connection weights or units (as a model analog of brain damage).

Moreover, connectionist models so trained explain other observations that challenge the symbolic approach. For example, although exception words do not, like most verbs, simply take -'ed' in their past-tense form, there are some very systematic tendencies among the exceptions – consider 'weep' → 'wept', 'keep' → 'kept', 'sleep' → 'slept', and so on. These formations are not just consistent with one another; they are also quite similar to the past-tense form that would be generated if the rule were applied – the only difference is that, for these words, the long vowel is shortened in the past tense. Such observations are difficult to explain under the rules-and-symbols view. If exceptions are generated by a lookup table, why are past-tense forms so systematic across different subgroups of exceptions? And, if the rule and exception systems are functionally independent of one another, why are so many exceptional forms so similar – often differing in just one or two phonemes – to the regular forms that would be generated under the rule system?

Connectionist theories of past-tense formation explain such observations by suggesting that past-tense forms for both regular and exception words are generated through the same set of units and weights. The weights are shaped by systematic structure in the language, via the operation of a simple learning rule such as backpropagation. Such learning mechanisms excel at discovering weights that simultaneously capitalize on systematic input–output relationships, where they exist, and tolerate mild or even strong deviations from such regularities where necessary. Thus, although mappings such as 'keep' → 'kept' are in some sense exceptions, they still share considerable structure with the regular verbs and with one another; so these exceptional forms actually benefit substantially by being processed through the same system that handles the regular verbs. And, the connectionist account predicts empirical findings that are difficult to reconcile with the rules-and-symbols view. For example, when presented with a new nonsense verb such as 'neep', people are actually more likely to generate an irregular past-tense form (e.g., 'nept') than the regular form (i.e., 'neeped'), even though, according to the rule-based view, they should always apply the past-tense rule to all novel forms.

Past-tense formation thus exemplifies a domain in which (1) there exist very intuitive and empirically fleshed-out reasons for believing that behavior must be supported by rules and symbols but for which (2) simulations with connectionist models demonstrate that there exist alternative explanations for the same behaviors, within which there are no analogs to rules and symbols. Similar issues and controversies arise in the study of reading, language comprehension, word and object recognition, and categorization and semantics. In all these domains, connectionist theories usually explain behavior without reference to rules and symbols, and consequently such theories are sometimes viewed as challenging the view that human minds are symbol-processing systems. Other domains of human behavior – including, arguably, language production, reasoning, problem solving, and mathematics – seem to many to require a symbolic approach; consequently, challenges to symbolic explanations of even relatively simple phenomena (such as past-tense formation or single-word reading) may be viewed either as flawed in principle (because it is difficult to see how such accounts can be extended to higher-level cognition) or as undermining the foundational assumptions of cognitive science.

There are, however, other less dialectical ways of conceiving the relationship between symbolic and connectionist approaches. One view is that human cognition is subserved by some hybrid of connectionist and symbol-processing systems. For instance, recent symbolic accounts of past-tense formation suggest that the exception system is supported by a connectionist-like associative memory (thus explaining the systematicity among exceptions) but that there also exists a separate and independent rule system for handling regular items that bear little resemblance to previously learned forms.

Another view is that symbolic and connectionist approaches account for human behavior at different levels of description. Symbolic approaches may, for instance, provide valid descriptions of human behavior much as a flowchart captures the operation of a computer program. The flowchart is a useful description of the program, even though it yields no insight into the causal mechanisms by which the underlying hardware carries out the resulting computations. Connectionist theories, in contrast, may capture a level of description that explains how cognitive behaviors that, roughly speaking, look symbolic, can arise from mechanisms similar to those that govern neural information processing.

Biological Plausibility

Connectionist models are sometimes criticized for making implausible claims to biological faithfulness. For instance, it is not clear to what the units in many connectionist models are intended to correspond: single neurons, cortical columns, or whole populations of neurons. Similarly, single units can be used to represent whole words, objects, or other entities that, in the brain, are probably represented by widely distributed patterns of activity across thousands of neurons; unit activations are represented with single

real-valued numbers, whereas actual neurons transmit information via discrete all-or-nothing action potentials; weights in connectionist networks often can take any real positive or negative value, whereas in the brain, some synapses are exclusively inhibitory and others are exclusively excitatory; in connectionist models, different units are often treated as functionally and structurally equivalent to one another, whereas in the brain there exist many different kinds of neurons, which may in turn participate in various different cytoarchitectonic structures; and so on. For such critics, claims that connectionist models capture important aspects of neural information processing may seem far-fetched.

One response to this criticism is to point out that the utility of any model system lies in abstracting away from the many complex details of the natural system, so as to investigate those factors that, under a given theory, are necessary to explain the relevant phenomena. Thus, it is certainly possible to construct neurally faithful computer simulations in which there exist multiple different kinds of neurons, connected via different kinds of synapses, organized into cortical columns, and projecting to one another via neuroanatomically faithful tracts. Should the theorist demonstrate that such a simulation replicates the behavior of interest, however, it would be comparatively difficult to understand why this should be so because the model is nearly as complex as the system itself. Connectionist models may be viewed as making simplifying assumptions about the details of the underlying neural systems so as to allow the theorist to focus on a relatively circumscribed set of factors of explicit theoretical interest.

It is also worth noting that the investigation of the properties of abstract computational systems can lead to important neuroscientific discoveries, even when the computational systems are not intended as faithful models of neural systems. For instance, in 1988 Sutton described an algorithm for reward-based learning of sequential structure (temporal-difference learning) in work that was purely computational (i.e., not guided by neuroscience). Nevertheless, it was subsequently discovered that dopamine signals in cortex, striatum, and midbrain closely track the reward signal generated by the algorithm, and it now appears as though some forms of learning may be supported by neural mechanisms that effectively implement temporal-difference learning. So, insights gained through computer simulations, even when they may seem divorced from what we currently know about neural processing mechanisms, can promote new insights into how neural systems function.

Introduction

Connectionist psycholinguistics is an emerging approach to modeling empirical data on human language processing using connectionist computational architectures. Over the last 20 years, a wide range of psycholinguistic phenomena have been modeled, such as speech processing, impaired and normal reading, aphasic word production, and structural priming in sentence production. This article focuses on syntax, and especially on the theoretical relationship between traditional notions in syntax (constituency, structure dependency, and recursion) and connectionist networks, which do not appear to make reference to these notions intrinsically.

Connectionist models, or neural networks, are neurally inspired devices based on numerical computation rather than symbolic manipulation. They are formed by several simple processing units, called nodes, which mimic the activity of single neurons. Each node is excited or inhibited by information coming from other units to which it is connected. A set of homogeneous nodes that collectively represents some information is often called a layer. For instance, there could be a phoneme layer, a word layer, and so on. A popular architecture in connectionist psycholinguistics is the feed-forward network (Figure 1), in which an input layer receives signals (e.g., raw words) from outside the network, an output layer sends signals to outside the network, and an intermediate layer of so-called hidden units does not directly connect outside of the network. Hidden unit layers are often considered the internal states that represent the knowledge acquired by the network at the end of training. Information flows from input to output, and training proceeds by adjusting the weights between single units until the network produces a desired output (for instance, the production of the correct word syntactic category in a given context).

Two aspects of neural networks are particularly interesting for syntactic processing. First, networks learn to perform some specific task, such as process an English sentence, from being exposed to relatively unanalyzed raw input, such as a sequence of words. This feature makes them suitable for explaining a great deal of language learning and language processing in a psychologically plausible manner. Second, the knowledge of the networks is not represented in any explicit way but rather emerges as a pattern of neuronal activity between the interconnected nodes in a parallel distributed processing fashion. This is particularly interesting because it contrasts with more-traditional symbolic views in cognitive science in suggesting that humans process sentences by transforming representations according to sets of rules. For instance, a representation of the sentence *the girl liked a boy* requires the constituents *the*, *a*, *girl*, *boy*, *liked*, and an explicit representation of the syntactic relationships between these constituents. The rules of syntax govern how constituents can be combined together, allowing, for instance, *the boy liked a girl* as a legal sentence but not *boy girl a liked the*. The following phrase structure rules describe the relationship between constituents in the above sentence (S stands for sentence; NP, noun phrase; VP, verb phrase; det, determiner; N, noun; and V, verb):

S → NP VP
NP → (det) N
VP → V (NP)

Besides such constituent structure, to capture the full generativity of human language, recursion needs to be introduced, for instance by adding a new rule that adds a potential prepositional phrase (PP) to the NP (prep stands for preposition):

NP → (det) N (PP)
PP → prep NP

These rules are recursive because the expansion of the right-hand sides of each can call the other. For example, the complex NP *the flowers in the vase* has the simple NP *the vase* recursively embedded within it. Because this process can be applied arbitrarily often, constructions of arbitrary complexity can in principle be generated. Constituency and recursion are some of the most fundamental concepts in linguistics. Because both are defined in terms of relations between symbols, symbolic models of language processing therefore incorporate these properties by fiat. This article discusses how constituency, structure dependency, and recursion may fit into a connectionist framework and the possible implications this work may have for linguistics and psycholinguistics.

Constituency

Connectionist models can address constituency in three increasingly radical ways. First, some models – especially early ones – are implementations of

Figure 1 A standard feed-forward network containing three layers of units. Information flows bottom up from input to output units. These types of networks are normally trained using the back-propagation algorithm, which minimizes the discrepancy between the network's actual and desired output. Redrawn from Onnis L, Christiansen H, and Chater N (2006) Human language processing: Connectionist models. In: Brown K (ed.) *Encyclopedia of Language and Linguistics,* pp. 401–409. Oxford: Elsevier, with permission from Elsevier.

symbolic language-processing models in neural hardware. For example, some models have implemented context-free grammars containing explicit representations of the constituent structure of a sentence in just the same way as a nonconnectionist implementation of the same model would have. Connectionist implementations of this kind provide feasibility proofs that traditional symbolic models of language processing are compatible with a brain style computational architecture, although they add little new to the treatment of constituency. The remaining two classes of connectionist models actually learn to process constituent structure rather than having this ability hardwired. One approach is to have a network learn from input tagged with information about constituent structure. One study trained a network to map a combination of orthographic and co-occurrence-based semantic information about a word onto a structured representation encoding the minimal syntactic environment for that word. With an input vocabulary consisting of 20 000 words, this model has an impressive coverage and can account for certain results from the psycholinguistic literature concerning ambiguity resolution in sentence processing. Another model, known as a simple synchrony network, was trained to parse sentences pre-encoded as parts of speech. The network takes the part of speech tags for the sentence constituents as input and is trained to output the parse tree fragment of a given constituent when that constituent is queried. The network learns to parse a corpus of written English reasonably well. However, because in these models constituent structure is compiled either into the input or the output representations, this style of model does not offer any fresh insight into how linguistic constituency might operate based on connectionist principles.

The third class of connectionist models addresses the more ambitious problem of learning the constituent structure of a language from untagged linguistic input. Such models have the potential to develop a new or unexpected notion of constituency and hence may have substantial implications for theories of constituency in linguistics and psycholinguistics.

To understand how the more radical connectionist models address constituency, one can divide the problem of finding constituent structure into two interrelated parts: segmenting the sentence into chunks which correspond, to some extent, to linguistic constituents and categorizing these units appropriately. The first problem is an aspect of the general problem of segmenting speech into appropriate units (phonemes, words, etc.) and more generally is an aspect of perceptual grouping. The second problem regards the general problem of classifying linguistic units – for instance, recognizing different classes of phonemes or establishing the parts of speech of individual lexical items. The segmentation and classification problems need not be solved sequentially. Indeed, there may be mutual influence between the decision to segment a particular chunk of language and the decision that it can be classified in a particular way. Nonetheless, it is useful to keep the two aspects of the analysis of constituency conceptually separate.

It is also important to stress the difference between the problem of assigning constituent structure to novel sentences when the language is known and the problem of acquiring the constituent structure of an unknown language. Statistical symbolic parsers are able to make some inroads into the first problem. For highly stylized language input, and given a prestored grammar, they can apply grammatical knowledge to establish one or more possible constituent structures for novel sentences. But symbolic methods are much less advanced in acquiring the constituent structure of language because this requires solving the hard problem of learning a grammar from a set of sentences generated by that grammar. It is therefore in relation to the acquisition of constituency that connectionist methods, with their well-developed learning methods, have attracted the most interest.

One may begin by focusing on the problem of classifying, rather than segmenting, the linguistic input. One connectionist model learns parts of speech

of individual words by clustering words together on the basis of the immediate linguistic contexts in which they occur. The rationale is based on the replacement test: if two words are observed to occur in highly similar immediate contexts in a corpus, they probably belong to the same syntactic category. Using a single layer network with Hebbian learning to store co-occurrences between target words and their immediate neighbors, each target word was associated with a vector representing the contexts in which it typically occurs. A competitive learning network classified these vectors grouping together words with similar syntactic categories. This method is able to operate over unrestricted natural language, in contrast to most symbolic and connectionist models. From a linguistic perspective, the model slices lexical categories too finely, producing, for example, many word classes that correspond to nouns or verbs. On the other hand, the words within a class tend to be semantically related, which is useful from a cognitive perspective. The same method can be extended to classify sequences of words as NPs, VPs, and so forth. An initial classification of words is used to recode the input as a sequence of lexical constituents. Then short sequences of lexical constituents are classified by their context, as before. The resulting groups of phrase (e.g., determiner–adjective–noun) are readily interpretable as NPs, VPs, PPs, and so on, but again, these groupings are too linguistically restrictive (i.e., only a small number of NPs are included in any particular cluster). Moreover, this phrasal-level classification has not yet been implemented in a connectionist network.

A different attack on the problem of constituency involves training simple recurrent networks (SRNs) on linguistic input. An SRN involves a crucial modification to a feed-forward network: the current set of hidden unit values is copied back to a set of additional input units and paired with the next input to the network (Figure 2). The current hidden unit values can thus directly affect the next hidden unit values, providing the network with a memory for past inputs. This enables it to tackle online sentence processing, in which the input is revealed sequentially over time.

Segmentation into constituents can be achieved in two ways by an SRN trained to predict the next input. One is based on the assumption that predictability is higher within constituents than across constituent boundaries, and hence that high prediction error indicates a boundary. This method has been advocated as potentially applicable at a range of linguistic levels, but in practice it has been successfully applied only on corpora of unrestricted natural language input in finding word boundaries. Even here, the prediction strategy is a very partial cue to segmentation. If the network is provided with information about

Figure 2 A simple recurrent network (SRN). An SRN is essentially a standard feed-forward network equipped with an extra layer of so-called context units. At each time step, an input propagates through the hidden units to the outputs (solid arrows). The hidden unit activation at the previous time step is copied back to the context layer (dashed arrows) and paired with the current input (solid arrows). Thus the hidden units influence the processing of subsequent inputs, providing a limited ability to deal with sequential inputs. Redrawn from Onnis L, Christiansen H, and Chater N (2006) Human language processing: Connectionist models. In: Brown K (ed.) *Encyclopedia of Language and Linguistics,* pp. 401–409. Oxford: Elsevier, with permission from Elsevier.

naturally occurring pauses between utterances (or parts of utterances), an alternative method is to assume that constituent boundaries occur where the network has an unusually high expectation of an utterance boundary. The rationale is that pauses tend to occur at constituent boundaries and hence the prediction of a possible utterance boundary suggests a constituent boundary may have occurred. This approach seems highly applicable to segmenting sentences into phrases but has also primarily been used for finding word boundaries in real corpora of language, when combined with other cues.

So far, this article has considered how SRNs might find constituents. But how well do they classify constituents? At the word level, cluster analysis of hidden unit activations shows that, to some extent, the hidden unit patterns associated with different word classes group naturally into syntactic categories, for SRNs trained on simple artificial grammars. These results are important because they show that even though the SRN may not learn to classify constituents explicitly, it is nevertheless able to use this information to process constituents appropriately. Another way of assessing constituency learning is to see whether networks generalize to predict novel sentences of a language. The logic is that to predict successfully, the SRN must exploit linguistic regularities which are defined across constituents and hence develop a notion of constituency to do so. However,

it has been pointed out that this type of evidence is not compelling if the novel sentences are extremely similar to the network's training sentences. That is, to show substantial evidence for generalization across constituents, the network should be able to handle novel sentences in which words appear in sentence locations where they have not previously occurred. For example, a novel sentence might involve a particular noun in object position that has previously occurred only in subject position. This property of the human brain, called systematicity, captures the idea that if one can understand the sentence *Bob loves Mary*, one can also understand *Mary loves Bob*; the underlying knowledge that supports understanding of the first sentence enables understanding the second. Hence, to generalize effectively, the network must presumably develop some abstract category of nouns.

The challenge of systematicity can be addressed by presenting evidence that connectionist models are in fact able to attain strong generalization. In the training corpus of one study, the noun *boy* was prevented from ever occurring in a noun phrase conjunction (i.e., noun phrases such as *John and boy* and *boy and John* did not occur). During training, the SRN had therefore been presented only with singular verbs following *boy*. Nonetheless, the network was able to correctly predict that a plural verb must follow *John and boy* as prescribed by the grammar. In addition, the network was still able to correctly predict a plural verb when a prepositional phrase was attached to *boy* as in *John and boy from town*, providing even stronger evidence for strong generalization. In contrast, when the SRN was presented with ungrammatical lexical items in the second noun position, as in *John and near*, it did not activate the plural nouns. Instead, it activated lexical items that were not grammatical given the previous context. This suggests that the SRN is able to make nonlocal generalizations based on the structural regularities in the training corpus. If the SRN relied solely on local information, it would not have been able to make correct predictions in either case. Thus, the network demonstrated sophisticated generalization abilities, ignoring local word co-occurrence constraints while appearing to comply with structural information at the constituent level.

Another strong test of generalizations that connectionist models seem to fail concerns equivalence relations: one SRN was trained on sentences like *A rose is a rose* or *A tulip is a tulip*, but when given a novel sentence fragment like *A blicket is a*..., the SRN could not predict that *blicket* was going to be the next word because it activated all the words that it had seen in this sentence position (e.g., *rose*, *tulip*, etc.). This suggests that it did not develop abstract variable-based frames like *a X is a X*, where *X* is a variable that can be bound to any word. In reply to this negative evidence, another study presented a model of sentence production that could generalize well if the input message was encoded in several separate representations that were linked together. The model had a dual-pathway architecture, with one pathway representing the mapping of object semantics to word forms and another representing and mapping objects (and the words that describe them) into appropriate sentence positions. The model contained a bank of units representing event roles (agent, patient, etc.) that fed onto a layer of lexical units (e.g., DOG, CAT, etc.). This way the model could represent the different roles of a word, say *dog*, in various events while activating a common semantics that all dogs have. Semantic units connected to word label units that represented the phonetics of each word, allowing the learning of a word label for each meaning. Because there was only one set of semantic units for different event role units, learning the mapping of the semantic feature DOG to the word label *dog* allowed the model to generalize this word to other event roles. Hence, even if the model had experienced only the sentence *the dog chases the cat*, it was able to generalize and produce a novel sentence *the cat chases the dog*. A variation of this model was further able to capture an important psycholinguistic phenomenon called structural priming, namely, a tendency for speakers to reuse previously experienced sentence structures. Because structural priming occurs in the absence of lexical and conceptual repetition and in the face of thematic role differences, it has been taken as convincing evidence that people make use of abstract syntactic representations and constructions, such as a the double-object dative construction (e.g., *John gave Mary a book*). The connectionist model could reproduce structural priming without having inbuilt syntactic constructions.

Another model, called CSCP, was developed to perform both comprehension and production of complex, multiclausal sentences using a larger corpus than previous models had. In this respect, neural networks promise to scale up to real samples of natural language. The model deals with several sentence comprehension and production phenomena that involve discovery of constituent structures such as multiple verb tenses and voices, adverbs and adjectives, prepositional phrases, relative and subordinate clauses, and sentential complements. The CSCP network has a semantics component, which is used to help the net predict the next word. The semantic component is also used to produce a word. When a word is selected for production, it is fed back into the comprehension input, and the model proceeds to produce the next word, and so on. Therefore, the model also claims that language production is learned primarily by

formulating implicit predictions while attempting to comprehend one's language.

This discussion must note that connectionist models do not mirror classical constituency precisely. That is, they do not derive rigid classes of words and phrases that are interchangeable across contexts. Rather, they divide words and phrases into clusters without precisely defined boundaries and treat them differently depending on the linguistic contexts in which they occur. This context-sensitive constituency can be viewed as either the undoing of connectionist approaches to language or their radical contribution. The potential problem with context-sensitive constituency is the productivity of language: to take Noam Chomsky's famous example, how do we know that the sentence *colorless green ideas sleep furiously* is syntactically correct, except by reference to a context-insensitive representation of the relevant word classes? This seems necessary because each word occurs in a context where it has rarely been encountered before. But this problem may not be fatal for context-sensitive notions of constituency. A neural network was trained to mutually associate two input sequences – a sequence of word forms and a corresponding sequence of word meanings. The network was able to learn a small artificial language successfully; it was able to regenerate the word forms from the meanings and vice versa. The network was tested to see whether, by passing information from form to meaning and back, it could recreate a sequence of word forms presented to it. Ungrammatical sentences were recreated much less accurately than grammatical sentences, and the network was thus able to distinguish grammatical from ungrammatical sentences. It is important to note that this was true for sentences in which words appeared in novel grammatical combinations, as specified by the systematicity criterion and as exampled in Chomsky's famous sentence. Thus, the context sensitivity of connectionist constituency may not rule out the possibility of highly creative and novel use of language, because abstract relations may be encoded at a semantic level, as well as at the level of word forms.

If the apparent linguistic limitations of context-sensitive constituency can be overcome, then the potential psychological contribution of this notion is enormous. First, context-sensitivity seems to be the norm throughout human classification. Second, much data on sentence processing can be naturally explained by assuming that constituents are represented in a fuzzy and context-bound manner.

Structure Dependency

A linguistic concept intimately tied to constituency is structure dependency, the notion that grammatical knowledge relies on the structural relationships between constituents rather than on the linear sequence of items. One of the fiercest arguments leveled at distributional models of learning (of which neural networks can be seen as an instantiation) concerns the uninformativeness of such mechanisms for detecting linguistically relevant properties. The most relevant properties of language appear to be abstract, such as phrase structure configurations, grammatical relations, and syntactic categories, whereas information contained in raw input pertains to serial position, adjacency, and co-occurrence relations among words. To the extent that connectionist models, and in particular SRNs, process information relying simply on the linear sequencing of linguistic elements (at any level of analysis – phonemes, morphemes, words, etc.), they would seem doomed to fail to capture structure dependency. It turns out that SRNs can master a classic example of structure dependency in English, auxiliary fronting. In the generative linguistics framework, declaratives are turned into questions by fronting the correct auxiliary. For example, to turn the declarative form *The man who is hungry is ordering dinner*, it is correct to front the main clause auxiliary, as in 1(a), but fronting the subordinate clause auxiliary produces an ungrammatical sentence, as in 1(b):

1(a) *Is the man who is hungry ordering dinner?*
1(b)* *Is the man who hungry is ordering dinner?*

A structure-independent rule would move the first *is*, but the correct structure-dependent rule involves only the movement of the *is* from the main clause. Because children do not erroneously move the first *is* to the front of the sentence, and because they receive too little direct evidence for inferring correct auxiliary fronting, it has been claimed that structure dependency could not be learned from positive evidence by an associative mechanism. To address this challenge, SRNs were trained to predict the next lexical category from a corpus of child-directed speech that contained no relevant examples of correct auxiliary fronting. The networks, tested on completely novel sentences, produced more accurate predictions for grammatical test sentences such as *Is the boy who is hungry nearby?* than for ungrammatical sentences, such as **Is the boy who hungry is nearby?* The prediction of the well-formed relative clause continuation, V (i.e., *is*), was highly preferred over the ill-formed version, ADJ (i.e., *hungry*). This pattern of predictions reflected the networks' sensitivity to the statistical properties of the corpus. The networks distinguished chunks of lexical categories that were more frequent in the training input from less-frequent ones (i.e., the lexical categories corresponding to PRON V ADJ (*who is hungry*) vs. PRON ADJ V (*who hungry is*)). This work suggests that the networks were sensitive to the indirect statistical evidence present in the

corpus, developing an appropriate bias toward the correct forms of AUX questions without having a built-in rule for question formation.

Recursion

As with constituency, connectionist models have dealt with recursion in three increasingly radical ways. The least radical approach is to hardwire recursion into the network (e.g., as in the model that implemented phrase structure rules) or to add an external symbolic (first-in-last-out) stack to the model. In both cases, recursive generativity is achieved entirely through standard symbolic means, and although this is a perfectly reasonable approach to recursion, it adds nothing new to symbolic accounts of natural language recursion. The more radical connectionist approaches to recursion aim for networks to learn to deal with recursive structure. One approach is to construct a modular system of networks, each of which is trained to acquire different aspects of syntactic processing: one trained to map words onto case-role assignments, another trained to function as a stack, and a third trained to segment the input into constituent-like units. Although such a model displays complex recursive abilities, the basis for these abilities and their generalization to novel sentence structures derive from the configuration of the stack network, combined with the modular architecture of the system, rather than being discovered by the model.

The most radical connectionist approaches to recursion attempt to learn recursive abilities with minimal prior knowledge built into the system. In this type of model, the network is most often required to discover both the constituent structure of the input and how these constituents can be recursively assembled into sentences. As with the similar approach to constituency described above, such models may provide new insights into the notion of recursion in human language processing.

Before these modeling efforts are discussed, the extent to which recursion is observed in human language behavior needs to be assessed. It is useful to distinguish simple and complex recursion. Simple recursion consists of recursively adding new material to the left (e.g., the adjective phrases (AP) in *the gray cat* → *the fat gray cat* → *the ugly fat gray cat*) or right (the PPs in *the flowers in the vase* → *the flowers in the vase on the table* → *the flowers in the vase on the table by the window*) of existing phrase material. In complex recursion, new material is added in more complicated ways, for example, through center embedding of sentences (*the chef admired the musicians* → *the chef who the waiter appreciated admired the musicians*). Psycholinguistic evidence shows that people find simple recursion relatively easy to process, whereas complex recursion is almost impossible to process with more than one level of recursion. For instance, the following sentence, with two levels of simple (right-branching) recursion, *The busboy offended the waiter who appreciated the chef who admired the musicians*, is much easier to comprehend than the comparable sentence with two levels of complex recursion, *The chef who the waiter who the busboy offended appreciated admired the musicians*. Because recursion is built into symbolic models, there are no intrinsic limitations on how many levels of recursion can be processed. Instead, such models must invoke extrinsic constraints, such as the competence–performance distinction, to accommodate the human performance asymmetry on simple and complex constructions. The radical connectionist approach models human performance directly without the need for extrinsic performance constraints.

The SRN model developed by Jeff Elman was perhaps the first connectionist attempt to simulate human behavior on recursive constructions. This network was trained on sentences generated by a small context-free grammar incorporating center embedding and a single kind of right-branching recursive structure. In related work, SRNs were trained on a recursive artificial language incorporating four kinds of right-branching structures, a left-branching structure, and center embedding. The behavior of these networks was qualitatively comparable to human performance in that the SRN predictions for right-branching structures were more accurate than for sentences of the same length involving center embedding, and performance degraded appropriately when depth of center embedding increased. Further simulations corroborated these results, suggesting that semantic bias (incorporated via co-occurrence restrictions on the verbs) can facilitate network performance in center-embedded constructions in a way similar to the semantic facilitation effects found in human processing. Using abstract artificial languages, it has been demonstrated that the SRN's general pattern of performance is relatively invariant across network size and training corpus, and the humanlike pattern of performance likely derives from intrinsic constraints inherent in the SRN architecture.

Connectionist models of recursive syntax typically use toy fragments of grammar and small vocabularies. Aside from raising concerns over scaling up, these factors make it difficult to provide detailed fits with empirical data. Nonetheless, some attempts have recently been made toward fitting existing data and deriving new empirical predictions from the models. One SRN model fits grammaticality ratings data from several behavioral experiments, including an account of the

relative processing difficulty associated with the processing of center embeddings (with the following relationship between nouns and verbs: $N_1_N_2_N_3_V_3_V_2_V_1$) versus cross-dependencies (with the following relationship between nouns and verbs: $N_1_N_2_N_3_V_1_V_2_V_3$). Human data have shown that sentences with two center embeddings (in German) were significantly harder to process than comparable sentences with two cross-dependencies (in Dutch). A measure of grammatical prediction error (GPE) was developed that allowed network output to be mapped onto human performance data. GPE is computed for each word in a sentence and reflects the processing difficulties that a network experiences at a given point in a sentence. Averaging GPE across a whole sentence, the SRN fit human data concerning the greater perceived difficulty associated with center embedding in German compared with cross-serial dependencies in Dutch. The simulation results demonstrated that the SRNs exhibited the same kind of qualitative processing difficulties as humans do on these two types of complex recursive constructions. Further simulations derived novel predictions concerning other types of recursive constructions, and these predictions were later confirmed experimentally. Single-word GPE scores were mapped directly onto reading times, providing an experience-based account for human data concerning the differential processing of singly center-embedded subject and object relative clauses in human participants with different levels of reading comprehension ability.

Just as the radical connectionist approach to constituency deviates from classical constituency, the above approach to recursion deviates from the classical notion of recursion. The radical models of recursion do not acquire true recursion because they are unable to process infinitely complex recursive constructions. However, the classic notion of recursion may be ill-suited for capturing human recursive abilities. Indeed, the psycholinguistic data suggest that people's performance may be better construed as being only quasi-recursive. The earlier mentioned semantic facilitation of recursive processing further suggests that human recursive performance may be partially context-sensitive; for example, the semantically biased *The bees that the hive that the farmer built housed stung the children* is easier to comprehend than neutral *The chef that the waiter that the busboy offended appreciated admired the musicians* even though both sentences contain two center embeddings. This dovetails with the context-sensitive notion of constituency and suggests that context sensitivity may be a more pervasive feature of language processing than is typically assumed by symbolic approaches.

Connectionist Models of Language Processing

What is the significance of connectionist models of language processing? Will connectionism ultimately replace, complement, or simply implement symbolic approaches to language? Early connectionists addressed this issue by attempting to show that connectionism could, in principle, capture aspects of language and language processing. These models showed that connectionist networks could in principle acquire parts of linguistic structure without extensive innate knowledge. Recent work has moved toward a connectionist psycholinguistics that captures detailed psychological data. This article has outlined several ways in which constituency and recursion – two fundamental properties of linguistic knowledge – may be accommodated within a connectionist framework, ranging from direct implementation of symbolic systems to the acquisition of constituency and recursion from untagged input. It has focused on the radical approach because this approach has the greatest potential impact on psycholinguistics and linguistic theory.

However, much of this research is still preliminary. Work is required to decide whether promising, but limited, initial results can eventually be scaled up to deal with the complexities of real language input or whether a radical connectionist approach is beset by fundamental limitations. Another challenge is to find ways – theoretically and practically – to interface models, which have been proposed at different levels of linguistic analyses, with one another (e.g., interfacing models of morphology with models of sentence processing).

Nevertheless, the connectionist models described in this article have already influenced the study of language processing. First, connectionism has helped promote a general change toward replacing box-and-arrow diagrams with explicit computational models. Second, connectionism has reinvigorated the interest in computational models of learning, including learning properties, such as recursion and constituent structure, which were previously assumed to be present *a priori* in humans and therefore taken for granted. Finally, connectionism tends to discard the separation between competence and performance as artificially construed and possibly misleading. From this perspective, linguistic recursion is a conceptual artifact of the competence–performance distinction instead of a necessary characteristic of the underlying computational mechanism. In this light, the problem facing connectionist models of language processing is not whether they can implement some kind of recursive mechanism but whether they will be able to account for the (limited) recursive structure found in

natural language behavior purely in terms of nonsymbolic computation.

Connectionism has already had a considerable impact on the psychology of language. However, the final extent of this influence depends on the degree to which practical connectionist models can be developed and extended to deal with complex aspects of language processing in a psychologically realistic way. Recent models have already started to scale up to more realistic corpora and sentence processing behaviors. If realistic connectionist models of language processing can be provided, then the possibility of a radical rethinking, not just of the nature of language processing, but of the structure of language itself, may be required.

Connectivity of Primate Reward Centers

S N Haber, University of Rochester School of Medicine, Rochester, NY, USA

© 2009 Published by Elsevier Ltd.

Introduction

At the center of the neural network that mediates reward-based learning is the cortical–basal ganglia circuit. This network is critical for the development of appropriate goal-directed behaviors and good decision making. Consistent with these normal behaviors, this circuit is also associated with pathological risk-taking and addictive behaviors. The frontal–basal ganglia network, in general, mediates all aspects of action planning, including reward and motivation, cognition, and motor control. However, specific regions within this network play a unique role in different aspects of reward processing and the evaluation of outcomes, including reward value, anticipation, predictability, and risk. Other brain areas also contain cells that respond to reward, including the hypothalamus that specifically process information about basic drives to maintain homeostasis of the animal. However, this article focuses on those areas that use information about reward to predict, evaluate, and plan future actions, based on perceived positive outcomes.

The prefrontal cortex, the ventral striatum (VS), the amygdala, and the dopamine neurons of the ventral tegmental area (VTA) are at the heart of the reward circuit (Figure 1). The anterior cingulate cortex (ACC) and orbital prefrontal cortex (OFC) areas mediate different aspects of reward-based behaviors, error prediction, value, and the choice between short- and long-term gains. In addition to these prefrontal areas, the dorsolateral prefrontal cortex (DLPFC) is engaged when working memory is required for monitoring incentive-based behavioral responses. Cells in the striatum respond to the anticipation of reward and reward detection. Reward prediction and error detection signals are generated, in part, from the midbrain dopamine cells. In addition, the medial temporal cortex also plays a central role in the motivation and memory for the development of incentive- and goal-directed behaviors. Moreover, although the VS and the VTA dopamine neurons are the basal ganglia areas most commonly associated with reward, reward-responsive activation is not restricted to these areas but is found throughout the striatum and substantia nigra pars compacta (SNc).

Prefrontal Cortex

The main areas of prefrontal cortex involved in the reward circuit are the ACC and OFC. Each of these regions comprises several specific cortical areas. However, based on specific roles for mediating different aspects of reward and error prediction, they can be functionally grouped into the dorsal ACC (dACC), which includes parts of areas 24 and 32; the ventromedial prefrontal cortex (vmPFC), which includes parts of areas 32, 25, and 14; and the OFC, which includes areas 11, 13, and 12. The vmPFC plays a role in monitoring correct responses based on previous experience and the internal milieu. It is selectively connected to the hippocampus, parahippocampal, and amygdala, as well as the hypothalamus. The OFC is engaged when a previously learned response is no longer appropriate and the response needs to be suppressed. This more lateral area is connected to multisensory regions, parts of the DLPFC, and the amygdala. The dACC is a unique part of prefrontal cortex, in that it contains within it a representation of many diverse frontal lobe functions, including motivation, cognition, and motor control. However, its overall functional role is to monitor these functions in conflict situations, which is reflected in its widespread connections with limbic, cognitive, and motor cortical areas.

The Ventral Striatum

The striatum is the main input structure of the basal ganglia. It receives a massive and topographic input from cerebral cortex (and thalamus). These afferent projections to the striatum terminate in a general topographic manner, such that the ventromedial striatum receives input from reward-related areas, the central striatum receives input from associative cortical areas, and the dorsolateral striatum receives cortical input from sensorimotor areas. The VS is the striatal region most associated with reward, supported not only by its cortical inputs but also by physiological, pharmacological, molecular, and imaging studies. Collectively, these studies demonstrate its key role in the acquisition and development of reward-based behaviors and its involvement in drug addiction and drug-seeking behaviors.

Although the VS is similar to the dorsal striatum in most respects, there are also some unique features. The VS contains a subterritory, called the shell, that plays a particularly important role in the circuitry

underlying goal-directed behaviors, behavioral sensitization, and changes in affective states. Because there is no histochemical or cytoarchitectonic boundary between the VS and dorsal striatum, the best way to define it is by its afferent projections from cortical areas that mediate different aspects of reward processing, the vmPFC, OFC, dACC, and medial temporal lobe. Finally, and of particular importance, although both the dorsal striatum and VS receive input from the cortex, thalamus, and brain stem, the VS alone also receives a dense projection from the amygdala and from the hippocampus.

Figure 1 Diagram demonstrating the key elements of the reward circuit. Red arrows indicate excitatory glutamatergic projections; blue arrows indicate inhibitory GABAergic projections. dACC, dorsal anterior cingulate cortex; GABA, γ-aminobutyric acid; OFC, orbital prefrontal cortex; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; vmPFC, ventromedial prefrontal cortex; VP, ventral pallidum; VS, ventral striatum; VTA, ventral tegmental area.

The vmPFC, OFC, and dACC project primarily to the rostral striatum, including the nucleus accumbens, rostral caudate nucleus, and the medial and ventral rostral putamen. Terminals from these cortical areas show a complex interweaving and convergence, providing an anatomical substrate for modulation between circuits to affect incentive learning and habit formation. The shell receives the most limited projection from cortex and is primarily derived from the vmPFC and agranular insular cortex, areas involved in monitoring the internal milieu. In addition, inputs from both the hippocampus and amygdala terminate in overlapping regions of the shell. The terminal field that receives input from the vmPFC and amygdala continues from the shell dorsally to lie adjacent to the lateral ventricles rostral to the anterior commissure. The OFC and dACC projection fields lie, for the most part, lateral to these fibers from the vmPFC. They occupy the ventral caudate and putamen and the centromedial part of the caudate nucleus. The entire reward-related striatum, as defined by vmPFC–OFC–dACC inputs, occupies a large rostral region and encompasses at least 22% of the entire striatum. The large extent of this region is consistent with the findings that diverse striatal areas are activated following reward-related behavioral paradigms (Figure 2).

Figure 2 Lateral view of a 3-D rendering of the striatum. Projections from the dorsal anterior cingulate are illustrated in orange and from the vmPFC and orbital prefrontal cortex in red. Note the large rostral striatal region associated with the reward processing areas of cortex. C, caudate nucleus; P, putamen; S, shell.

The Amygdala

The amygdala is a prominent limbic structure that plays a key role in the emotional coding of environmental stimuli and provides contextual information used for adjusting the motivational level that is based on immediate goals. It comprises the basolateral nuclear group (BLNG), the corticomedial region, and the central amygdaloid complex. Overall, the basal nucleus and the magnocellular division of the accessory basal nucleus are the main sources of inputs to the VS. The lateral nucleus has a relatively minor input to the VS. The amygdala innervates the entire ventromedial striatum and has few to no inputs to the dorsal striatum in primates. The basal and accessory basal nuclei innervate both the shell and ventromedial striatum outside the shell. Moreover, there is a topographical organization to that innervation, such that inputs from basal nucleus subdivisions target different regions of the VS. The shell is set apart from the rest of the VS by a specific set of connections derived from the medial part of the central nucleus (CeM) and periamygdaloid cortex and the medial nucleus of the amygdala. The BLNG, the source of all amygdaloid input to the all the VS outside the shell, processes higher-order sensory inputs in all modalities except olfactory and responds to highly palatable foods and multimodal cues. The CeM and periamygdaloid cortex inputs directed to the shell add important information on whether a stimulus matches the animal's internal drive state. Thus, much like the topography of prefrontal inputs to the VS, the nuclei of the amygdala that mediate various functions, target subterritories of the ventromedial striatum.

The Midbrain Dopamine Neurons

Dopamine neurons play a key role in the incentive learning and acquisition of newly acquired behaviors. Behavioral and pharmacological studies of dopamine pathways have led to the association of the mesolimbic pathway and nigrostriatal pathway with reward and motor activity, respectively; however, more recently both of these cell groups have been associated with reward. The midbrain dopamine neurons project widely throughout the brain. However, studies of the rapid signaling that is associated with incentive learning and habit formation focus on the dopamine striatal pathways. Before turning to this projection to the striatum, it is important to understand the organization of the midbrain dopamine cells.

The midbrain dopamine neurons are divided into two fundamental groups: the VTA and the SNc (Figure 3). These cells are also referred to as the dorsal and ventral tier neurons, based on projection and chemical signatures. The dorsal tier includes the VTA and the dorsal part of the SNc (also referred to as the retrorubral cell group). The cells of the dorsal tier are calbindin positive and contain relatively low levels of mRNA for the dopamine transporter and D2 receptor subtype. They project to the VS, cortex, hypothalamus, and amygdala. The ventral tier of dopamine cells is calbindin-negative, has relatively high levels of mRNA for the dopamine transporter and D2 receptor, and projects primarily to the dorsal striatum. The relatively high levels of the dopamine transporter indicate that the ventral tier cells have tight control over regulating extracellular dopamine. Moreover, high levels of the transporter molecule result in these cells being more vulnerable to degeneration in Parkinson's disease and to *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced toxicity, whereas the dorsal tier cells are selectively spared. As already mentioned, despite these distinctions both cell groups respond to unexpected rewards but do not respond to movement-related activity.

Figure 3 Schematic demonstrating the arrangement of the dopamine cell groups in the midbrain. The dorsal tier includes the ventral tegmental area and retrorubral cell groups. The ventral tier includes the main part of the pars compacta. n., nucleus; SNc, substantia nigra, pars compacta; SNr, substantia nigra, pars reticulata; VTA, ventral tegmental area.

Afferent Projections

Input to the midbrain dopamine neurons is primarily from the striatum, from both the external segment of the globus pallidus and the ventral pallidum, and from the brain stem. In addition, there are projections to the dorsal tier from the bed nucleus of the stria terminalis, the sublenticular substantia innominata, and the extended amygdala (the bed nucleus of the stria terminalis) (Figure 4(a)).

The striatal–nigral projection is the most massive projection to the SN and terminates in both the

Figure 4 Diagram of the projections of the midbrain dopamine neurons: (a) main afferent projections; (b) main efferent projections. n., nucleus; SNc, substantia nigra, pars compacta; SNr, substantia nigra, pars reticulata; STN, subthalamic nucleus; VTA, ventral tegmental area.

VTA-SNc and the substantia nigra pars reticulata (SNr). The ventral (like the dorsal) striatal–nigral connection terminates throughout the rostrocaudal extent of the SN. There is an inverse ventral–dorsal topography to the striatal–nigral projections. The dorsolateral striatal–nigral inputs are concentrated in the ventrolateral SN. These striatal cells project primarily to the SNr, but also terminate on the cell columns of dopamine neurons that penetrate deep into the SNr. In contrast, the ventral striatal–nigral inputs terminate in the VTA, medial and dorsal SNr, and much of the dorsal part of the ventral tier. Thus, the VS projects not only throughout the rostrocaudal extent of the SN, but also covers a wide mediolateral range.

Descending projections from the central nucleus of the amygdala also terminate in a wide mediolateral region, but they are limited primarily to the dorsal tier cells. In addition, there are projections to the dorsal tier from the bed nucleus of the stria terminalis and from the sublenticular substantia innominata that travel together with those from the amygdala. Both the external segment of the globus pallidus and the ventral pallidum project to the SN. The internal segment of the globus pallidus does not. The pallidal

projection follows a similar inverse dorsal–ventral organization as the striatal–nigral projection. Thus, the ventral pallidum projects dorsally, primarily to the densocellular region of the pars compacta. The pedunculopontine nucleus sends a glutamatergic input to the dopaminergic cells bodies. In addition, there is a serotonergic innervation from the dorsal raphe nucleus, although there is disagreement regarding whether fibers terminate primarily in the pars compacta or pars reticulata. Other brain stem inputs to the dopamine neurons include those from the superior colliculus, the parabrachial nucleus, and the locus coeruleus. Finally, in primates, there is a small and limited projection from the prefrontal cortex to the midbrain dopamine neurons, to both the VTA and SNc. However, relative to the density of its other inputs, this projection is weak.

Efferent Projections

The striatum receives the largest efferent projection from the midbrain dopamine neurons (Figure 4(b)). As with the descending striatal–nigral pathway, there is a mediolateral and an inverse dorsoventral topography arrangement to the projection. The ventral pars compacta neurons project to the dorsal striatum and the dorsally located dopamine neurons project to the VS. The shell region receives the most limited input, primarily derived from the VTA. The rest of the VS receives input from the entire dorsal tier. In addition, there are some afferent projections from the medial region and dorsal part of the SNc. In contrast to the VS, the central striatal area (the region innervated by the DLPFC) receives input from a wide region of the SNc. The dorsolateral (motor-related) striatum receives the largest midbrain projection from cells throughout the ventral tier. In contrast to the dorsolateral region of the striatum, the VS receives the most limited dopamine cell input. Thus, in addition to an inverse topography, there is also a differential ratio of dopamine projections to the different striatal areas. The ascending midbrain dopaminergic striatal afferents terminate on the spines of the medium spiny projection neurons, in close apposition to cortical synapses, and are in a position to influence cortical input. Thus, a relatively smaller midbrain projection to the VS has a large impact on the modulation of the larger cortical projection.

The dorsal tier cells also project widely throughout the primate cortex and are found not only in the granular areas but also in the agranular frontal regions, parietal cortex, temporal cortex, and, albeit sparsely, occipital cortex. The majority of dopamine cortical projections are from the parabrachial pigmented nucleus of the VTA and the dorsal part of the SNc. The VTA also projects to the hippocampus, albeit to a lesser extent than found in neocortex. The dopamine cells that project to functionally different cortical regions are intermingled with one another, in that individual neurons send collateral axons to different cortical regions. Thus, nigral–cortical projection is a more diffuse system compared to the nigral–striatal system and can modulate cortical activity at several levels. Dopamine terminals are located throughout layer I, providing a general modulation of cortical cells at the distal apical dendrites and in layers V–VI, in specific cortical areas. The basolateral complex and the central amygdala nuclei have reciprocal connections to the midbrain. Projections to the amygdala arise from the dorsal tier. These terminals form symmetric synapses primarily with the spiny cells of the amygdala. Dopamine fibers also project directly to the subthalamic nucleus (STN) and the ventral pallidum.

Completing the Cortical–Basal Ganglial Reward Circuit

In addition to the cortical and amygdaloid projections and the midbrain, inputs to the striatum also include projections from the ventral pallidum, the dorsal and median raphe nuclei, and the midline thalamic nuclei. Finally, in addition to the extrinsic inputs, the projection neurons also receive input from interneurons and from local collaterals of other medium spiny cells. The output from the VS targets the ventral pallidum and the VTA of the midbrain, and the medial and dorsal SNc and SNr.

The ventral pallidum is an especially important component of the reward circuit in that cells in this forebrain region respond specifically during the learning and performance of reward-incentive behaviors and it is an area of focus in the study of addictive behaviors. This ventral extension of the globus pallidus was identified based on histological criteria and found to receive its primary input from the VS. The ventral pallidum extends not only ventrally, below the anterior commissure, but also rostrally to invade the rostral and ventral portions of the VS, sending fingerlike extensions into the anterior perforated space. The ventral pallidum has common features of both the external and internal segments. The external pallidal component of the ventral pallidum lies ventrally and rostrally to the external segment and projects to the striatum, the STN, and the SN. The internal segment component of the ventral pallidum lies primarily in the medial and rostral portions of the internal segment proper and projects to the mediodorsal nucleus of the thalamus, and to the midline thalamic nuclei, which in turn project to the prefrontal

cortex, thus completing the basic reward circuit through the basal ganglia (see Figure 1).

Complex Network Features of the Reward Circuit

To develop an appropriate behavioral response to external environmental stimuli, information about motivation and reward needs to be combined with a strategy and an action plan for obtaining the goal. In other words, it is not sufficient to desire or want, for example, to win at a card game. We must understand the rules of the game, remember the cards played, and so forth before executing the play. In addition, there is a complex interaction between the desire to put cards in play and the inhibition of impulse to play them too early. The cortico-cortical interaction plays a central role in strategic planning, memory, and impulse control that allows the ability to inhibit responses that will result in long-term loss. The cortical–basal ganglia circuit serves a different function. This system is particularly important in procedural and incentive-based learning leading to the development of goal-directed behaviors. The resulting action plans for obtaining a goal require a combination of reward processing, cognition, and motor control. Emphasis has generally been placed on the separation between these functions within the striatum, with no substantial overlap among these different cortical–basal ganglia circuits (referred to as parallel processing). However, recent work clearly shows that there are dual corticalbasal ganglia systems permitting both parallel and integrative networks. The integrative role for the basal ganglia is critical in learning new behavior-guiding rules, associations, and habits.

The Cortical–Striatal Network

Focal terminal projections from the different reward-processing areas of the prefrontal cortex (vmPFC, OFC, and dACC) converge in specific regions of the VS (Figure 5; see also Figure 2). The areas of convergence also receive input from the amygdala. These convergent points provide an anatomical substrate for the integration of different reward-processing circuits within specific striatal areas. Areas of convergence among the different reward-related cortical areas are likely to be relatively large and may represent interactions (hot spots) of plasticity to integrate reward value, predictability, and salience. These regions may especially be critical for the development of appropriate action plans and habits, and they are also especially vulnerable to the development of addictive disorders. Moreover, there are also specific points of convergence from the vmPFC, OFC, dACC, and those

Figure 5 Diagram showing convergence of cortical projections from different reward-related regions of the prefrontal cortex. Note that there is also some convergence between reward areas and the dorsolateral prefrontal cortex. dACC, dorsal anterior cingulate cortex; DLPFC, dorsal lateral prefrontal cortex; OFC, orbital prefrontal cortex; vmPFC, ventral medial prefrontal cortex.

from the DLPFC. The DLPFC plays an important role in executive functions and projects primarily to a large rostral region of the caudate nucleus, extending into the putamen. The hot spots between reward-related cortical areas and the DLPFC form a potential zone for dynamic restructuring of neural ensembles fundamental to learning and habit formation. Finally, the premotor terminals in the striatum converge with those from the DLPFC, placing these projections in a pivotal position in the striatum to integrate reward processing with planned action outcomes. In addition, whereas the projections from the cortex terminate in a general topography through the basal ganglia structures, the dendrites and axons within each structure extend outside of the functional boundaries, increasing the cross-talk between functional regions. This is particularly prominent in the globus pallidus, where the dendrites are extensive, stretching among limbic, cognitive, and motor control areas. In this way, the distal dendrites from one region receive information from other functional areas of the striatum.

The Striatal–Nigral–Striatal Network

The role of dopamine in reward is well established. However, the latency between the presentation of the reward stimuli and the activity of the dopamine cells is too short to reflect higher cortical processing necessary for linking a stimulus with its rewarding properties. The fast burst-firing activity is likely, therefore, to be generated from other input such as in the brain stem glutamatergic nuclei. An interesting issue is, then: How do the dopamine cells receive information concerning reward value? The largest forebrain input to the dopamine neurons is from the striatum. However, this is a relatively slow γ-aminobutyric acid

(GABAergic) inhibitory projection and unlikely to result in the immediate, fast burst-firing activity. Nonetheless, the collective complex network of prefrontal cortex, amygdala, and hippocampal inputs integrates information related to reward processing and memory to modulate striatal activity. These striatal cells then impact directly a subset of medial dopamine neurons, which, through a series of connections, influences the dorsal striatum. Thus, although the short latency burst firing activity of dopamine that signals the immediate reinforcement is likely to be triggered from brain stem nuclei, the cortical–striatal midbrain pathway is in the position to influence dopamine cells to distinguish rewards and modify responses to incoming salient stimuli over time. This pathway is further reinforced via the nigral–striatal pathway, placing the striatal–nigroalstriatal pathway in a pivotal position for incentive-based learning.

As already mentioned, projections from the striatum to the midbrain are arranged in an inverse dorsal–ventral topography and there is also an inverse dorsal–ventral topographical organization to the midbrain striatal projection. When considered separately, each limb of the system creates a loose topographical organization such that the VTA and medial SN are associated with the limbic system, and the lateral and ventral SN are related to the associative and motor-striatal regions. However, each functional region also differs in its proportional projections that significantly alter its relationship with other functional regions. The VS receives a limited midbrain input, but projects to a large region. In contrast, the dorsolateral striatum receives a wide input, but projects to a limited region. In other words, the VS influences a wide range of dopamine neurons, but is itself influenced by a relatively limited group of dopamine cells. On the other hand, the dorsolateral striatum influences a limited midbrain region, but is affected by a relatively large midbrain region.

With this arrangement, while the VS receives input from the vmPFC, OFC, dACC, and amygdala, its efferent projection to the midbrain extends beyond the tight VS–dorsal tier dopamine–VS circuit. It terminates also in the ventral tier to influence the dorsal striatum. Moreover, this part of the ventral tier is reciprocally connected to the central (or associative) striatum. The central striatum also projects to a more ventral region than it receives input from, which, in turn, projects to the dorsolateral (or motor) striatum (Figure 6). Taken together, the interface between different striatal regions via the midbrain dopamine cells is organized in an ascending spiral interconnecting different functional

Figure 6 Diagram showing the complex interactions between the prefrontal cortex and the basal ganglia. Illustrated are areas of interaction through which the reward circuit interfaces with associative circuits that mediate action plans. The colors represent different cortical functional regions. Note that the parallel system is carried from the cortex to the striatum, to the output structures of the pallidum and pars reticulata, to the thalamus, and back to the cortex. There is some convergence between terminals from different functional areas of cortex in the striatum. Moreover, the dopamine neurons are in a position to channel information from limbic to cognitive to motor circuits. Also illustrated are the parallel functional circuits from the cortex, through the basal ganglia, and back to cortex via the thalamus. dACC, dorsal anterior cingulate cortex; DLPFC, dorsal lateral prefrontal cortex; OFC, orbital prefrontal cortex; PM, premotor area; SNr, substantia nigra pars reticulata; vmPFC, ventral medial prefrontal cortex.

regions of the striatum and creating a feed-forward organization, from reward-related regions of the striatum to the cognitive and motor areas.

Summary

The reward circuit comprises several cortical and subcortical regions that form a complex network to mediate different aspects of incentive learning. The cortical–basal ganglial network is a fundamental component of this circuit, leading to adaptive behaviors and good decision making. This complex network involves a system in which the prefrontal cortex exploits the basal ganglia for additional processing of rewards to effectively modulate learning, which leads to the development of goal-directed behaviors and action plans. However, the reward circuit does not work in isolation. The development and modification of goal-directed behaviors require continual processing and updating of outcomes relative to response. As such, this complex circuitry interfaces with pathways that mediate cognitive function and motor planning. Within each of the cortical–basal ganglial structures, there are regions of convergence linking up areas that are associated with different functional domains (**Figure 6**). In this way the reward circuit impacts cognition and motor control through several different interactive networks, including cortico-cortical connections, convergence between cortical terminals in the striatum, and a feed-forward system via the midbrain. This complex set of systems allows information about reward channeled in different ways through cognitive and motor-control circuits to mediate the development of appropriate action plans.

Consciousness: Neural Basis of Conscious Experience

B Libet[†], Davis, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Basic Definitions and Concepts

Conscious or subjective experience or awareness is clearly accessible only introspectively to the individual having the experience. Consequently, the valid operational definition of it in scientific investigations is the introspective report by the individual, under conditions of reliability and credibility. That requires the availability of human study participants, awake and forthcoming, in whom simultaneous observations and manipulations of neural functions can be made. This combination of requirements imposes severe limitations on potential studies.

The observer must ask the individual the appropriate question about the latter's conscious experience and be confident that the individual understands the question. The report is often most conveniently verbal, but it may be nonverbal (e.g., a sign made by a finger) if the latter clearly represents the individual's introspective experience. Any report should be made only after sufficient time for introspection and not as part of any speedy reaction-time procedure. The issue of the accuracy and reliability of the individual's communication of introspective experience must be dealt with in each study individually. Suitable control tests can in fact be devised, and satisfactory reliability of reports is obtainable.

Physical Nature; System Property

Conscious subjective experience is a primary phenomenon whose nature cannot be defined by any other externally observable event, whether molecular or behavioral. Subjective experience arises as a system property of appropriate neural activities in the brain. It is a 'nonphysical' event, in that it cannot be detected or described by direct physical measurements, although a correlation with neural patterns may be discernible in relation to an individual's report of an experience. It is well known that the properties of a system are not predictable from those of the elements in the system. A 'nonphysical' property could, in principle, appear as a system property of the 'physical' neuronal activities. Even a complete knowledge of the observable neural processes in the brain of another individual would not in itself tell us what that individual is experiencing or feeling.

There are no *a priori* rules governing the relationship between conscious mental events and brain events; the rules must be discovered. The phenomenon of subjective referral of a sensory experience in the spatial dimension illustrates this principle. The spatial configuration of a subjectively experienced visual image, for example, is considerably different from the configuration of the brain neuronal activities that accompany and represent the sensory input and give rise to the visual images; the image that is seen, subjectively, is quite different from the neuronal pattern for that image. The cerebral neuronal representation is actually a spatial distortion of the original image coming into the eye, but subjectively the image is 'referred' to the original source of the input in a way that corrects the neuronal distortion. Direct electrical stimulation of primary sensory cortex provides an even more obvious demonstration of this; a stimulus applied to the lateral portion of the postcentral gyrus produces a sensation that is felt to be located not at the stimulated site of the brain, but is rather subjectively referred to, and felt in, the hand or arm and in a direction reversed from the postcentral representation. Clearly, a complete knowledge of the neuronal representation would not, without validation by the individual's report, tell us where or what sensation is being subjectively experienced. Similarly, the experience of color cannot be described by finding that certain neural units may respond to specific frequency bands of the light spectrum.

Although each individual has access to and can be certain about only his own conscious experiences and feelings, we do commonly concede and accept the premise that other human beings have their subjective experiences (except for those of us who want to adopt Bishop Berkeley's solipsism as a serious view of life). We are also confident that one person can communicate something about his subjective experiences to another. But the validity of what is communicated depends upon the degree to which both individuals have had similar or related experiences. A congenitally completely blind person can never share the conscious experience of a visual image, regardless of how detailed a verbal description he is given by a sighted individual. The same limitation applies to all experiences in less dramatic, more subtle ways. For example, electrical stimulation of somatosensory cortex can produce sensations related to but sufficiently different from those generated by normal sensory input, so that the individuals could only relate some roughly understandable approximation

[†]Deceased.

of these experiences to the experimental observer, in whom similar modes of sensory generation had never been employed.

Reports of Conscious Experience versus Behavioral Detection

There is an imperative corollary of the foregoing operational definition of conscious experience: any measured indicator that can be dissociated from or independent of subjective awareness would be invalid, not acceptable as a primary indicator of subjective experience. This would even include behavioral responses that depend on cognitive and decision-making processes, unless these were validated by the primary evidence of the individual's introspective reports. For example, we have all had the experience of driving an automobile and becoming subjectively engrossed in thoughts not related to the mechanics of driving; nevertheless, the driving proceeds while all sorts of sensory signals are being properly recognized, evaluated, and acted upon (usually successfully), without any consciously introspective awareness or later recallability. Among experimental paradigms, signal detection studies provide sophisticated examples of a generally unacceptable approach to conscious experiences. The forced-choice responses in such studies could be made independent of introspective awareness of the signal, although they may be excellent indicators of whether some type of detection has occurred. Even when individuals are giving confidence ratings of their responses in a signal detection study, they are rating their forced choices and are not necessarily directly reporting their subjective experiences. There is, in fact, evidence that signal detection can occur with signals that are distinctly below the threshold required for any conscious awareness of the signal. Indeed, most sensory signals probably do not reach conscious awareness; however, many of them lead to modified responses and behaviors, as in simple everyday postural and walking activities, and have therefore clearly been detected and utilized in complex brain functions.

Do Animals Have Conscious Experience?

There is no way to answer this in any absolute sense. But it should be clear that it is difficult, if not impossible, to carry out valid studies of conscious experience in nonhuman animals. Obviously, we cannot meaningfully ask an animal to report about a shared introspective experience, the validity of which we have confidence. Second, as just noted, complicated cognitive and purposeful behaviors can proceed even in human beings without introspective awareness of them, and so we cannot safely assume that such behaviors in animals are expressing subjective experience. Some investigators and writers have proposed that adaptive, problem-solving behaviors in animals indicate conscious thought and experience. However, even in humans, the most complex and even mathematical problem solving can and often does proceed at unconscious levels, as has been repeatedly described by many creative thinkers, artists, and others. Again, one must be careful to hold to the primary criterion of conscious experience *per se*, as a phenomenon that cannot automatically be described by any nonvalidated behavioral expression.

Are Computers Conscious?

Some enthusiasts of machines with artificial intelligence have tended to equate complexity of abstract processing with the existence of conscious experience. As we have noted, there is no such necessary connection even in the human brain. Again, there is the fundamental error in assuming that conscious experience can be identified based on purely behavioral criteria, whether for humans or machines. It has been argued that a machine might eventually be constructed with such sophistication that an external observer could not distinguish its behavior and responses from those of a human being. Even if we grant such a possibility, for the sake of argument, such an apparent identity of behavioral responses does not require that the two systems, machine and human brain, are alike in every respect. In fact, they are constituted differently and operate with different mechanisms. The unique makeup of the brain, and indeed certain special neuronal actions in it (see later), may be essential correlates of what we recognize as conscious subjective experience.

Studies of Neural Basis

Effects of Cerebral Lesions

It was, of course, long known that lesions of the cerebral cortex that destroyed a primary sensory area resulted in severe sensory impairment. For example, with loss of striate cortex area 17 patients are blind; that is, they report being unaware of signals in the affected visual field. But further analyses are showing that these patients can detect signals without any reportable awareness, by pointing correctly to them in forced-choice tests; this is the 'blindsight' phenomenon. In a related manner, patients with lesions that abolish their reportable awareness of differences in color can correctly discriminate among different colors in

forced-choice tests, and with lesions that obliterate conscious identifiability of the shapes and locations of objects, patients can retain correct visuomotor guidance (of their hands) to these objects. A similar discrepancy, between conscious and unconscious (or nonconscious) processes, can be produced by lesions in the frontal medial cortex: patients exhibit the 'alien-hand sign,' in which the affected arm and hand perform spontaneous purposeful-looking movements that are not consciously willed or amenable to direct conscious control. A variety of other cerebral lesions can produce other interesting distortions of, or losses in, various kinds of awareness.

The foregoing kinds of findings in neuropsychology indicate cortical areas that are necessary for developing conscious experiences of sensory and volitional events. But they do not demonstrate that these areas are sufficient for this function; that is, they do not show where the conscious experience actually forms or arises. This distinction between necessity and sufficiency has at times been neglected, leading to potentially erroneous conclusions about the 'seat of consciousness'; it presents a problem that is difficult to address experimentally. Also, the neuropsychological findings do not themselves provide evidence on the physiological activities and interactions of the neuronal groups involved in the conscious process.

Regional Cerebral Blood Flow and Metabolism

The ability to measure regional cerebral blood flow (rCBF) and relating this to psychological functions in awake humans was introduced over 25 years ago by N Lassen and D Ingvar. The analysis has since been technically improved, as to localizability and quantitativeness, by the introduction of positron emission topography (PET) scan and by the coupling of this with the structural mapping by magnetic resonance imaging (MRI). These techniques are essentially non-invasive, except for the administration of presumably harmless tagged agents, and have thus opened a highly productive avenue for studying brain activity in the awake and responsive human. However, while these methods tell us which areas or nuclei in the brain are changing in their rate of metabolism, they do not give information on the physiological dynamics involved; that is, the information is essentially topographical. The timing of the change is also still only possible to within some seconds, for PET scans, but MRIs are faster. The rCBF studies in which individuals are asked to perform conscious mental operations are of special interest to the issue of brain and conscious experience. In one such study, individuals were asked to imagine moving their fingers without actually moving them; a selective increase in blood flow appeared in the supplementary motor area (SMA). Such findings might bear on the question of whether and where a conscious mental function can initiate or influence neural processes. The time resolution of the rCBF method, however, as well as the absence of indicators of the precise relative timing of the onset of the mental imagining, vitiate any answers to the question. It has been shown experimentally that conscious intention to move, for example, actually follows onset of electrophysiological activity associated specifically with the volitional process.

It should be noted that, although the machine for the functional MRI (fMRI) responses can show changes within a few milliseconds, the relevant fMRI responses cannot appear for perhaps 1000 ms or more after the relevant neuronal event. This is because fMRI measures a local change in blood flow or in some neural metabolite. Such changes require a substantial time to become evident after the relevant neural event has initiated the processes that produce them. That is, the time of a relevant fMRI change is delayed by the slower circulatory and metabolic changes that follow the neural activity, even though the machine itself can be very fast. Timing of the relevant neuronal activities can only be obtained by direct recordings of the electrical or magnetic changes that immediately are manifested by the relevant neural activities.

Electrophysiological Stimulation and Recording

The numerous studies with extracranial (scalp) recordings of event-related potentials (ERPs) over recent decades have not generally been sufficiently relevant to the issue of conscious experience. This is partly because the associated psychological tasks for the study participants were mostly those of detection of, recognition of, and responsiveness to signals, functions that could all potentially be performed unconsciously unless direct introspective reports of awareness are demanded. Scalp recordings also suffer from uncertainties of localization of the neuronal sources of the ERPs, although this is improving with recent technological advances. Whether the recording of magnetic rather than electrical fields will improve localizability significantly remains to be seen. Also, even when conscious reports are appropriately included, it is extraordinarily difficult to design experiments that may indicate causal interrelationships, as there is little possibility to manipulate one of the independent variables, the cerebral neural activity.

Intracranial electrodes can greatly improve both the localizability of electrical manifestations and the ability to manipulate neuronal functions in some

quantitative fashions by electrical stimulation. On the other hand, the availability of such electrodes in loci suitable for study in awake, responsive patients is not common, and the kinds of experimental procedures permitted by the therapeutic and risk factors are greatly restricted. Fruitful experimental avenues have, however, been found. Stimulation can elicit conscious experiences, especially when applied in the cerebral sensory systems. It can also reversibly interfere with or 'disrupt' normal cerebral functions. This latter ability can be used to investigate functions of cerebral areas where stimulation does not itself elicit any conscious responses; it has been employed fruitfully in recent years by GA Ojemann and colleagues to analyze the language functions of temporal (and other) cortical areas.

Many neural responses to stimulation can develop without leading to any conscious experience. For example, stimulating the cortical surface can produce large electrophysiological direct cortical responses (DCRs) with no awareness by the individual. Similarly, the primary evoked potential elicited by a peripheral sensory stimulus leads to no conscious sensation if the appropriate later event-related potentials do not accompany the primary one. Unique kinds and durations of neuronal activities appear to be required to elicit a conscious sensory experience, but not unconscious forms of stimulus detection.

In recent years the ability to deliver brief magnetic pulses repetitively has been achieved, thus permitting effective stimulation of a cortical area with a magnetic device placed on the overlying scalp. This makes it possible to stimulate the cortex without the invasive surgery required to place an electrical stimulating wire in a local region, expanding the pool of potential individuals greatly, to include normal individuals. However, magnetic stimulation may be deficient in some important ways, relative to an intracranial electrical stimulator. Stimulation with an electrode inserted intracranially can be more localizable and affect more identifiable groups of stimulated neural elements. Also, one can be more certain of a threshold level for eliciting a neural or a subjective response; with a magnetic stimulus, it is possible that each single stimulus pulse at an apparently threshold level is actually producing an undetected series of repetitive neural responses.

Time Factors in Conscious and Unconscious Mental Functions

Neural Delay for Sensory Experience

Substantial duration of specific cerebral activations, of up to about 500 ms, have turned up experimentally as one of the most interesting neuronal requirements. This implies there is a substantial delay before neuronal adequacy for a sensory experience is achieved. However, further evidence indicates there is a subjective referral of the experience back to the time of the initial sensory signal that normally arrives at the cerebral cortex within 15–25 ms after a sensory stimulus; the primary evoked potential represents the response to this early signal, which comes up by way of the fast, specific projection system. Subjectively, then, the skin sensation would appear to have no significant delay, even though the experience is not neuronally elicitable until some hundreds of milliseconds later. Such a subjective referral in the temporal dimension is analogous to that in the spatial dimension. Both referrals serve to project the subjective image closer to the spatial and temporal features of the real stimuli, even though the adequate neuronal representation distorts both the spatial pattern and the timing of the process.

Neural Delay for Intention to Act

When individuals perform a self-initiated voluntary motor act, a slow surface-negative potential is recordable at the vertex (the 'readiness potential,' or RP); this begins 550 ms before the muscle is activated, in a fully spontaneous act. However, conscious intention to act appears only 350 ms after onset of the RP, although 200 ms before the act. This indicates that initiation of a voluntary act is made unconsciously by the brain before there is any awareness of the wish to act. But, also, there is time after conscious intention appears during which the volitional process could be consciously stopped or vetoed.

'Time-On' Theory for Conscious versus Unconscious Functions

Based on their earlier lines of evidence indicating a requirement for a substantial duration of neural activities in order to elicit a conscious experience, whether a sensation or intention (to move now), in 1991 Libet and colleagues devised and tested a theory to explain how the brain may distinguish between conscious and unconscious mental functions. The theory proposes the duration, or 'time-on,' of appropriate neural activities as one controlling factor in achieving this distinction: durations must exceed minimum values of up to about 500 ms to achieve conscious awareness of a mental process, but durations distinctly below those minimum values can mediate unconscious mental functions (without awareness). A specific experimental test of the proposal was carried out in relation to detection of a sensory signal with and without awareness.

Unity of Conscious Experience

One of the most mysterious and seemingly intractable problems in the mind–brain relationship is that of the unitary and integrated nature of conscious experience. This phenomenon is somehow a product of a brain with an estimated 100 billion neurons, each of which may have thousands of interconnections with other neurons. There is increasing evidence that many functions of cerebral cortex are localized, apparently organized into specialized columns of neurons. In spite of the enormously complex array of structures and functions, whatever does reach awareness is experienced as unified and integrated.

A recent neurophysiological observation may offer one possible route to investigating the issue of experiential integration, or, as it is often referred to, the 'binding problem.' This is the discovery by Charles M Gray and Wolf Singer of widespread synchronization of oscillatory neuronal electrical potentials in response to a visual image. It has led to some speculation that a 'correlation' model (based on the widely occurring synchronization of some activities) might represent the neural coding for a unified mental image in an otherwise chaotic background. This speculation is still to be tested.

A testable field theory We may view subjective experience as if it were a field, produced by appropriate though multifarious neuronal activities of the brain. This conscious mental field (CMF) would have the attribute of a unitary, integrated experience or awareness, and it would also have a causal ability to affect or alter neuronal function. The theory of a CMF makes some crucial experimental predictions. If local areas of cerebral cortex could independently contribute to or alter the larger, unitary CMF, it should be possible to demonstrate such contributions when (1) that cortical area is completely isolated or cut off from neuronal communication with the rest of the brain, but (2) the area remains *in situ*, alive, and kept functioning in some suitable manner that sufficiently resembles its normal behavior. A fuller discussion of this theory and the experimental design to test it have been previously elaborated. The point here is to show that it is possible to formulate a theory and design an experimental test of it, even when the theory deals with the profound issues of conscious unity and with the question of whether the conscious function can actually influence brain function.

Consciousness: Neurophysiology and Visual Awareness in

S L Macknik and S Martinez-Conde, Barrow Neurological Institute, Phoenix, AZ, USA

Published by Elsevier Ltd.

Consciousness as a Neurophysiological Problem

Consciousness is the feeling of life's experience. It is a difficult concept to define precisely, however, because the word 'consciousness' means different things in different contexts. For instance, one may say that we are unconscious during sleep, despite the fact that, while asleep, we sometimes experience powerful and highly salient dreams (these dreams fit the definition of consciousness as stated in the first sentence above). Does this mean that it is possible to be conscious of our unconscious experiences (an obvious semantic contradiction)? Or does this mean that dreams during sleep are not really unconscious? Because of these and many other semantic difficulties, the theorist Francis Crick (who also described the structure of DNA with James Watson), and his collaborator Christof Koch, suggested that we set aside the semantics and avoid defining the term consciousness linguistically. Instead, we should strive to establish the neural correlates of experience, or the neural correlates of consciousness (NCC). By determining the NCC, we will eventually arrive at a neurophysiological definition of consciousness. Following from this proposal, the field is currently at work to define consciousness by its neurophysiological underpinnings. Today, thanks in large extent to Crick and Koch's efforts to validate the neurobiological study of consciousness, most neuroscientists and cognitive scientists are receptive to, and familiar with, the concept that consciousness, as with any other brain function (sensory, motor, emotional, and/or cognitive), must have a neurobiological substrate.

In studying the NCC, one of the main strategies has been to make use of the vast library of knowledge that neurobiologists have accumulated, for many decades, on the primate visual system. Therefore, our discussion of the neurophysiological underpinnings of consciousness focuses on those studies conducted in the visual system. The visual system of primates and humans offers the most extensive library we have available on the anatomy, physiology, and psychophysics of perceptual experience. The authors of this article have begun to research the nature of the neurobiological substrate of consciousness by isolating the neural correlates of a very small facet of our conscious experience: the experience of visibility, which is arguably the most basic function of the visual system. By 'visibility,' we do not mean the entire process of vision, but simply whether a stimulus is visible, or not. In this sense, visibility is the beginning of (or the necessary condition for) visual perception, not the conclusion. Without visibility, the stimulus cannot have significance or meaning: we perceive stimulus attributes such as color, motion, and depth only if the stimulus is also visible. Thus, when the underpinnings of visibility are discovered, they will include at least some of the circuits that cause awareness. This does not imply that visibility circuits must come before other types of circuits. For instance, it may not be necessary that a stimulus be visible before other types of processing take place (i.e., the corneal reflex). Whereas an unconscious visual reflex such as the accommodation of the eye may be a type of visual experience, stimuli that invoke visual reflexes are not necessarily consciously visible. That is, we are not aware of them despite the fact that they produce an appropriate and automatic response. As far as we know, visibility may take place subsequently to the processing of other visual attributes, or all visual attributes may come together in parallel, or there may be a disunity of processing for different attributes (as suggested by Semir Zeki), or there could be a combination of all these possibilities. Whatever the sequence of events that eventually leads to visual awareness, we cannot be aware of a visual stimulus, by our definition, unless it is visible.

Requirements for Establishing the NCC

Let us assume that visual awareness is correlated to brain activity within specialized neural circuits, and that not all brain circuits maintain awareness. It follows that the neural activity that leads to reflexive or involuntary motor action may not correlate with awareness because it does not reside within awareness-causing neural circuits.

By our proposal, a stimulus that has become just-noticeable, or just-visible, has already activated awareness-producing circuits. Thus, awareness is neither a final process in vision, nor a very low-level process, but it is instead an intermediate-level process. A less than just-noticeable stimulus may activate neurons within early visual areas, but within circuits that do not maintain awareness; therefore, the stimulus remains invisible. Varying the level of salience of a percept (for instance, by varying its brightness above and beyond the just-noticeable threshold) may equate to varying the level of visibility and awareness.

The idea of consciousness as an intermediate-level process, limited to intermediate brain areas, was first

proposed by Jackendoff. According to Jackendoff's proposal, the 'homunculus' in the frontal lobe is probably not conscious: we do not have direct conscious access to our thoughts, but only to images, sounds, speech, and other bodily feelings associated with intermediate brain representations. Jackendoff's theory provides a solution for the classical problem of the infinite regress of consciousness: given that the top homunculus is not conscious, there is no need for infinite homunculi at higher and higher levels in the brain in order to read the output of the previous, conscious homunculus.

Let us begin with the hypothesis that there is a minimal set of conditions necessary to achieve visibility, in the form of a specific type (or types) of neural activity within a subset of brain circuits. This minimal set of conditions will not be met if the correct circuits have the wrong type of activity (too much activity, too little activity, sustained activity when transient activity is required, etc). Moreover, if the correct type of activity occurs, but solely within circuits that do not maintain awareness, visibility will also fail. Finding the conditions in which visibility fails is critical to the research described here: although we do not yet know what the minimal set of conditions is, we can nevertheless systematically modify potentially important conditions to see if they result in stimulus invisibility. If so, the modified condition is potentially part of the minimal set.

To establish the minimal set of conditions for visibility we need to answer at least four questions:

1. What stimulus parameters are important to visibility?
2. What types of neural activity best maintain visibility (transient vs. sustained firing, rate codes, bursts of spikes, etc. – that is, what is the neural code for visibility)?
3. What brain areas must be active to maintain visibility?
4. What specific neural circuits within the relevant brain areas maintain visibility?

We must also determine the set of standards that will allow us to conclude that any given brain area, or neural circuit within an area, is responsible for generating a conscious experience. Parker and Newsome developed a "list of idealized criteria that should be fulfilled if we are to claim that some neuron or set of neurons plays a critical role in the generation of a perceptual event." If one replaces the words "perceptual event" with "conscious experience," Parker and Newsome's list can be used as an initial foundation for the neurophysiological requirements needed to establish whether any given neuron or brain circuit may be the neural substrate of awareness. The list is as follows:

1. The responses of the neurons and of the perceiving subject should be measured and analyzed in directly comparable ways.
2. The neurons in question should signal relevant information when the organism is carrying out the chosen perceptual task. Thus, the neurons should have discernable features in their firing patterns in response to the different external stimuli that are presented to the observer during the task.
3. Differences in the firing patterns of some set of the candidate neurons to different external stimuli should be sufficiently reliable in a statistical sense to account for, and be reconciled with, the precision of the organism's responses.
4. Fluctuations in the firing of some set of the candidate neurons to the repeated presentation of identical external stimuli should be predictive of the observer's judgment on individual stimulus presentations.
5. Direct interference with the firing patterns of some set of the candidate neurons (e.g., by electrical or chemical stimulation) should lead to some form of measurable change in the perceptual responses of the subject at the moment that the relevant external stimulus is delivered.
6. The firing patterns of the neurons in question should not be affected by the particular form of the motor response that the observer uses to indicate his or her percept.
7. Temporary or permanent removal of all or part of the candidate set of neurons should lead to a measurable perceptual deficit, however slight or transient in nature.

However, visual circuits that may pass muster with Parker and Newsome's guidelines may nevertheless fail to maintain awareness, as explained below. To isolate awareness-maintaining processes, some additional strategies and principles must be added to guide the search for the NCC.

The first strategy concerns the use of illusions as the tool of choice to test whether a neural tissue maintains awareness. Visual illusions, by definition, dissociate the subject's perception of a stimulus from its physical reality. Thus, visual illusions are powerful devices in the search for the NCC, as they allow the differentiation of neural responses to the physical stimulus from neural responses that correlate to perception. Our brains ultimately construct our perceptual experience, rather than reconstruct the physical world. Therefore, an awareness-maintaining circuit should express activity that matches the conscious

percept, irrespective of whether it matches the physical stimulus. Neurons (circuits, brain areas) that produce neural responses that fail to match the percept provide the most useful information because they can be ruled out, unambiguously, as part of the NCC. The result is that the search for the NCC can be focused to the remaining neural tissue. Conversely, neurons that do correlate with perception have not necessarily been shown to be critical to awareness, as they could potentially be maintaining awareness or they may simply play a support role (among other possibilities) without causing awareness themselves; they would correlate with perception either way.

The second strategy derives from a major contribution of Crick and Koch's framework: the distinction between explicit and implicit representations. In an explicit representation of a stimulus feature, there is a set of neurons that represent that feature without substantial further processing. In an implicit representation, the neuronal responses may account for certain elements of a given feature; however, the feature itself is not detected at that level. For instance, all visual information is implicitly encoded in the photoreceptors of the retina. The orientation of a stimulus, however, is not explicitly encoded until the level of area V1, where orientation-selective neurons and functional orientation columns are first found. Crick and Koch propose that there is an explicit representation of every conscious percept.

We propose the following corollary to Crick and Koch's idea of explicit representation. Before one can test a neural tissue for its role in the NCC, such tissue must be shown to explicitly process the test stimulus. This corollary constrains the design of neurophysiological experiments aimed to test the participation of specific neurons, circuits, and brain areas in the NCC.

For instance, if one found that retinal responses do not correlate with auditory awareness, such a discovery would not carry great weight. The neurons in the eye do not process auditory information, and so it is not appropriate to test their correlation to auditory perception. However, this caveat also applies to more nuanced stimuli. What if area V1 was tested for its correlation to the perception of faces versus houses? Faces and houses are visual stimuli, but area V1 has never been shown to process faces or houses explicitly, despite the fact that visual information about faces and houses must implicitly be represented in area V1. Therefore, one cannot test area V1's correlation to awareness using houses versus faces and expect to come to any meaningful conclusion about V1's role in the NCC. Because that form of information is not explicitly processed in V1, it would not be meaningful to the NCC if neurons in V1 failed to modulate their response when the subject is presented with faces versus houses.

It follows that some stimuli are inadequate for localizing awareness within neural tissues, because no appropriate control exists to test for their explicit representation. For example, binocular rivalry stimuli pose a special problem in the study of visual awareness. Binocular rivalry (discovered by Charles Wheatstone in 1838) is a dynamic percept that occurs when two disparate images that cannot be fused stereoscopically are presented dichoptically to the subject (i.e., each image is presented independently to each of the subject's eyes). The two images (or perhaps the two eyes) appear to compete with each other, and the observer perceives repetitive undulations of the two images, so that only one of them dominates perceptually at any given time (if the images are large enough then binocular rivalry can occur in a piecemeal fashion, so that parts of each image are contemporaneously visible).

This bistable stimulus has been used as a tool to assess the neuronal correlates of visibility but has generated controversy because of conflicting results. Some human functional magnetic resonance imaging (fMRI) studies report that blood oxygenation level-dependent (BOLD) activity in V1 correlates with visual awareness of binocular rivalry percepts. In contrast, other human fMRI studies, and also single-unit recording studies in primates, suggest that activity in area V1 does not correlate with visual awareness. One possible reason for this discrepancy is that none of these studies determined that the visual areas tested contain the interocular suppression circuits necessary to mediate binocular rivalry. That is, since binocular rivalry is a process of interocular suppression, the neural tissue underlying the perception of binocular rivalry must be shown to produce interocular suppression – explicitly. Otherwise, it cannot be demonstrated that binocular rivalry is a valid stimulus for testing the NCC in such tissue. Thus, awareness studies using binocular rivalry are valid only in those areas that have been shown to maintain interocular suppression. If binocular rivalry fails to modulate activity within a visual area, one cannot know, by using binocular rivalry alone, whether the perceptual modulation failed because awareness is not maintained in that area or because the area does not have circuits that drive interocular suppression. This is more than just a theoretical possibility: we have shown, as we describe further below, that the initial binocular neurons of the early visual system (in areas V1 and V2) are binocular for excitation, but they nevertheless fail to process interocular suppression explicitly.

Since there is no monoptic form of binocular rivalry, one cannot use binocular rivalry by itself to test the strength of interocular suppression. One could use binocular rivalry in tandem with a different stimulus, such as visual masking stimuli (described below), to test for the explicit representation and strength of interocular suppression. But in such a case, the role of the tissue in maintaining visibility and awareness would have been probed by the visual masking stimuli, thus obviating the need for binocular rivalry stimuli. Because one must rely on non-binocular rivalry stimuli to determine the explicit representation and strength of interocular suppression in a given area, it is not possible to unambiguously interpret the neural correlates of perceptual state using binocular rivalry alone.

Visual masking is a type of visual illusion that has been used as a primary tool to isolate the NCC. Visual masking illusions come in different flavors, but in all of them a visible target (a visual stimulus, such as a rectangle), or some specific aspect of a visible target (for instance, the semantic content of a word displayed visually), is rendered invisible by changing the context in which the target is presented, without actually modifying the physical properties of the target itself (Figure 1). That is, the target becomes less visible due solely to its spatial and/or temporal context. Visual masking illusions allow us to examine the brain's response to the same physical target under varying levels of visibility. All we need to do is measure the perceptual and physiological effects of the target when it is visible versus invisible and we will determine many, if not all, of the conditions that cause visibility.

Our visual masking studies have shown that binocular neurons in areas V1 (the first stage in the visual hierarchy where information from the two eyes is combined) and V2 of humans and monkeys can integrate excitatory responses between the eyes. However, these same neurons do not express interocular suppression between the eyes. That is, binocular neurons in V1 are largely binocular for excitation while nevertheless being monocular for suppression. In summary, most early binocular cells do not explicitly process interocular suppression, and so these neurons cannot process binocular rivalry explicitly. Thus, binocular rivalry is an inappropriate stimulus to probe these visual areas for the NCC. This finding renders the results from binocular rivalry studies in the early visual system uinterpretable with respect to localizing the NCC: the fact that early visual areas are not correlated to awareness of binocular rivalry is equivalent in significance to concluding that these areas are not correlated to auditory awareness.

Figure 1 Temporal sequencing of stimuli in backward visual masking. A target and/or mask presented alone, or in simultaneous combination, is visible. When the mask is presented after the target with the appropriate timing (backward masking), the target is rendered invisible. Visual masking illusions provide a powerful tool for investigating the neural underpinnings of visibility and invisibility.

We propose that, to test for explicit processing in neural tissue, one should use a visual illusion with two modes of operation: one mode to ensure that the tissue processes the stimulus explicitly, and one mode to test the correlation to awareness. In visual masking, the monoptic mode establishes that the neural tissue processes masking stimuli explicitly, and then the dichoptic mode can be used to probe the NCC.

The third strategy involves controlling for the effects of attention when designing experiments to isolate the NCC. Attention is a process in which the magnitude of neural activity is either enhanced or suppressed by high-level cognitive mechanisms. Attention may increase or decrease the likelihood of awareness of a given visual stimulus. But attention is a process distinct from awareness itself, as shown by Phillip Merikle and others. For instance, low-level bottom-up highly salient stimuli (such as flickering lights) can lead to awareness and draw attention, even when the subject is actively attending to some other task, or not attending to anything (i.e., when the subject is asleep). Thus, attention can manipulate awareness, but the opposite is also true. This double-dissociation suggests that the two

processes are mediated by separate brain circuits. It follows that in experiments to isolate the NCC, if the subject is conducting a task that requires attention to the stimulus of interest, then attentional and awareness processes may be confounded. Therefore, experiments to isolate the NCC should control for the effects of attention. If experimental manipulation of attentional state affects the magnitude of neural response, then the neural mechanism of interest may not be related to awareness, but instead to attention.

Therefore, we add the following three criteria to Parker and Newsome's list:

8. The candidate neurons should be tested with an illusion that allows dissociation between the physical stimulus and its perception. If the candidate set of neurons is capable of maintaining awareness, the neural responses should match the subjective percept, rather than the objective physical reality of the stimulus.
9. The candidate neurons must explicitly process the type of information or stimulus used to test them.
10. The responses of the neurons, and of the perceiving subject, should be measured with experimental controls for the effect of attention.

Techniques to Study the Neurophysiology of Consciousness

The search for the NCC requires the localization of circuits in the brain that are sufficient to maintain awareness. To this end, brain areas have been sought within the ascending visual hierarchy that correlate, or more importantly, fail to correlate, with visual perception. For instance, the circuits of the brain that are critical to the visibility of targets must be circuits whose activity is suppressed during target invisibility due to visual masking. A corollary: if we identify circuits in which the target response is not suppressed during masking, we can rule out those circuits as sufficient to maintaining visual awareness. This section discusses the techniques used to identify parts of the brain whose activity correlates with visibility and visual awareness.

Table 1 compiles some of the neurophysiological techniques used in awareness research, as well as their strengths and weaknesses. All of these techniques may be paired with psychophysical measures of awareness. No single technique is perfect, but the combination of single-unit electrophysiology with anatomical analysis, fMRI, macroscopic optical recording, and two-photon laser scanning microscopy (2PLSM) may be most powerful to discover the cortical circuits that maintain visual awareness *in vivo*.

Single-Unit Recordings Accompanied by Anatomical Analysis

David Hubel and Torsten Wiesel championed the combined use of single-unit recordings and anatomical staining techniques to achieve high-resolution cortical maps. The tungsten microelectrode, invented by Hubel, was similar to the electrodes used in humans by neurosurgeons such as Wilder Penfield and Benjamin Libet, but it was about 100–1000 times smaller at the tip, so it could be used to discover meaningful, if limited (on the scale of tens of microns), functional patterns within brain areas. Hubel and Wiesel combined electrode penetrations that were angled perpendicularly, obliquely, and tangentially to the cortical surface, with histological staining techniques to reconstruct the electrode tracks in postmortem tissue. Clever application of these techniques led to the first model (on the scale of tens to hundreds of microns) of the two-dimensional pattern of visual function across the surface of the primary visual cortex. They discerned functional domains: repeating patterns of physiological circuits across the surface of the cortex, such as ocular dominance and stimulus orientation columns. They also determined general principles of structure and function of the cortical layers: this added a third dimension to their functional anatomical circuit model.

Ultimately, Hubel and Wiesel found that mapping the three-dimensional cortex with a one-dimensional device was too limiting. By combining their recordings with anatomical staining techniques, such as the Nauta method, radioactive 2-deoxyglucose uptake, horseradish peroxidase staining, and radioactive amino acid pathway tracing, they were able to better relate their electrode tracks to the direct postmortem analysis of cortical and subcortical maps.

Modern versions of these methods are used today to determine the physiological underpinnings of visibility and awareness in anesthetized and awake monkeys (Figure 2) and humans.

Functional Magnetic Resonance Imaging

fMRI is the magnetic imaging of blood flow across differential behavioral conditions. Magnetic resonance imaging (MRI) scanners allow the radiologist to view the density of protons in the various tissues of the body in three-dimensional space, which essentially results in a very high resolution X-ray like image of the internal structures of the body. Blood is one of the tissues that can be imaged in the MR scanner. The magnetic properties of blood change as a function of neural activity: neural activity causes neurons to use more oxygen from the blood, and oxygenated blood has different magnetic properties

Table 1 Summary of neurophysiological techniques to study the NCC

Techniques	*Noninvasive*	*Awake*	*High temporal resolution*	*In vivo application*	*Directly visualizes macroscopic maps*	*High spatial resolution*	*Provides 3-D anatomical reconstruction*	*Provides subcellular anatomical reconstruction*	*Samples from deep structures*	*Provides laminar mapping*

Figure 2 The electrophysiology of visual masking. (a) The standing wave of invisibility (SWI): a temporal sequence of target and mask presentations that results in very powerful masking of the target. (b) A single-neuron recording from the lateral geniculate nucleus (LGN) of a monkey. The stimulus presentation layout on the monkey's computer monitor is illustrated in the inset of each row. The cross is the monkey's fixation point. The target (T) is centered over the receptive field of the LGN neuron and color-coded in black (actual presentation color was white on a black background). The mask (M) is color-coded in purple (actual color same as target) and is presented at four different distances from the target (one distance per row). The physiological traces are represented in black (when the target was presented alone), purple (when the mask was presented alone), and blue (when the target and mask were presented together in the SWI condition). Notice that when the mask is near the target, the target response during the SWI condition (blue) is lower than the target response when presented alone; this is the neural correlate of visual masking. As the mask is moved away from the target, the target response during the SWI condition recovers its magnitude, just as the target becomes more visible perceptually. Reproduced from Macknik SL, Martinez-Conde S, and Haglund MM (2000) The role of spatiotemporal edges invisibility and visual masking. *Proceedings of the National Academy of Sciences of the United States of America* 97: 7556–7560, with permission from the National Academy of Sciences of the United States of America.

than deoxygenated blood. Therefore, functional MR imaging of blood flow (fMRI) is particularly amenable to magnetic imaging analysis. The basis is the following: iron (deoxygenated hemoglobin) is magnetic, whereas rust (oxygenated hemoglobin) is not magnetic. Thus, by isolating the parts of the brain in which blood changes its magnetic properties in correlation to a task, we can infer where the neurons of the brain have responded functionally. It was this line of reasoning that led Ogawa and colleagues to discover that BOLD signal can be used to map brain function noninvasively.

fMRI has sparked a major revolution in the discovery and mapping of human cortical brain areas. However, the method has relatively low spatial resolution (on the order of millimeters, rather than the micron resolution we enjoy with anatomical staining techniques). It also has low temporal resolution (the hemodynamic neural response function occurs over seconds, rather than the microsecond resolution we enjoy with electrophysiology).

Figure 3 shows a map of many of the retinotopic visual areas that may be relevant to maintaining visual awareness. These visual areas can be probed with illusory stimuli, such as visual masking stimuli, to determine whether BOLD activity correlates with the subject's perception (Figure 4).

Macroscopic Optical Imaging

Lack of oxygen not only changes blood from nonmagnetic to magnetic, but also turns its color from red (rusty) to bluish (iron). The regions of the brain's surface that are active during a given task remove more oxygen from the blood, and so these regions appear bluer than the regions where neurons are less active. Gary Blasdel and Guy Salama discovered that when red light was shone onto the exposed surface of the cortex, more red photons were absorbed by the active regions, as blue blood absorbs more red light than red blood. This decrease in reflectance can be measured with a video camera to map cortical function.

fMRI and macroscopic optical recording of intrinsic signals have the same physical substrate (blood oxygenation level), and therefore the same slow temporal resolution. However, macroscopic optical recording enjoys a much higher spatial resolution than fMRI: the resolution of the capillary network just below the brain's surface is tens to hundreds of microns, depending on the tissue.

Figure 5 illustrates how macroscopic optical maps may be used to examine area V1 responses to standard visual stimuli. Figure 6 shows an optical image

Figure 3 Example of retinotopy mapping from a human subject. Visual areas delineated by retinotopic mapping analysis are indicated in different colors. Reproduced from Tse Pu, Martinez-Conde S, Schlegel AA, and Macknik SL (2005) Visibility, visual awareness, and visual masking of simple unattended targets are confined to areas in the occipital cortex beyond human V1/V2. *Proceedings of the National Academy of Sciences of the United States of America* 102: 17178–17183, with permission from the National Academy of Sciences of the United States of America.

of V1 responses to visual masking illusions, such as the standing wave of invisibility.

Two-Photon Laser Scanning Microscopy

One of the great problems with standard light microscopy is that the light source is inevitably brighter than the tissue of interest, which drastically decreases the quality of the imaging. To make matters worse, the images are also contaminated by light coming from sources outside of the plane of focus. The invention of fluorescence microscopy was a major leap forward for microscopic analysis: it allowed for the illumination of tissue with one color of light (the excitation wavelength) while imaging only the fluoresced photons of a different color (the emission wavelength). Thus, fluorescence microscopes filter out the photons outside the emission wavelength, which improves the quality of the imaging greatly. The main problem with fluorescent imaging in biological tissues is that fluorescence, by its quantum mechanical nature, turns a high-energy (bluish) photon into a lower energy (reddish) photon. Because brain tissue tends to absorb blue photons, one must use extremely high-powered light sources to image tissues more than ~100 microns deep; this carries the risk of burning the brain.

In 1990, Denk et al. used two-photon fluorescence excitation to work around these problems. The idea behind the two-photon quantum effect is that a fluorescent molecule, which has an excitation wavelength of, say, 400 nm, will fluoresce a photon when excited by two photons of 800 nm (which each have exactly half the energy of a single 400 nm photon). So the same fluorescent dye will fluoresce a greenish emission photon after receiving a single bluish (400 nm) excitation photon, or two simultaneous infrared (800 nm) photons. The advantage is that the brain is relatively transparent to infrared light (as compared with blue light) and so one can image much deeper and with a much lower power light source (i.e., infrared) than when using a blue light source. The illumination method is moreover inherently focused on a given focal plane because the two infrared photons must land on the same exact fluorescent dye molecule within femptoseconds of each other to result in the emission of a green photon. Any excitation (infrared) light that is scattered by irrelevant tissue outside the focal point does not cause noise in the imaging (it is simply lost), and so only the single point of focus (in three dimensions) of the laser will generate fluorescence. Because of these features, 2PLSM solves all of the problems above: it combines fluorescence (which allows one to filter out noise from the light source) with the ability to use an infrared light source to image deeply within the cortex (on the order of 1 mm), and furthermore to maintain an optical resolution that is roughly the size of a single photon.

2PLSM has not yet been used to examine circuits that are critical to visibility or consciousness. However, it is only a matter of time before this method is employed to determine the microscopic neural interactions that are the fundamental basis of awareness.

Figure 4 Human cortical responses to visible and invisible stimuli. Green shading represents the various cortical brain regions. (a) The union of responses from 17 normal human subjects viewing target stimuli alone (blue). These blue areas represent the areas of the brain that encode simple unattended target stimuli. The yellow areas represent the cortical modulation during visual masking of targets. Therefore, the yellow areas represent the portions of the occipital lobe that encode target visibility. These results suggest that awareness of simple attended targets is processed within the occipital cortex. (b) Further analysis of the occipital lobe's role in awareness of visibility, in an individual subject. Here the yellow regions represent the occipital areas that correlate with target perception during monoptic visual masking, but not during dichoptic visual masking. Since these areas explicitly process visual masking but fail to correlate with dichoptic masking, they can be ruled out as sufficient for maintaining the awareness of targets. The pink areas correlate with target perception during both monoptic and dichoptic masking and thus cannot be ruled out. The results from (a, b) combined suggest that awareness of simple unattended targets is maintained by circuits downstream of area V2 but nevertheless confined to the occipital lobe. Reproduced from Tse Pu, Martinez-Conde S, Schlegel AA, and Macknik SL (2005) Visibility, visual awareness, and visual masking of simple unattended targets are confined to areas in the occipital cortex beyond human V1/V2. *Proceedings of the National Academy of Sciences of the United States of America* 102: 17178–17183, with permission from the National Academy of Sciences of the United States of America.

Current Findings on Visibility and Visual Awareness

We have begun to establish the minimal set of conditions necessary to maintain the awareness of simple unattended stimuli. We have determined that the target's spatiotemporal edges are crucial to the target's perceptual visibility. Visibility at the spatiotemporal edges is encoded by transient bursts of spikes in the early visual system. If these bursts are inhibited, visibility fails. The specific circuits that maintain visibility are not yet known, but we propose that lateral inhibition plays a critical role in sculpting our perception of visibility, both by causing interactions between stimuli positioned across space and by shaping the responses to stimuli across time.

We have tested several retinotopic visual areas of the early visual cortex for their correlation to visibility, using visual masking illusions. We first confirmed that the perceptual strength of visual masking is equivalent in monoptic and dichoptic conditions. This established that neurons that may potentially maintain visual awareness should correlate equally well to both monoptic and dichoptic masking. Next, we established that all retinotopic areas tested (lateral geniculate nucleus (LGN), V1, V2, V3, and V4) explicitly processed visual masking with monoptic visual masking illusions. We retested with dichoptic masking and found that activity in the LGN, V1, and V2 did not match perception. Therefore, we were able to rule out these areas as part of the NCC. Only V4 responses (and, weakly, area V3

Figure 5 The optical image of a flickering bar. The left column represents the layout of the stimuli used to stimulate the cortical window imaged in the right column. Top: Image of the area V1 cortical intrinsic signal generated by a flickering bar 50 ms on and 100 ms off, 0.13° wide with an orientation of 132°. The imaged patch is 1 cm^2 and was approximately 10–12° below and to the left of the foveal representation and subtended about 4° of visual angle (as measured with microelectrode penetrations at each edge of the image) at the anterior-medial border of the operculum. The vertical meridian is parallel to the lower edge of the image; the fovea is to the right. Bottom: Image of the intrinsic signal generated by a flickering bar 0.64° wide in the same piece of cortex (the center of the bar was also shifted approximately 0.29° away from the fovea). Notice that the widened optical image of the bar has shifted in position and split into two edges, showing that edges generate much stronger signals that the interiors of objects at the level of V1. Reproduced from Macknik SL, Martinez-Conde S, and Haglund MM (2000) The role of spatiotemporal edges invisibility and visual masking. *Proceedings of the National Academy of Sciences of the United States of America* 97: 7556–7560, with permission from the National Academy of Sciences of the United States of America.

responses) matched perception, making area V3 the lower boundary in the visual hierarchy for the processing of visual awareness. Moreover, we found that only areas within the occipital lobe correlate with awareness of simple unattended targets. This finding provided us with the first experimental evidence of an upper boundary (the edge of the occipital lobe) for the processing and maintenance of visual awareness. These results localized visual awareness of simple unattended targets to a relatively small part of the brain, between area V3 and the edge of the occipital lobe. Future research will more precisely localize the specific circuits within this region that maintain awareness.

The results support Jackendoff's theory that consciousness is an intermediate-level process, and not a low- or high-level process. However, it remains possible (contrary to Jackendoff's proposal) that higher brain areas, such as the frontal lobes, maintain awareness of higher cognitive functions and that only sensory awareness is maintained at intermediate levels.

Future Challenges

The field of the neurobiology of consciousness is at its very incipient stage. We and others have begun to narrow down the potential brain regions or circuits that may maintain various types of sensory awareness. However, we are far from having a solid understanding of the NCC. Once the NCC are localized, a bigger challenge will be to determine the specific nature of the underlying circuits that maintain awareness. This is further complicated by the possibility that there may be multiple different circuits that maintain awareness of different types of events.

On the bright side, the field is converging on a set of techniques and methods that can be used to test neural tissue at multiple levels of resolution, both

Figure 6 Optical imaging of the standing wave of invisibility (SWI). (a) A visual target with a width of 0.12° and the correlated optical image. (b) Two masking stimuli presented without a target and the correlated response. (c) The SWI stimulus (target and masks were never presented on the display at the same time) and the correlated response. Notice that the image of the target in (c) is now missing, compared to the response seen in (a), despite the fact that both targets were physically identical. invasively and noninvasively. Once these techniques are fully developed, long hours in the lab and clever experimental design will accomplish much of the remaining work.

Conciousness: Philosophy

This article is reproduced from the previous edition © 2004, Elsevier B.V.

Consciousness is everything we experience, from a city scene teeming with shapes, colors, and noises to darkness and silence. It has been defined as what abandons us every night when we fall into dreamless sleep and returns the next morning when we wake up. We know that consciousness depends on the functioning of the brain; yet many philosophers have claimed that understanding how the brain produces subjective experience may lie forever beyond the realm of scientific explanation. Scientists often find it safer to dispense with explanations and to explore instead which parts of the brain are important for consciousness and which aspects of neual activity accompany it. For example, clinical observations and classic experiments have shown that the level of consciousness is associated with an activated electroencephalogram. Brain lesions have demonstrated that different brain areas are important for specific contents of consciousness. New experimental tools are refining our appreciation of when and where changes in neural activity are correlated with changes in conscious experience.

Important as it is, however, gathering data on the neural correlates of consciousness is no substitute for a principled explanation. Otherwise, how can we establish whether newborn babies or animals are conscious and to what extent, or whether a conscious artifact can be constructed with nonneural ingredients? And how can we determine, in the absence of verbal reports, whether a person with akinetic mutism – awake with eyes open, but mute, immobile, and unresponsive – is conscious or not, or how much consciousness there is during sleepwalking or psychomotor seizures? A genuine understanding of consciousness requires, in addition to empirical studies, a theoretical analysis.

The Two Problems of Consciousness

Two main problems need to be addressed. The first problem has to do with the necessary and sufficient conditions that determine whether consciousness is present or not. For example, why are changes of neural activity in thalamocortical regions so important for conscious experience, whereas changes in activity in cerebellar circuits are not, given that the number of neurons in the two structures is comparable? Why is consciousness strikingly reduced during deep slow-wave sleep, given that the level of neuronal firing is similar to that of wakefulness?

The second problem has to do with the necessary and sufficient conditions that determine the specific nature of consciousness. For example, what makes the activity of specific cortical areas contribute specific dimensions of conscious experience – auditory cortex to sound, visual cortex to shapes and colors? What aspect of neural organization is responsible for the fact that shapes look the way they do, and different from the way colors appear or pains feel? Solving the first problem means that we would know whether a physical system can generate consciousness and to what extent – the *level* of consciousness. Solving the second problem means that we would know what kind of consciousness is generated – the *content* of consciousness.

Consciousness and the Brain: Facts and Enigmas

Let us briefly consider the first problem by examining some facts about consciousness and the brain and some of the baffling questions they pose:

1. Consciousness is produced by certain parts of the brain and not, or much less, by others. For example, we know that certain portions of the thalamocortical system are essential for consciousness. Other regions of the brain, such as the cerebellum, are not and can be stimulated or lesioned without giving rise to changes in conscious experience. Yet the cerebellum has as many neurons and is every bit as complicated as the thalamocortical system. Why is consciousness associated with some but not with other neural structures?
2. Consciousness is associated with a distributed neural system: there is no single area where it all comes together. For example, different areas of the thalamocortical system each contribute different dimensions to conscious experience, but no single area is solely responsible for consciousness.
3. Consciousness can be split if the thalamocortical system is split. Studies of split brain patients, whose corpus callosum was sectioned for therapeutic reasons, show that each hemisphere has its own, private conscious experience.
4. Within the thalamocortical system, the activity of certain neurons correlates well with conscious experience; that of others does not. For example, during binocular rivalry, the activity of certain visual cortical neurons follows what the subject consciously

perceives, while that of other neurons follows the stimulus, whether the subject is perceiving it or not. What determines whether the firing of neurons within the thalamocortical system contributes directly to consciousness or not?

5. Many neural processes in the thalamocortical system can influence conscious experience yet do not seem to contribute directly to it. For example, what we see and hear depends on elaborate computational processes in the cerebral cortex that are responsible for object recognition, depth perception, and language parsing; yet such processes remain largely unconscious.

6. Neural activity in sensory afferents to the thalamocortical system usually determines what we experience at any given time. However, such neural activity does not appear to contribute directly to conscious experience. For example, although retinal cells can tell light from dark and convey that information to visual cortex, their rapidly shifting firing patterns do not correspond well with what we perceive. Moreover, a person who becomes retinally blind as an adult continues to have vivid visual images and dreams. Why is it that the activity of retinal cells *per se* does not contribute directly to conscious experience, but only indirectly through its action on thalamocortical circuits?

7. Neural processes occurring in brain regions whose inputs and outputs are closely linked to the thalamocortical system, such as the basal ganglia, are important in the production and sequencing of action, thought, and language. Yet such processes do not seem to contribute directly to conscious experience. Why is this so?

8. When first learning a new task, we are conscious of every detail of the task; we are slow, make mistakes, and must make an effort. When we have learned the task well, we become much better, faster, and effortless, but also less aware of it. During learning, many cortical areas are involved, whereas well-learned tasks may employ different neural circuits. Why does automatic performance become less conscious?

9. The mode of neuronal firing in the thalamocortical system is important for consciousness. For example, cortical neurons fire almost as much during deep slow-wave sleep as during wakefulness, but the level of consciousness is much reduced in the former condition. Similarly, in absence seizures, neural firing is high and synchronous; yet consciousness is seemingly lost. Why is this the case?

10. The firing of the same cortical neurons may correlate with consciousness at certain times, but not at others. For example, multiunit recordings in the primary visual cortex of monkeys show that, after a stimulus is presented, the firing rate of many neurons increases regardless of whether the animal reports seeing a figure or not. After 80–100 ms, however, their discharge accurately predicts the conscious detection of the figure. What determines when the firing of the same cortical neurons contributes to conscious experience and when it does not?

Many more facts and puzzles could be added to this list. This state of affairs is not unlike the one biologists faced when, knowing a great deal about similarities and differences between species, fossil remains, and breeding practices, they still lacked a theory of how evolution might occur. What was needed, then as now, were not just more facts, but a theoretical framework that could make sense of them. Unfortunately, theoretical approaches that try to provide a coherent explanation for some of the basic facts about consciousness and the brain are few and far between. Here, in order to offer a tentative but at least unified perspective on the issues that need to be addressed, we discuss a theoretical approach, according to which consciousness is related to the brain's ability to integrate information. This theory comprises (a) an examination of phenomenology indicating that consciousness has to do with information integration, (b) a definition of what information integration is and how it can be measured, (c) an attempt at accounting for basic facts about consciousness and the brain, and (d) some corollaries and predictions.

Phenomenology: Consciousness as Information Integration

In this view, perhaps the most important thing to realize about consciousness is that, when one experiences a particular conscious state – for example, the one experienced when reading *this particular phrase* here and now – each of us is gaining access to an extraordinarily large amount of information. This information has nothing to do with how many letters or words we can take in at any one time, which is a very small number. Instead, the occurrence of a particular conscious state is extraordinarily informative because of the very large number of alternative conscious states that it rules out. Just think of all possible written phrases you could read, multiply them by the number of possible fonts, ink colors, sizes in which you could read them; then think of the same phrases spoken aloud, or read and spoken, or think further of all other possible visual scenes you might experience, multiplied by all possible sounds you might hear at the same time, by all possible moods you might be in, and so on *ad libitum*.

The point is simply this: every time we experience a particular conscious state out of such a huge repertoire of possible conscious states, we gain access to a correspondingly large amount of information. This conclusion is in line with the classical definition of information as reduction of uncertainty among a number of alternatives. For example, tossing a fair coin and obtaining heads corresponds to $\log_2(2) = 1$ bit of information, because there are just two alternatives; throwing a fair die yields $\log_2(6) = 2.59$ bits of information, because there are six equally likely possibilities. Similarly, the information generated by the occurrence of a particular conscious state lies in the large number of different conscious states that *could potentially* have been experienced but were not. Although no attempt has been made to estimate the size of the repertoire of conscious states available to a human being, it is clear that such repertoire must be extraordinarily large, and so is the information yielded by entering a particular conscious state out of this repertoire. This point is so simple that its importance has been overlooked.

Another key aspect of this theory is that the information associated with the occurrence of a conscious state is information from the perspective of an *integrated* system. When each of us experiences a particular conscious state, that conscious state is experienced as an integrated whole – it cannot be subdivided into independent components, that is, components that are experienced independently. For example, the conscious experience of *this particular phrase* cannot be experienced as subdivided into, say, the conscious experience of how the words look independently of the conscious experience of how they sound in our mind. Similarly, we cannot experience visual shapes independently of their color, or perceive the left half of the visual field of view independently of the right half. Furthermore, we cannot simultaneously experience both aspects of an ambiguous figure, nor can we simultaneously think two different thoughts. If we could, this would be tantamount to having two separate 'centers' of consciousness. Separate centers of consciousness exist, of course, but each is a different person with a different brain (or a different hemisphere of a split brain). Indeed, if two people each experience a different conscious state in two separate rooms, the information to which each person gains access depends only on the repertoire of conscious states available to that person. A superordinate consciousness associated with the joint states of two different people considered together is an absurd notion, because the two people are causally independent and do not constitute an integrated system.

Finally, it is important to appreciate that every conscious experience takes some time. Studies of how a percept is progressively specified and stabilized – a process called *microgenesis* – indicate that it takes up to 100–200 ms to develop a fully formed sensory experience and that the surfacing of a conscious thought may take even longer. Other evidence indicates that a single conscious moment cannot extend beyond 2–3 s. Although it is arguable whether conscious experience unfolds more like a series of discrete snapshots or a continuous flow, its time scale is certainly comprised between these lower and upper limits. Thus a phenomenological analysis indicates that consciousness has to do with the ability to integrate a large amount of information over a short period of time.

Measuring Information Integration

If consciousness is integrated information, then a physical system should be able to generate consciousness to the extent that it can rapidly enter any of a large number of available states (information); yet it cannot be decomposed into a collection of causally independent subsystems (integration). How can one identify such an integrated system, and how can one measure its repertoire of available states?

At first sight, it might seem that all one needs to do is choose a system, for example, the brain, and measure the repertoire of states that are available to it with their probability. One could then calculate the information associated with the occurrence of each brain state, just as one can measure the information associated with tossing a coin or a die, by using the entropy function, that is, the weighted sum of the logarithm of the probability of system states: $H = -\Sigma p(s)\log_2 p(s)$. Measuring the available repertoire would easily account for why a seemingly similar task can be performed unconsciously (or nearly so) by a simple device and consciously by a human being. For example, when a retinal cell, or even a photodiode – a simple semiconductor device that changes its electrical resistance depending on the illumination – detects complete darkness, it generates a minimal amount of information, since it can only discriminate between darkness and light. When we consciously detect complete darkness, however, we perform a discrimination that is immensely more informative: we are not just ruling out light, but an extraordinary number of other possible states of affairs, including every possible frame of every possible movie, every possible sound, and every possible combination of them.

Measuring information this way, however, is insufficient, because it is completely insensitive to whether the information is available to an integrated system. To give a simple example, consider a collection of 1 million photodiodes constituting the sensor chip of a digital camera. From the perspective of an external

observer, such a chip can certainly enter a very large number of different states, as could easily be demonstrated by presenting it with all possible input signals. However, because of the absence of any physical interaction among the photodiodes, the chip as such cannot integrate any information: the state of each element is causally independent of that of other elements. In other words, what we have is 1 million photodiodes with a repertoire of two states each, rather than a single integrated system with a repertoire of $2^{1\,000\,000}$ states. Thus to measure integrated information, it is essential to know whether a set of elements constitutes a causally integrated system or can be broken down into a number of independent or quasi-independent subsets among which no information can be integrated.

To see how one can achieve this goal, consider an extremely simplified neural system composed of a set of elements. Each element could represent, for instance, a group of locally interconnected neurons that share inputs and outputs, such as a cortical minicolumn. We could further assume that each element can go through discrete activity states, corresponding to different firing levels, each of which lasts for a few hundred milliseconds. Finally, for the present purposes, let us imagine that the system is disconnected from external inputs, just as the brain is disconnected from the environment when it is dreaming.

Effective Information

Consider now a subset S of elements taken from the system. We want to measure the information generated when S enters a particular state out of its repertoire, but only to the extent that such information can be integrated (i.e., it can be the result of causal interactions within the system). To do so, we start by dividing S into two complementary parts A and B, give maximum entropy to the outputs from A (i.e., substitute its elements with independent noise sources) and determine the entropy of the resulting responses of B. Specifically, we define the *effective information* between A and B as $EI(A \rightarrow B) = MI(A^{Hmax} \rightarrow B)$. Here $MI(A;B) = H(A) + H(B) - H(AB)$ stands for mutual information, the standard measure of the entropy or information shared between a source (A) and a target (B). Since A is substituted by independent noise sources, the entropy that B shares with A is due to causal effects of A on B. In neural terms, we try out all possible combinations of firing patterns as outputs from A and establish how differentiated is the repertoire of firing patterns they produce in B. Thus if the connections between A and B are strong and specialized, different outputs from A will produce different firing patterns in B, and $EI(A \rightarrow B)$ will be high. On the other hand, if the connections between A and B are such that different outputs from A produce scarce effects, or if the effect is always the same, then $EI(A \rightarrow B)$ will be low or zero. Note that, unlike measures of statistical dependence, effective information measures causal interactions and requires perturbing the outputs from A. Moreover, by enforcing independent noise sources in A, effective information measures all possible effects of A on B, not just those that are observed if the system were left to itself. Also, $EI(A \rightarrow B)$ and $EI(B \rightarrow A)$ will generally differ; that is, effective information is not symmetric. For a given bipartition of a subset, the sum of the effective information for both directions is indicated as $EI(A \rightleftharpoons B) = EI(A \rightarrow B) + EI(B \rightarrow A)$.

Information Integration

Based on the notion of effective information for a bipartition, we can assess how much information can be integrated within a system of elements. To this end, it is important to realize that a subset S of elements cannot integrate any information if there is a way to partition S in two complementary parts A and B such that $EI(A \rightleftharpoons B) = 0$. In such a case we would obviously be dealing with two (or more) causally independent subsets, rather than with a single, integrated subset. More generally, to measure how much information can be integrated within a subset S, we should search for the bipartition(s) for which $EI(A \rightleftharpoons B)$ reaches a minimum. Since $EI(A \rightleftharpoons B)$ is necessarily bounded by the maximum entropy available to A or B, to be comparable over bipartitions, $\min\{EI(A \rightleftharpoons B)\}$ should be normalized by $\min\{H^{max}(A), H^{max}(B)\}$. Thus the *minimum information bipartition* of subset S, or MIB(S), is its bipartition for which the normalized effective information reaches a minimum, corresponding to $\min\{EI(A \rightleftharpoons B)/(\min\{H^{max}(A), H^{max}(B)\})\}$ for all A. The capacity for *information integration* of subset S, or $\Phi(S)$, is simply the value of $EI(A \rightleftharpoons B)$ for the minimum information bipartition: $\Phi(S) = EI(MIB(S))$. The symbol Φ is meant to indicate that the information (the 'I') can be integrated within a single entity (the 'O'). This quantity is also called ^{MIB}*complexity*, for minimum information bipartition complexity. In most cases, the bipartitions for which the normalized value of EI will be at a minimum, everything else being equal, will be bipartitions that cut the system in two halves, that is, midpartitions.

Complexes

If $\Phi(S)$ is calculated for every possible subset S of a system, we can establish which subsets are actually capable of integrating information, and how much of it. Consider thus every possible subset S of *m* elements out of the *n* elements of a system, starting

with subsets of two elements ($m = 2$) and ending with a subset corresponding to the entire system ($m = n$). A subset S with $\Phi > 0$ is called a *complex* if it is not included within a larger subset having higher Φ. For a given system, the complex with the maximum value of $\Phi(S)$ is called the *maximum* or *main complex*, where the maximum is taken over all combinations of $m > 1$ out of n elements of the system. Note that a complex can be causally connected to elements that are not part of it. The elements of a complex that receive inputs from or provide outputs to other elements not part of that complex are called *ports in* and *ports out*, respectively. In summary, a system can be analyzed to identify its complexes – those subsets of elements that integrate information – and each complex will have an associated value of Φ – the amount of information it integrates.

Consciousness, Information Integration, and the Brain

If consciousness has to do with the ability to integrate information, and if such ability can be measured as suggested previously, it follows that a physical system will have consciousness to the extent that it constitutes a complex having high values of Φ. How do these concepts apply to the brain, and can they account, at least in principle, for some of the facts and puzzles listed previously? Can they shed any light, for instance, on why the thalamocortical system is essential for consciousness whereas the cerebellum is not, or on why consciousness is reduced during slow-wave sleep?

Although performing an exhaustive analysis of complexes on the brain itself is not feasible at present, it is nevertheless possible to obtain some insights by considering computer simulations that capture basic aspects of brain organization. To be sure, the effective information between subsets of neurons is heavily constrained by biological factors affecting maximum firing rates, firing duration, and postsynaptic excitability. Everything else being equal, however, the single most important determinant of a network ability to integrate information is its anatomic organization. Connection patterns can determine whether a system is highly modular (i.e., splits into small, nearly independent complexes) or whether it forms a single, large complex. Moreover, complexes having the same number of elements and connections may have widely different values of Φ depending on how the connections are arranged. It is worth considering a few representative instances.

Thalamocortical System

Using small networks of linear elements, it is possible to show that Φ is maximized by having cach element develop a different connection pattern with the rest of the complex (functional specialization) while ensuring that, no matter how the system is divided in two, the two parts are well connected (functional integration). The thalamocortical system – the brain structure most directly associated with consciousness – appears to be an excellent candidate for the rapid integration of information. It is composed of a large number of widely distributed elements that are functionally specialized. At the same time, these elements are intricately interconnected and exhibit short- and long-range synchronization, a hallmark of functional integration. Indeed, computer simulations suggest that the connectivity of the visual thalamocortical system, characterized by many local groups of heavily connected neurons, forward connections that increase functional specialization, back connections that can distribute information widely, and a large number of entangled short loops, is well suited to generating high values of Φ. It is not yet clear to what extent the connectivity may differ in other cortical regions, or whether certain cortical layers and cell types may play a privileged role in integrating information among distant areas. However, it is clear that the organization of the thalamocortical system is well suited to forming a complex capable of integrating a large amount of information.

Cerebellum

This brain region contains probably more neurons and as many connections as the cerebral cortex, receives mapped inputs from the environment, and controls several outputs. However, in striking contrast to the thalamocortical system, lesions or ablations indicate that the direct contribution of the cerebellum to conscious experience is minimal. As suggested by computer simulations, the reason may be that the organization of synaptic connections within the cerebellum is radically different from that of the thalamocortical system and is not well suited to the integration of information. Specifically, the organization of the connections is such that individual patches of cerebellar cortex tend to be activated independently of one another, with little interaction between distant patches. This suggests that cerebellar connections may not be organized so as to generate a large complex of high Φ, but rather very many small complexes each with a low value of Φ.

Split Brain

When the corpus callosum is sectioned, consciousness is split. The level of consciousness of the dominant hemisphere and most of its contents are not altered severely after the operation. The nondominant hemisphere also appears to be conscious, although it

loses some important abilities. Some information, for example, emotional arousal, seems to be shared across the hemispheres, probably due to subcortical common inputs. As illustrated by simple computer models, a 'callosal' cut produces, out of a large complex corresponding to the connected thalamocortical system, two separate complexes. However, because there is great redundancy between the two hemispheres, their Φ value is not greatly reduced compared with when they formed a single complex. The analysis of complexes also identifies a complex corresponding to both hemispheres and their subcortical common inputs, although with much lower Φ values. That is, there is a sense in which the two hemispheres still form an integrated entity, but the information they share is minimal.

Cortical Input and Output Systems

Why is it that retinal cells do not appear to contribute directly to visual consciousness, given that they evidently influence it by providing powerful signals to the thalamocortical system? According to computer simulations, input circuits providing powerful inputs to a complex add nothing to the information it can integrate if their effects are entirely accounted for by ports in, that is, by the elements of the complex to which they connect. Similar considerations apply to output circuits triggered by ports out.

Basal Ganglia and Cortico-Subcortical Loops

The basal ganglia are large neural structures that contain many circuits arranged in parallel, some implicated in motor and oculomotor control, others, such as the dorsolateral prefrontal circuit, in cognitive functions, and others, such as the lateral orbitofrontal and anterior cingulate circuits, in social behavior, motivation, and emotion. Further specialization appears to occur within each of these broad domains. Each basal ganglia circuit originates in layer V of the cortex, and through a last step in the thalamus, returns to the cortex, not far from where the circuit started. Similarly arranged cortico-cerebello-thalamo-cortical loops also exist. Are such subcortical loops that are connected at both ends to the thalamocortical system necessarily part of the main thalamocortical complex? According to computer models, adding a loop to a large complex does not necessarily produce a larger complex with higher Φ. Instead, the elements of the main complex and those of the loop form a joint complex that can only integrate the limited amount of information exchanged within the loop. Thus subcortical loops could implement specialized subroutines that influence the states of the main thalamocortical complex, even if the neural interactions within the loop remain informationally insulated from those of the main complex. Informationally insulated cortico-subcortical loops may thus constitute substrates for unconscious processes that influence conscious experience.

Slow-Wave Sleep

Even if the anatomic connectivity is the same, a change in a few key parameters may radically alter the Φ value of a complex, with corresponding consequences on consciousness. When the brain enters the deepest stages of slow-wave sleep, consciousness is substantially reduced; yet neurons fire almost as intensely as in wakefulness. However, because of certain conductances modified by changes in neuromodulatory levels, neurons undergo periods of hyperpolarization, during which they are much further from their firing threshold. Computer simulations indicate that, if during such periods a part of the thalamocortical complex is perturbed in many different ways, the resulting states of the rest of the complex would be much less differentiated than during normal wakefulness. Although this conjecture has not yet been explicitly tested *in vivo*, if it were confirmed, it would indicate that the ability to integrate information is significantly reduced during slow-wave sleep.

Spatial and Temporal Scales

Values of Φ are dependent on both spatial and temporal scales that determine what counts as a state of the system. In general, the right 'grain size' in both space and time should be the one at which Φ/t reaches a maximum. Biological considerations suggest that synchronous firing of heavily interconnected groups of neurons sharing inputs and outputs (e.g., cortical minicolumns) may produce significant effects in the rest of the brain, whereas asynchronous firing of various combinations of individual neurons should not.

Thus, Φ values may be higher when considering as elements cortical minicolumns rather than individual neurons, even if their number is lower. In regard to time, Φ values in the brain are likely to show a maximum between tens and hundreds of milliseconds. It is clear, for example, that if one were to perturb one half of the brain and examine what effects this produces on the other half, no perturbation would produce any effect whatsoever after just a tenth of a millisecond ($\Phi = 0$). However, after 100 ms, for example, there is enough time for differential effects to be manifested. On the other hand, given the duration of conduction delays and of postsynaptic currents, longer intervals will not increase Φ values. Thus the time scale of

neurophysiologic interactions needed to integrate information among distant cortical regions is consistent with that required by the microgenesis of conscious experience.

A Few Corollaries and Predictions

Several corollaries and predictions derive from viewing and measuring consciousness as the amount of information that can be integrated within a complex of elements. Some of them are straightforward. For instance, stimulation and recording studies should indicate that groups of neurons in the thalamocortical system form a large complex of high Φ, whereas those in the cerebellum do not. Moreover, they should indicate that effective information among various cortical areas in high during waking and REM sleep and low in slow-wave sleep. Other predictions are less intuitive. For example, as long as neurons belong to a complex with high Φ, they should contribute to conscious experience whether they are firing or not, just as the sound of an orchestra is specified both by the instruments that are playing and by those that are silent. This is because the level of consciousness is a property of a system – a complex with high Φ – not of a state. Another prediction is that the same neurons can contribute or not to consciousness depending on whether they are part of the main thalamocortical complex. Yet another prediction states that when a task becomes automated, its execution fades from consciousness because the neural circuits that carry it become informationally insulated.

At a more general level, this approach makes it easy to see that consciousness provides an adaptive advantage and may have evolved precisely because it corresponds to the ability to rapidly integrate a lot of information. If such information is about the environment, the implication is that the more an animal is conscious, the larger the number of variables it can take into account jointly to guide its behavior. Also, in this view, consciousness would not be an all-or-none property, but rather would increase in proportion to a system's ability to integrate information rapidly. Indeed, this approach provides a principled way of establishing, through the analysis of complexes, whether consciousness increases during development, whether and to what extent it is present in animals, and how much consciousness is left in neurologic conditions such as psychomotor seizures and akinetic mutism. Finally, an intriguing implication is that it should be possible to construct a conscious artifact, provided its physical basis is a complex having high Φ/t.

In summary, according to this theoretical framework, consciousness comes about when the parameters of a physical system are such that it can integrate a large amount of information over a short period of time. The level of consciousness can be determined, at least in principle, by evaluating $\Phi(S)/t$ for all subsets of a system at the spatial and temporal scale at which this quantity reaches a maximum. Such an evaluation identifies complexes – subsets of elements that can genuinely integrate information – and determines how much information they can integrate. At present, the validity of this theoretical framework rests on its ability to account, in a coherent manner, for some elementary but puzzling facts about consciousness and the brain. However, several experimental and theoretical developments are needed to establish whether it can provide a useful approach to the first problem of consciousness. Moreover, it remains to be seen whether the second problem of consciousness – what determines the way consciousness is – can be usefully addressed within the same framework. An interesting possibility is that, just as the amount of effective information that can be integrated within a complex would determine the level of consciousness, the space defined by the values of effective information among the elements of a complex would determine its content. Undoubtedly, a full understanding of how the brain generates consciousness remains a formidable task. However, if experimental investigations can usefully be complemented by principled theoretical approaches, it may not lay necessarily beyond the reach of science.

What Phenomena Does a Science of Consciousness Need to Explain?

There are many definitions of consciousness, with some scholars arguing that it cannot be defined at all and others stating that it can only be defined by example. A common philosophical definition is "Consciousness is what it is like to be something." This would include such experiences as what it feels like to see red, or to be angry. This what-it-feels-like-from-within definition expresses what many believe is the most unique and irreducible characteristic of consciousness: being conscious means to experience something. This characteristic is called the phenomenal aspect of consciousness (from the Greek 'phenomenon,' i.e., appearance or experience). "What it feels like to be me, to see red, or to be angry" also emphasizes the subjective or first-person perspective of consciousness: it is a subject, an I, who is having the experiences, and experiences are inevitably private. What it feels like to have a particular experience is also called the quale of that experience: the quale of red is what is common to such disparate conscious states as seeing a red sunset, the red flag of China, arterial blood, or a ruby gemstone. All four distinct subjective states share 'redness.' There are countless qualia (the plural of quale): the ways things look, sound, and smell, the way it feels to have a pain, the way it feels to have thoughts and desires, and so on. To have an experience means to have qualia, and the quale of an experience is what specifies it and makes it different from other experiences.

The science of consciousness must explain the exact relationship between brain states and phenomenal, mental states. This is the heart of the classical mind–body problem. It can be dissected into several subproblems:

1. Why is there any experience at all? Or, put differently, why does a brain state feel like anything? In philosophy, this is referred to by some as the Hard Problem (note the capitalization), or as the explanatory gap between the material, objective world and the subjective, phenomenal world. Throughout the ages, many scholars have argued that the exact nature of this relationship will remain a central puzzle of human existence, without an adequate reductionistic, scientific explanation. However, as similar sentiments have been expressed in the past for the problem of seeking to understand life or to understand of what material the stars are made out of, it is best to put this question aside for the moment and not be taken in by defeatist arguments.
2. Why is the relationship among different experiences the way it is? For instance, red, yellow, green, cyan, blue, and magenta are all colors that can be mapped onto the topology of a circle. Why? Furthermore, as a group, these color percepts share certain communalities that make them different from other percepts, such as seeing motion or smelling a rose.
3. Why are feelings private? As expressed by poets and novelists, we cannot communicate an experience to somebody else except by way of example.
4. How do feelings acquire meaning? Subjective states are not abstract states but have an immense amount of associated explicit and implicit feelings. Think of the unmistakable smell of dogs coming in from the rain or the crunchy texture of potato chips.
5. Why are only some behaviors associated with conscious states? Much brain activity and associated behavior occurs without any conscious sensation.

Another aspect of the mind–body problem is the question of freedom of choice or free will. This is orthogonal to the problem of consciousness; whether volition is illusory or truly 'free' in the libertarian sense does not answer the question of how subjective states relate to brain states. On the other hand, the perception of free will, what psychologists call the feeling of authorship or agency (e.g., "I raised my left hand"), is a subjective state with an associated quale no different in kind from the quale of a toothache or hearing a high C.

Unless and until science can explain how subjective experiences arise from physical states, its claim to provide an adequate account of all phenomena in the universe will ring hollow. Sources of data about subjective states come not only from persons that can directly report (i.e., talk) about their subjective experiences, but also from nonlinguistic competent individuals – newborn babies or locked-in syndrome patients – and from appropriately trained animals. There are three reasons to assume that many species, in particular those with complex behaviors, such as mammals, share at least some aspects of consciousness with humans:

1. Similar neuronal architectures. Except for size, there are no large-scale, dramatic differences between the cerebral cortex and thalamus of mice, monkey, humans, and whales. In particular, the macaque

monkey is taken to be a powerful model organism to study visual perception, since it shares with the human visual system three distinct cone photopigments, binocular stereo, a foveated retina, and similar eye movements.

2. Similar behavior. An appropriately trained macaque monkey behaves in a manner similar to that of a trained human observer. Almost all human behaviors have precursors in the animal literature. Take the case of pain. The behaviors seen in humans when they experience pain – facial contortions, moaning, yelping, or other forms of auditory vocalization; motor activity such as writhing; expressing fear at the prospect of a repetition of the painful stimulus – can be observed in mammals and most other animals. Likewise for the physiological signals that attend pain – change in blood pressure, dilated pupils, sweating, increased heart rate, release of stress hormones, and so on. Indeed, the debate concerning cortical pain responses in premature babies shows the fallacy of relying on language as sole criteria for consciousness.

3. Last, there is a great evolutionary continuity between *Homo sapien*s and other mammals. Thus, while it is likely that certain aspects of consciousness – in particular those relating to the notion of self and to abstract, culturally transmitted knowledge – are not widespread in nonhuman animals, there is little reason to doubt that other mammals share conscious feelings – sentience – with humans. The extent to which nonmammalian species, such as crows, squids, or bees, with very complex, nonstereotyped behaviors, including delayed matching and non-matching-to-sample and other forms of learning, are conscious is difficult to answer at this point in time.

Distinctions between States and Levels of Consciousness

As long as you are awake, you experience a specific conscious state with a specific content. You see a face, you hear the radio, or you think of your mother. This usage of conscious states to refer to individual experiences is quite distinct from the expression of states of consciousness, which is used in a different context. Clinicians talk about impaired states of consciousness as in "the comatose state," "the persistent vegetative state (PVS)," or "the minimal conscious state (MCS)." Here, state refers to a different level of consciousness, from a total absence in coma and in PVS to a minimal amount of consciousness in MCS, as compared to full-blown waking consciousness. The repertoire of distinct conscious states (in the sense of distinct experiences) that are accessible to a patient in MCS is presumably minimal (mainly pain and discomfort, at times limited visual or other sensory experiences), immeasurably smaller than the possible conscious states that can be experienced by a healthy brain. A related use of differentiation is when psychologists refer to altered states of consciousness – for instance, state after taking psychedelic drugs or during dreaming, when insight and introspection are usually missing and events often have a stronger emotional connotation than in normal life. In both cases, the basic physiology of the brain is changed, affecting the space of possible conscious experiences. (This dual use of the word 'state,' referring both to a specific state of consciousness as well as to different levels or modes of consciousness, is analogous to the use of 'state' in physics. There, the state of a system can both refer to its position in an underlying phase space and to different states of matter – solid, liquid, gas, and plasma.)

Neuronal Correlates of Consciousness

It is often assumed in the debate concerning the nature of consciousness that there are few relevant facts and therefore everybody is entitled to their own theory of consciousness. Nothing could be further from the truth. There is an immense amount of psychological, clinical, and neuroscientific data and observations that need to be accounted for. In particular, the contemporary focus on the neuronal basis of consciousness in the brain – rather than on eristic philosophical debates concerning exact definitions, whether true zombies can exist, or whether or not the Hard Problem can or cannot be solved – has given neuroscientists the tools to effectively attack this problem. As defined by FC Crick and C Koch, the neuronal correlates of consciousness (NCC) are the minimal neuronal mechanisms jointly sufficient for any one specific conscious percept (minimal, as the entire brain is sufficient to give rise to consciousness). For instance, it is likely that neural activity in the cerebellum does not underlie any conscious perception, and thus it is not part of the NCC. That is, trains of spikes in Purkinje cells (or their absence) will not induce a sensory percept, although they may ultimately affect some behaviors (such as eye movements).

Every phenomenal state will have associated NCC: one for seeing a red patch, another one for seeing grandmother, yet a third one for hearing a tone, and so on. Perturbing or inactivating the NCC for any one specific conscious experience will affect the percept or cause it to disappear. If the NCC could be induced artificially – for instance, by drugs or with the aid of extracellular electrical stimulation – the subject will experience the associated percept.

What characterizes the NCC? What are the communalities between the NCC for seeing and for

hearing? Will the NCC involve all pyramidal neurons in cortex at any given point in time? Or only a subset of long-range projection cells in frontal lobes that project to the sensory cortices in the back? Only layer 5 cortical cells? Neurons that fire in a synchronous manner? These are some of the proposals that have been advanced over the past years.

The NCC for the current content of consciousness has to be distinguished from the general, enabling factors in the brain that are needed for any form of consciousness to occur and that also control the level of consciousness. One very general enabling factor is a proper blood supply. Inactivate the heart and consciousness ceases within a fraction of a minute. This does not imply that the neural correlates of consciousness is in the heart (as Aristotle thought). A more specific neuronal enabling factor for consciousness is the reticular activating system. This heterogeneous set of cells in the midbrain and posterior hypothalamus release neuromodulators such as acetylcholine, noradrenaline (norepinephrine), serotonin, and histamine. These neuromodulators control the excitability of thalamus and forebrain and mediate the alternation between wakefulness and sleep. Acute lesions of the reticular activating system can result in loss of consciousness and coma. However, eventually the excitability of thalamus and forebrain recovers and consciousness can return. Another enabling factor for consciousness are the five or more intralaminar nuclei (ILN) of the thalamus. These project strongly to the basal ganglia and, in a more distributed manner, to much of neocortex. Comparatively small (1 cm^3 or less), bilateral lesions in the thalamic ILN completely knock out all awareness. Of course, it is possible that future research will demonstrate hidden aspects of neuronal specificity, such that particular neuronal subpopulations in the ILN are responsible for different conscious modalities (e.g., vision vs. audition).

In functional magnetic resonance imaging (fMRI) studies, much of the contemporary work aimed at establishing the NCC has concentrated on visual consciousness. Visual psychologists have perfected a number of techniques – masking, binocular rivalry, continuous flash suppression, motion-induced blindness, change blindness, inattentional blindness – in which the seemingly simple and unambiguous relationship between a physical stimulus in the world and its associated percept in the privacy of the subject's mind is disrupted. In particular, a stimulus can be perceptually suppressed for seconds or even minutes at a time: the image is projected into one of the observer's eyes but invisible, not seen. This permits the footprints of visual consciousness to be tracked in the brain. In binocular rivalry, a small image – say, of a horizontal grating – is presented to the left eye and another image – say, a vertical grating – is shown to the corresponding location in the right eye. In spite of the constant visual stimulus, observers 'see' the horizontal grating alternate every few seconds with the vertical one. The brain does not allow for the simultaneous perception of both images. It is possible, though difficult, to train a macaque monkey to report whether it is currently seeing the left or the right image. The distribution of the switching times and the way in which changing the contrast in one eye affects these leaves little doubt that monkeys and humans experience the same basic phenomenon.

In a series of elegant experiments, N Logothetis and colleagues recorded from a variety of visual cortical areas in the awake macaque monkey while the animal performed under binocular rivalry condition. In primary visual cortex, only a small fraction of cells modulated their response as a function of the percept of the monkey. The majority of cells increased their firing rate in response to one or the other retinal stimulus with little regard to what the animal perceived at the time. In contrast, in a high-level cortical area such as the inferior temporal (IT) cortex, almost all neurons responded only to the perceptual dominant stimulus (in other words, a 'face' cell only fired when the animal indicated by its performance that it saw the face and not the pattern presented to the other eye). This makes it likely that the NCC involves activity in neurons in the IT lobe. Lesions in the homologous area in the human brain are known to cause very specific deficits in conscious face or object recognition. However, it is possible that specific interactions between IT cells and neurons in parts of the prefrontal cortex are necessary in order for the NCC to be generated. However, sophisticated functional brain imaging experiments in human volunteers demonstrate quite conclusively that hemodynamic activity in V1 does follow the percept rather than the retinal stimulus, unlike the majority of neurons in monkey primary visual cortex. This discrepancy between single cell and fMRI data, operating at quite different spatiotemporal scales, has not yet been resolved.

There is a lively debate of the extent to which neurons in primary visual cortex simply encode the visual stimulus or are directly responsible for expressing the observer's conscious percept. That is, is V1 part of the NCC? It is clear that retinal neurons are not part of the NCC for visual experiences. While retinal neurons often correlate with visual experience, the spiking activity of retinal ganglion cells does not accord with our visual experience (e.g., there are no photoreceptors at the blind spot, yet we do not see a hole in our field of view; there is a dramatic drop in cone photoreceptor density away from the fovea, yet

the visual field appears everywhere colorful; the eyes moves three to four times each second, yet the world is seen as stable). Furthermore, in dreams, the eyes are closed while we experience vivid visual scenes. Other empirical problems of contemporary interest include the question of whether each conscious attribute is all-or-none, whether perception is not continuous but is actually quantized in batches of variable duration, and whether different percepts (i.e., color, motion, position) are simultaneously experienced or not.

In order to advance these and similar questions, it will be imperative to record from large numbers of neurons simultaneously at many locations throughout the cortico-thalamo system. Our growing ability to manipulate identified populations of cortical or thalamic cells, in a reversible, transient, deliberate, and delicate manner, using tools from molecular biology, combined with optical stimulation techniques, opens the possibility of moving from correlation (observing that a particular conscious state is associated with some neural or hemodynamic activity) to causation. Of course, this requires the development of appropriate behavioral assays and model organisms amenable to large-scale genomic analysis and manipulation.

Zombie Behaviors

Many actions in response to sensory inputs are rapid, transient, stereotyped, and unconscious. They could be thought of as cortical reflexes and are characterized by rapid and somewhat stereotyped responses, in addition to a slower, all-purpose conscious mode. Consciousness deals more slowly with broader, less stereotyped aspects of the sensory inputs (or a reflection of these, as in imagery) and takes time to decide on appropriate thoughts and responses. A general purpose, consciousness mode is needed because otherwise a vast number of different zombie modes would be required to react to unusual events. The conscious system may interfere somewhat with the concurrent zombie system. It would be a great evolutionary advantage to have both zombie modes that respond rapidly in a stereotyped manner, and a slightly slower system that allows time for thinking and planning more complex behavior. This latter aspect would be one of the functions of consciousness. It seems possible that visual zombie modes in the cortex mainly use the dorsal stream in the parietal region. However, parietal activity can affect consciousness by producing attentional effects on the ventral stream, at least under some circumstances. The conscious mode for vision depends largely on the early visual areas (beyond V1) and especially on the ventral stream. It is well known that seemingly complex visual processing (such as recognizing animals in natural scenes) can be accomplished by cortex within 130–150 ms, far too slow for conscious perception to occur. Furthermore, reflexes such as the vestibuloocular reflex (VOR) take place at even more rapid timescales. It is plausible that such behaviors are mediated by a purely feed-forward moving wave of spiking activity while conscious activity requires more sustained, reverberatory neural activity that in turn requires excitatory feedback to maintain its activity above a critical threshold. This would be true of any cortical region: fast, transient, and feed-forward activity can trigger behavior without conscious sensation.

Consciousness and Information Integration

Progress in the study of the NCC on one hand, and of the neural correlates of zombie behaviors on the other, may lead to a better understanding of what distinguishes neural structures or processes that are associated with consciousness from those that are not. But even if we come closer to this goal, we still need to understand why certain structures and processes have a privileged relationship with subjective experience. For example, why is it that neurons in corticothalamic circuits are essential for conscious experience, whereas cerebellar neurons, despite their huge numbers, are not? And what is wrong with cortical zombie systems that makes them unsuitable to yield subjective experience? Or why is it that consciousness wanes during slow-wave sleep early in the night, despite levels of neural firing in the corticothalamic system that are comparable to wakefulness? Other questions are even more difficult to address in the absence of a theory. For example, is consciousness present in animals that have a nervous system considerably different from ours? And what about com puterized robots or other artifacts that behave intelligently but are organized in a way radically different from that of human brains?

To address these questions we need a theoretical approach that establishes at the fundamental level what consciousness is, how it can be measured, and what requisites a physical system must satisfy in order to generate it. The information integration theory of consciousness represents such an approach. According to this theory, the most important property of consciousness is that it is extraordinarily informative. Whenever a particular conscious state is experienced, it rules out a huge number of alternative experiences, and, classically, the reduction of uncertainty among a number of alternatives constitutes information. For example, with the experience of reading a particular

phrase in a book, a huge number of other possible experiences are ruled out. Just think of all possible written phrases that could have been read, in all possible fonts, ink colors, and sizes, then think of the same phrases spoken aloud, or read and spoken, or think further of all other possible visual scenes that might have been experienced, and then multiplied by all possible sounds that might have been heard at the same time, and by all possible moods that the reader might have been in, and so on. Thus, every time we experience a particular conscious state, it is out of a huge repertoire of possible conscious states, and we gain access to a correspondingly large amount of information. This point is so simple that its importance has been overlooked. It is essential to realize, however, that the information associated with the occurrence of a conscious state is integrated information. When a particular conscious state is experienced, that conscious state is an integrated whole – it cannot be subdivided into components that are experienced independently. For example, the conscious experience of reading a particular phrase cannot be experienced as subdivided into, say, the conscious experience of how the words look independently of the conscious experience of how they sound in the mind of the reader. Similarly, visual shapes cannot be experienced independently of their color, or the left half of the visual field of view perceived independently of the right half. Based on these and other considerations, the theory claims that a physical system can generate consciousness to the extent that it can integrate information. This requires that the system has a large repertoire of available states (information) yet it cannot be decomposed into a collection of causally independent subsystems (integration).

Importantly, the theory introduces a measure of a system's capacity to integrate information. This measure, called Φ, is obtained by determining the minimum repertoire of different states that can be produced in one part of the system by perturbations of its other parts. Although this measure is not easy to calculate exactly for realistic systems, in principle it can be applied to any system of elements. For example, by using simple computer simulations, it is possible to show that Φ is high for neural architectures that conjoin functional specialization with functional integration, like the mammalian thalamocortical system. Conversely, Φ is low for systems that are made up of small, quasi-independent modules, like the cerebellum, or for networks of randomly or uniformly connected units. Thanks to the theoretical notion of consciousness as information integration, it becomes possible to provide a principled account for key neurobiological observations concerning consciousness, including (1) the association of consciousness with certain neural systems rather than with others, (2) the fact that neural processes underlying consciousness can influence or be influenced by neural processes that remain unconscious, (3) the reduction of consciousness during slow-wave sleep and generalized seizures, and (4) the time requirements on neural interactions that support consciousness. Recently, the notion that consciousness has to do with the brain's ability to integrate information has been tested directly by measuring electroencephalogram responses evoked by transcranial magnetic stimulation (TMS) when study participants were awake and conscious, compared to when they were deeply asleep early in the night – a time during which consciousness is much reduced. During quiet wakefulness, an initial response at the stimulation site was followed by a sequence of waves that moved to connected cortical areas several centimeters away. During slow-wave sleep, by contrast, the initial response was stronger but was rapidly extinguished and did not propagate beyond the stimulation site. Thus, the fading of consciousness during certain stages of sleep may be related, as predicted by the theory, to the breakdown of information integration among specialized thalamocortical modules.

Consciousness: Theories and Models

Introduction

There are only a few basic ways to study conscious brain events. One is to compare conscious and unconscious states, and here we can look to classical experiments on the brain stem and basal nuclei such as the reticular formation, zona incerta, and parts of the thalamus. There is a large literature on neuromodulation and cortical activation in waking, sleep, rapid eye movement (REM) dreams, comalike states, general anesthesia, and so on.

Conscious contents are commonly indexed by voluntary reports in humans and by accurate match-to-sample responses in related species. In humans, the simplest approach is to ask about easily described events, such as a visual coffee cup or a mental image of a rotating kitchen chair. Conscious contents such as these can be reported with good accuracy under the proper conditions, such as immediate report, freedom from distraction, and independent verification. These conditions apply to numerous standard experiments.

Traditional sensory science compares conscious stimuli to one another, a method that dates back to Newton's prism experiments. However, in a recent wave of research, conscious events are compared to unconscious events which appear to be physiologically similar, although they cannot be reported as conscious even under optimal conditions. Many experimental paradigms allow for such comparisons. Such experiments may be said to isolate the issue of conscious content as such in that they treat it as an experimental variable. A classic example is binocular rivalry, in which two different images are shown simultaneously to the two eyes and conscious perception alternates between them. As long as the input to the two eyes cannot be integrated into a single, coherent visual event, they compete against one another for conscious dominance. The brain differences between conscious perception and unconscious input registration provides evidence about visual consciousness as such.

With the advent of this burgeoning new literature, the idea that conscious cognition cannot be studied scientifically has largely faded. Instead, there is now a growing need for theoretical frameworks and neuroscience-based models able to integrate the rapidly growing body of experimental data. Theories and models of consciousness are also needed to guide future experiments and to make testable predictions.

Major Features

Much of the evidence to be accounted for is summarized in Table 1 and in the following discussion. Needless to say, this is an open set that will expand as we learn more.

Conscious Events Recruit Widespread Brain Activity

Many studies suggest that conscious contents mobilize the frontal and parietal brain regions, even if they originate posteriorly, as in the case of sensory events. For example, Dehaene and colleagues used visual backward masking to compare conscious and unconscious words, using a pattern mask presented immediately afterward. Masked words are unconscious, but they are not physically blocked from entering the eyes. Brain imaging analysis showed that both conscious and unconscious words activated the cortical vision and word recognition areas, which are known to analyze stimulus location, shape, color, and word identity. However, conscious words triggered 12 times more activity in these regions than identical unconscious ones. In addition, conscious words evoked a great deal of additional activity in the parietal and frontal cortex. It seems as if the stimulus-related activity in the conscious case may be widely distributed from visual regions to other areas in the brain. This is, in fact, predicted by several current theories.

An alternative hypothesis is that, because any conscious event is presumed to be reportable, the prefrontal-parietal component may be related to readiness to report rather than conscious experience as such. This is a difficult alternative to test conclusively. As we gain a more detailed understanding of the specific functional regions of the cortex, it may become possible to do so.

Many sources of evidence suggest that conscious events show wider cortical activity than matched comparison cases. A major theoretical question, therefore, concerns the contribution of frontoparietal activity in conscious perception.

Integration and Dissemination of Focal Information

The visual cortex is clearly involved in the integration of relatively simple visual features into objects

Table 1 Some basic features of conscious brain events

Feature	*Description*
1	Consciousness is characterized by irregular, low-amplitude, fast (12 to 70 Hz) electrical field activity
2	Consciousness is associated with activity in the thalamocortical complex, modulated by subcortical nuclei
3	Consciousness involves distributed cortical activity related to conscious contents
4	Conscious events are integrated into unitary consistent scenes
5	Integrated conscious scenes occur serially; only one is experienced at a time
6	Conscious scenes are metastable and reflect rapidly adapting discrimination in perception and memory
7	Conscious scenes comprise a wide multimodal range of contents and involve multimodal sensory binding
8	Conscious scenes have a focus/fringe structure; focal conscious contents are modulated by attention
9	Consciousness is subjective and private and is often attributed to an experiencing self, which may involve distinctive brain regions
10	Conscious experience is reportable by humans, verbally and nonverbally
11	Consciousness facilitates various forms of learning; even implicit learning initially requires consciousness of the stimuli from which regularities are unconsciously inferred
12	Conscious scenes have an allocentric (world-centered) character, yet are shaped by egocentric (subject-centered) frameworks; they generally show intentionality (aboutness)
13	Consciousness is needed for much decision making, adaptive planning, and voluntary control

Adapted from Seth AK, Izhikevich E, Reeke GN, and Edelman GM (2006) Theories and measures of consciousness: An extended framework. *Proceedings of the National Academy of Sciences of the United States of America* 103(28): 10799–10804.

and scenes. Because humans in a natural environment are conscious of objects and scenes rather than isolated features (such as contrast or spatial frequency), it is plausible to think that there is a close link between these end products of visual integration and visual consciousness. N Logothetis and colleagues recorded single-cell activity in response to different kinds of binocular rivalry from the V1/V2 areas, middle temporal (**MT**)/middle superior temporal (MST) cortical areas (motion), V4 area (color), and finally inferotemporal cortex (IT)/superior temporal sulcus (STS) cortical areas, the object perception regions of the macaque temporal lobe. Only 20–40% of neurons sampled in early visual regions responded to the reported (conscious) percept, with a roughly equal number responding to the unreported percept. However, in the temporal lobe, 90% of the neurons responded only to the conscious percept. Because object recognition combines many basic features such as color, motion, and location into a single percept, this region is a plausible place for conscious objects to arise. One hypothesis is that visual integration settles into a stable equilibrium when object and scenes are identified and is then disseminated to other parts of the brain. In this view conscious contents represent the result of integration, but the integrated percept then interacts with numerous regions elsewhere in the brain.

V Lamme and others have raised the question of whether visual consciousness can be said to arise from the visual cortex alone or whether it requires selective attention and other top-down influences from other regions. For example, dorsal visual stream activity is widely considered to be unconscious in itself, but it may provide allocentric and egocentric spatial maps for objects defined in the ventral visual stream. Thus, dorsal parietal regions may be contextual with respect to conscious object and scene perception. Parietal maps may be necessary for conscious visual perception, but they may not enter into experience directly. Lamme has proposed that reentrant activity in the visual cortex may be the key to visual consciousness. Cortical reentry, like other forms of reentry, will have the effect of stabilizing and strengthening activity in particular neural pathways.

F Crick and C Koch have suggested that consciousness may require competition among coalitions of neurons, in which winning coalitions determine the contents of consciousness at a given time. Such neuronal coalitions bear similarities to Hebbian cell assemblies on a very large and dynamic scale. They also suggest that unconscious processing may consist largely of feed-forward cortical waves, whereas consciousness may involve standing waves created by bidirectional signal propagation. Direct brain imaging and electrophysiological evidence for such phenomena has been found by W Freeman, R Srinivasan, P Nunez, and others. A distinctive aspect of Crick and Koch's view is the reintroduction of the controversial notion of an inner homunculus; they suggest that conscious perception may involve anterior brain regions looking at posterior activity.

Fast Cortical Interactions (Gamma–Theta)

A conscious task, such as pointing to a coffee cup, involves a great many cortical and subcortical regions. A range of evidence and theory suggests that synchronized or coherent firing of large numbers

of neurons plays a part. Gamma and alpha-range synchrony have been implicated in the conscious interpretation of ambiguous stimuli. However, coherent oscillatory activity of large populations of cells has been observed in other tasks as well, including theta activity in episodic retrieval (involving the medial temporal lobe (MTL) and higher cortex), in μ oscillations in motor regions, during preparation of motor acts (?), and possibly in 10 Hz coherence during endogenous mentation in posterior cortex. These circa 10 Hz oscillations may serve to group faster rhythms such as beta and gamma. Only delta oscillations (<2.5 Hz) are generally associated with unconscious states.

Several studies suggest that synchronous activity during conscious perception is widely distributed in the brain. However, not all brain areas are firing in synchrony – if they did, the result might resemble an epileptic seizure, in which one single rhythm entrains large regions of cortex. Rather, there seem to be rapid moments of synchrony between different brain regions that need to work together to accomplish the task of conscious perception. In deep sleep and other unconscious conditions, the individual firing rate of cortical neurons may not change, but rapid interactive linking between regions seems to be disrupted.

Current Theories and Models

Consciousness is often viewed as an architectural aspect of the nervous system because it is involved with a variety of specific contents and functions. Such architectures can be expressed neurocomputationally, or in terms of symbolic computations. Neural network mathematics has broad flexibility and explanatory potential. Formally, even symbolic information processing models are expressible in neurocomputational terms. In practice, however, it is a challenge to scale neural networks up to the massive complexity of real brains.

Qualitative and Hybrid Architectures

B Baars has summarized a body of cognitive and brain evidence for a globalist view of conscious cognition, interpreted in a theoretical framework called global workspace theory (GWT). GWT assumes the existence of multiple knowledge sources that work to identify vague, ambiguous, or unpredictable stimuli in a cooperative and competitive fashion, by posting hypotheses about the identity of the input in a common memory space, a blackboard or global workspace. This approach was surprisingly successful when first applied in the 1970s to the difficult problem of computer-based speech recognition in a noisy acoustical environment. Today, global workspace architectures are widely used in robotics and artificial intelligence. They can be implemented in both symbolic and neural network formats.

S Dehaene, J-P Changeaux, and colleagues proposed a neuronal implementation of a global workspace architecture, called neuronal global workspace. In this model, sensory stimuli mobilize excitatory neurons with long-range cortico-cortical axons, leading to the genesis of a global activity pattern among workspace neurons. Any such global pattern can inhibit alternative activity patterns among workspace neurons, thus preventing the conscious processing of alternative stimuli. The global neuronal workspace model predicts that conscious presence is a nonlinear function of stimulus salience (i.e., a gradual increase in stimulus visibility should be accompanied by a sudden transition of the neuronal workspace into a corresponding activity pattern). Such ignition of the workspace is consistent with the notion that consciousness is an all-or-nothing, as opposed to a graded, process.

The neuronal global workspace has been used to model a number of experimental phenomena in consciousness. In one study, spontaneous workspace activity blocked external sensory processing, in a manner analogous to inattentional blindness, in which normal subjects engaged in effortful mental activity fail to notice salient but irrelevant stimuli. A similar phenomenon is the attentional blink, in which subjects are unable to report a stimulus S2 presented within a short time interval (100–500 ms) following the presentation of a first stimulus S1. In a neuronal global workspace model of this paradigm, the presentation of S1 evoked both bottom-up and top-down signal flow, leading to the sort of sustained activity that might underlie conscious reportability in human subjects. However, the presentation of S2 immediately after S1 evoked only bottom-up activity because of the global activity constraints imposed by S1. Plausibly, this absence of sustained activity relating to S2 corresponds to the lack of conscious access apparent in the attentional blink.

An advantage of the GWT approach is that it is clearly functional; that is, it describes a known architecture for integrating and distributing focal information in a large-scale, massively parallel, brain-like organ. However, scaling neural net architectures up to the level of real brains present major challenges. Current neuronal GWT models make use of simplified network architectures where entire brain areas are represented by single neurons.

Several other groups are currently applying GW-based ideas to the question of conscious cognition. In another approach to circumventing the difficulty

of capturing high-level and low-level features in a single model, S Franklin and colleagues made use of a hybrid computational approach, combining in their learning IDA (LIDA) model several types of existing computational methods using a quasi-neuronal activation-passing design. High-level conceptual models such as LIDA can provide insights into the processes implemented by the neural mechanisms underlying consciousness, without necessarily specifying the mechanisms themselves Although it is difficult to derive experimentally testable predictions from large-scale architectures, this hybrid architecture approach is broadly consistent with the major empirical features discussed in this article. It predicts, for example, that consciousness may play a central role in the classic notion of cognitive working memory, selective attention, learning, and retrieval.

A variety of neurocomputational models have been proposed to deal with aspects of consciousness. Some of these make global or qualitative claims, whereas others make quite specific experimental predictions.

Dynamical and Field Theories

Several theorists have advanced nonlinear dynamical theories that are thought to be able to model larger-scale neuronal architectures and time-locked nonlocal effects among brain regions. Some have used formalisms borrowed from physics, such as electromagnetic fields, wave mechanisms (W Freeman, P Nunez, R Srinivasan, and R Wallace), and even quantum mechanics (K Pribram and S Hameroff). The notion that quantum effects play a critical role in consciousness has been widely criticized on the grounds that significant quantum effects seem unlikely in neurophysiological environments unless body-temperature versions can be found.

ER John proposed that consciousness emerges from global negative entropy, which is a property of an electrical field resonating in a critical mass of brain regions. John suggested that sensory stimuli can evoke localized synchronous neuronal activation, causing deviations from a baseline brain state of maximum entropy. These deviations establish spatially distributed islands of local negative entropy, which correspond to fragments of sensation. These fragments can be bound into a unified global percept via integrative interactions within thalamocortical (TG) loops. In similar vein, P Nunez and R Srinivisan described large-scale cortical dynamics in terms of synaptic action fields, which are continuous mathematical functions representing the density of active synapses. According to these authors, consciousness depends on resonance in these fields within characteristic frequency ranges (e.g., 4–15 Hz).

Neural field theories may account well for the unified nature of conscious experience, as well as for associated properties including seriality and metastability. Although they have inspired empirical work using quantitative electroencepahlography (EEG), detailed modeling of the generation of conscious neural fields is still needed.

Neural Darwinism

Because the thalamocortical (TC) complex has extraordinarily interactive connectivity compared to other brain structures, such as the cerebellum, it is attractive to suppose that the different modalities of consciousness make use of the TC complex as a common anatomical substrate. This is not to deny the need for content-specific cortical regions.

An extensively developed TC theory of consciousness is provided by G Edelman's neural Darwinism (ND). ND suggests that brain development and dynamics are selectionist in nature, not instructionist, in contrast to computers, which carry out explicit symbolic instructions. Selectionist processes have four features:

1. A set of elements are characterized by diversity, such as populations of neuronal groups in the brain.
2. These elements can reproduce or amplify.
3. A process of selection operates on the products of diversity; for example, differential reproductive success serves to select some offspring and not others.
4. Degeneracy, the ability of different combinations of elements to perform the same function, is inherent in such systems.

In the brain, selectionism applies both to neural development and to moment-to-moment functioning. Selection in the brain is directed by value, which reflects the salience of an event and can be positive or negative. Value is analogous to selective pressure in evolution; the magnitude of a value signal corresponds to fitness. In the brain, it involves pleasure, pain, and emotional salience networks. Finally, according to ND, spatiotemporal coordination in the brain is enabled by reentry, the recursive exchange of signals among neural areas across massively parallel reciprocal connections.

According to ND, the neural systems underlying consciousness arose in evolution as a result of their ability to integrate a large number of sensory inputs and motor outputs occurring in parallel. This integration allows the discrimination of sensorimotor signals in a high-dimensional space, yielding adaptive behavior. Primary (sensory) consciousness is associated with an interaction between perceptual categorization and memory, where primary consciousness

refers to the presence of a multimodal scene of perceptual and motor events (William James's specious present or Edelman's remembered present). Primary consciousness, by this view, provides an animal with increased discriminatory selectivity, flexibility, and planning capacity when responding to complex environments, compared to its preconscious ancestors. Edelman, along with many other theorists, distinguished between primary consciousness and higher-order consciousness which in humans is associated with verbal reportability, the attribution of sensory scenes to a temporally stable self, and the ability to project conscious experiences both forward and backward in time.

Recent extensions of ND focused on informational aspects of consciousness. In the dynamic core hypothesis (DCH), Edelman and colleagues suggested that the occurrence of any particular conscious scene constitutes a highly informative discrimination for the reason that conscious scenes are at once integrated (every conscious scene is experienced all of a piece) and differentiated (every conscious scene is distinct from others). The DCH claims that conscious qualia are these discriminations and that the neural mechanisms underlying consciousness consist of a functional cluster in the TC system, within which reentrant neuronal interactions yield a succession of differentiated yet unitary metastable states. They suggested that the boundaries of the dynamic core shift over time, with some neuronal groups leaving and others being incorporated, these transitions occurring under the influence of internal and external signals.

According to the DCH, high values of a measure called neural complexity accompany consciousness. Neural complexity measures the extent to which the dynamics of a neural system are both integrated and differentiated. The component parts of a neurally complex system are differentiated; however, as larger and larger subsets of elements are considered, they become increasingly integrated. Modeling studies suggest that the distinctive reentrant anatomy of the TC system is ideally suited to producing dynamics of high neural complexity.

Similar to the DCH, and proposed by one of its originators (G Tononi), the information integration theory of consciousness (IITC) claims that consciousness corresponds to the capacity of a system to integrate information. A system is deemed capable of information integration to the extent that it has available a large repertoire of states and that the states of each element are causally dependent on the states of other elements. Like the DCH, the IITC is based on the notion that the occurrence of any conscious scene simultaneously rules out the occurrence of a vast number of alternatives and therefore constitutes a highly informative discrimination. Also like the DCH, the IITC proposes that the TC system provides the neuroanatomical substrate for the neural processes that underlie consciousness.

The IITC proposes a novel measure of the quantity of consciousness generated by a system. This measure, Φ, is defined as the amount of causally effective information that can be integrated across the weakest link of a system. Unlike neural complexity, Φ measures directed causal interactions within a system. According to the IITC, consciousness as measured by Φ is characterized as a disposition or potentiality. The contents of any given conscious scene are specified by the value, at any given time, of the variables mediating informational interactions within the system. A distinguishing feature of the IITC is that Φ is proposed to be a sufficient condition for consciousness, so that any system with sufficiently high Φ is conscious.

Both neural complexity and Φ can be considered to measure the spatial aspect of the balance between differentiation and integration in the dynamics of a neural system. A Seth and colleagues suggested useful additional measures of neural dynamics to measure other aspects of this balance, including complexity across time (temporal complexity) and across different levels of description (recursive complexity). Temporal complexity reflects the fact that consciousness extends over time in several ways. Many experiments suggest that it takes $\sim$100 ms for sensor stimuli to be incorporated into a conscious scene and that neuronal readiness potentials can appear several hundred milliseconds before the awareness of an intention to act. Recursive complexity reflects the fact that brains show rich organization at multiple levels, from molecular interactions within individual synapses to reentrant interactions among distinct brain regions. The phenomenal structure of consciousness also appears to be recursive; individual features of conscious scenes are gestalts and share organizational features with the conscious scene as a whole. Therefore, a combination of distinct measures may be needed to adequately characterize the neural dynamics relevant to consciousness.

Other Approaches

Because theoretical approaches to consciousness remain in their infancy, there is a large and growing body of alternative approaches which we are unable to describe fully here. These include the interplay of conscious experience with attention, immediate memory, selective attention, and input to an executive self.

Other approaches have focused on neuroanatomical constraints. S Zeki proposed that consciousness arises at micro features from local cortical circuits.

This micro-consciousness view is at variance with much of the evidence summarized here and is a minority position. B Merker challenged the dominant view that conscious contents depend on cortex and proposed an alternative model in which basic consciousness arises from the activity of subcortical areas including the thalamus, superior colliculus, and zona incerta.

Summary

What should we expect from a neural theory of consciousness? One thing we should not ask for is that the theory produce consciousness. After all, a theory of hurricanes is not itself windy. Rather, a useful theory should help move from establishing correlations between brain activity and conscious experience toward developing explanations that link features of brain activity with features of conscious phenomenology, as well as accounting for the relevant experimental evidence. Because consciousness is a rich biological phenomenon, the theories surveyed in this article vary in emphasis, level of abstraction, and the extent to which they provide satisfying explanations of conscious phenomena. At present, no single effort accounts for all the evidence, but we have seen marked progress in the last few decades.

Contextual Interactions in Visual Perception

D Sagi, Weizmann Institute of Science, Rehovot, Israel

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The visual world is sampled by the photoreceptors in the eyes' retinas, which produce an array of local light measurements. However, perception is definitely nonlocal. Both the subjective measures of stimulus qualities and the objective measures of related discrimination thresholds strongly depend on the spatial and temporal contexts within which the stimulus is embedded. This is true for points of light as well as for higher order visual features such as color, motion, depth, texture, and shape. These effects are thought to be of major importance in assigning meaning to the visual input and in the formation of behaviorally relevant perceptual objects by the brain. The underlying neuronal mechanisms are termed 'contextual interactions.'

Contextual interactions affect all aspects of visual processing, including low-level processes at the sensory end, which are related to basic image qualities (Figure 1) and higher level processes that are concerned with the identification of visual objects. The low-level processes at the sensory end are especially intriguing because they cannot be abolished by familiarity with the stimulus, and thus introduce a profound gap between the objectively measured physical world and our intimate knowledge of it as obtained with our perceptual system. This gap is explained by the nontrivial relationship between measurements and their causes: the latter is believed to constitute the content of perception. Typical examples include a variety of perceptual constancies, such as size and color constancies, which demonstrate that perception corresponds to actual object properties in the world (distal), such as actual size and surface reflectance, rather than to the corresponding retinal (proximal) measurements. Since perception involves reasoning about sensory effects by attributing measurements to causes, it is based on a large variety of assumptions that are made by the brain while the sensory measurements are being transformed into perceivable objects. These assumptions are found to underlie many perceptual processes and are probably the result of long-term adaptation to the environment, partly through a slow evolutionary process and partly through brain plasticity operating on a time scale of human life. As such, they can be viewed as constraints on the perceived world, capturing regular events occurring in the environment, the consequences of which are implemented in the brain to allow for improved processing and information transmission in a perceptual system with inherently limited measuring and processing devices. These constraints are crucial for resolving ambiguities when different scenes produce equivalent measurements, by choosing the more reasonable perception, the one that makes sense. Sensory ambiguities are resolved within the perceptual system without reference to, and often in conflict with, real-world knowledge that can be obtained by nonsensory means, as shown in Figures 1 and 2. By exploring the choices made by our visual system in generating perceptions, it is possible to theorize about the content of perceptual objects. Current research supports the notion that perception concerns the description and segmentation of visual surfaces. The biological mechanisms required for recovering such properties from the visual stimulus can be found in early stages of visual processing and include processes that detect boundaries between surfaces as well as surface characteristics such as color, texture, and layout in space and time. All of these processes are context sensitive, meaning that these processes are affected by remote image parts, or that different image attributes affect each other.

Phenomenology

First-Order Spatial Interactions

First-order spatial interactions are contextual effects that are related to the spatial distribution of light and to influences on the perception of light intensity (brightness).

Subjective estimates of light intensity The most basic contextual effect in visual perception is seen when attempting to evaluate the amount of light falling on a small retinal area (definitions: 'luminance' is the physical quantity of light; 'brightness' is the perceived quantity of light). The light will be evaluated as being less intense when the target is surrounded by light of a higher intensity, whereas it will be evaluated as more intense when the target is surrounded by light of a lower intensity. This phenomenon, illustrated in Figure 1, is termed 'simultaneous contrast'; Figure 1 demonstrates that the perceptual qualities of dark and bright (or black and white) do not correspond to absolute light intensities but rather to gradients of intensity. Similarly, the perceived color of an object depends on the colors surrounding the object ('color contrast,' 'chromatic induction'). In a related phenomenon, called Mach bands, sharp intensity transients are

Figure 1 Context effects in brightness perception – first-order spatial interactions. The two bars have the same intensity; however, their perceptual effects differ significantly because of the different background. What we perceive are 'white' surfaces that are brighter than their immediate surround and 'black' surfaces that are darker than their immediate surround.

enhanced so that the dark side of an edge looks darker whereas the bright side of an edge looks brighter. The occurrence of Mach bands can be explained by lateral inhibition between neighboring light-detection arrays; high response is predicted when the neighboring arrays receive different levels of stimulation, and no response is predicted when the neighboring arrays receive the same level of stimulation. This type of transformation takes part in sensory tasks involving different sense organs and affects different features within the same sensory organ (see later, discussions of spatial interactions in the perception of motion and depth). A hierarchy of lateral-inhibition operations within the visual system was proposed to account for spatial interactions involved in the perception of light contrast

Figure 2 The Wavertree (South Street Seaport Museum, New York, NY). These images, rich in details and contours, do not pose a particular challenge to the visual system, and objects are effortlessly segmented. Such an achievement is impossible without contextual interactions within the perceptual system. However, details of shape are not reliable and the ship in the background (top image) is seen as curved. The distortion is even stronger under natural viewing conditions when the ship covers a larger part of the field of view. A slightly different point of view produces a more reasonable percept (bottom image). It is difficult to estimate the frequency of such misperceptions in our daily encounters with the visual world.

(see the section titled 'Second-order spatial interactions'). Lateral inhibition can be used to explain, at least in part, 'simultaneous contrast,' because sensory systems equipped with lateral inhibition respond to relative intensity rather than to the absolute intensity level. However, such an explanation cannot be complete because the perceived simultaneous contrast also depends on long-range interactions and on the spatial arrangement of the edges in the stimulus.

Sensitivity to changes in light intensity Discrimination thresholds depend on the light distribution in the area around the target. For a small, fixed-size target of light on a background of variable size, incremental threshold increases when the background size is initially increased – a larger increment is required to induce an appreciable difference in light intensity (desensitization) – but then decreases (sensitization) with a further increase of size.

Neurophysiological correlates Light-discrimination thresholds and the corresponding spatial interactions are successfully modeled with receptive fields of a shape found in the mammalian retina and the lateral geniculate nucleus (LGN). These receptive fields integrate light over some spatial areas, with regions in the center of the integration zone and its periphery having opposite signs (ON–OFF receptive field). This can be viewed as an implementation of the lateral-inhibition theory suggested by Mach. Thus, a neuron with such a receptive field responds to contrast – that is, to spatial variations in light intensity. Given the stimulus presented in Figure 1, such neurons, with the appropriate receptive-field size and retinal location, will respond vigorously to the left bar if their center is positively weighted (ON) and their surround is negatively weighted (OFF), whereas the right bar activates neurons with a receptive field having an opposite weight. Since this effect is possible with bars having a wide range of sizes (it can be experienced by changing the viewing distance) while receptive sizes are limited, most neuronal activity occurs around the edges of the bars, at locations of maximum contrast, and not within the uniform region within the bars. Thus, the brightness of the bars is thought to be perceived through a process of interpolation or filling-in (see later).

Second-Order Spatial Interactions

Second-order spatial interactions consist of contextual effects that are related to the distribution of light contrast in the visual field and to the perception of light contrast.

Subjective estimates of light contrast When attempting to evaluate the amount of light contrast within a textured stimulus region, the contrast will be evaluated as being weaker when the target is surrounded by a texture of higher contrast, whereas it will be evaluated as having more contrast when surrounded by a texture of lower contrast. This phenomenon, presented in Figure 3, suggests the existence of lateral inhibition within arrays of contrast detectors.

Sensitivity to changes in light contrast The detection threshold for light contrast is affected by the contrast around the target. For a localized and oriented contrast target (Gabor signal), detection thresholds increase (desensitization) in the presence of nearby high-contrast stimuli (flankers), but when the distance between the target and the flankers is increased, then there is a range in which the detection threshold decreases (sensitization). These effects are strongest when the target and flankers are co-oriented and co-aligned, as if lying on the same contour.

Figure 3 Second-order spatial interactions. The two smaller squares have the same contrast but their perceptual effects differ significantly because of the different background. Adapted from Chubb C, Sperling G, and Solomon JA (1989) Texture interactions determine perceived contrast. *Proceedings of the National Academy of Sciences of the United States of America* 86(23): 9631–9635.

Neurophysiological correlates Contrast-discrimination thresholds and the corresponding contextual effects can be modeled by receptive fields of neurons found in the primates' primary visual cortex and by their lateral interactions. These neurons respond to oriented contrast – that is, to nonisotropic first-order changes taking place along one direction on the retinal surface. In addition, these neurons are also affected by stimuli placed outside their classically defined receptive field (meaning that neuronal activity cannot be elicited by these stimuli when presented in isolation) if these are properly aligned with the stimuli that are placed within the receptive field. Both inhibitory and excitatory contextual interactions have been found in the visual cortex.

Spatial Interactions with respect to the Perception of Motion

The detection of motion is carried out by special mechanisms that are sensitive both to translation of luminance (first-order motion) and to contrast (second-order motion), with their resulting motion vectors combined. The perceived motion within a retinal area depends on the surrounding motion ('motion induction'). In the case of ambiguous random-dot cinematograms, when the moving target region is perceived with equal probability as moving to the left or to the right, an unambiguous surround biases the target motion in the surround direction. This result indicates the existence of lateral interactions between motion detectors that integrate motion signals to reduce local ambiguities. On a larger spatial scale, inhibitory interactions are found, with antagonistic interactions between motion signals of the same direction. The neurophysiological correlates of these effects are believed to reside in the middle temporal (MT) visual area, the specialty of which is the analysis of motion, whereby neuronal response to movement is suppressed in the presence of surround movement in the same direction.

Spatial Interactions with respect to the Perception of Depth

The detection of a three-dimensional structure is based on multiple cues (see later), but at the most basic level it is based on the detection of small displacements between features of the two retinal images captured by the two retinas (stereopsis). Stereoscopic information is often highly ambiguous and thus the existence of unique perception implies a strong dependence on other depth cues, if available, or on internal brain structure. For example, the lines seen in Figure 4 can be matched between both eyes in different ways, because each green line is a potential match for every red line (the 'correspondence problem'); however, one perceives flat surfaces. Such a product of the perceptual system cannot be achieved without spatial integration. The range of spatial interactions between isolated stereoscopic stimuli is limited to a few minutes of arc when lines are used and to three times the object's size when Gaussian blobs are used as matched features. However, with textured stimuli, disparity information is found to propagate across much larger distances of a few degrees with both real and illusory disparity edges. Neurophysiological correlates of these effects are thought to reside in visual area V2.

Plasticity of Contextual Interactions

There are many indications that perceptual processes are affected by experience. Context effects are found

Figure 4 Ambiguous stereo images (require red–green glasses). The center part of each of the two displays is ambiguous with respect to disparity and can be seen either in front of the page or at the back when viewed alone. In the left-hand image, the flanking lines, which form depth plans different from each of the ambiguous center states, do not resolve the ambiguity, but in the right-hand image, the flanking lines attract the central bars to form a continuous plan (the depth of unambiguous regions should reverse with reversal of the glasses, viewing distance >40 cm is recommended).

to change with practice. Studies of texture segmentation show a large decrease in processing time (threefold) due to practice, and this is found to be highly specific to visual features known to be encoded in the primary visual cortex. In particular, second-order spatial interactions are found to propagate over larger distances after practice, implying increased range of excitatory interactions. First-order context effects are generally more stable and do not change with practice. However, a recent report by Adini et al. show changes in contrast discrimination thresholds after practicing with stimuli that activate second-order interactions, indicating that first-order contextual interactions are affected by practice. Electrophysiological recordings from the primary visual cortex of primates show experience-dependent activity, with receptive-field shape modified with practice. Of particular interest here is the finding by Crist et al. that changes in receptive-field size depend on the specific configuration practiced. This latter finding also shows that contextual interactions in the visual cortex are task dependent – that is, they can be specifically modulated by the current behavioral context. Psychophysical experiments show that excitatory spatial interactions are task dependent. Overall, current research provides strong evidence for different time scales involved in the adaptability of contextual interactions to the environment.

Functional Significance

Surface Properties

The brain infers (or, according to some views, reconstructs) the properties of objects in the visual field from the available measurements made by the eye; however, these measurements do not always have a unique interpretation. To reduce the number of possible interpretations, the brain relies on contextual information that may be found in the retinal image or is made available through other senses. The usefulness of such 'cues' depends on the validity of the assumptions implemented in the brain as constraints on the structure of objects in the world and their behavior.

This problem arises, for example, when estimating the light-reflectance properties (i.e., lightness) of a surface, when querying whether it is dark or bright and regarding its color. The recovery of surface reflectance requires, in addition to measuring the light reflected from the object (brightness, perceived luminance), knowledge of the light illuminating the object as well as of the geometric properties of the surface. However, the illumination cannot be measured directly and is inferred from the distribution of light reflected from regions surrounding the target object. In Figure 1, our visual system seems to assume that the illumination is gradually increasing from left to right, so that bars on the left and on the right that reflect the same light intensity (as measured by the eye), which is a product of the incident light and the surface reflectance, are expected to have different reflectance properties: higher on the left and lower on the right. Thus, it is assumed that our perceptions report the reflectance properties of objects rather than the light reflected. There is also an uncertainty regarding the shape of the surface presented in Figure 1. It is possible that the light source is uniform, and so is the surface reflectance, but the surface is curved so that the darker region is from a surface section that is more tilted relative to the direction of light and thus reflects less light. Often variations of surface shades are perceived as depth variations; however, this is not the case in Figure 1. In general, the geometric properties of the surface are also not directly available for the brain to use and therefore the recovery of a three-dimensional structure is required. Furthermore, other effects, such as cast-shadow, transparency, and air-transfer function, need to be taken into account. The reflected light reaches the eyes after traveling in air with unknown properties that need to be taken into account when the distance between the object and the eyes is large (atmospheric effects). As will be shown later, the three-dimensional structure is not available to the brain unambiguously and its recovery makes use of shading cues. Given this situation, one may doubt whether reliable perception is possible at all. The answer is that perception is not always reliable (as shown in Figure 2 and in many illusions that push our perceptual abilities to the limit) and is heavily dependent on intrinsic assumptions that are based on regularities in the world in which we live. Contextual interactions can be viewed, at least in part, as an implementation of these environmental regularities in the brain.

The recovery of geometrical properties of objects from the retinal image is ambiguous due to a reduction in dimensionality. The retinal sampling array is two-dimensional (2-D) whereas the world around us is three-dimensional (3-D); thus the lost dimension needs to be determined from contextual cues. In the case of recovering the 3-D structure of objects from their 2-D retinal projections, the brain makes use of geometric information related to perspective, shadows (cast and attached), occlusion, transparency, image blur, atmospheric perspective, optic-flow and motion parallax, texture gradients, retinal size, accommodation, eye vergence, and eye disparity. The recovery of depth information from these cues requires further assumptions about the relationship between the depth measures available from the cues and the actual depth. In addition, contextual information related to viewing

conditions needs to be integrated with the visual measurements to yield a reliable perception of the three-dimensional structure. Furthermore, ambiguity can often be resolved by combining information from different cues.

Segmentation

Surface properties are used by the visual system to locate boundaries of objects, since boundaries are often marked by a change in brightness and texture. The process of boundary detection is thought to involve contextual interactions within low-level vision, and recent studies have suggested neurophysiological correlates in the visual cortex. Object boundaries are marked by differences in luminance across the boundary when objects differ from their background in their reflectance properties. These luminance differences can be detected by edge detectors that are based on first-stage receptive fields of the type proposed to account for first-order spatial interactions that operate on different spatial scales. However, such a mechanism is not sufficient for successful image segmentation because object surfaces often include intensity edges that do not delineate the boundaries of objects but instead are produced by other causes such as surface texture. In Figure 1 the boundaries of objects are denoted by intensity differences (edges), but in Figure 3 the intensity edges are present everywhere, not only at the boundaries of objects. When looking at Figure 3, first-stage receptive fields are activated by the textured surface, though to different degrees: the higher contrast parts produce larger responses and the lower contrast parts produce lower responses. These responses do not mark the locations of boundaries but rather the changes in these responses correspond to the relevant boundaries. Thus, the task of boundary detection here involves the detection of spatial variations in the activity of first-stage receptive fields. Early texture models attempted to define global texture properties that would enable discrimination between two given textures based on their image statistics. Later models introduced local feature detection into the texture process, and assumed that segmentation is done by comparing statistics of such features. Current theories assume a local 'textural gradient' detection mechanism, thus avoiding global processes, or transferring it to the final decision stage with a simple feed-forward design. Recent theories of texture segmentation contain two processing stages that correspond to the two stages discussed earlier: first- and second-order spatial interactions.

In addition to boundary-sensitive processes, image segmentation is supported by grouping processes that bind different image parts to form objects. The underlying mechanism is presently not clear, but recent results suggest a mechanism that is based on linking local orientation signals across space. Such a mechanism can be useful in enhancing long contours, as in Figure 5, in particular closed contours, and in texture images that correspond to an object's boundaries. It was suggested that the neuronal implementation of these contour interactions includes non-isotropic excitatory connections between orientation-specific detectors within the same network that produce second-order spatial interactions. Global effects that were found, such as higher sensitivity to long and closed contours, are believed to be achieved via propagation of activity within the network.

Figure 5 Evidence for efficient contour integration within the visual system. The elipse created by the closely aligned (Gabor) patches clearly stands out from the noisy background. Without the 'built-in' connectivity that allows for orientation signals to propagate along contours, we would see all patches as having equal saliency. Note that shorter contours are not as salient as the closed one is. History

Perception: Back to Gestalt from a New Reductionism

Gestalt psychology – an influential theory of perception early in the twentieth century – proposed that perception was determined not by the elemental sensations of light and dark but by laws of similarity, good continuation (analogous to smoothness), closure, symmetry, etc. that grouped such elements within a larger visual context (Figure 1). The founder of this school, Max Wertheimer, first came to prominence with his studies of 'phi motion,' the illusory percept of smooth motion that appears when a spot of light flashes in sequence over a set of discrete points in space; this illusion of motion – which underlies our perception of smooth motion in movies – cannot be reduced to its underlying elemental light flashes.

Two historical exigencies shortened the life of Gestalt psychology in its initial incarnation. First, the rise of Hitler forced Wertheimer and many of the other proponents of Gestalt ideas to flee Germany as refugees. More important, Gestalt ideas could not point to any underlying neurophysiological mechanisms. By contrast, the discovery of apparently elemental neuronal receptive fields in the retina and later in visual cortex starting building a powerful body of physiological and anatomical evidence for a reductionist model of visual perception. Namely, that the visual input was decomposed first into the smallest independent elements of light and dark. These were then built up into independent short lines and so on through a set of progressively more complex but independent features higher along the visual pathway, toward the final percept.

Recent work in the field has revived more holistic ideas of visual perception reminiscent of Gestalt concepts, this time with neurophysiological and anatomical backing. Using perceptual tests and a quantitative measure of curve smoothness, Field and colleagues showed that our visual systems find it progressively easier to pick out 'smoother' curves. This gave a rigorous basis for the Gestalt concept of 'good continuation' and was further backed up with physiological and anatomical results showing selectivity for smoothness in V1 neurons. More generally, quantitative perceptual tests suggest that we appear to parse visual scenes into surfaces, contours, and objects rather than into elemental edges. Our interpretation of objects in the scene then influences our perception of their color, the presence (or absence) of edges, and other nominally elemental aspects of the visual scene. Many of these results are now finding corroborative evidence in physiological results.

Neurophysiology: The Changing Concept of the Receptive Field

Starting with the recordings by Hartline in the limulus retina in the 1930s, visual neurophysiologists described neurons in the visual pathway as having small, independent, spatially delimited receptive fields (RFs). This was exemplified by Kuffler's characterization of small, independent circularly symmetric center-surround RFs in the retina and Hubel and Wiesel's description of small, independent elongated orientation-tuned simple cell and complex cell RFs in primary visual cortex. Notably, the response of each neuron was independent of the stimulation of other neurons with different RFs. These discoveries laid the basis for the influential, reductionist view of visual perception.

This classical description of elemental, independent RFs was a consequence of the types of simple stimuli used by early neurophysiologists – small isolated single spots or bars of light which stimulated neurons vigorously (or suppressed responses sharply) but only when shown within crisp, small regions of space.

There were several early indications, however, that the idea of the spatially limited RF was oversimplified and that responses of neurons to stimuli within their receptive fields could be influenced by distant visual inputs. As early as 1953, Barlow showed that the responses of a particular class of ganglion cells in the frog retina – the 'on–off' cells – were suppressed by spots of light outside their receptive fields. This was distinct from the inhibitory (or excitatory) subfields that Kuffler and others had described for the receptive field, where a small spot of light could, on its own, cause a reduction (or increase) over background activity. Barlow showed that a spot of light that was incapable of changing an on–off neuron's firing pattern on its own – thus, by definition, lying outside the classically defined receptive field – could entirely suppress the response to a second spot of light lying inside the receptive field. In 1964, McIlwain showed that the responses of (cat) retinal ganglion cells to stimuli inside their RFs increased when moving a stimulus (e.g., a small black disk) up to 90° away in the periphery. In 1965, Hubel and Wiesel

Figure 1 Some Gestalt principles used by our visual system to group simple elements into visual objects: (a) proximity (grouping the dots into nearby pairs); (b) similarity (grouping the dots into alternating sets of small and large dots); (c) good continuation (we see this figure as a sinusoid and a square wave, not as alternating pairs of the more complicated objects shown in red and green to the side).

described the phenomenon of 'hypercomplexity' (now known as end-stopping) in cat area 18, where the response of a neuron to its preferred bar stimulus could be suppressed entirely by a second, collinear bar outside the neuron's receptive field.

Evidence accumulated through the 1970s and 1980s established this basic parsing of the input receptive field of neurons in all visual areas – a small classically defined RF where stimuli were capable of driving neuronal responses directly, and a surround where stimuli could suppress or facilitate the neuron's response to a stimulus in its classical RF. During this period, Blakemore and Tobin, Nelson and Frost, and later Allman and colleagues showed that the modulatory surrounds of RFs could be characterized by their tuning for properties similar to the properties of the 'classically' defined RFs ('CRFs'). Their studies using a particular class of surround stimuli – bars or gratings or moving dots in an annulus outside the RF – showed that the influence of the surround was typically strongest (most inhibitory or most excitatory) when its features (orientation, spatial frequency, and direction of motion) matched the features of the optimal stimulus inside the neuron's classical RF.

This parsing into a classical RF and modulatory surround is not rigid and some authors prefer to define a neuron's RF as encompassing the entire complex of responses, both direct and modulatory. Furthermore, the bounds separating the core of an RF from its surround are not fixed but depend on the stimulus being used. Bright, high-contrast stimuli induce neuronal responses with smaller, crisper cores, whereas low-contrast stimuli or stimuli surrounded by busy textured surrounds can drive the same neurons from core RF regions that extend out much further. The distinction between core and surround in a receptive field, although not precise, is still useful and is likely to reflect the neuroanatomical distinction between the feed-forward (or local) inputs to a neuron versus the inputs from longer range connections and feedback from higher visual areas.

Neuroanatomy: The Substrate underlying Contextual Influences

Since the 1980s, new, sensitive anatomical tracing techniques have made it possible to see precise, long-range anatomical interconnections both within and between cortical regions, giving a plausible anatomical basis for contextual interactions in vision. In 1979, Gilbert and Wiesel showed that pyramidal neurons in V1 not only make local connections within their cortical columns (over a few hundred micrometers) but also send out axonal collaterals that extend for many millimeters and connect with distant neurons in discrete and well-separated clumps. Later work has shown that these long-range connections are precise and selective for neuronal response properties (Figure 2). Thus, neurons selective for vertical lines, for example, at one point of visual space, send out axonal connections that skip over other orientations to connect selectively with distant cortical columns of other vertical-preferring neurons with receptive fields at a different point in visual space, up to 10 RF diameters away. This anatomical network provides a plausible substrate for orientation-tuned contextual interactions. Thus, a neuron responding to a vertical edge in its RF will receive long-range axonal input from other neurons responding to more distant vertical edges (but not other orientations) in their RFs. This axonal input could be facilitatory, from direct excitatory pyramidal-to-pyramidal connections, or it could be inhibitory since the long-range connections also target local inhibitory interneurons.

V1 also receives extensive and widely divergent feedback from higher visual areas, with single locations in the higher areas sending connections over V1 regions extending many millimeters (i.e., the same lateral extent as the intrinsic axonal collaterals). This feedback can be very rapid. The fibers interconnecting different visual areas are myelinated and fast, unlike the slower unmyelinated fibers within a cortical region. In 1996, Movshon and Newsome showed that the transit time between V1 and area MT, a cortical area specializing in visual motion processing one level beyond V1, is only 1.4 ms. Feedback from higher areas contributes a significant component to the contextual modulation of neuronal responses in V1. Bullier and colleagues showed that a number of contextual modulatory responses, even ones with short latencies, are considerably reduced or even eliminated on silencing higher visual areas either by cooling or with the inhibitory neurotransmitter GABA. Most of these feedback connections lack the precise orientation-specific patterns characteristic of intrinsic connections. They are thus believed to mediate overall attentional or task-dependent

Figure 2 The anatomy of axonal arbors radiating out from V1 pyramidal neurons, shown superimposed on an optically imaged orientation map from the same region of V1 (in tree shrew). The optical image is color-coded to identify the orientation preference of each column (key below). The anatomical trace was obtained by first optically imaging the animal's V1, injecting a neural tracer into a selected orientation column and processing the tissue after allowing the tracer to spread along axonal arbors. In the immediate vicinity of the injection site (white dots: cell bodies that have taken up the tracer) the axonal arbors spread uniformly, independent of local orientation. At more distant sites, however, the axonal arbor forms clumps of connections with other neurons in columns of the same orientation as the injection site, skipping over intervening cortical columns of different orientations. Reprinted from *Journal of Neuroscience* 17(6): 2112–2127. Bosking WH, Zhang Y, Schofield B, and Fitzpatrick D: Orientation selectivity and the arrangement of horizontal connections in tree shrew striate cortex. (1997).

modulations rather than orientation-tuned contextual modulations in V1.

The extent and sources of these long-range inputs stand in contrast with the mostly local connections and feed-forward inputs that are believed to determine RF cores. Thus, the input whose geometric alignment determines the core elongated shapes and orientation tuning of V1 neurons is mostly feed forward from lower areas (e.g., lateral geniculate nucleus (LGN)) combined with connections within the cortical column (i.e., extending a few hundred micrometers).

The Role of Contextual Modulation

The patterns of surround-induced modulation discovered in physiological studies during the 1980s were interpreted as mechanisms of adaptation or of sharpening the discrimination among features in the visual input. The typical stimulus consisted of a center at the preferred orientation or direction of motion of the neuron and a surround consisting of a uniform background pattern similar to the center but with variable orientation or direction. Such surrounds typically induced suppression or facilitation tuned to the angular difference between center and surround. The overall response was weakest when the surround blended with the center, and it was strongest when the surround was antagonistic. These center–surround interactions were interpreted as a way of accentuating regions of visual contrast while suppressing regions of uniform visual texture. They were also believed to be mechanisms for perceptual constancy; for example, a means of integrating (and thus discounting) the color over the background, allowing us to see objects in their true color independent of the illumination.

Work since the 1980s has uncovered a much larger and more complex repertory of neurophysiological center–surround interactions. Neuronal responses to contextual stimuli seem well matched to parsing visual scenes into perceptually relevant midlevel features – into smooth contours, the inside versus the outside of objects, foreground versus background, identifying occlusion of one object by another, etc. These broad classes of contextual interactions are laid out in the following sections.

Grouping Lines into Smooth Contours

The Gestalt idea that the visual system is sensitive to smooth contours (the principle of 'good continuation') has been borne out by quantitative perceptual

as well as physiological experiments. Using contours consisting of disjointed line segments, Field, Hayes, and Hess showed that the ease with which a contour could be detected in a noisy background was related, quantitatively, to its smoothness. Subjects' detection performance decreased monotonically as the contours were made more sharply curved or had increased angular or positional jitter between the line elements. Field and colleagues quantified this interaction by introducing the concept of an 'association field' tuned for smoothness around each visual line element (Figure 3).

Our sensitivity to smoothness in contours may be mediated through the mutual facilitation between V1 neurons responding to the individual elements of the smooth curve. Kapadia showed, for example, that a (monkey) V1 neuron responding to a line inside its RF was strongly facilitated by flanks lying outside the classical RF. The degree of facilitation was strongest for flanks that were collinear and nearby, and it diminished as the flanks were drawn further apart, to a side, or at an increased angle. In a parallel perceptual study in which subjects were asked to detect a barely visible low contrast line, the ease of detection improved almost twofold with a collinear flank; the improvement decreased monotonically as the flanking line was moved away, as in the physiological experiments (Figure 4).

The close match between the physiological pattern of facilitation, the perceptual association field, and the anatomical layout of axonal collaterals in V1 (Figure 2) suggests that V1 intrinsic connections may mediate contour detection; findings by Grinvald of orientation-tuned feedback from V2 open the possibility, however, that feedback from higher areas also plays a role.

Figure 3 (a) A smooth contour with 30° jumps between adjacent elements (right) is easy to pick out of a complex background (left). (b) A contour with 60° jumps between adjacent elements (right) is perceptually less 'smooth' and is much harder to see against a background. (c) The proposed association field mutually facilitates the perception of line elements that lie on smooth contours relative to each other (left) while suppressing the perception of elements that are orthogonal or displaced (right). Reproduced from Field DJ, Hayer A, and Hess RF (1993) Contour integration by the human visual system: Evidence for a local "Association Feild". *Vision Research* 33(2): 174–193, with permission from Elsevier.

Completing Occluded Surfaces

Smooth curves broken up into short line segments are a special case of a feature that is common to everyday perception. Namely, that in natural environments we rarely see objects in their entirety. They are generally partially occluded by other objects in front of them. Yet, we (and other animals with sophisticated visual systems) have no problem perceptually interpolating and identifying object boundaries behind occluders – reaching, for example, for a fruit obscured by a branch. This process of identifying occluded objects is believed to involve the intermediate step of assigning 'border ownership': when one object is seen as lying in front of another, the visual boundary between the two is perceived as 'belonging' to and defining the outlines of the object in front. The object in the background is seen as continuing behind the occluder.

The process of identifying occlusion and border ownership was believed to be largely bottom–up and hierarchical. Our visual systems were believed to first identify local cues suggesting the presence of one surface lying across another: 'T' junctions, corners, and disparity (i.e., depth) ordering between surfaces. These cues were then used to assign border ownership locally (T junction means that the straight edge lies on top), building up a sequential process of identifying surfaces and their boundaries (Figure 5).

Quantitative perceptual work, for example, by Nakayama and Shimojo, suggests that the process is not entirely bottom-up. Rather, we form intermediate hypotheses about surfaces and objects early in the perceptual process, which then influence our perception of local features. By presenting visual stimuli dichoptically (i.e., with one image to the left eye and a slightly shifted image to the right eye so as to give

Figure 4 Comparing perceptual results for detecting a low-contrast line (in human subjects) with the physiological responses of V1 neurons to a similar line (in monkeys). Top left: Human subjects were asked to detect a low-contrast line ('target') that was flashed on while the subject maintained steady fixation. The subjects' detection performance as a function of target contrast (red curve) improved when the single low-contrast line was flanked by a collinear flank (green curve). For the closest flank position, the threshold for detection is reduced to roughly 50%. Bottom left: Responses of a monkey V1 neuron to a low-contrast line flashed in its RF (square) while the animal maintained steady fixation. The response to the line alone (red) was facilitated by a second line outside the RF (green) even though the second bar did not stimulate neuronal responses by itself (empty box showing line outside the RF). Top right: The threshold for human subjects' ability to detect a dim line improves 50% with a collinear flank; this improvement reduces steadily as the flank is rotated away from collinear. Bottom right: The facilitation by a collinear flank of a monkey V1 neuron's response drops as the flank is rotated away from collinear. Reproduced from Kapadia MK, Ito M, Gilbert CD, and Westheimer G (1995) Improvements in visual sensitivity by changes in local context: Parallel studies in human observers and in V1 of alert monkeys. *Neuron* 15(4): 843–856, with permission from Elsevier.

the percept of objects in three dimensions), they showed that simply switching images between the left and right eye dramatically changed our interpretation of a scene. With an object seen as lying behind an occluder, we automatically 'complete' the occluded object with perceptually salient continuous boundaries. Just switching the order of images so that the image on the left now gets presented to the right eye and vice versa turns occluders lying above the plane of the object into holes extending below. Despite the presence of the same local information (T junctions, corners, etc.), switching images breaks the foreground object into discontinuous strips that are much more difficult to identify, even eradicating the percept of continuous edges, a nominally 'elementary' percept.

These perceptual results are supported by physiological results showing that the grouping of lines into smooth contours – the facilitation of neuronal responses by collinear flanks – is not automatic. Rather, it depends on being able to interpret the gaps between lines as occluders. In V1, a small fraction of neurons respond thus to illusory lines lying behind occluders (Figure 6). In V2, on the other hand, a large number of neurons (possibly 50%) have such a disparity-selective response to the presence of collinear flanks (Figure 7).

Explicitly Identifying Border Ownership

Several studies by Rudiger Von der Heydt and colleagues have identified neurons at various stages along the visual pathway – in V4 and V2 and, to a limited

extent in V1 – that signal border ownership *per se*. That is, the response of a neuron to an edge at its preferred orientation, running through the neuron's receptive field, depends on whether the edge 'belongs' to an 'object' or 'foreground' lying on one side or the other of the neuron's RF (Figure 8). The neuron's response does not depend on lower order features of the edge such as contrast polarity (i.e., whether the edge is white against black or black against white). These neurons appear capable of generalizing across objects cues; that is, whether objects are defined through solid blocks of color or through disparity shifts in random dot patterns. Note that in all cases the distant boundaries marking whether the object lies on one side or the other of the neuron's RF lie far outside the neuron's classical RF; these neurons are capable of spatially integrating contextual cues that extend at least 20° (i.e., more than 10 times the diameter of the classical RF). Moreover, the neuronal response difference signaling 'object to one side' versus 'other side' emerges at a latency no greater than the initial response of the neuron, suggesting a rapid processing of the contextual information regarding border ownership (Figure 8), thus indicating that the processing occurs intracortically within the same cortical region rather than involving feedback from higher areas.

Figure 5 A simple scheme for extracting depth order amongst occluded surfaces using T junctions: the junctions, for example between lines A and C or B and C, help identify this as a horizontal bar (M) lying atop a vertical bar (U + L).

Figure versus Background

The responses of neurons even in V1 are modulated depending on whether their RFs lie inside 'figures' or

Figure 6 Neurons in monkey V1 respond to a line that appears to be completed behind an occluder. The neuron (RF shown in (a) responses to a line in its RF in (b–d)) shows no response to an unconnected pair of lines outside its RF (f) but does respond when simultaneously shown a patch that could be interpreted as a foreground surface occluding a continuous line underneath (h). Controls (g, i, j, k) to show that the cell respond only to a stimulus geometry that is consistent with an occluder lying above a line. Reprinted from *Nature* 401: 269–272. Sugita Y Grouping of image fragments in primary visual cortex (1999).

Figure 7 Collinear lines provide facilitation only when they lie on the same plane and are seen as potentially continuous. A V2 neuron's response to a single line (vertical center line) in a complex background (a) improves when flanked with collinear lines on the same depth plane (b). This improvement is 'vetoed' by an orthogonal line on the same depth plane (b, extreme right) but returns when the perpendicular line is placed on a different depth plane consistent with being an occluder lying above a continuous line (arrow, last item in c). Reproduced from Bakin JS, Nakayama K, and Gilbert CD (2000) Visual responses in monkey areas V1 and V2 to three-dimensional surface configurations. *Journal of Neuroscience* 20(21): 8188–8198, with permission.

on the 'background.' In some of the earliest studies of neurophysiological correlates of figure–ground separation, Zipser and Lamme created (flat, two-dimensional) rectangular figures distinguished from their backgrounds by some simple visual contrast – a pattern of dots moving in one direction in the figure versus the opposite direction in the background, or a pattern of lines tilted in one direction in the figure versus the orthogonal tilt in the background. With V1 neuronal RFs lying on the figure boundary, or at various distances away either into the figure or into the background, the neurons showed a consistently higher delayed response inside the figure versus outside on the background (Figure 9). Unlike the 'border ownership' response modulation, the neuronal response signaling 'figure versus Background' arrives with a considerable latency of 50–100 ms after the initial onset of the neurons' responses to visual stimulation. Furthermore, this neuronal response difference is seen only when recording from alert behaving animals and disappears under anesthesia. These observations suggest that the figure versus background contextual modulation is mediated through feedback from higher areas.

Border Ownership and Visual Motion Perception

The assignment of boundary ownership can radically alter our perception of motion. A line seen moving behind an aperture appears to move perpendicular to its edge even though its actual direction of motion may be quite different, a perceptual confound that gives rise to the classical 'barber pole' illusion. The critical feature of such a visual scene, as pointed out by Nakayama, is that the ends of the line be interpreted as being occluded by the aperture as opposed to 'belonging' to the line. On the other hand, a moving line seen in the foreground has ends that clearly belong to the line and there is no ambiguity about the direction of motion of the line.

Figure 8 Cell (monkey V2) responds to 'foreground' versus 'background' independent of whether the 'foreground' is defined by contrast or by disparity. Top (a, c): Cell responds vigorously when a 'foreground' object defined as a square of contrast different from the background lies to the left of the RF. Note that the boundaries of the object are well beyond the boundaries of the cell's RF. (b, d) There is no response when the foreground object lies to the right of the RF even though the local visual stimulus running through the cell's RF is the same (compare a, b and c, d). (e–h) The visual stimulus here consists of a random dot stereogram, presented dichoptically to the two eyes with different disparities over the image such that a portion of the image appears to float above a background. The cell responds vigorously when the floating foreground lies to the left of the border running through the RF (e, f), but not when it lies to the right of the RF (g, h). Bottom: Comparing the response of another V2 neuron to foreground (continuous line) vs. background (dotted line) lying on one side of the RF, whether defined by contrast or by disparity (RDS: random dot stereogram). Reprinted from *Neuron* 47: 155–166. Qiu FT and von der Heydt R Figure and ground in the visual cortex: V2 combines stereoscopic cues with gestalt rules (2005).

Albright and colleagues used this insight to construct a 'barber diamond' in which they could vary the perceived direction of motion by changing the depth order of the surfaces surrounding the diamond. The pair of bounding surfaces (e.g., top right/bottom left) positioned in front of the moving lines were seen as an aperture occluding the lines, whereas the other pair, behind the moving lines, became the background. The motion of the line ends seen against the background boundaries then determines the perceived direction of motion of the lines (Figure 10). Switching the depth order of the surfaces switches

Figure 9 V1 neurons respond with different temporal dynamics depending on whether their RFs lie on the foreground, background, or border of a figure. Top: Figure versus background defined by a texture of oriented lines. Bottom: (a) The figure was flashed on at different locations relative to the neuron's RF while the monkey maintained fixation. (b), (c) At RF locations lying within the figure, the neurons showed a delayed sustained activity that was higher than when the RF lay on the background. When the RF lay on the figure boundary, the delayed response was stronger and had a shorter latency. Reprinted from *Cerebral Cortex* 9(4): 406–413. Lamme VAF, Rodriguez-Rodriguez V, and Spekreijse H Separate processing dynamics for texture elements, boundaries and surfaces in primary visual cortex of the macaque monkey. (1999).

'aperture boundary' and 'foreground' and changes the perceived direction of line motion. Neurons in macaque monkey area MT, a visual cortical area that is believed to be critical to the perception of visual motion, switched their response in accordance with the perceived shift of line motion (Figure 11). Not only does this show that neurons in MT can integrate contextual information lying well outside their classical RFs but also it is an example of an 'intermodal' interaction in which information about

Figure 10 The 'barber diamond' illusion. With vertical stripes moving horizontally in the diamond-shaped aperture, (a) the perception is also, typically, of an object moving horizontally seen through an aperture in an occluding screen. When the visual stimulus is presented dichoptically, however, with diagonal pairs of quadrants floating above and behind the vertical stripes, (b,c) the percept changes dramatically. With the disparity arranged so that the top-left/bottom-right are far while the top-right/bottom-left are near, the percept is clearly of a rectangular strip moving diagonally to top right as shown over the far surface; the angle of the diagonal motion switches on switching the order of the far/near quadrants (c). Reproduced from Duncan RO, Albright TD, and Stoner GR (2000) Occlusion and the interpretation of visual motion: Perceptual are neuronal effects of context. *Journal of Neuroscience* 20(15): 5885–5897, with permission.

depth (disparity) influences response tuning to motion through an intermediate interpretation of the scene into a set of surfaces.

Filling 'Holes' in the Visual Stimulus

Perceptually, the visual system is able to bridge holes or scotomas in the visual field. This is the case for the pair of holes present naturally in all individuals – the blind spot, or exit point of the optic nerve in each eye, a region approximately $5 \times 8°$ in size ('large enough to conceal 76 full moons') lacking photoreceptors and hence any visual input in that eye. Not only do we not notice the hole – even monocularly, shutting one eye at a time – but also visual objects straddling the blind spot are seen as continuous even if they have gaps that fall within the blind spot. Mechanisms of visual fill-in are present not only at the blind spot – which could be special, being part of the visual system from birth – but also appear to be a dynamic property of neurons in adult visual cortex. Ramachandran and Gregory simulated the blind spot with 'artificial scotomas' – visual stimuli that are busy everywhere except for a small patch of neutral gray or black. Maintaining fixation steadily on a point in the stimulus bleeds in the surrounding color or texture, perceptually filling the 'scotoma.'

There are likely physiological correlates of visual fill-in at multiple levels of the visual cortex. In (anesthetized cat or monkey) V1, RFs expanded, reversibly, when presented with artificial scotomas. This expansion appears to be mediated by increased coupling among neurons with nonoverlapping RFs but similar orientation preferences – thus likely mediated by the orientation-tuned long-range axonal collaterals in V1. In V2 and V3 (but not V1) in alert rhesus monkeys, neurons with RFs within similar artificial scotomas also start responding as though expanding to include the initially distant texture.

Signaling Surface Luminance

The perceived color and luminance of a surface can often be very different from their physical correlates. Thus, if the spectral distribution of light reflected off a surface (as measured using spectrophotometers) remains constant while changing the hue or brightness of a distant surround, we can get a dramatic percept of the surface color or brightness changing in the 'opposite' direction. In real life, this leads to 'perceptual constancy,' in which we get a largely veridical sense of the intrinsic color and reflectance of surfaces independent of the illumination.

In the visual pathway, neurons that could signal perceived brightness are first encountered in V1 but not earlier. In the retina and LGN, neuronal RFs largely transmit local information on brightness or color differences; that is, signaling the presence of an edge and which side of the edge is darker. Responses are not modulated by the global modulation of the brightness of distant surrounds. Paradiso and colleagues showed that in V1, on the other hand, neurons with RFs on a surface of uniform and constant brightness modulate their responses with the modulation of distant surrounds, integrating luminance information from regions of visual space more than ten RF dimensions away.

Perceptual Learning and Task-Dependent Changes in Contextual Influences

Perceptual training on new visual discrimination tasks can lead to distinct improvements in our

Figure 11 Neurons in monkeys, area MT respond to perceived motion, as determined by distant contextual cues, rather than local motion. (a) Response of the neuron to circular gratings: the neuron is tuned to motion to the bottom right. (b) Response of the neuron to 'barber diamond' motion. The neuron responds when the perceived motion is to the bottom right. (c–e) Predictions of what the neuronal response would have been under different conditions. (c) If the neuron were responding only to local motion of objects in its classical receptive field it would see a 'horizontal' motion for all possible arrangements of occluder quadrants, giving a sub-optimal response to rightward moving stimuli vs. left. (d) If responding to the 'barber diamond' motion (as determined by a human observer) the neuron would respond when the occluder quadrants are arranged to give perceived motion to the bottom right. (e) If the neuron were responding to the line ends moving behind the near-occluder boundary it would respond to top right ('extrinsic'). Clearly the neuron responds to the perceived motion as in (d). Reproduced from Duncan RO, Albright TD, and Stoner GR (2000) Occlusion and the interpretation of visual motion: Perceptual are neuronal effects of context. *Journal of Neuroscience* 20(15): 5885–5897, with permission.

visual abilities. This is true not only for complex stimuli (e.g., learning to remember and discriminate between new faces) but also for simple visual tasks (e.g., learning to discriminate the tilts of different lines). Perceptually, improvements in low-level tasks do not transfer well; learning to discriminate between near-vertical lines lying in one quadrant of visual space will not transfer, for example, to lines at other orientations or other locations in visual space. This suggests that perceptual improvement in such low-level tasks leads to changes in early visual areas (V1, V2, etc.) with relatively small and orientation-selective RFs. By contrast, learning to recognize faces probably involves changes in high-level areas such as inferior temporal cortex with face-selective neurons that have large RFs.

Training on tasks of intermediate levels of complexity – learning to discriminate some simple geometric shapes – leads to dramatic, task-dependent changes in the contextual modulation responses of V1 neurons. Gilbert and colleagues showed that training on simple geometric patterns leads to very specific pattern-dependent improvements; training on one geometric pattern (a 'bisection task' – whether the middle line in a triplet of parallel

Figure 12 The visual system shows long-term task-selective improvements in simple perceptual discriminations. (a) Human observers trained on a bisection task — determining whether the center bar of a vertical triplet was offset to one side or the other of the center position — improve over 2 months of training by more than a factor of 2. (b) This improvement is task-specific and occurs only for the vertical bisection task (left, as indicated by icon below figure) but not for a vernier task on which the subject had not been trained (middle; determining whether two lines were offset to the right or left relative to each other), even though the two discrimination tasks are very similar and are presented at that same position in visual space. This task selectivity is not because subjects are already at their best for the vernier task: training specifically on the vernier task leads to specific improvement in the task (right). Reprinted from *Journal of Neurophysiology* 78: 2889–2894. Crist RE, Kapadia MK, Westheimer G, and Gilbert CD Perceptual learning of spatial localization: Specificity for orientation, position and context (1997).

lines is closer to one side or the other) does not transfer to other very similar patterns (a 'vernier' task – detecting small lateral shifts between two almost collinear lines; Figure 12). They then trained monkeys on the same pair of tasks, showing the animals the same stimulus for both tasks but cueing the animals to perform either the bisection or the vernier match. After the animals had learned to perform the geometric tasks, neurons in V1 showed a task dependence in their contextual modulation. With the same set of lines surrounding the neuron's RF, the response of the neuron depended on the specific geometric match in which the animal was engaged, implying that intracortical interactions between the different line elements were being further modulated by higher order feedback about the task (Figure 13).

Conclusion

An earlier reductionist view of visual processing that involved breaking scenes into independent elements (tiny independent edge segments) and building the percept hierarchically along parallel and independent channels (depth, color, and motion) is giving way to a view in which visual elements interact to give information about surfaces and objects early in visual processing. The strong perceptual and physiological evidence for such contextual interactions is backed up, in some cases, with plausible underlying anatomy. It is likely that this visual processing has evolved to match the statistical properties of natural scenes, and, in particular, to detect the types of visual object properties (object boundaries, textures, and occlusion of one object by another) that are important in interpreting natural scenes.

Figure 13 Neurons in monkey V1 respond differentially to the same visual stimulus depending on task context. Left: (a) Monkeys were trained on both a bisection task and a vernier task using the same visual stimulus (a set of five bars with the center bar at various offsets relative to the surrounding four bars). The color of the bars cued the animal as to whether to look at bisection offsets (b) or vernier offset (c). The animals improved on both tasks over training sessions (d). Right, top: The pair of side flanks gave a strong, separation-tuned modulation of a neurons's response when the animal engaged in a bisection task (where the flanks were relevant to the task) vs. when engaging in a vernier task (where the same side flanks at the same positions were irrelevant to the task). Right, bottom (Different neuron): the end flanks gave a strong, position-tuned modulation when the animal was engaged in a (relevant) vernier task but not during the (irrelevant) bisection task. Cornelia De Lange Syndrome

M A Deardorff and I D Krantz, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The first description of a patient with Cornelia de Lange syndrome (CdLS) has been attributed to Vrolik (1849) who described the case as an extreme example of oligodactyly. In 1916 Brachman provided a detailed account of another CdLS patient in a paper whose title translates as "a case of symmetrical monodactyly representing ulnar deficiency, with symmetrical antecubital webbing and other abnormalities (dwarfism, cervical ribs, hirsutism)." However, it was not until the 1930s that the condition began to be classified as a distinct entity. Cornelia de Lange, a pediatrician in Amsterdam, described two unrelated young girls with strikingly similar features and in honor of the city in which she worked she termed the condition "degeneration typus amstelodamensis." In recognition of her major contribution, the disorder has subsequently been widely described as CdLS, although some publications refer to Brachmann-de Lange syndrome. The prevalence of this syndrome has been estimated to be approximately 1 in 10 000. Since these early reports there have been over 100 papers describing various aspects of this disorder and it was not until recently that the underlying etiology was elucidated as being caused by disruption of the normal functioning of the cohesin complex. This implicated the multiprotein cohesin complex, well characterized for its role in chromosomal cohesion and segregation during mitosis and meiosis, for the first time with a human developmental disorder.

Clinical Features

Structural Features

The CdLS phenotype consists of neurocognitive and somatic growth delays in addition to numerous structural differences. The typical structural anomalies seen in CdLS include: characteristic facial features (including synophrys, long eyelashes, ptosis, depressed nasal bridge with an uptilted tip of the nose and anteverted nares, small widely spaced teeth, small head, and low-set ears), hirsutism, various ophthalmologic abnormalities, abnormalities of the upper extremities (ranging from subtle changes in the phalanges and metacarpal bones to oligodactyly and severe reduction defects primarily affecting the ulnar structures), and gastroesophageal abnormalities (gastroesophageal reflux, malrotation, pyloric stenosis) (Figure 1). Other frequently seen findings include ptosis, myopia, cryptorchidism, hypospadias, congenital diaphragmatic hernia, cardiac defects (most commonly atrial septal defects), seizures, and hearing loss (sensorineural, conductive and mixed have been reported).

Neurodevelopmental Features

The mental retardation seen in CdLS is variable with IQs ranging from less than 30 to 102 with an average of 53. Many affected individuals also demonstrate autistic behavior, including self-destructive tendencies, and they may avoid or reject social interactions and physical contact. Historically, most individuals with classical CdLS have been reported to have severe to profound mental retardation. More recently, reports of CdLS children and adults with milder cognitive retardation have suggested a broader range of intellectual potentials. Achievement of all developmental milestones are generally found to be significantly delayed. On average, children with CdLS sit at 12 months, have their first words at 18 months, walk alone at 24 months, speak (put words together) by 4.5 years, and are toilet trained by 3 years. In severely affected individuals many or all of these milestones are never met. There is no evidence to indicate that individuals with CdLS experience regression (loss of skills) and new skills are acquired even into adulthood. Areas of relative strength were noted to be visual–spatial memory and perceptual organization, while some of the weakest areas involved language skills, especially expressive language. Less than 5% of children with CdLS have language skills within normal to low-normal ranges. In general, those children with essentially no speech and more severe cognitive delays were found to also have more severe physical manifestations of CdLS. CdLS individuals with a greater degree of mental retardation had more pronounced autistic features, hyperactivity, self-injury, aggression, and sleep disturbances.

Clinical Variability

While the facial features seen in individuals with classical CdLS are striking and easily recognizable (Figure 1), and may be one of the most useful diagnostic signs, there is marked variability and a milder phenotype has been consistently described. With increasing recognition of a milder CdLS phenotype, both isolated and familial cases have been diagnosed and reported. The mild phenotype, which has been estimated to account for approximately 20–30% of

Figure 1 Phenotypic features of CdLS. Top row: characteristic facial features including arched eyebrows connected in the midline (synophrys), ptosis, long eyelashes, short upturned nose, long philtrum with thin upper lip, and small chin (micrognathia) with low set and posteriorly rotated ears. Bottom row: phenotypic variability in the involvement of the forearms ranging from severe olygodactyly on the left, through variable types of reduction defects to small hands as seen on the lower right.

the CdLS population (although likely an underestimate due to decreased ascertainment), is distinguished by less significant psychomotor and growth retardation, a lower incidence of major malformations, and milder limb anomalies.

Genetics

Although CdLS is one of the most distinctive dysmorphic syndromes known, having been formally described over 70 years ago, identification of the molecular etiology had remained elusive until recently. Due to a lack of informative families and conserved chromosome abnormalities, standard positional cloning approaches had been difficult to undertake. The CdLS gene was initially presumed to map to chromosome 3q26 based on phenotypic similarities between individuals with duplication of this region and individuals with CdLS. Recently mutations in three genes, *NIPBL* and *SMC1A* (also known as *SMC1L1*) and *SMC3*, have been found to cause CdLS in approximately half of studied probands.

NIPBL, located on chromosome 5p, is a regulator of the cohesin complex and is the human homolog of the *Drosophila Nipped-B* gene. While the role of NIPBL in humans or mammals has not been elucidated, much of what is known about its function comes from work in *Drosophila*. *Nipped-B* was identified in *Drosophila* using a screen to map genes involved in long-range enhancer promoter interactions. Once isolated Nipped-B was found to be homologous to *Saccharomyces cerevisiae* sister chromatid cohesion protein 2 (SCC-2) that played a critical role in sister chromatid cohesion during mitosis and meiosis. It was subsequently shown that through interactions with the cohesin complex, Nipped-B has a dual, but related, role in sister chromatid cohesion, as well as in long-range enhancer–promoter interactions. Preliminary studies evaluating genotype–phenotype correlations in CdLS suggest that some of the phenotypic variability seen in CdLS (severity of cognitive and growth retardation and severity of limb defects) is dependant on the type of mutation identified (with missense mutations for the most part resulting in a milder phenotype when compared to protein truncating mutations).

SMC1A, located on the X chromosome, is a subunit of the cohesin complex and has also recently been demonstrated to cause CdLS when mutated. Even though localized to the X chromosome, this gene is not silenced by X inactivation and both males and females have been reported to be equally affected by mutations, although in familial cases males appear to be more severely affected. SMC3 another subunit that functions in concert with SMC1, was subsequently found to be mutated in a single patient with CdLS. Overall individuals with mutations in *SMC1A* and *SMC3* appear to be more mildly affected, both cognitively and structurally, than individuals with CdLS caused by mutations in *NIPBL*. None of the reported individuals with *SMC1A* or *SMC3* mutations had overt limb abnormalities, several individuals had normal head circumferences and a few appeared to have very subtle features of CdLS and would appear for all intents and purposes as having apparent isolated mental retardation.

CdLS was the first developmental disorder shown to be caused by disruption of cohesin function.

Subsequently, the Roberts/SC phocomelia syndrome (an autosomal recessive condition of mental retardation, growth delay, craniofacial anomalies including cleft lip and palate, upper and lower limb defects, and chromosomal mitotic abnormalities including cohesion defects) was found to be caused by mutations in *ESCO2*, which is required for the establishment of cohesion during S-phase. The implication of the cohesin complex and its regulation in causing the highly conserved phenotypes of specific human developmental disorders was somewhat surprising giving its fundamental role in chromosomal cohesion and is likely due in part to disruption of its function as a mediator of long-range enhancer–promoter interactions.

The Cohesin Complex

In eukaryotic cells, replicated DNA remains physically connected from its synthesis in S-phase until separated during anaphase. This phenomenon called sister chromatid cohesion is essential for the equal separation of the duplicated genome. The cohesin complex is a multimer that consists of at least four proteins: SMC1 (SMC1A in humans), SMC3, SCC3 (STAG 1 and 2 in humans), and SCC1 (RAD21 in humans). Like other structural maintenance of chromosome proteins, SMC1 and SMC3 fold back upon themselves to form antiparallel coiled coils with their N- and C-termini forming ATPase head domains (Figure 2). Their hinge regions interact to form the SMC heterodimer, which acts as a ring-like structure to encircle chromatids. The head domains of SMC3 and SMC1 interact with SCC1 that along with SCC3 serves to form a clasp on the ring-like structure. NIPBL orthologs are known to be a subunit of the adherin protein, which is required for sister chromatid cohesion. It is believed that adherins are required for the attachment of cohesin to chromosomes.

Figure 2 The cohesin complex and its key regulators. The four main proteins composing the cohesin complex (SMC1, SMC3, SCC1, and SCC3) are indicated. The adherin complex of which NIPBL is a component is in the lower left and is involved in loading the complex on and off of the chromosomes.

Long-Range Enhancer–Promoter Interaction and Control of Gene Expression

While chromosomal cohesion may be mildly perturbed in CdLS (there is some evidence for mild precocious sister chromatid separation in CdLS probands), this mechanism is not felt to be the major contributor resulting in the multiple clinical findings seen in CdLS. Rather the critical means by which disruption of NIPBL, SMC1A and SMC3 appears to result in the CdLS phenotype is through the effects on long-range enhancer–promoter interactions and resultant disruption of transcriptional regulation. For most genes the region immediately upstream of the minimal promoter contains the requisite transcription factor binding sites to regulate expression of the gene; however, for many genes multiple *cis*-acting distal elements (most commonly enhancers, but also repressors and insulators) are required for correct spatiotemporal expression. These elements may be located upstream, downstream, or within introns and can reside greater than 1 Mb from the target gene. Disruption of these long-range regulatory interactions can result in human disease phenotypes through either global or partial tissue-specific loss or gain of expression. The majority of genes responsible for these disorders when disrupted are transcription factors that in turn regulate the expression of tissue-specific targets critical for normal morphogenesis of the organ systems involved. In the study that first identified *Nipped-b* in Drosophila, alteration of this gene and the resulting disruption of long-range enhancer–promoter interaction was noted to affect the regulation of the critical transcription factors called homeobox genes. Homeobox genes are critical in normal body plan formation and in the development of the brain and other organ systems.

Corpus Callosum: Agenesis

D Kamnasaran, The Hospital for Sick Children, Toronto, ON, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The corpus callosum was first described in 1812 by Johann Christian Reil and has since been considered an intriguing structure with respect to its development, function, and aftermath of malformation. It represents a unique commissure of placental mammals (eutherians), with a composition of 200–350 million fibers in the human and about 7 million fibers in the mouse, to connect the two cerebral hemispheres, and to perform neocortical sensory functions across the central nervous system (CNS) midline, in addition to providing an advantage for bimanual coordination with accelerated interhemispheric transmission periods. Numerous factors such as language dominance, handedness, and disorders such as schizophrenia and epilepsy are postulated to influence the morphology of the corpus callosum. Pathological assessments of the corpus callosum have indeed captivated the medical community over the centuries. The absence or malformation of this structure correlates with dispensability to some extent among patients and therefore is not mandatory for a normal life. Studies of human subjects with malformations of the corpus callosum are very limited to understanding the structural and molecular processes involved in the development of the corpus callosum. The use of genetically engineered model (GEM) organisms, especially the mouse, has come to a forefront to accelerate our understanding of these processes. This article describes the development of the corpus callosum in humans and mice and the underlying factors (including genetic), which are implicated in acallosal defects.

Embryology of Human Corpus Callosum Development

The development of the corpus callosum occurs in a spatiotemporally defined manner, that is, in anteroposterior and ventrodorsal polarities. Events that initiate the development of the corpus callosum commence between the 6th and 8th week of gestation. During this period, the lamina reuniens forms antecedently near the paraphysis by the agglomeration of the rostral wall of the telencephalon (Figure 1(a)). It is the lamina reuniens that is the origin of commissure fibers for the corpus callosum and anterior commissure. Between the 8th and 10th week, the bundle of commissure fibers augment medially from the ventrolateral wall of the right and left cerebral hemispheres and extend over the midline within the lamina reuniens in order to develop the anterior commissure. It is during the 8th week of gestation that the sulcus medianus telencephai medii (SMTM) develops by a process that involves the medial infolding of the lamina reuniens (Figure 1(b)). Cells from the dorsal lamina reuniens subsequently develop into the hippocampal commissure. These events are a prerequisite for the superior migration of cells from the lamina reuniens by the 9th week of gestation. At this stage, a mass of cells undergo programmed cell death (apoptosis) leaving a fraction of cells that develop into the massa commissularis (Figure 1(b)). It is the massa commissularis (part of the midline glial structures such as glial sling and indusium griseum glia) that serves as a bridge for the migration of the callosal axons in order to establish the higher-order structure of the corpus callosum (Figures 1(b)–1(d)). Different mechanisms may exist for the migration of axons to the corpus callosum between the 11th and 20th week of gestation. However, based on recent magnetic resonance imaging (MRI) findings and studies in mouse models, it is most likely that the initial regions of the corpus callosum to develop are the lamina rostralis (part of the rostrum) and the anterior region of the body (Figure 1(e)). Callosal axons of the rostral regions are speculated to use pioneering axons derived from the cingulated cortex and midline glial structures, while those from the caudal region (future regions of the body) may follow the axons of the fornix and hippocampal commissure to cross the midline, in order to establish the primary architecture of the corpus callosum (Figure 1(e)). Additional axons are then progressively appended to develop the genu and finally the splenium of the corpus callosum (Figure 1(e)). Augmentation of the cortical plates in the hemispheres is accompanied by progressive crossing of callosal axons through the corpus callosum, with distal extensions into the contralateral hemisphere, a process required in the production of a thicker corpus callosum. The principal architecture of the corpus callosum is defined prenatally, with completion of neuronal cell division and migratory events. Size increases are noted among subjects up the age of 25 years, initially in the splenium, and then accompanied by size increases in the body and rostrum. Such a size increase is postulated as a requirement to mediate higher-order neurological functions.

Embryology of Mouse Corpus Callosum Development

The development of the murine corpus callosum is astonishingly similar to humans. Initial events are documented as early as embryonic day 15.5, a stage where callosal axons originate from the cingulated cortex, and by embryonic day 16, from the frontal cortex. Richards and colleagues recently describe possible callosal projection pathways; however, these are yet to be precisely defined. In general, with the use of axonal mapping experiments, some evidence is suggestive of callosal axons originating from differentiating neurons of the cortical plate (specifically layers 2/3 and 5). These axons initially extend radially and downward into the cortical white matter, then change direction and migrate toward the midline. At the midline, the fibers migrate between the hippocampal commissure and pia membrane, and over a mass of glial cells including those from the midline glial structures such as the glial sling and indusium griseum glia (Figures 1(c) and 1(d)). The glial sling and indusium griseum glia act as a bridge between the two cerebral hemispheres for the crossing of fibers over to the contralateral side.

It is postulated that the size of the cerebral hemispheres dictates the precision of these events, a phenomenon not documented in humans. Interestingly, an alternative migratory pathway may be mediated by the hippocampal commissure. At E15, the first hippocampal axons cross the midline and continue onto the contralateral fornix and fimbria to targeted regions during the formation of hippocampus. At this stage, some callosal axons bundle just rostral to the hippocampal commissure. At E16, the callosal axons cross the midline by associating with the hippocampal axons, suggestive of a role of the hippocampal commissure as pioneering axons for the midline crossing of callosal axons. In support of this hypothesis, in acallosal murine strains, the hippocampal axons cross the midline at least 2 days later than normal due to a cleft extending deep between the hemispheres. This delay impairs the proper midline crossing of the callosal axons resulting in acallosal mice. Furthermore, patients

with semilobar holoprosencephaly have an intact hippocampal commissure and with a partial corpus callosum (splenium), suggesting that perhaps the presence of the hippocampal commissure may serve to direct the partial midline migration of callosal axons among these patients.

As soon as the callosal axons gain entry into the contralateral cortex, reentrance into the gray matter is noted, however, at specific positions depending on the site of their origin. By 2 days prior to birth, the callosal axons form synapses with relevant targets. After birth, an increase of 2 mm is noted in the size of the corpus callosum. Between 11 and 50 days after birth, myelination of the callosal axons is documented leading to a progressive augmentation of the corpus callosum.

Factors Shaping the Development of the Corpus Callosum

There are specific physical building blocks that are critical to remain functionally intact as prerequisites for the normal development of the corpus callosum. First, normal development of prosencephalic (embryonic forebrain) structures are absolutely crucial to prevent malformation of the corpus callosum. An early defect in the development of the overall prosencephalon, including the midline, is anticipated to result in acallosal defects accompanied with other CNS anomalies (described below). A classic example of the latter is observed among patients with holoprosencephaly (the improper patterning of the prosencephalon into the bilateral cerebral hemispheres resulting in an absent midline to varying extents).

Second, since callosal axons are derived from the cortex, the proper development of the cortex including processes of proliferation within the ventricular zones, migration to relevant regions, and differentiation into neuronal and glial cell lineages are critical. Furthermore, within the cortex, pioneering axons are necessary for the guidance or direct fasciculation of callosal axons, and reside in regions such as in the cingulated cortex. In this instance, malformed callosal axons, parent cell bodies, or callosal guidance pioneer axons can serve as sources for callosal agenesis. An excellent example of a callosal axon migration defect leading to callosal agenesis is demonstrated among patients with lissencephaly.

Third, intermediate structures or molecules involved in callosal axon guidance are critical to remain functionally intact to prevent malformation of the corpus callosum. Current evidence supportive of this postulate includes the following. Numerous axonal guidance molecules have been identified and include secreted factors, and molecules that are prevalent within the cell membrane or extracellular matrix. Among these groups are included those with chemoattractant, chemo-repellent, growth-permissive, and growth-suppressive properties. Proteins that serve as transcription factors to regulate the expression of these molecules, as well as intracellular signal transduction molecules, have also been identified (see below). The growth cones (tips) of axons have the ability to sense these molecules that will inevitably influence the migration, growth, or death during callosal development. It must also be noted that these axonal guidance molecules are present in variable amounts at intermediate structures of the prosencephalon to fine-tune axonal migratory or projection pathways. Examples of axonal guidance intermediate structures include the midline glial structures such as the glial wedge (part of radial glial scaffold), glial sling (Figure 1(e)), and indusium griseum glia (Figure 1(e)) and glial tunnel (associated with the anterior commissure). Evidence in support of the necessity of these intermediate structures is from several sources. For instance, it is noted that glial wedge explants grown in collagen gels have demonstrated the secretion of short-range diffusible growth regulatory molecules, such as Slit2, that act as factors implicated in the guidance of callosal axons. Most remarkable are findings from grafting and lesioning experiments of the glial sling in the murine developing brain that induces acallosal defects. Furthermore, the reorientation of the glial wedge and glia within the indusium griseum in organotypic slices can induce misguidance of the callosal axons away from the midline.

In general, the absence of these functional building blocks of the corpus callosum coupled with the timing of the absence influences to a large extent the severity of the malformation. For instance, in this manner, it is hypothesized that between the 12th and 20th week of gestation, an insult in the migration of the callosal axons will spare the normal development of the genu, but partial callosal agenesis of varying extents will be noted among other regions of the corpus callosum.

Agenesis of the Corpus Callosum in Humans

Congenital Malformations of the Corpus Callosum

The incidence of agenesis of the corpus callosum varies worldwide based on autopsy reports and other factors such the population studied and diagnostic method utilized. However, an incidence of about 1 in 19 000 (0.005%) subjects in the general population is estimated, and among the pediatric population, the incidence is about 0.0005–0.7%.

The incidence is also noted as being 2–3% in the mentally impaired population and in about 47% of patients with an existing CNS anomaly. Examples of subjects with a normal morphology of the corpus callosum are demonstrated in Figures 2(a) and 2(b), using T1-weighted MRI scans.

Agenesis of the corpus callosum is prevalent as two types. The first type manifests as partial or complete agenesis of the corpus callosum, and is associated with malformations of contiguous and phylogenetically related structures. The most cardinal feature is the lack of commissural fibers to cross the midline. These fibers instead migrate ipsilaterally and reside along the superomedial region of the lateral ventricles in the form of a structure known as Probst bundles (Figures 2(c) and 2(d)). The Probst bundles indent and partition the anterior horns of the lateral ventricles. Frequently, the third ventricle may be displaced upward, and the septum pellucidum is absent. Since the corpus callosum forms in an anteroposterior polarity, consequently, partial agenesis is manifest by a structurally intact genu and body (i.e., anterior regions), and the absence of the splenium and rostrum (i.e., posterior regions) (Figure 2(e)). The second type of callosal agenesis is associated with perturbations in the formation of the forebrain analage, resulting in an increased incidence of callosal agenesis associated with other CNS anomalies. In this type of callosal agenesis, Probst bundles are not documented. Examples of the second type of callosal agenesis include disorders with polymicrogyria and heterotopias of the gray matter.

Symptoms of Patients with Congenital Callosal Agenesis

Subjects with isolated agenesis of the corpus callosum are generally asymptomatic with an incidence estimated as low as 10–17% of all callosal agenesis cases. Isolated callosal agenesis cases are most frequently detected during fetal ultrasound screenings, or during follow-up after birth, with subjects not presenting any clinical symptoms in due course. However, symptomatic subjects are evident when patients have callosal agenesis associated with other

Figure 2 Magnetic resonance imaging (MRI) images from normal and acallosal-defect subjects. (a) Sagittal image of a normal mature corpus callosum from a 15-year-old subject. (c) Sagittal image showing agenesis of the corpus callosum with the medial hemispheric sulci radiating into the third ventricle (white arrow). (d) Coronal image of true agenesis of the corpus callosum with Probst bundle formation (black arrows). (e) Sagittal image showing a patient with Chiari II malformation and partial agenesis of the corpus callosum. The rostrum and splenium are absent (black arrows). Adapted from Kamnasaran D (2005) Agenesis of the corpus callosum: Lessons from humans and mice. *Clinical and Investigative Medicine* 28: 267–282.

CNS anomalies and with the tendency to demonstrate neurological symptoms such as sleep disorders, feeding disorders, neuropsychiatric problems, language and social communication disorders, motor impairments, mental delay, and epileptic seizures. Complete agenesis of the corpus callosum is estimated between 53% and 74% of all diagnosed callosal agenesis cases, while partial agenesis of the corpus callosum is estimated among 26–47% of these cases. Complete agenesis of the corpus callosum is more frequently associated with malformations of cortical development, while partial agenesis of the corpus callosum is more correlated with malformations of the posterior CNS fossa. As high as 85% of all callosal agenesis cases are associated with other primary and secondary CNS anomalies, while 62–65% with other non-CNS anomalies. Examples of the spectrum include macrocephaly, microcephaly, hypertelorism, broad and depressed nasal bridge and cleft lip/palate, and sometimes costovertebral defects, gastrointestinal, cardiovascular, and genitourinary anomalies. Patients usually have normal cognitive abilities, but most function at lower than the average range resulting in learning disablities. These patients also demonstrate delayed response periods to interhemisperhic tasks, and impairments in asynchronous distal movements, tactuomotor learning, and cross-localization of finger stimulation. In general, there is no unique prognosis of patients with callosal agenesis.

Differences between Congenital Callosal Agenesis Patients and Those with Complete or Partial Callosotomy

Patients with congenital acallosal defects were originally utilized as natural models of the split brain to understand the role of the corpus callosum and other topologically relevant regions of the CNS. The split brain refers to a completely surgically sectioned corpus callosum/interhemispheric callosal commissure, as in patients treated with a surgical procedure known as callosotomy. A preponderance of patients with congenital acallosal defects are however noted to lack most symptoms of the disconnection syndrome (neurological symptoms as a consequence of a loss of communication between the cerebral hemispheres), as noted in patients treated by callosotomy. To elaborate, congenital callosal agenesis subjects, for instance, do not typically experience difficulties for tachistoscopic tasks requiring interfield comparisons, or tasks involving recognition and verbal identification of an object placed unilaterally to either hemisphere. Callosotomized patients, however, are dysfunctional with respect to these tests. One possible explanation for this phenomenon is that patients with a congenital acallosal brain may utilize neural plasticity and reorganization of the subcallosal migratory tracts to compensate for the lack of the principal commissure during early stages of gestational development and possibly before birth. In this instance, the anterior commissure and subcortical commissures can therefore act to compensate and to prevent impaired visual interhemispheric tasks. In support of this hypothesis, an enlarged anterior commissure is reported among some congenital acallosal patients.

Acquired Malformations or Lesions of the Corpus Callosum

Apart from congenital callosal agenesis, acquired malformations or lesions of the corpus callosum also exist, but are relatively rare. These lesions are most often underestimated as a consequence of absent neurological symptoms and the type of cranial imaging detection method utilized. The prevalence is estimated at 3% in the general population. Several examples are described below.

Vascular or arteriovenous malformations These represent about 9–11% of all cerebral vascular anomalies among patients. In a large fraction of these patients, intraventricular hemorrhaging occurs resulting in ischemic-induced callosal atrophy (Figure 3(a)). Infarcts are uncommon (8%) in the corpus callosum since ischemic injury is rare in the dense white matter typically residing within this commissure. This may be a consequence of the resilient angioarchitecture of the corpus callosum that can supply blood from a combination of both anterior and posterior cerebral arteries to prevent atrophy.

Repair of hydrocephalus Dilated ventricles as a result of increases in cerebrospinal fluids most often indents the middle and posterior regions of the corpus callosum causing ischemia. Ischemia occurs because of a reduction in the number of capillaries leading to atrophy of the posterior corpus callosum (Figure 3(b)). Repair of the hydrocephalus after ventriculoperitoneal shunting can induce both diffuse and focal lesions of the corpus callosum. This occurs because overdrainage can distend pericallosal artery branches resulting in ischemia and demyelination.

Trauma Among subjects who have died of severe head injuries, about 16–100% are noted to have traumatic lesions of the corpus callosum, which are typically hemorrhagic. These lesions are also prevalent in some nonfatal head traumas. Larger lesions extend throughout the corpus callosum, and smaller lesions are most prevalent in the splenium of the corpus callosum (Figure 3(c)). Focal atrophy of the corpus callosum may be a consequence of Wallerian

Figure 3 Magnetic resonance imaging (MRI) examples of acquired malformations/lesions of the corpus callosum. (a) An early forties male with arteriovenous malformation and intraventricular hemorrhage (arrows). (b) A mid-forties male with cystic lesions (arrows) associated with long-term hydrocephalus and multiple prior shunt revisions. (c) An early 20-year-old male with a tramautic nonhemorrhagic hypointense lesion (arrow) of the corpus callosum, after a motor vehicle accident. (d) A mid-fifties male with the demyelinating disease, Marchiafava–Bignami disease, after 30 years of alcohol abuse. Atrophy of the corpus callosum (arrows) is noted. (e) A 4-year-old girl with gliomas in the body of the corpus callosum (arrow). Adapted from Bourekas EC, Varakis K, Bruns D, et al. (2002) Lesions of the corpus callosum: MRI and differential considerations in adults and children. *American Journal of Roentgenology* 179: 251–257.

degeneration or direct callosal injury. Wallerian degeneration refers to antegrade degeneration of axons in conjunction with their myelin sheaths secondary to proximal axonal injury or cell death.

Demyelinating diseases Chronic alcoholics eventually present at late stages atrophy of the corpus callosum as observed in Marchiafava–Bignami disease (Figure 3(d)). In these subjects, the central regions of the corpus callosum are most commonly affected, and atrophy is postulated as a result of demyelination induced by necrosis. Lesions can also be multifocal within the corpus callosum. Other types of demyelinating diseases leading to callosal atrophy include multiple sclerosis with patients usually showing symptoms within the disconnection syndrome, and progressive multifocal leukoencephalopathy.

Tumors High-grade infiltrative tumors along the white matter tracts across the corpus callosum are common in glioblastoma multiforme (GBM), a high-grade glioma (Figure 3(e)). GBMs are the most common type of adult primary brain tumors. Moreover, as high as 65% of lipoma cases are documented with lesions in the corpus callosum and in the pericallosal cistern, but these patients are usually asymptomatic. Other types of tumors that induce lesions within the corpus callosum include lymphomas, carvenous angiomas, and juvenile pilocytic astrocytoma.

Generalized etiology The etiology of callosal agenesis is very much heterogeneous. Apart from the lack of functional building blocks during callosal development, callosal agenesis is also observed among conceptuses of mothers with alcohol abuse, maternal rubella infections, congenital toxoplasmosis, and diabetes. Although these cases clearly demonstrate a most likely induced teratogenic gestational environment, and mothers demonstrating increased associations/risk with callosal agenesis conceptuses, the underlying pathological mechanisms are yet to be determined.

Understanding the Genetic Etiology of Congenital Agenesis of the Corpus Callosum

The genetic etiology of agenesis of the corpus callosum is enthralling and extremely genetically heterogeneous for both isolated callosal agenesis and callosal agenesis associated with other complex CNS malformation syndromes. This extreme genetic heterogeneity may be a consequence of the complex embryological processes underlying the development

of the corpus callosum. Although several mechanisms may be implicated in callosal agenesis, the same genetic defects responsible for callosal agenesis can be used to comprehend the causes of other associated CNS malformations – in those instances where callosal anomalies are associated with other complex CNS anomalies. Interestingly, the prevalence is skewed with higher detection of acallosal defects among males compared to females (1.6:1 ratio), suggestive of possible X-linked modifier genes regulating sex-specific incidences of callosal agenesis.

Genetic syndromes/disorders/malformations The familial recurrence of callosal agenesis is relatively rare. This is suggestive that callosal agenesis may be primarily caused by *de novo* or sporadic genetic mutations (either by germline or early postzygotic mechanisms) rather than a familial mutation. Autosomal recessive, dominant, and X-linked forms are reported in at least 22 malformation syndromes with autosomal inheritance, and at least 13 malformation syndromes with X-linked inheritance (Table 1). A total of 16 malformation syndromes are yet to be associated with a specific genetic mode of inheritance among affected families. A few families with isolated callosal agenesis have been reported with autosomal dominant, autosomal recessive, and X-linked inheritance. Moreover, at least 56 malformation syndromes and metabolic disorders associated with agenesis of the corpus callosum have been documented to date (Table 1). Currently, at least 33 genes were identified with mutations among some of these disorders. Syndromes, such as Joubert, septo-optic dysplasia, and Kabuki, are rarely associated in patients with partial or complete agenesis of the corpus callosum. Furthermore, patients with inborn errors of metabolism such as neonatal adrenoleukodystrophy, kinky hair disease, mucopolysaccharidosis, nonketotic hyperglycinemia, pyruvate dehydrogenase deficiency, Zellweger syndrome, and glutaric aciduria type II demonstrate associations with accallosal defects. For both the callosal agenesis-associated syndromes that are rare, and inborn errors of metabolism disorders, the genetic perturbations underlying the CNS malformations may not necessarily be directly related to the cause of callosal agenesis, a hypothesis yet to be tested.

Chromosome aberrations Apart from the use of syndromes to discern the genetic basis of the development of the corpus callosum, the use of chromosomal anomalies has been informative to define possible minimal critical regions (MCRs) for agenesis of the corpus callosum in the human genome. More than 11% of all callosal agenesis patients tested have been documented with a chromosome anomaly. This may however be an underestimate since most of these cases were analyzed using classic cytogenetic karyotyping methods that are sensitive to detecting only large chromosomal rearrangements. Recent usage of bacterial artificial chromosome (BAC) genome microarrays has improved the sensitivity and detection of submicroscopic chromosome rearrangements among patients that were previously undetected by utilizing classic cytogenetic karyotyping methods. In general, human chromosomes 8, 11, 13–15, and 18 are most commonly associated with agenesis of the corpus callosum. A wider spectrum of frequent chromosomal aneuploidies is anticipated with the use of higher-resolution karyotyping methods such as with BAC genomic microarrays. Numerical and structural aberrations involving chromosomes 1, 2, 3, 4, 6, 11, 13, 15, 16, 21, 22, and X suggest that a reduction in gene dosage of one or more genes on these chromosomes contributes to agenesis of the corpus callosum. An increase in gene dosage as a possible cause of agenesis of the corpus callosum is suggested by reports of partial trisomies (i.e., two normal chromosomes and a partial chromosome), or duplications of chromosomes 4, 5, 6, 8, 11, 12, 14, and 19, triploidy (i.e., three copies of every chromosome) and trisomies (i.e., three copies of a chromosome) of chromosomes 13, 18, 21, and 22. Figure 4 illustrates a genetic map of candidate regions for callosal agenesis on human chromosomes defined by the use of affected patients with chromosome aberrations. Many of these chromosomes harbor genes that are already identified with mutations among patients with acallosal defects (Table 1).

Agenesis of the Corpus Callosum in Mouse

Comprehending the cause of callosal agenesis in humans is very much limited with respect to unraveling perturbations in structural and molecular pathways. To circumvent this limitation, model organisms have been utilized, not only to understand the structural basis of the development of the corpus callosum, but also to validate the roles of genes discovered. The mouse has served as an excellent model system among other models such as the cat, rat, dog, or even chimpanzee to provide effectively outstanding structural and molecular insights into the development of the corpus callosum.

Murine Strains with Spontaneous Callosal Agenesis

It must be first recognized that some murine strains demonstrate spontaneous acallosal defects at different frequencies (as shown in Table 2). These strains are hypothesized to have mutations in yet-to-be-identified genes that collectively contribute toward

Table 1 Syndromes/disorders/malformations associated with agenesis of the corpus callosum

Syndrome/disorder	*Gene(s)*	*Location on chromosome*	*Mouse model with accallosal defects*

callosal agenesis. Breedings undertaken among these strains show variations in callosal agenesis. For instance, breedings between the BALB/cWah1 and 129/ReJ strains have a normal corpus callosum, but crosses between strains BALB/c and I/LnJ or I/LnJ and 129/ReJ, have agenesis of the corpus callosum. With this knowledge, modeling a mutant candidate callosal agenesis gene with one of the strains listed in Table 2 will increase the possibility of observing a callosal agenesis phenotype. This phenomenon has been well documented with the modeling of the *Emx1* (a transcription factor of unknown function), *bApp* (a β-amyloid precursor transmembrane glycoprotein), and *L1Cam* (transmembrane glycoprotein with roles in cell adhesion, neurite outgrowth, and axon bundling) genes that result in true agenesis of the corpus callosum with Probst bundle formation. For instance, when both copies of the *Emx1* gene are defective in a 129Sv strain, all mice have partial or complete callosal agenesis. However, in a hybrid 129Sv-C57BL/6 strain, mice develop only a slight atrophy or reduction in size after the eighth generation.

Genetically Engineered Models of Callosal Agenesis

Callosal agenesis models were developed in the past by utilizing nongenetic manipulation methods such as with the use of prenatal irradiation. With these methods, the perturbed molecular (genetic) parameters are unknown. GEMs have come to a forefront to model and understand the role of candidate callosal agenesis genes in mice. GEMs, however, do have advantages and disadvantages to comprehend the pathogenesis of callosal agenesis (Table 3), which to some extent impose caution in understanding this anomaly in humans. For instance, some of these differences are explicit when callosal agenesis is

observed among patients affected with Anderman syndrome and with mutations in the *SLC12A6* (Solute carrier family 12, member 6) gene; however, no acallosal defects are observed in the murine GEM when one or both copies of the *Slc12A6* gene are defective. Other examples are listed in Table 1.

Table 3 Pros and cons of using murine genetically engineered models to study acallosal defects

Advantages	*Disadvantages*
Thorough knowledge on neuroanatomy and neuroembryology	Strains with spontaneous acallosal defects
Large panel of genetic markers available for genetic mapping experiments	Differences in the spatiotemporal expression of genes
Numerous mutant strains available from public consortiums	Differences in gene function
Efficient and improved technologies for the creation of genetically engineered mice	Differences in gene redundancy

Complete agenesis of the corpus callosum Numerous GEMs were created to model true agenesis of the corpus callosum, that is, mice with Probst bundle formation (as listed in Table 4) or agenesis of the corpus callosum associated with other CNS malformations (as listed in Table 1). GEMs with true agenesis of the corpus callosum are more informative to directly correlate gene function with the molecular–structural parameters required for callosal axon guidance and migratory events leading toward the development of the corpus callosum. Several genes have been identified to result in complete true agenesis of the corpus callosum and have diverse functions. These include *Vax1* (a transcription factor implicated in the formation of the midline commissure tracts and guidance of axons mediated by molecules such as Netrin-1, EphB3, and EphB2), *Nfia* (a transcription factor that regulates the development of the midline glia and axonal chemorepellent molecules such as

Table 4 Mouse models for callosal agenesis (true complete agenesis and hypoplasia)

[a]ACC, complete agenesis of the corpus callosum.
[b]HCC, hypoplasia (dysgenesis) of the corpus callosum.

Slit2), *Map1B* (a structural protein with role in microtubule assembly and neuronal morphogenesis, by mediating axonal guidance perhaps through laminin-enhanced axonal growth/migration), *Netrin-1* (a soluble protein involved in axonal guidance), *Marcks* (an intracellular signal transduction substrate for protein kinase C), *Mena* (a suppressor of the Abl nonreceptor kinase that regulates actin cytoskeletal elements), *Slit2* (a soluble protein involved in axonal guidance), and *EphA5* (a tyrosine kinase receptor, regulating axonal guidance).

Hypoplasia/dysgenesis of the corpus callosum Atrophy of the corpus callosum maybe misdiagnosed as true agenesis of the corpus callosum, and may be a consequence of an aberrant event during cortical development (such as in preterm infants or perinatal asphyxia). Genes implicated with this phenotype, however, have crucial roles such as in the growth of the corpus callosum. The GEMs demonstrate hypoplasia (dysgenesis) of the corpus callosum (see also Table 4), and include mutations in genes such as *Frizzled-3* (a transmembrane receptor with possible roles in axon growth by coordinating cytoskeletal polarity), *Tlx* (a transcription factor with unknown function), *p35* (an activator of cyclin-dependent kinase 5), and *Creb1* (a cAMP response element-binding protein involved in cellular growth and differentiation).

Concluding Remarks

Numerous autopsy cases and patients have been diagnosed with agenesis of the corpus callosum for over two centuries and have perplexed both the medical community and developmental biologists as to what are the underlying causes. An understanding of both the structural and molecular (genetic) mechanisms implicated in accallosal defects have been minimal thus far, most likely as a consequence of the immense complexity apparent as a consequence of genetic heterogeneity and/or possible phenotypic modifications by the gestation environment. Both structural and molecular parameters have been determined in a complementary human–mouse system using standard genetic and developmental biology approaches. With the availability of the human and mouse genomic sequences plus improved mouse modeling resources and mutation detection technologies, our understanding of these processes is anticipated to accelerate exponentially.

Cortical Control of Eye Movements

P H Schiller and E J Tehovnik, Massachusetts Institute of Technology, Cambridge, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Several cortical areas contribute to the generation of visually guided saccadic eye movements. The major areas we shall consider here area striate cortex (area V1), the lateral intraparietal sulcus (LIP), the frontal eye fields (FEFs), and the medial eye fields (MEFs). Figure 1 shows a view of the monkey cortex with these areas indicated by the arrows; also named are some of the major sulci.

Electrical stimulation of these cortical areas elicits saccadic eye movements. In areas V1, LIP, and the FEFs constant vector saccades are elicited. The amplitude and direction of such saccades depends on where within each structure the electrode is placed. The vector is constant in the sense that it is unaffected by the initial position of the eye in orbit. Also shown in the upper portion of Figure 2(a) are the effects of electrical stimulation in the superior colliculus (SC), which are similar to those obtained in V1, LIP, and the FEFs. Not shown is that similar saccades also can be elicited by the electrical stimulation of area V2. It may be said that these areas use predominantly a retinocentric code. By contrast, a different kind of coding operation is evident in the MEFs. In this structure, electrical stimulation moves the eyes to a particular orbital position. Different subregions of the MEF code different orbital positions, which are arranged in topographic order.

Electrical stimulation in the SC, FEFs, and MEFs can elicit saccadic eye movements at low current levels and can produce saccades with latencies as short at 15–25 ms. By contrast, whereas electrical stimulation of areas V1 and LIP can elicit eye movements at correspondingly low thresholds, the minimal saccadic latencies are notably higher, at 35–50 ms.

How do the signals from areas V1, LIP, the FEFs and the MEFs reach the brain stem oculomotor centers? These regions have numerous connections. All project to the SC. However, the FEFs and the MEFs also have direct connections with the brain stem oculomotor centers. To determine whether the commands from all of these areas pass through the SC, we can ablate the SC and then stimulate the various cortical areas to determine whether saccades can still be elicited. The results of such an experiment are shown in Figure 2(b). After SC ablation, saccades can no longer be elicited from V1, V2, and LIP. However, stimulation of the FEFs and MEFs still elicits the same kinds of saccades as before the SC ablation. These findings have led to the suggestion that there are two major cortical systems for saccadic eye-movement generation: the anterior and the posterior. The posterior system passes through the SC, whereas the anterior system gains direct access to the brain stem oculomotor centers. These observations then raise the question of why we have two such systems. In what follows, we examine these areas in more detail using several different methods that include single-cell recordings, lesions, microstimulation, and pharmacological manipulations.

The Neural Circuits of Visually Guided Saccadic Eye Movements as Revealed by Anatomical and Physiological Studies

In the retina, there are several different classes of retinal ganglion cells. Two of these classes, the midget and the parasol cells, are believed to play a central role in the generation of visually guided saccadic eye movements. The parasol cells project to the magnocellular layers of the lateral geniculate nucleus (LGN), whereas the midget cells project to the parvocellular layers. The major projections of these two classes of cells from the LGN of the primate are to layers 4Cα and β in the V1.

Area V1 makes extensive reciprocal connections with numerous extrastriate areas and also projects to the SC from layer 5. These cortico-tectal cells are comprised of complex cells and are driven predominantly by the parasol system. Although the superficial layers of the SC receive direct connections from a class of small, relatively slowly conducting retinal ganglion cells, this input does not have the capacity to activate the deeper layers of the SC; when the visual cortex is cooled or ablated, neurons in stratum opticum and below can no longer be driven visually in the SC. Thus it appears that in primates the deeper layers of the SC are under cortical control.

In V1, many cells receive selective input from either the midget or parasol cells, but there is a significant portion of cells that receive a convergent input from these two systems. Such convergent input is also evident in V4. However, the middle temporal area (MT) and other regions of the parietal lobe receive an input that appears to be dominated by the parasol system.

In area LIP of the parietal lobe, several different classes of cells involved in saccadic eye movements generation have been identified. In some regions of this structure neurons discharge prior to the initiation of saccadic eye movements, whereas in other regions neurons are found that discharge vigorously while the

Figure 1 View of the monkey cortex. FEF, frontal eye field; LIP, lateral intraparietal area; MEF, medial eye field.

animal maintains fixation. The firing of these neurons is also affected by different reward contingencies.

As in LIP, in the FEFs several different classes of neurons have been identified. Neurons discharge vigorously in association with a particular size and direction of saccades irrespective of the starting eye position. These neurons, as already noted, appear to carry a vector code. Some of these neurons discharge prior to the initiation of eye movements, and some discharge during or after saccade initiation. Neurons coding for different sizes of saccades are organized topographically within the FEFs such that lateral portions of FEFs code for small amplitude saccades while medial portions code for large amplitude saccades. Neurons in the superficial layers discharge to both the onset of visual targets and saccade initiation, whereas neurons in the deeper layers discharge mainly during saccade initiation. Neurons in

Figure 2 Effects of electrical stimulation in the superior colliculus (SC) which are similar to those obtained in V1, the lateral intraparietal area (LIP), and the frontal eye field (FEF): (a) intact animal; (b) SC-ablated animal. a, arcuate; BS, brain stem; ce, central sulcus; ls, lunate; MEF, medial eye field; p, principalis; sts, superior temporal sulcus.

the FEFs are believed to be involved in target selection as well as in the generation of sequences of eye movements.

In the MEFs, most neurons code for the position of the eyes in orbit. A group of neurons has been identified in the MEFs that discharge vigorously for fixations within different parts of the visual field such that neurons in anterior MEFs discharge for fixations of targets in the contralateral field, neurons in posterior MEFs discharge for fixations of targets in the central field, neurons in medial MEFs discharge for fixations of targets in the lower field, and neurons in lateral MEFs discharge for fixation of targets in the upper field. Vigorous activity of these cells occurs when the eyes shift to the orbital position coded by them. This coding operation, as already noted, has also been confirmed by electrical microstimulation studies. Finally, much like the neurons in LIP, the neurons in the MEFs are modulated by different reward contingencies.

The Effects of Selected Lesions on Saccadic Eye-Movement Generation

When monkeys are examined informally following lesions of the SC, there are only subtle deficits. The animals make fewer eye movements per unit time, and, following, unilateral lesions they tend to orient toward the side of the lesion. Deficits are even less evident after FEF and MEF lesions. However, when the SC and the FEFs are both removed bilaterally, a dramatic deficit surfaces – monkeys can no longer generate saccadic eye movements at all. This suggests that the anterior and posterior systems are essential for the generation of saccades.

When more careful measurements are taken, several specific deficits are revealed by studies in which the SC, the FEFs, or the MEFs have been removed. One set of studies has examined the distribution of saccadic latencies to single visual targets. These studies have established an interesting fact – the distribution of saccadic latencies made to single targets is bimodal. The first mode peaks around 100 ms. These short-latency saccades have been termed express saccades. The second mode peaks around 135–145 ms, and the eye movements have been called regular saccades. Following SC lesions that disrupt the input from posterior cortex to the brain stem, express saccades are entirely eliminated. Furthermore, the latency of the regular saccades also becomes longer. By contrast, when the FEFs or the MEFs are ablated, the bimodal distribution of saccades is unaffected. Thus, it appears that the posterior system is essential for the generation of express saccades.

Using several other tests, we have established that the FEFs play a significant role in the selection of targets for the generation of saccadic eye movements as well as in the planning of sequences of saccadic eye movements. Following lesions of the FEFs, monkeys showed long-term deficits in both target selection and in the execution of sequences of saccadic eye movements.

Eye Movements Elicited by Two Visual Targets and by Electrical Stimulation at Two Brain Sites

Experiments have assessed eye movements elicited by the simultaneous presentation of two visual targets and compared such performance with what is obtained when two brain sites are electrically stimulated simultaneously. The way such experiments have been carried out is to first map the receptive fields of neurons located at the tips of two electrodes and to then place a visual target into each receptive field. The eye movements elicited this way can then be compared with the eye movements elicited by electrically stimulating the neurons at the tip of each electrode. Results obtained at two sites – area V1 and the FEFs –-are compared here. When in area V1, the location of the two receptive fields at the tip of the two electrodes is close to 90 angular deg relative to the center of fixation. Saccades are made to visual targets presented at either one or the other location; vector-averaged saccades that land the eye in between these two points are rare. The same result is obtained with electrical stimulation of V1. By contrast, at two sites in the FEFs or in the SC, electrical stimulation produces vector-averaged saccades as depicted in Figure 3. These observations suggest that electrical stimulation in V1 produces predominantly a visual percept, whereas in the FEFs and the SC it produces a motor command.

Eye Movements Elicited by Combined Visual and Electrical Stimulation

Using similar procedures, we can determine what happens when a visual target placed into the receptive field of a set of neurons is coupled with the delivery of electrical current. When this is done in the FEFs or the MEFs, combining electrical stimulation with the visual target always leads to facilitation; the likelihood of producing a saccade is significantly increased. This occurs even when the current levels used are below the threshold of eliciting a saccadic eye movement in the absence of a visual stimulus.

This effect can also be obtained in some subregions of the LIP. LIP is a rather complex structure, however, and in some subregions the electrical stimulation results, instead, in a decreased disposition to make a saccade to the target placed into the receptive or motor field of the stimulated cells. Furthermore, in

Figure 3 Effects of stimulating two sites in the frontal eye fields (FEFs) and in area V1: (a) top view; (b) FEF; (c) V1.

yet some other subregions of LIP, electrical stimulation delays the initiation of a saccade. This happens in those regions of LIP, as previously noted, in which neurons discharge vigorously while fixation is maintained. The characteristics of these cells and the delay produced by electrical stimulation suggest that these subregions in LIP play a significant role in determining the time when the eye movement should be initiated. Presumably this occurs subsequent to when the object under view has been satisfactorily analyzed.

When a similar procedure is used in V1, an interesting finding emerges. Stimulation in the lowers layers, especially in layer 5, which contains neurons that project to the SC, produces facilitation; the monkey is more likely to make a saccade to the visual target in the receptive field when it is paired with electrical stimulation. By contrast, in the upper layers electrical stimulation produces interference. Systematic variation of the location of the visual target relative to the center of the receptive field shows that the interference is effective only when the visual target is within the receptive field. Thus, the area affected by the electrical stimulation is confined to the receptive field.

The Visual Percept Elicited by Electrical Stimulation of Area V1

These considerations suggest that electrical stimulation of the SC, the FEFs, and the MEFs produces a command to generate a saccadic eye movement, but that in V1 it creates predominantly a visual percept that under some circumstances, as defined by other brain areas, can lead to an eye movement. This, then, raises the question as the nature of the visual percept created by electrical stimulation of V1. It is well known that electrical stimulation of this area in humans produces a starlike image called a phosphene. To assess what percepts are produced in monkeys, procedures have been used in which various stimulus parameters are varied for a visual stimulus which is paired with electrical stimulation of neurons whose receptive fields are at another location. The monkeys have been extensively trained to make saccadic eye movements to the larger and brighter of two simultaneously presented visual stimuli. The size and contrast of the visual stimulus is varied while the current delivered through the microelectrode to the neurons whose receptive fields are at another location is kept constant. Under these conditions, when the visual target is very small and dim, the monkey makes saccades to the receptive field site of the electrically stimulated neurons, whereas when the visual target is large and bright, the monkey makes a saccadic eye movement to the visual stimulus. When the percepts elicited by the visual stimulus and the electrical stimulus are similar, the monkey is expected to select them with equal probability, just as the animal does when two identical visual stimuli are presented. Thus, by systematically varying the size and contrast of the visual target we can establish the point of equivalence. These studies show that when 20–120 μamp current pulses are delivered at 200 Hz within 80 ms trains, the visual percept created has 6–12% contrast and 15–20 min of visual angle in size at locations 2.5–3.5° from the fovea.

The Role of Cortical GABAergic Inhibitory Circuits in the Generation of Saccadic Eye Movements

In the natural environment subsequent to each saccadic eye movement, dozens of objects impinge on the

retina. Two central tasks with each fixation are the analysis of the scene and a decision as to where to look next. To be able to generate an accurate saccade to a desired location, a decision has to be made not only where to look but also where not to look; otherwise, all the visual signals would probably create a vector-averaged saccadic eye movement that would not be helpful in analyzing the visual scene. To maintain high accuracy for the direction of gaze, the nervous system relies on a complicated interplay between excitatory and inhibitory circuits. The substantia nigra makes extensive GABAergic inhibitory connections with the SC. The planning of a saccade requires that a specific region of the SC be disinhibited while inhibition is maintained in other regions. Furthermore, the disinhibited region must also receive an excitatory signal. When muscimol, a γ-aminobutyric acid (GABA) agonist, is injected locally in the SC, an animal has difficulties generating saccades with vectors represented by the injected neurons. By contrast, the administration of bicuculline, a GABA antagonist, produces irrepressible saccades with vectors coded by the affected neurons.

The administration of these two agents, muscimol and bicuculline, in the cortex has clarified the role of GABAergic circuits in vision and eye movement. Such studies have examined how both visual processing and saccade generation are affected. The results show that in the FEF muscimol and bicuculline produce effects similar to those seen in the SC. Muscimol interferes with saccade generation, and bicuculline produces irrepressible saccades. The processing of visual information is only mildly affected. The administration of similar dosages in LIP has little effect on either saccade generation or visual processing. In area V1, both agents produce a major disruption in visual analysis; when monkeys are asked to detect or discriminate visual stimuli they fail when either muscimol or bicuculline is administered. These findings suggest that the GABAergic circuits in the FEFs and SC play a central role in eye-movement generation, whereas in V1 they play a major role in analyzing the visual scene.

Outline of the Basic Tasks and the Neural Circuitry Involved in the Generation of Visually Guided Saccadic Eye Movements

Figure 4 outlines the basic steps and brain areas involved in the generation of visually guided saccadic eye movements. Five steps are identified and formulated in terms of task questions:

1. What are the objects in the visual scene? During maintained fixation, the visual scene is analyzed to determine what the objects are in the scene. This is accomplished by numerous brain areas that include V1, V2, V4, LIP, and inferotemporal area (IT).
2. Which object to look at? A decision process has to be generated that picks out the object which is to be the target of the saccadic eye movement. The prime areas involved are V1, V2, LIP, FEF, and MEF.
3. Which object not to look at? To be able to generate an accurate saccade to a desired location, it is necessary to inhibit regions activated by visual stimuli toward which saccades should not be generated. The areas that play a role in this decision process include V1, V2, and LIP.
4. Where are the objects in space? The position of the object in space to be looked at must be computed. Prime candidates for this computation include V1, V2, FEF, and SC, in which retinocentric coordinates are arranged in topographic order.
5. When to initiate the saccadic eye movement? The decision to initiate a saccade presumably arises when the central scene at the fixation site has been satisfactorily analyzed. Areas LIP and MEF have been shown to contain neurons whose activity must cease before an eye movement can be initiated.

Figure 5 outlines the basic circuitry involved in these tasks. Three major classes of retinal ganglion cells that project to area V1 via the LGN are shown. The midget and parasol system remains separate only in part in V1; there are many neurons that receive a convergent input from these to channels. The layer 5 complex cells in V1, which are driven predominantly by the parasol system, project to the stratum opticum of the SC. Cortico-cortical projections show that area MT and the parietal lobe receive inputs that are dominated by the parasol system, whereas area V4 and the temporal lobe receive a mixed input from the midget and parasol systems. The question marks in the figure indicate pathways and areas whose composition and destination are not yet known.

The posterior system involves cortical areas in posterior cortex, which sends its signal to the brain stem through the SC. Furthermore, the SC is under inhibitory control by the substantial nigra, a control that is modulated by cortex. The projection from the retina to the superficial layers of the SC does not appear to have direct access to the deeper layers of this structure. The anterior system from the FEF and MEF of the frontal lobe connects with the SC, but also has direct projections to the brain stem oculomotor centers. The FEF contains its own inhibitory circuits for keeping saccadic eye-movement generation in check. The coordinate execution of various types of saccadic eye movements is accomplished in part by the extensive interconnections, both feed-forward and feedback, among the brain structures depicted in Figure 5.

Figure 4 Five basic steps and the brain areas involved in the generation of a visually guided saccadic eye movements, formulated in terms of task questions. FEF, frontal eye field; IT, inferotemporal visual areas; LIP, lateral intraparietal area; MEF, medial eye field; SC, superior colliculus.

Cortical Plasticity and Learning: Mechanisms and Models

D V Buonomano and H A Johnson, University of California at Los Angeles, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Sensory and motor processing, as well as cognition in general, is critically dependent on cortical computations. A fundamental aspect of cortical function is the ability of the cortex to adapt and remodel itself in an experience-dependent fashion. Thus, to a certain extent, cortical circuits are optimized to perform specific computations. Experience-dependent cortical plasticity has been demonstrated in sensory and motor areas, although most studies have been performed in primary sensory areas, in large part because of the relative ease in characterizing cortical responses and manipulating sensory experience. Two general features of primary sensory cortex are generally examined: topography and stimulus selectivity. Topography refers to the fact that neighboring sites in the cortex represent neighboring areas of the sensory surface. Stimulus selectivity refers to the fact that neurons respond to a specific subset of sensory features, such as tone frequency, skin location, or orientation of visual edges. Stimulus sensitivity is generally defined by the receptive field characteristics of a neuron.

Experience-Dependent Cortical Plasticity

Experience-dependent changes in the receptive field and cortical map topography have been reported throughout various developmental stages and sensory modalities. The common principle in these studies is that plasticity seems to be driven by the ability of cortical networks to detect patterns and changes in the spatiotemporal structure of the input to which they are exposed. More specifically, the correlational structure of the inputs to the cortex, or lack thereof, seems to be a primary determinant in cortical organization.

It is well established that the removal of patterned input during development has profound consequences on cortical function. In kittens, for example, eyelid suture leads to a dramatic decrease in the number of neurons in the visual cortex responsive to the deprived eye. Changes in the structure of the input patterns also alter cortical function; rearing kittens in environments in which they are predominately exposed to lines of a certain orientation will result in an overrepresentation of neurons selective to this orientation. Similar experience-dependent alterations in cortical function have been reported in other modalities. Presentation of auditory noise during early ontogenesis alters the normal development of cortical tonotopic maps, and removing whiskers early in development produces changes in the functional somatotopy of the barrel cortex.

In adults, sensory experience also elicits cortical plasticity. These experiential changes can consist of complete sensory deprivation or more-subtle changes in the input structure, such as those that would occur during perceptual learning. Merzenich and colleagues demonstrated in monkeys that after amputation of a finger or transection of a peripheral nerve, the cortical areas previously responsive to that finger would develop responses to neighboring fingers. The same mechanisms underlying reorganization induced by broad sensory deprivation are also assumed to causally contribute to certain forms of learning. This has been directly examined in the context of perceptual learning. For example, studies in auditory cortex suggest that frequency discrimination learning results in increased representation of the trained frequencies, and orientation discrimination learning is associated with shifts in the orientation tuning of neurons in area V4, consistent with improved discrimination of the trained orientations.

One shared principle in the above studies is the relevance of the correlational structure of the inputs. The correlational structure refers to whether different afferents are generally activated in a synchronous or near-synchronous manner. For example, two close points on the skin are more likely to be coactivated than are two distant points. Theoretical work has demonstrated that the information embedded in the correlational structure of the inputs driving cortical activity can be used to guide the formation or reorganization of topographic maps and their receptive fields. The importance of temporal correlations in the plasticity of cortical receptive fields was directly demonstrated by experiments in which the proximal or distal portions of the fingers of monkeys were consistently co-stimulated – that is, there was an artificially high likelihood that the portions of the adjacent fingers would be co-stimulated. Cortical maps of the primary sensory cortex from these animals revealed a high incidence of neurons that had multiple-digit receptive fields (Figure 1).

Together, a large body of experimental data indicates that the amount of stimulation and the structure of the input patterns to the cortex play instructive roles in the formation of topographic maps and receptive fields. Furthermore, it is hypothesized that what the spatiotemporal patterns of action potentials arriving in the cortex represent – whether they are generated

Figure 1 Cortical map reorganization. After monkeys received behavioral training where digits 2 through 4 were consistently co-stimulated, the receptive fields and map of hand representation in area 3b of somatosensory cortex was reorganized to reflect the experienced training pattern. (a) Two tactile stimulation bars alternately made simultaneous contact with the distal (red line) or proximal (blue line) portions of digits 2 through 4. (b) In normal untrained monkeys, cortical maps rarely show multiple-digit receptive fields. In contrast, this cortical map of a trained monkey shows areas of multiple-digit receptive fields which are specific to either the distal (striped area) or proximal (grey area) portions of the digits. D2, D3, and D4 are areas representing digits 2, 3, and 4, respectively. Areas responding to distal, medial, and proximal digit receptive fields are designated d, m, and p, respectively. (c) Multiple-digit receptive fields (RFs) in a trained monkey. by auditory, somatosensory, or visual stimuli – may not be particularly relevant. This notion is supported by experiments that show that rerouting visual information to the auditory cortex produces 'auditory' neurons that respond selectively to orientation of bars of light. This suggests that there may be a set of universal synaptic and cellular learning rules that underlie cortical organization and plasticity.

Models of Cortical Plasticity

Given the inherent complexity of cortical networks and the computations performed, theoretical approaches have proven critical in establishing a framework to study cortical plasticity by generating predictions and demonstrating, as a proof of principle, that a given set of learning rules is sufficient to account for experimental observations. Computational models of cortical plasticity have focused primarily on two interrelated issues: (1) describing the rules that govern changes in synaptic strength and (2) characterizing how cortical features, such as topography, receptive fields, and stimulus selectivity, emerge in an experience-dependent manner.

Structure from Correlations

To understand the models of cortical plasticity, it is useful to consider the problem of stimulus selectivity from the perspective of a single neuron, for example, a neuron that receives four inputs (Figure 2). If all these inputs are always coactivated (100% correlated), they are functionally indistinguishable; that is, from the perspective of the postsynaptic neuron, it is not possible to discriminate between them. On the other hand, if one pair of neurons is always activated in a correlated manner and the other pair is also highly correlated, yet both pairs are rarely coactive, they may represent two distinct and unrelated sensory stimuli (e.g., stimulus A and stimulus B). In this case, how would the postsynaptic neuron develop a selective response to one but not the other? From the perspective of an individual neuron, two related learning rules must be in place for stimulus selectivity to emerge in a general and robust manner:

1. Associative synaptic plasticity: If a neuron is to develop selective responses to a subset of its synaptic inputs (representing a subset of external

Figure 2 Cortical learning rules. A neuron receives four sources of input, whose synapses onto the neuron are initially weak. (a) Associative synaptic plasticity. The activation pattern of the four inputs is organized into two subsets (A and B), which are active independent of each other and can be thought of as representing two separate stimuli, each consisting of two inputs with correlated activity. Because of this correlation, the inputs from group A will cooperate to drive the postsynaptic neuron, and both inputs onto the neuron will be strengthened in accordance with associative plasticity rules. Since the two inputs representing stimulus B are also correlated, a similar processes will occur. The result is potentiation of all inputs and a postsynaptic neuron that will respond robustly to both stimuli but not exhibit any stimulus selectivity. (b) Associative synaptic plasticity with competition. However, if there is an additional mechanism, such as postsynaptic normalization or a sliding long-term potentiation/long-term depression threshold, competition occurs between the inputs representing the different stimuli, resulting in potentiation of one set of inputs, depression of the other, and the formation of a stimulus-selective neuron.

stimuli), some synapses have to become stronger. In computational models this is achieved by assuming that coincident presynaptic inputs cooperate to drive postsynaptic depolarization, which results in associative synaptic potentiation.

2. Competition: The strengthening of synapses alone will not necessarily lead to selectivity. Thus, the second condition for cortical plasticity is that uncorrelated groups of inputs compete for control of the postsynaptic cell. Functionally, this competition takes the form of decreases in the synaptic strength of a subset of inputs.

Associative synaptic plasticity is sufficient to account for the strengthening of the inputs that will comprise the preferred stimulus. Specifically, if all inputs onto a postsynaptic neuron are initially weak, when a subset of these synapses is consistently activated together, they may cooperate to drive postsynaptic activity, leading to the selective potentiation of this subset. However, if a second independent subset is also consistently coactivated, they will also be potentiated. Without competition, the cell will be driven by more than one input pattern and thus will not be stimulus-selective (Figure 2(a)). Hence, any set of synaptic learning rules capable of accounting for the emergence of stimulus-selective responses must also provide a mechanism by which different inputs 'compete' for control of the postsynaptic cell (Figure 2(b)). Two general classes of models have been proposed to account for this competition: postsynaptic normalization and a sliding long-term potentiation/long-term depression (LTP/LTD) threshold.

Postsynaptic normalization If two stimuli, A and B, are capable of engaging associative plasticity mechanisms, the synaptic weights from both inputs will grow until some saturation point is achieved. Postsynaptic normalization assumes that, through a homeostatic mechanism, neurons actively maintain a fixed level of total synaptic input. Although there is no consensus regarding the mechanisms by which such a process would be expressed, for didactic purposes one could imagine that the total number of postsynaptic glutamate receptors was constant. In this manner, if one synapse is potentiated by a factor X, all synapses would become weaker by a specific fraction (a function of X and the total number of synapses). According to this model, all synapses would be depressed by the same amount after each stimulus presentation, but the synapse that started off a bit stronger would eventually dominate because it would undergo proportionally more LTP after each stimulus presentation.

Sliding threshold for LTP and LTD A second model of cortical plasticity is referred to as the sliding-threshold learning rule, or BCM (representing the initials of the authors of the model, Bienenstock, Cooper, and Munro). In this model, associative plasticity and competition are tightly linked. Here, presynaptic activity can result in either LTP or LTD, depending on the voltage of the postsynaptic neuron. Specifically, if the postsynaptic cell is depolarized above a critical value (the LTP/LTD threshold, θ) during presynaptic activity, LTP ensues; if the postsynaptic voltage is below this threshold, LTD ensues. Mathematically this can be expressed as follows:

$$\Delta W_{\text{pre, post}} = \alpha V_{\text{pre}}(V_{\text{post}} - \theta)$$

where V reflects the degree of activation of the pre- or postsynaptic cell, ΔW is the change in the weight of the synapse, and α is a constant which controls the rate of synaptic change. If θ is equal to zero, we are left with the standard Hebbian term of synaptic plasticity.

Figure 3 Sliding long-term potentiation–long-term depression (LTP–LTD) threshold. The BCM model (named for its authors, Bienenstock, Cooper, and Munro) postulates a sliding threshold for the induction of LTP–LTD. Synaptic input which drives postsynaptic activity above this threshold level undergoes LTP, and one which drives postsynaptic activity below this level undergoes LTD. If the average activity rate for the neuron increases over time (red trace), the threshold slides to the right, thus requiring more postsynaptic activity for the induction of LTP and facilitating the induction of LTD. The reverse is also true: if the average activity rate decreases (blue trace), the threshold slides to the left, and less activity is needed for inputs to drive enough postsynaptic activity to induce potentiation.

When θ is positive, the level of postsynaptic activity determines whether LTP or LTD will occur. Competition arises from the fact that θ is not a constant but varies as a running average of activity in the postsynaptic cell (Figure 3). Specifically, θ changes in a manner proportional to the average postsynaptic activity, albeit at a slow rate (hypothesized to occur on the scale of hours). Assuming a state in which all the inputs onto the postsynaptic neuron are initially strong, the cell will be nonselective, responding to any and all stimuli. However, because the average cell activity rate will also be high, precisely because of the absence of selectivity, θ will increase. As this happens, there will be a point when the weaker of the two inputs will produce a depolarization that falls below θ and will undergo LTD. This will create a divergence in the synaptic weights representing different stimuli, resulting in a stimulus-selective neuron.

These models differ significantly in relation to the competitive mechanisms but share a number of common features, particularly in regard to the associative potentiation of active synapses. In addition, both models rely on the calculation of some global (cellwide) parameter capable of influencing all synapses of the postsynaptic cell. In the normalization model, a global mechanism must estimate the sum of all synaptic weights onto a cell and adjust these weights in a cellwide manner. While there is no direct experimental evidence for this exact mechanism, related forms of plasticity have been observed experimentally. Specifically, a form of homeostatic plasticity referred to as synaptic scaling appears to adjust the strength of all synapses in a manner proportional to overall activity levels. Alternatively, the sliding-threshold model requires neurons to estimate their activity level, and the result of this estimate must be locally available at each synapse to control for the induction of LTP or LTD. Experimental evidence also provides some support for such a sliding-threshold; however, to date, these studies are indirect.

In addition to postsynaptic normalization and the sliding-threshold model, it has been proposed that spike timing-dependent plasticity (STDP) may provide a mechanism for competition between stimuli and thus the formation of stimulus-selective responses. STDP refers to an experimentally well-characterized form of associative synaptic plasticity in which presynaptic spikes arriving before a postsynaptic spike produce LTP, while those arriving after result in LTD. This state of affairs can result in active competition between groups of presynaptic cells representing different inputs. However, in contrast to postsynaptic normalization and the sliding-threshold rules, competition is limited to stimuli that occur in close temporal proximity (within the time window for STDP). Thus STDP by itself does not represent a general learning rule for cortical organization and plasticity.

At the theoretical level, both the postsynaptic normalization and sliding-threshold models provide a general mechanism that is sufficient to account for the formation of stimulus-selective neurons in a self-organizing manner. Note, however, that the mechanisms discussed would not explain why neighboring neurons would have similar receptive field characteristics, because each postsynaptic neuron is independent of the other. Topography is postulated to arise from the lateral interaction within cortical networks. Specifically, it has been shown that if neurons excite their near neighbors and inhibit their far ones, 'macroscopic' features of cortical maps can be simulated, including the topography and the presence of ocular dominance stripes observed in primary visual cortex.

Mechanisms and Cellular Correlates of Cortical Plasticity

Normal cortical development and cortical plasticity rely on a complex set of activity-dependent and molecular guidance mechanisms. Although these mechanisms are incompletely understood, there is significant agreement between the experimental findings and the

theoretical models, particularly in regard to the role of synaptic plasticity in experience-dependent cortical plasticity. The majority of excitatory neurons in the cortex that have been examined exhibit both LTP and LTD. The LTP is typically associative in nature and dependent on the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors, which act as coincidence detectors. Experiments in both the visual system and the barrel cortex (the area of the rodent somatosensory cortex that represents the whiskers) reveal alterations in sensory-evoked responses after deprivation consistent with LTP or LTD. In the barrel cortex model of cortical plasticity, removal of all but one or two whiskers produces enhanced responses to the spared whiskers and decreased responses to the cut whiskers. Evidence for the role of LTD in decreasing the responsiveness comes from the observation that the induction LTD in this pathway is occluded after sensory deprivation. Pharmacological and genetic manipulations that alter normal NMDA receptor function (or downstream biochemical pathways) and impair the induction of associative LTP also impair cortical plasticity. For example, pharmacological blockade of NMDA receptors prevents the normal reorganization of the barrel cortex observed after removing whiskers. Also, in the visual cortex, the pattern of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor phosphorylation produced by LTP/LTD *in vitro* resembles those patterns produced *in vivo* in response to protocols that induce cortical plasticity. These and other experiments demonstrate a role of associative, NMDA receptor-dependent LTP and LTD in cortical plasticity.

Theoretical studies have focused primarily on the role of synaptic plasticity and competition as the mechanisms underlying cortical plasticity. However, it is clear that changes in excitatory synaptic strength alone provide an incomplete picture. For example, deprivation of sensory inputs is known to result in changes in dendritic and axonal morphology, intrinsic membrane excitability, as well as changes in the levels of γ-aminobutyric acid-mediated inhibition. Thus, cortical plasticity is believed to rely on complex and highly orchestrated changes at many cellular and synaptic loci in parallel. The mechanisms may be dependent on the forms of plasticity being examined, the cortical areas involved, as well as the developmental stage. Indeed, evidence suggests that cortical plasticity induced by sensory deprivation relies on different loci in young and adult animals. Specifically, early in development, depression and potentiation of the deprived and spared inputs, respectively, is observed. In adults, however, the potentiation of the spared inputs appears to be the dominant response to deprivation. In addition, there is evidence suggesting that in adults plasticity relies more heavily on synaptic plasticity occurring in supra- and infragranular layers of the cortex, and less on thalamocortical plasticity.

Cortical Plasticity: Spatiotemporal Stimuli

Most studies of cortical plasticity have focused primarily on the neural response to simple spatial stimuli – such as somatic receptive fields or ocular dominance preference. However, a fundamental aspect of cortical function is the processing and categorization of complex spatiotemporal stimuli, such as animal vocalizations. It is well established that perceptual learning of spatiotemporal stimuli results in robust improvement in the ability to discriminate between complex stimuli, and it is widely accepted that perceptual learning is dependent on cortical plasticity.

In contrast to changes in spatial receptive field properties, which can be explained in terms of simple potentiation and depression of the inputs to a neuron, the mechanisms underlying the response properties to complex stimuli are not well understood. One general class of models proposes that the cortical circuits are intrinsically able to process spatial and temporal stimuli as a result of the inherent complexity of cortical networks and the presence of time-dependent neuronal properties. These models, referred to as state-dependent networks, consist of recurrently connected excitatory and inhibitory neurons and the presence of time-dependent properties, particularly short-term synaptic plasticity. In the same manner that long-term plasticity provides a trace or memory determined by a set of events that occurred sometime in the past, short-term synaptic plasticity provides a 'trace' that a given synapse was recently (on the scale of hundreds of milliseconds) active. Consequently, the state of a cortical network is dependent on the previous stimuli to which it was exposed, and the response to subsequent inputs will inherently encode both the stimulus and the context in which it was presented. Relatively few experiments have examined the neural mechanisms underlying experience-dependent plasticity to complex stimuli. However, it has been shown in primates and ferrets that the neural responses to animal vocalizations are indeed dependent on experience. Furthermore, exposure to specific auditory patterns paired with stimulation of the nucleus basalis results in reorganization of primary auditory cortex and changes in the neuronal sensitivity to temporal sequences. Additional studies are needed to elucidate the mechanisms by which neurons develop selective responses to spatiotemporal stimuli.

Conclusion

Cortical plasticity allows circuits to flexibly adjust and optimize processing in a manner that reflects the environmental and behavioral demands. This ability encompasses both relatively simple features such as the formation of topographic maps and the spatial receptive field characteristics of neurons, as well as the processing of complex stimuli, such as speech and vocalization recognition. Theoretical and experimental studies have established that associative forms of synaptic plasticity and synaptic competition are critical to cortical plasticity. While the molecular and cellular mechanisms underlying associative synaptic plasticity are partially understood, the mechanisms underlying competition remain to be elucidated. Similarly, much remains to be learned regarding the contribution of other cellular and synaptic loci, including intrinsic neuronal excitability and inhibition, in cortical plasticity.

Cortical Processing of the Reward Value of Food

E T Rolls, University of Oxford, Oxford, UK

© 2009 Elsevier Ltd. All rights reserved.

The Pleasantness of the Taste of Food

The modulation of the reward value of a sensory stimulus, such as the taste of food, by motivational state – for example, hunger – is one important way in which motivational behavior is controlled. The subjective correlate of this modulation is that food tastes pleasant when a person is hungry, and tastes hedonically neutral when a person has eaten to satiety. To make the results relevant to understanding these processes and to the control of food intake in humans, complementary evidence is provided by neurophysiological studies in nonhuman primates, and by functional neuroimaging studies in humans. The macaque taste and olfactory system may be particularly relevant to understanding these processes in humans, for the primate taste system does not have a pontine taste area and direct subcortical connections, but instead relies on thalamic-to-cortical processing.

Rolls and colleagues have found that the modulation of taste-evoked signals by motivation is not a property found in early stages of the primate gustatory system. The responsiveness of taste neurons in the nucleus of the solitary tract and in the primary taste cortex (in the frontal operculum and anterior insula) is not attenuated by feeding to satiety. (Figure 1 shows a schematic diagram of a lateral view of some of the primate brain taste, olfactory, visual, and somatosensory pathways.) In contrast, in the secondary taste cortex, in the caudolateral part of the orbitofrontal cortex, it has been shown that the responses of the neurons to the taste of glucose decreased to zero while the monkey ate it to satiety, during the course of which the behavior turned from avid acceptance to active rejection. This modulation of responsiveness of the gustatory responses of the orbitofrontal cortex neurons by satiety could not have been due to peripheral adaptation in the gustatory system or to altered efficacy of gustatory stimulation after satiety was reached, because modulation of neuronal responsiveness by satiety was not seen at the earlier stages of the gustatory system, including the nucleus of the solitary tract, the frontal opercular taste cortex, and the insular taste cortex.

Sensory-Specific Satiety

In the secondary taste cortex, it was also found that the decreases in the responsiveness of the neurons were relatively specific to the food with which the monkey had been fed to satiety. For example, in seven experiments in which the monkey was fed glucose solution, neuronal responsiveness decreased to the taste of the glucose but not to the taste of blackcurrant juice (see example in Figure 2). Conversely, in two experiments in which the monkey was fed to satiety with fruit juice, the responses of the neurons decreased to fruit juice but not to glucose. An example of this sensory-specific decrease in the responsiveness of a neuron after feeding to satiety is shown in Figure 2. This neuron had taste, olfactory, and visual responses to food, and the satiety was produced by a food, blackcurrant juice, with of all these components.

This evidence shows that the reduced acceptance of food which occurs when food is eaten to satiety, and the reduction in the pleasantness of its taste, are not produced by a reduction in the responses of neurons in the nucleus of the solitary tract or frontal opercular or insular gustatory cortices to gustatory stimuli. Indeed, after feeding to satiety, humans reported that the taste of the food on which they had been satiated tasted almost as intense as when they were hungry, though much less pleasant. This comparison is consistent with the possibility that activity in the frontal opercular and insular taste cortices, as well as in the nucleus of the solitary tract, does not reflect the pleasantness of the taste of a food, but rather its sensory qualities, independently of motivational state. On the other hand, the responses of the neurons in the caudolateral orbitofrontal cortex taste area and in the lateral hypothalamus are modulated by satiety, and it is presumably in areas such as these that neuronal activity may be related to whether a food tastes pleasant, and to whether the food should be eaten. In addition to providing an implementation of sensory-specific satiety (probably by habituation of the synaptic afferents to orbitofrontal neurons with a time course of the order of the length of a course of a meal), it is likely that visceral and other satiety-related signals reach the orbitofrontal cortex (as indicated in Figure 1) (from the nucleus of the solitary tract, via thalamic areas), and there modulate the representation of food, resulting in an output that reflects the reward (or appetitive) value of each food.

It is an important principle that the identity of a taste, and its intensity, are represented separately from its pleasantness. Thus it is possible to represent what a taste is, and to learn about it, even when we are not hungry.

Figure 1 Some of the pathways involved in sensory processing involved in the control of food intake and emotion are shown on this lateral view of the brain of the macaque monkey. Connections from the primary taste and olfactory cortices to the orbitofrontal cortex and amygdala are shown. Connections are also shown in the 'ventral visual system' from V1 to V2, V4, the inferior temporal visual cortex, etc., with some connections reaching the amygdala and orbitofrontal cortex. In addition, connections from the somatosensory cortical areas 1, 2, and 3 that reach the orbitofrontal cortex directly and via the insular cortex, and that reach the amygdala via the insular cortex, are shown. as, arcuate sulcus; cal, calcarine sulcus; cs, central sulcus; lf, lateral (or Sylvian) fissure; lun, lunate sulcus; ps, principal sulcus; io, inferior occipital sulcus; ip, intraparietal sulcus (which has been opened to reveal some of the areas it contains); sts, superior temporal sulcus (which has been opened to reveal some of the areas it contains); AIT, anterior inferior temporal cortex; FST, visual motion processing area; LIP, lateral intraparietal area; MST, visual motion processing area; MT, visual motion processing area (also called V5); PIT, posterior inferior temporal cortex; STP, superior temporal plane; TA, architectonic area including auditory association cortex; TE, architectonic area including high-order visual association cortex, and some of its subareas TEa and TEm; TG, architectonic area in the temporal pole; V1–V4, visual areas V1–V4; VIP, ventral intraparietal area; TEO, architectonic area including posterior visual association cortex. The numerals refer to architectonic areas, and have the following approximate functional equivalence: 1, 2, 3, somatosensory cortex (posterior to the central sulcus); 4, motor cortex; 5, superior parietal lobule; 7a, inferior parietal lobule, visual part; 7b, inferior parietal lobule, somatosensory part; 6, lateral premotor cortex; 8, frontal eye field; 12, part of orbitofrontal cortex; 46, dorsolateral prefrontal cortex.

Representation of the Pleasantness of the Smell and Sight of Food in the Brain

It has also been possible to investigate whether the olfactory representation in the orbitofrontal cortex is affected by hunger, and thus whether the pleasantness of odor is represented in the orbitofrontal cortex. In satiety experiments, Critchley and Rolls showed that the responses of some olfactory neurons to a food odor are decreased during feeding to satiety with a food (e.g., fruit juice) containing that odor. In particular, seven of nine olfactory neurons that were responsive to the odors of foods, such as blackcurrant juice, were found to decrease their responses to the odor of the satiating food. The decrease was typically at least partly specific to the odor of the food that had been eaten to satiety, potentially providing part of the basis for sensory-specific satiety. It was also found for eight of nine orbitofrontal cortex neurons that had selective responses to the sight of food that they demonstrated a sensory-specific reduction in their visual responses to foods following satiation. These findings show that the olfactory and visual representations of food, as well as the taste representation of food, in the primate orbitofrontal cortex are modulated by hunger. Usually a component related to sensory-specific satiety can be demonstrated. Hunger does not influence the responses of neurons in the inferior temporal visual cortex to visual stimuli, so that the representation of the pleasantness or reward

Figure 2 Orbitofrontal cortex neuron with visual, olfactory, and taste responses, showing the responses before and after feeding to satiety with blackcurrant juice. The solid circles show the responses to blackcurrant juice. The olfactory stimuli included apple (ap), banana (ba), citral (ct), phenylethanol (pe), and caprylic acid (cp). The spontaneous firing rate (sp) of the neuron is shown. Adapted from Critchley HD and Rolls ET (1996) Hunger and satiety modify the responses of olfactory and visual neurons in the primate orbitofrontal cortex. *Journal of Neurophysiology* 75: 1673–1686.

value of the sight of food is a special property of the orbitofrontal cortex, which receives visual inputs from the inferior temporal visual cortex.

These findings link at least part of the processing of olfactory and visual information in this brain region to the control of feeding-related behavior. This is further evidence that part of the olfactory representation in this region is related to the hedonic value of the olfactory stimulus, and in particular that at this level of the olfactory system in primates, the pleasure elicited by the food odor is at least part of what is represented.

As a result of the neurophysiological and behavioral observations showing the specificity of satiety in the monkey, experiments were performed to determine whether satiety was specific to foods eaten in humans. It was found that the pleasantness of the taste of food eaten to satiety decreased more than for foods that had not been eaten. One consequence of this is that if one food is eaten to satiety, appetite reduction for other foods is often incomplete, and this will lead to enhanced eating when a variety of foods is offered. Because sensory factors such as similarity of color, shape, flavor, and texture are usually more important than are metabolic equivalences in terms of protein, carbohydrate, and fat content, in influencing how foods interact in this type of satiety, this has been termed 'sensory-specific satiety.' It should be noted that this effect is distinct from alliesthesia, in that alliesthesia is a change in the pleasantness of sensory inputs produced by internal signals (such as glucose in the gut), whereas sensory-specific satiety is a change in the pleasantness of sensory inputs and is accounted for at least partly by the external sensory stimulation received (such as the taste of a particular food), in that it is at least partly specific to the external sensory stimulation received.

To investigate whether the sensory-specific reduction in the responsiveness of the orbitofrontal olfactory neurons might be related to a sensory-specific reduction in the pleasure produced by the odor of a food when it is eaten to satiety, Rolls and Rolls measured humans' responses to the smell of a food which was eaten to satiety. It was found that the pleasantness of the odor of a food (but much less significantly its intensity) was decreased when persons ate the food to satiety. It was also found that the pleasantness of the smell of other foods (i.e., foods not eaten in the meal) showed much less decrease. This finding has clear implications for the control of food intake, for ways to keep foods presented in a meal appetitive, and for effects on odor pleasantness ratings that could occur following meals. In an investigation of the mechanisms of this odor-specific, sensory-specific satiety, Rolls and Rolls

allowed humans to chew a food without swallowing, for approximately as long as the food is normally in the mouth during eating. They demonstrated sensory-specific satiety with this procedure, showing that the sensory-specific satiety does not depend on food reaching the stomach. Thus at least part of the mechanism is likely to be produced by a change in processing in the olfactory pathways. It is not yet known which stage of olfactory processing is the earliest at which this modulation occurs. It is unlikely to be in the receptors, because the change in pleasantness found was much more significant than was the change in the intensity.

The increase of food intake that can occur when a variety of foods is available, as a result of the operation of sensory-specific satiety, may have been advantageous in evolution in ensuring that different foods with important different nutrients were consumed. However, today, humans have a wide variety of foods readily available, and this may be a factor that can lead to overeating and obesity. In a test of this in the rat, it has been found that variety itself can lead to obesity.

Mouth Feel of Fat: Orbitofrontal Cortex, Primary Taste Cortex, and Amygdala

Texture in the mouth is an important indicator of whether fat is present in a food, which is important not only as a high-value energy source, but also as a potential source of essential fatty acids. In the orbitofrontal cortex, Rolls, Critchley, and colleagues have found a population of neurons that responds when fat is in the mouth. An example of such a neuron is shown in Figure 3. The fat-related responses of these neurons are produced at least in part by the texture of the food rather than by chemical receptors sensitive to certain chemicals, in that such neurons typically respond not only to foods, such as cream and milk, containing fat, but also to paraffin oil (which is a pure hydrocarbon) and to silicone oil ($Si(CH_3)_2O)_n$). Moreover, the texture channels through which these fat-sensitive neurons are activated are separate from viscosity-sensitive channels, in that the responses of these neurons cannot be predicted by the viscosity of the oral stimuli, as illustrated in Figure 3. Some of the fat-related neurons do, though, have convergent inputs from the chemical senses, in that in addition to taste inputs, some of these neurons respond to the odor associated with a fat, such as the odor of cream. Feeding to satiety with fat (e.g., cream) decreases the responses of these neurons to zero on the food eaten to satiety, but if the neuron receives a taste input from, for example, glucose taste, that is not decreased by feeding to satiety with cream. Thus there is a representation of the macronutrient fat in this brain area, and the activation produced by fat is reduced by eating fat to satiety.

For some neurons, a combination of taste, fat texture, oral viscosity, and temperature is represented in the macaque primary taste cortex in the rostral insula and adjoining frontal operculum. These oral sensory properties of food, and also the sight and smell of food, are also represented in the primate amygdala. Interestingly, the responses of these amygdala neurons do not correlate well with the preferences of the macaques for the oral stimuli, and feeding to

Figure 3 A neuron in the primate orbitofrontal cortex responding to the texture of fat in the mouth independently of viscosity. The cell (bk265) increased its firing rate to a range of fats and oils (the viscosity of which is shown in centipoises, cP). The information that reaches this type of neuron is independent of a viscosity-sensing channel, in that the neuron does not respond to the carboxymethyl cellulose (CMC) viscosity series. The neuron responded to the texture rather than to the chemical structure of the fat in that it also responded to silicone oil ($Si(CH_3)_2O)_n$) and paraffin (mineral) oil (hydrocarbon). Some of these neurons have taste inputs. Adapted from Verhagen JV, Rolls ET, and Kadohisa M (2003) Neurons in the primate orbitofrontal cortex respond to fat texture independently of viscosity. *Journal of Neurophysiology* 90: 1514–1525.

satiety does not produce the large reduction in the responses of primate amygdala neurons to food that is typical of orbitofrontal cortex neurons.

Imaging Studies in Humans

Taste

In humans it has been shown in neuroimaging studies using functional magnetic resonance imaging (fMRI) that taste activates an area of the anterior insula/frontal operculum, which is probably the primary taste cortex, and part of the orbitofrontal cortex, which is probably the secondary taste cortex. O'Doherty et al. showed that the human amygdala was as much activated by the affectively pleasant taste of glucose as by the affectively negative taste of NaCl, and thus provided evidence that the human amygdala is not especially involved in processing aversive as compared to rewarding stimuli.

Another study has shown that umami taste stimuli, of which an exemplar is monosodium glutamate (MSG) and which captures what is described as the taste of protein, activate cortical regions of the human taste system similar to those activated by a prototypical taste stimulus, glucose. A part of the rostral anterior cingulate cortex (ACC) was also activated. When the nucleotide 0.005 M inosine 5′-monophosphate (IMP) was added to MSG (0.05 M), the blood oxygenation-level-dependent (BOLD) signal in an anterior part of the orbitofrontal cortex showed supralinear additivity, and this may reflect the subjective enhancement of umami taste that has been described when IMP is added to MSG. Overall, these results illustrate that the responses of the brain can reflect inputs produced by particular combinations of sensory stimuli with supralinear activations, and that the combination of sensory stimuli may be especially represented in particular brain regions.

Odor

In an investigation of where the pleasantness of olfactory stimuli might be represented in humans, O'Doherty et al. showed that the activation of an area of the orbitofrontal cortex to banana odor was decreased (relative to a control vanilla odor) after bananas were eaten to satiety. Thus activity in a part of the human orbitofrontal cortex olfactory area is related to sensory-specific satiety, and this is one brain region where the pleasantness of odor is represented.

An important issue is whether there are separate regions of the brain discriminable with fMRI that represent pleasant and unpleasant odors. To investigate this, we measured the brain activations produced by three pleasant and three unpleasant odors. The pleasant odors chosen were linalyl acetate (floral, sweet), geranyl acetate (floral), and α-ionone (woody, slightly food related). The unpleasant odors chosen were hexanoic acid, octanol, and isovaleric acid. We found that these unpleasant odors activated dissociable parts of the human brain. Pleasant, but not unpleasant, odors were found to activate a medial region of the orbitofrontal cortex. Further, there was a correlation between the subjective pleasantness ratings of the six odors given during the investigation with activation of a medial region of the rostral orbitofrontal cortex. In contrast, a correlation between the subjective unpleasantness ratings of the six odors was found in regions of the left and more lateral orbitofrontal cortex. Activation was also found in the anterior cingulate cortex, with a middle part of the anterior cingulate activated by both pleasant and unpleasant odors, and a more anterior part of the anterior cingulate cortex showing a correlation with the subjective pleasantness ratings of the odors. These results provide evidence that there is a hedonic map of the sense of smell in brain regions such as the orbitofrontal cortex and cingulate cortex.

Olfactory–Taste Convergence to Represent Flavor, and the Influence of Satiety

To assess how satiety influences the brain activations to a whole food which produces taste, olfactory, and texture stimulation, we measured brain activation by whole foods before and after the food is eaten to satiety. The aim was to determine using a food that has olfactory, taste, and texture components the extent of the region that shows decreases when the food becomes less pleasant, in order to identify the different brain areas where the pleasantness of the odor, taste, and texture of food are represented. The foods eaten to satiety were either chocolate milk or tomato juice. A decrease in activation by the food eaten to satiety relative to the other food was found in the orbitofrontal cortex, but not in the primary taste cortex (see Figure 4). This study provided evidence that the pleasantness of the flavor of food, and sensory-specific satiety, are represented in the orbitofrontal cortex.

Oral Viscosity and Fat Texture

The viscosity of food in the mouth is represented in the human primary taste cortex (in the anterior insula), and also in a midinsular area that is not taste cortex, but which represents oral somatosensory stimuli. In these regions, the fMRI BOLD activations are proportional to the log of the viscosity of carboxymethyl cellulose in the mouth. Oral viscosity is also represented in the human orbitofrontal and perigenual cingulate cortices, and it is notable that the perigenual

Figure 4 Areas of the human orbitofrontal cortex with activations correlating with pleasantness ratings for food in the mouth. (a) Coronal section through the region of the orbitofrontal cortex from the random-effects group analysis, showing the peak in the left orbitofrontal cortex (Talairach coordinates *X*, *Y*, *Z* = −22, 34, −8; z-score = 4.06), in which the blood oxygenation-level-dependent signal in the voxels, shown in yellow, was significantly correlated with the individual's subjective pleasantness ratings of the foods throughout an experiment in which the individuals were hungry and found the food pleasant, and were then fed to satiety with the food, after which the pleasantness of the food decreased to neutral or slightly unpleasant. The design was a sensory-specific satiety design, and the pleasantness of the food not eaten in the meal, and the blood oxygenation-level-dependent activation in the orbitofrontal cortex, were not altered by eating the other food to satiety. The two foods were tomato juice and chocolate milk. (b) Plot of the magnitude of the fitted hemodynamic response from a representative single individual against the subjective pleasantness ratings (on a scale from −2 to +2), and peristimulus time in seconds. Adapted from Kringelbach ML, O'Doherty J, Rolls ET, et al. (2003) Activation of the human orbitofrontal cortex to a liquid food stimulus is correlated with its subjective pleasantness. *Cerebral Cortex* 13: 1064–1071.

cingulate cortex, an area in which many pleasant stimuli are represented, is strongly activated by the texture of fat in the mouth and also by oral sucrose.

The Sight of Food

Visual stimuli associated with the taste of glucose activate the orbitofrontal cortex and some connected areas, consistent with the primate neurophysiology. Consistent with these findings, Pelchat and colleagues found that after consuming a monotonous diet, study participants who were instructed to imagine foods that they craved showed more activation in some brain areas, including part of the insula, than did participants who had consumed a normal diet.

Satiety Signals

Satiety signals can be thought of as occurring in a sequence. In addition to sensory-specific satiety, which involves reduced activity in cortical areas that represent the pleasantness of food, further temporally overlapping signals include gastric distension, duodenal chemosensory signals, glucose utilization, and hormonal (including leptin) signals. Many of these signals are likely to have influences, in some cases via the lateral hypothalamus, on the orbitofrontal cortex, and by modulating sensory activity there, to set the current pleasantness and reward value of food. Investigation of hunger and satiety signals has been a major and difficult issue for many years, but whatever the details of these signals, they must influence processing in brain areas such as the orbitofrontal cortex. The outputs of the orbitofrontal cortex then reach brain regions such as the striatum, cingulate cortex, and dorsolateral prefrontal cortex, where behavioral responses to food may be elicited, because these structures produce behavior which makes the orbitofrontal cortex reward neurons fire, as they represent a goal for behavior. At the same time, outputs from the orbitofrontal cortex and amygdala, in part via the hypothalamus, may provide for appropriate autonomic and endocrine responses to food to be produced, including the release of hormones such as insulin.

Corticomotoneuronal System

R N Lemon, University College London, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Definition

The term 'corticomotoneuronal (CM)' is used exclusively to denote a direct monosynaptic linkage between the axon of a corticospinal neuron and spinal motor neurons. The term was first introduced by Bernhard and Bohm in their classic papers in the early 1950s. They demonstrated that electrical stimulation of the motor cortex evoked responses in limb nerves of the monkey which had such short latencies that they could only have resulted from a direct, monosynaptic response of motor neurons to the descending volleys in the corticospinal tract (CST) excited by cortical stimulation. This suggestion was subsequently confirmed physiologically by Phillips, who made intracellular recording in alpha motor neurons of monosynaptic CM excitatory postsynaptic potentials (EPSPs) in response to stimulation of the motor cortex in the baboon. Anatomical confirmation was provided by Kuypers and others, who demonstrated labeled boutons from the CST terminating on dendrites of spinal motor neurons. The term CM is quite specific to the monosynaptic connection and should not be confused with more general terminology that refers to the influence of the motor cortex over motor neurons and muscles through less direct (oligosynaptic) or otherwise undefined pathways. The term CM is not usually applied to corticobulbar and other cortical projections which innervate cranial motor nuclei.

Anatomy of the CM System

The CM system is made up of a subset of CST fibers that terminate upon spinal motor neurons. There are at least two aspects to the anatomy of the CM system. One relates to the cortical origin of the CM system and its course between cortex and spinal cord, and the second to the spinal termination of CM fibers upon spinal alpha motor neurons. Because the CM system appears to be uniquely present in primates, most of the experimental evidence referred to below has been obtained in humans or in nonhuman primates (mainly Old World macaque monkeys).

Pattern of Termination

Little is known about the number, size, or density of CM terminals on individual motor neurons, but a single CST axon probably makes only one or only a few contacts with a given target motor neuron, and those contacts are located on medium to distal dendrites. There is as yet no direct evidence for CM effects on gamma motor neurons.

Distribution of CM Projections to Different Motor Nuclei

Early studies by Kuypers and others using silver degeneration provided widespread evidence in primates, including humans, that CST fibers terminated widely among the motor nuclei that supply limb muscles, and particularly those supplying muscles of the distal extremity (hand, foot, and, in some species, tail). This was confirmed by later studies using anterograde neuroanatomical tracers. In the macaque, the density of CS terminals among the lateral motor nuclei shows an increasing rostral to caudal gradient (from low cervical (C7) to high thoracic (T1) segments); this gradient corresponds to the increasing density of the motor neurons innervating the intrinsic hand muscles.

Origins of CM Projections

An important issue is to discover which components of the CST give rise to CM projections. The CST itself is derived from widespread regions of the frontal and parietal lobes. The major cortical area that terminates directly among motor neurons is the classical primary motor cortex (termed M1, Brodmann area 4). There is accumulating anatomical evidence that most of the CST that gives rise to CM projections arises from M1 and rather less from the secondary motor areas (such as the supplementary motor area (SMA) and premotor areas). Recent studies using retrograde transneuronal labeling techniques have suggested that cells with CM projections are mainly located in the rostral bank of the central sulcus and that CM neurons are not found on the convexity of the precentral gyrus. These studies have also indicated that CM projections arose from CST neurons with both large and small cell bodies.

The postcentral (somatosensory) cortex also gives rise to large numbers of corticospinal projections, and those originating from cortical area 3a have been shown to give rise to CM connections. It has been speculated that these connections might involve gamma motor

neurons, which provide motor innervation to muscle spindles, whose feedback is thought to converge heavily on cortical area 3a. There is no evidence to date for a specific molecular marker distinguishing CM from other corticospinal neurons.

Physiology of the CM System

Electrical Stimulation Methods

The CM system has classically been identified by monosynaptic responses in target motor neurons or muscles evoked by direct electrical stimulation of the CST at the level of the medullary pyramid (the pyramidal tract, PT) or of the motor cortex. Such stimulation gives rise to one or more descending volleys of CS activity. These methods have been complemented in humans by the use of transcranial magnetic and electrical stimulation.

Identification of Monosynaptic CM Effects in Motor Neurons

The monosynaptic nature of CM responses to the earliest corticospinal volley has been inferred from the delay (~1.0 ms) between arrival of the volley and the onset of the response, which delay is shorter than the minimum value normally associated with disynaptic transmission (1.3 ms or greater). All CM synapses are excitatory, and responses take the form of a compound EPSP. Any inhibitory effects are thought to be mediated by spinal inhibitory interneurons activated by CST inputs. The monosynaptic nature of the CM connection is also shown by its ability to follow high-frequency stimulation of the PT (up to 500 Hz or higher).

If a CM-EPSP is large enough, it will discharge the motor neuron. In awake or lightly sedated animals, stimulation of the PT can be shown to evoke short-latency responses in motor units. These responses are probably monosynaptic because of their short and invariant latency.

Interpretation of effects resulting from electrical stimulation of the motor cortex is more difficult because this stimulation usually gives rise to repetitive high-frequency (~600 Hz) activation in the CST. The first wave of excitation is the D-wave, due to direct activation of CST neurons, and this is followed by I-waves, thought to be due to indirect, transsynaptic activation of CST neurons. It is possible to demonstrate that each successive wave of CS activity gives rise to a CM-EPSP.

Physiological Properties of CM Synapses

CM synapses are excitatory and involve glutamate as the neurotransmitter. The size of the unitary CM-EPSP synapse (i.e., the amplitude of the EPSP evoked in a target motor neuron by activation of a single CM input) is not known, but it is probably quite small (50–100 μV). High-frequency stimulation causes temporal facilitation of CM-EPSPs and may explain in part the powerful motor response to stimulation of the cortex, such as transcranial magnetic stimulation (TMS; see the section titled 'Transcranial stimulation in humans'). CM synapses are not thought to be under control of presynaptic inhibition. Excitation of motor neurons by CM inputs is severely depressed or abolished by general anesthetics.

Distribution of CM Effects in Different Motor Nuclei

The size of compound CM-EPSPs (i.e., the amplitude of the EPSP evoked in a target motor neuron by activation of all its CM inputs) varies considerably, both within a motor nucleus innervating a single muscle and across motor nuclei. In general, the largest effects are seen in the motor nuclei supplying the most distal (hand, foot) muscles and in extensor muscles of the upper limb (such as the common extensor of the digits) and dorsiflexors of the foot (such as the tibialis anterior). In monkeys, CM effects are weaker or absent in motor nuclei supplying more proximal (shoulder, hip) muscles. In humans tested with trancranial stimulation of the cortex, these same general rules apply, and there is evidence that the compound EPSP is probably larger in humans than in most nonhuman primates that have been investigated. In humans, putative CM effects have also been reported in many other muscle groups, including those of respiratory muscles, girdle, trunk, and sphincter muscles.

Origins of CM Effects

Because CST fibers arising from different regions of the cortex and terminating at different spinal levels are intermixed at the level of the pyramidal tract, PT stimulation activates the CST in an indiscriminate manner. To investigate which cortical regions give rise to CM effects, local, single-pulse electrical stimulation of different cortical areas can be used. Such studies indicate that M1 gives rise to large CM effects in hand motor neurons, consistent with the anatomical findings reviewed already. Much weaker effects are obtained from secondary motor areas such as the SMA, and CM effects are generally absent after stimulation of the premotor cortex.

Transcranial Stimulation in Humans

TMS and transcranial electrical stimulation (TES) have allowed detailed investigation of CM effects in awake humans with a wide variety of neurological diseases.

Both forms of stimulation result in high-frequency, repetitive activation of the CST, which complicates interpretation of the effects, normally recorded as a motor evoked potential (MEP) in the electromyogram (EMG) or from single motor units. The earliest muscle responses are probably due to the arrival of waves of activity in the CST induced by TMS (dominated by I-waves) or TES (dominated by D-waves), and these responses have properties which confirm their CM origin. However, it is probable that MEPs in whole EMG recordings undoubtedly include motor neuron responses to CM inputs as well as to indirect, oligosynaptic inputs. Motor responses, probably including CM effects, have also been evoked by transmastoid electrical stimulation, which is thought to activate the CST at brain stem level.

Identification of CM Effects by Spike-Triggered Averaging

Fetz and Cheney first showed that CM cells can be identified in the awake animal by use of correlational methods to demonstrate that a motor cortex neuron exerts a facilitatory effect on a motor neuron pool that is consistent with CM action. This method involves spike-triggered averaging (STA) of EMG activity. In this approach, EMG activity recorded from limb muscles is full wave rectified and averaged with respect to the spontaneous, natural discharge of a single neuron, recorded from the contralateral motor cortex. If the neuron makes direct CM connections with the motor neurons of the recorded muscle, there should be a postspike facilitation (PSF) of EMG activity. This PSF reflects the CM-EPSPs generated by the cortical neuron causing motor neurons to fire, resulting in the discharge of motor unit(s) in the EMG that is a time locked to the spikes of the cortical neuron. Because of the small size of unitary EPSPs from CM cells, the probability of such CM cell-triggered discharge of motor neurons is low, and therefore large numbers of spikes (typically at least 2000–4000) must be averaged before any PSF can be detected in the average. The amplitude, form, and latency of the PSF are used to judge whether the PSF is indeed the result of CM action. It is now generally accepted that the STA method reveals a spectrum of postspike effects in EMG, which may include some effects due to synchronization among populations of cortical neurons.

'Pure' PSF effects in STA are characterized by a sharp onset and offset at latencies consistent with CM action. This means that the onset latency should be equal to the central conduction time for action potentials in a particular CM neuron to reach the motor neuron pool from the cortex, plus one synaptic delay plus the peripheral conduction time from motor neuron pool to muscle.

In contrast, 'synchrony' PSF usually consists of slower, broader features in the STA with onset latencies that are much shorter than the predicted total conduction delay and which in some cases precede the trigger spike. This implies that the spikes used to generate the STA emanate from a neuron that is not itself a genuine CM cell but whose discharges are synchronized with one or more CM cells. Although such effects lack any direct evidence of CM action, some investigators take them as indicative of a more general involvement of the recorded neuron in influencing motor output. Both pure and synchrony PSF can occur in the same STA.

STA has demonstrated that PSF is most commonly derived from large CST neurons with fast conducting axons. However, in agreement with anatomical studies, PSF is also produced by small, slower conducting CST neurons. Recording in awake animals is generally biased toward the larger neurons, and it may be that CM contribution from the much more numerous smaller, but undersampled, CST neurons has been seriously underestimated.

Stimulus-triggered averaging of EMG has also been used to look at the organization of corticospinal outputs from cortical motor areas. This method is useful for detecting weaker outputs and for mapping the whole motor output. It undoubtedly excites multiple corticospinal neurons, including CM cells. Even single stimuli can excite quite complex effects within the cortex, and identification of motor effects as unequivocally CM is more problematic, but in general there is agreement between stimulus-evoked effects from a cortical site and spike-triggered effects from single neurons recorded at the same site.

Finally, it should be emphasized that most CM cells, as well as producing PSF in one muscle or group of muscles, have also been shown to produce postspike suppression of EMG activity in other muscles. This is most clearly seen in CM cells that facilitate a group of agonist muscles (e.g., wrist flexors) but suppression of activity in antagonists (e.g., wrist extensors). Suppression is considered to be mediated via spinal inhibitory interneurons.

Distribution of CM Effects in Different Motor Neuron Pools

PSF has been observed to occur in many upper limb and particularly hand muscles. It is generally larger in more distal muscles, especially intrinsic hand muscles. It has been demonstrated to occur during a wide range of different types of upper limb and hand movements, including different types of hand

grasp, precision and power grip, fractionated finger movements, wrist extension and flexion movements, elbow movements, and whole arm movements such as are used in reaching and pointing. For a given CM cell and target muscle combination, PSF is generally found to be present across a range of tested tasks and movements, although there may be significant changes in its form and amplitude.

The 'muscle field' of a CM cell defines the group of muscles in which it exerts PSF. When a reasonable sample of muscles is tested (e.g., at least five active muscles, recorded simultaneously with the CM cell), it is relatively rare to find that the CM cell produces PSF in a single target muscle. To date all studies have shown that PSF is found only in a subset of the muscles that are coactivated with the cortical neuron, and this has been interpreted as a key characteristic of the CM system: it is a 'one to not-so-many' divergent control system, with the capacity to facilitate activity in a relatively small, focused group of muscles. This capacity is further underlined by the finding that in some cases the muscle field represents a group of muscles that act as functional synergists: that is, they act together to produce a particular type of movement. For example, CM cells can be found which facilitate both long extrinsic digit muscles and short intrinsic hand muscles, whose combined activity is needed to produce digit movements involving action over a multiarticulate system of carpal, metacarpal, and phalangeal joints.

Development of the CM System

It is generally recognized that the CM system, like the CST more generally, has a protracted timetable of postnatal development. Studies in both humans and nonhuman primates have indicated that the CST extends its fiber projection along the full length of the spinal cord long before birth, but both the myelination of the tract and its growth, arborization, and synaptic termination within the spinal gray matter occur postnatally. In the macaque monkey, there is direct anatomical and electrophysiological evidence for a rapid development of the CM projection to the cervical enlargement during the first 6 postnatal months. This time course matches exactly the monkey's ability to grip and manipulate fine objects.

Kuypers first showed that there are striking differences in the degree of development of the CM system across different species. Although in some species, such as the rat and the raccoon, there are sparse CST projections into the vicinity of the cervical motor neuron pools, electron microscopy and electrophysiological studies have since demonstrated that there are no functional CM connections in these species, and it would now appear that the CM system is a uniquely primate feature. Both physiology and anatomy demonstrate that even within the primates, this system is developed to very different extents. For example, the CM system is absent in tree shrews, lemurs, and the marmoset. It is well developed in some New World monkeys such as the capuchin monkey and in Old World monkeys, including the macaque. CM connections are generally most numerous in the great apes and in humans.

There has been considerable interest in the possible significance of these differences. There is a clear relationship across species between the extent of CST projections among the motor neuron pools of the spinal gray matter and the 'index of dexterity,' a linear score of hand junction used to assess hand/paw use in a wide variety of mammalian species. This index reflects functional attributes of the skilled forelimb used, and in particular the use of digits for prehensile purposes and for manipulation. It also assesses the extent to which independent use of the digits is developed in a given species. All the primates known to have high levels of dexterity (index 6 or above) possess a well-developed CM system.

Lesions Affecting CM Function

Lesions of the CST at a cortical, capsular, brain stem, or spinal level will of course also involve the CM system. However, there is currently no means of investigating a lesion selective for CM connections alone. Classical work has shown that complete, bilateral pyramidotomy in macaques (cutting both pyramidal tracts at the brain stem medullary level) has relatively small effects on many motor functions, including walking, running, and climbing, although causing a permanent deficit in fine motor skill and independent finger movements. A wealth of studies have demonstrated that CM neurons are particularly active during such movements. It has therefore been speculated that deficits in fine motor control are largely the result of interrupting CM fibers terminating on motor neurons supplying hand and digit muscles. However, the observed deficits indicate a breakdown in fine sensorimotor control rather than a pure motor deficit. This implies not only a deterioration in motor performance, but also in the ability to correctly interrogate sensory feedback from the hand, a function likely to reflect CST projections to dorsal rather than ventral spinal gray matter.

With subtotal lesions of the CST, a somewhat different picture emerges. Such lesions include unilateral lesions interrupting all or most of the fibers in the lateral CST. The effects are initially similar to a complete lesion, a striking deterioration in the speed,

force, and accuracy of more distal hand and/or foot movements. Interestingly, these deficits often show a substantial degree of recovery, the extent of which seems to be related to the amount of CST fiber spared. These results both confirm the importance of the CM system and the CST for distal control and underline the capacity for plastic mechanisms to compensate for subtotal damage.

Pathological Diseases Affecting CM Function

Pathological damage and disease that affect the CST include stroke, cerebral palsy, and spinal cord injury. These disorders disrupt CST function in general and will, of course, also affect the CM system. There is some evidence that large fibers in the CST, including those giving rise to CM projection, may be especially vulnerable to damage in stroke and spinal cord injury. In the early phase of some forms of ALS, there is evidence of lowered cortical threshold to TMS for evoking MEPs in hand muscles, and this may be due to an excitotoxic glutaminergic mechanism operating within the motor cortex. Coupled with this have been observations that the primary peak responses of single motor units to TMS may be enhanced during onset of ALS, suggesting that the CM system may be a particular target of the disease process; later in the disease, there is evidence for a selective loss of the fastest corticospinal neurons, many of which make CM connections. Finally, monitoring of descending CST volleys and/or the response of upper and lower limb motor neurons to them has been shown to be a very effective form of interoperative monitoring during neurosurgical procedures in the brain and spinal cord, preventing potential damage to the CST.

Functional Significance of the CM System

The first point is that the CM system is only a component of the CST. The CST is known to influence spinal circuitry involved in a wide variety of sensory, motor, and autonomic functions. In addition to the CST, there are a number of descending pathways operating in parallel to it. Thus, the CM system does not operate in isolation, and it is important to consider how the CM system works alongside these parallel systems. Cortical control of limb movements is of course highly developed in many species without CM connections, and these species have provided good models for control via indirect or oligosynaptic pathways.

The electrophysiology, neuroanatomy, development, and comparative biology of the CM system have all demonstrated its role in the control of distal movements, movements which are under high levels of voluntary control. Although most research has focused on the role of CM control of digit and hand movements, there is plentiful evidence that many upper- and lower-limb muscles receive CM projections. A general function for the CM system is in providing the capacity for fractionation of movements and the control of small groups of muscles in a highly selective manner. Thus, the CM system may contribute to the 'analytical' basis of motor control. The breaking down of relatively hardwired motor patterns can be regarded as an important feature of voluntary motor actions and one that is probably essential for the acquisition of new motor skills. CM action could be superimposed on background drive to motor neurons, provided by other descending motor pathways, so as to sculpture selective patterns of muscle activity.

The available data suggest that the CM system is a recently evolved feature and that it subserves evolutionarily newer aspects of motor behavior, including voluntary control of relatively independent finger movements. Although such movements are not exclusive to species with CM connections, they are far and away better developed in primates than in nonprimates.

Skilled hand movements are thought to be driven in a feed-forward manner by an internal model, a model that is richly supplied with somatosensory and other sensory inputs so that it is constantly updated in terms of the outcome of each movement. The internal model system 'learns' from these updates to generate predictable motor outcomes. This might explain why CM commands apparently bypass the spinal mechanism: Their control signals are faithfully transmitted to the motor neurons because the outcome is already predictable on the basis of past programs stored in the internal model that are regularly updated after each new action. Many of the species with well-developed CM systems possess the capacity to acquire motor skill using fine hand and finger movements. Thus, it may be that the CM system provides an efferent pathway that is accessed by the extensive motor network of the primate brain for the development of adaptive motor programs. These programs exhibit massive flexibility in the combinatorial patterns of selective muscle recruitment, and the CM system is well placed to provide this.

Corticospinal Development

Introduction

The corticospinal (CS) system is the principal motor system for controlling skilled movements. In humans, this system is so important that damage to it during development or later in life invariably produces significant motor impairment. The primary motor cortex and adjoining premotor and somatic sensory cortices are the principal origins of the CS system. Neurons in these cortical areas project to the spinal cord through the CS tract. This is the last motor pathway to develop, growing into the spinal cord during the late prenatal and early postnatal periods. Even with this early start, development of the CS system is protracted, in humans especially, in whom it takes 10–15 years to gain some of its mature characteristics. It is remarkable that most CS system development occurs while the individual is acquiring motor skills during early postnatal life.

Like other neural systems, development of the CS system depends on a complex interplay between factors intrinsic to the developing central nervous system (CNS) – including the CS neurons themselves, the regions through which CS axons grow to reach their spinal gray matter targets, and the spinal gray matter – and on neural activity and behavioral experience. This article first considers milestones of CS system development in several species, including humans, and then examines, in a bottom-up sequence, the critical steps in development of the CS system's role in skilled movement control.

Phases and Time Course of CS System Development

While there are a bewildering number of steps leading to development of this motor system, four major steps can be identified, and each is governed by different mechanisms. First, precursor cells differentiate into CS neurons; this occurs prenatally. Second, CS axons grow through the brain and into the spinal cord to form the CS tract. Once CS axons are in the cord, there is outgrowth from the tract into the gray matter. This is the pathfinding stage and leads to the initial selection of postsynaptic targets. Pathfinding occurs primarily prenatally in humans, monkeys, and cats but primarily postnatally in rodents. Both the commitment to become a CS neuron and axon outgrowth and guidance to postsynaptic target neurons are determined by cell-specific and regional-intrinsic factors. Through genetic approaches, many key molecules have been identified recently. The third step is to establish connectional specificity at the circuit level, which involves refinement of the gray matter terminations. This typically includes both elimination of axon branches and growth of new branches to nearby targets. For spinal circuits, physiological studies in humans indicate that this happens during the first 2 years, while anatomical studies in animals show that refinement occurs within the first postnatal weeks and months, depending on the species. The rapid phase of myelination of CS tract axons occurs during this period. Fourth, the cortical motor representation forms, and the CS system's role in limb control is expressed. During this period, many other neural systems are developing and contributing to movement control. An individual's motor experience and other activity-dependent processes during the third and fourth stages have important long-term developmental functions.

CS Neuron Differentiation

CS neurons are layer-5 pyramidal neurons in a variety of cortical motor and somatic sensory areas. Early in development, CS neurons are distributed from the frontal to the occipital poles but later are restricted primarily to the posterior frontal and anterior parietal cortices. The reduction in the number of CS neurons is principally due to the elimination of spinal axon branches, not widespread cell death. The homeodomain transcription factor Otx1 is required for axon branch elimination. Mice in which the gene for Otx1 has been deleted fail to develop the limited distribution of CS neurons restricted to the somatic sensory and motor cortices.

Significant progress has been made recently in determining factors important for differentiation of CS neurons from precursor cells. It has been proposed that the combinatorial expression of many genes delineates the population of CS neurons. Experiments show that some of these genes are needed for development of the CS tract. For example, in mice without the forebrain embryonic zinc fingerlike transcription factor (Fezl), cortical neurons fail to grow an axon into the caudal brain stem and spinal cord (Figure 1). Moreover, the loss of Fezl results in the loss of other molecular markers of layer 5 and 6 neurons, including another transcription factor required for CS tract formation, Ctip2. This suggests that Fezl acts upstream to regulate neuronal differentiation.

Figure 1 Forebrain embryonic zinc fingerlike transcription factor (Fezl) is important for specification of CS neurons. Images along the top row are from a wild-type mouse and along the bottom row, from a Fezl −/− mouse. (a, d) Anterograde labeling (bright white) of cortical efferent axons. Note that the wild-type shows projections to the brain stem and spinal cord (arrows), but the knockout mouse does not; both show projections to the thalamus (thal). (b, e) Anterograde labeling (red) of CS axons in the spinal cord of the wild-type but not the knockout mouse. (c, f) Retrograde labeling (red) of CS neurons in the wild-type mouse only. Development of the Projection to the Brain Stem and Spinal Cord

Pathfinding from Cortex and Subcortical White Matter Tracts

Traversing the CNS to reach its targets is a complex problem for any projection neuron, but particularly for a CS neuron because its axon has the longest distance to travel. Pathfinding is organized by complex tissue molecular cues that are detected by the primary growth cone of the axon. Studies suggest that cortical pyramidal cells simplify the task of reaching their final targets, for example, spinal cord neurons, by achieving a sequence of intermediate targets, such as first projecting into the internal capsule. Many chemorepellant and chemoattractant molecules have been identified as necessary for keeping CS neuron axons 'on tract,' else the axons stray into aberrant locations.

Decussation and Midline Crossing

Functionally, the CS system exerts its effects on the contralateral spinal cord and contralateral muscle through a descending projection that is primarily crossed. Most axons decussate in the medullary pyramid. In the rodent, the axons course from the ventral to dorsal surfaces as they cross from one side to the other, forming an X shape (Figures 2(a) and 2(b)). Three sets of molecules and receptor families have been identified that play key roles in the crossing of CS axons: (1) the L1 cell adhesion molecule (L1-CAM), which is a member of the immunoglobulin superfamily of cell adhesion molecules; (2) the Eph A4 receptor and Ephrin B3, which is a protein that repels axon growth and is the membrane bound ligand for EphA4; and (3) members of the roundabout (Robo) family of transmembrane proteins and Slit, another protein with axon growth-repulsive properties.

L1-CAM is expressed along the CS tract; CD24, which is a ligand for L1-CAM, is localized at the pyramidal decussation. L1 knockout mice display profound errors in CS axon decussation in the medulla and guidance into the appropriate spinal white matter regions (Figure 2(b)). Human L1 mutations produce hypoplasia of the CS tract and spasticity, as well as a variety of other brain structural and functional impairments. Patients with L1 mutations show elevations in transcranial magnetic stimulation (TMS)

Figure 2 The pyramidal tract decussation and the role of L1-CAM in forming the contralateral descending CS projection. (a1) Image from a normal mouse showing the pyramidal decussation. Axons from the two sides are labeled red and green. (Image courtesy of Drs. Kyoko Itoh and Vance Lemmon.) (a2) Normal decussation in a wild-type mouse (arrow; similar to the red axons in (a1)). thresholds and increased latencies for evoking motor responses. These CS functional defects correlate with impairments in performance on several tests of hand/digit dexterity.

CS axons in EphA4 knockout mice decussate in the pyramid and descend into the appropriate white matter regions of the cord, but they terminate bilaterally in the spinal gray matter (Figure 3). This is because ephrin B3 is a midline growth barrier. Normally, it is present extensively along the spinal midline (Figure 3), thereby limiting recrossing. In the medulla, ephrin B3 is located only dorsal to the pyramidal decussation and at this level does not block CS axon crossing. Two Robo proteins, Robo1 and 2, are receptors for Slit. Robo is expressed on CS axons. CS axons may be prevented from aberrant recrossing through interactions between these Robo proteins on developing axons and Slit at the floor plate of the hindbrain and spinal cord. A third member of this family, Robo3, is functionally different from the other two members because it is required for decussation. In patients with a rare genetic disorder, horizontal gaze palsy with progressive scoliosis, mutation in the Robo3 gene prevents decussation of the CS tract. While most CS axons decussate in the medulla, approximately 10% do not and project to the ipsilateral cord. Moreover, once in the spinal cord, many CS axons – whether or not they decussate in the medulla – cross the midline before terminating on spinal neurons. The logic of the pattern of decussation of CS axons is not yet known.

Collateral Branching into the Gray Matter

Once CS axons reach the caudal brain stem, a small contingent pioneer the path into the spinal cord, followed later by waves of axons that further populate the CS tract. Long-distance growth of the primary descending CS axon is followed by formation of side, or collateral, branches that extend into the surrounding gray matter after a variable delay period. Spinal gray matter innervation is mediated by target-specific chemotropic factors that induce branching. In tissue explant experiments, for example, neurites from a portion of the prospective forelimb area of the sensorimotor cortex grow toward a cervical spinal explant but not to a lumbar explant.

Development of Connectional Specificity between CS Axon Terminals and SC Neurons

Topographic Refinement of CS Terminations in the Spinal Gray Matter

When CS axons initially grow into the spinal gray matter, their termination pattern is not what it is in maturity. The most common pattern is that CS axons have a widespread spinal termination pattern found early in development that is subsequently refined, or 'pruned,' to a more restricted distribution in maturity (Figure 4(a)). Terminations that are normally present

Figure 3 Ephrin B3 and its receptor EphA4 prevent recrossing of CS axons. (a, b) Ephrin B3 messenger RNA expression (dark blue staining; arrow heads) in the caudal medulla of a normal mouse, at the level of the pyramidal decussation ((a), dashed arrows) and in the spinal cord (b). (c1)–(c4) Region of the central canal. (c) Effects of EphA4 knockout on the development of the laterality of CS axon terminations in a 7-day-old mouse. In the normal mouse, terminations remain predominantly contralateral to the CS neurons of origin (c1) and (c2), whereas in the knockout mouse (c3) and (c4) there are abundant ipsilateral terminations. The arrows in (c4) point to aberrant terminations in the ventral and lateral gray matter. The distribution of terminal axons is also more extensive in the knockout mouse, suggesting a role for ephrin-Eph receptor interactions in determining regional distributions as well as laterality. Scale bars = 200 μm. (a, b) From Kullander K, Croll SD, Zimmer M, et al. (2001) Ephrin-B3 is the midline barrier that prevents corticospinal tract axons from recrossing, allowing for unilateral motor control. *Genes & Development* 15: 877–888. (c) From Coonan JR, Greferath U, Messenger J, et al. (2001) Development and reorganization of corticospinal projections in EphA4 deficient mice. *Journal of Comparative Neurology* 436: 248–262.

early in development and are eliminated later on are often termed 'transient terminations'. The rhesus monkey shows a pattern of progressive increase in CS axon terminal growth during early postnatal development rather than a broader distribution of terminations that is subsequently refined. Figure 4(b) shows that terminations within the central region of the gray matter become progressively denser (more red), especially within the lateral motor nucleus (yellow arrow). Irrespective of the particular pattern, the refined distribution of connections ultimately is achieved late in development: by 6–7 weeks in the cat, 8 months in the monkey, and after several years in the human. An important question for future research is why the CS system in some animals prunes back exuberant connections while others use a delayed outgrowth strategy.

CS terminations early in development are able to excite their spinal targets. This has been shown in the cat and rat by electrically stimulating CS axons in the CS tract and recording postsynaptic field potentials (i.e., focal synaptic potentials) in the spinal gray matter. In immature cats, for example, stimulation of the CS system evokes postsynaptic responses throughout the dorsoventral extent of the gray matter (Figure 5(a)). This broad distribution is similar to the one of CS terminations. By contrast, in mature animals, when CS axon terminals are restricted to the middle region of the cord, responses are largely limited to the same middle layers (Figure 5(b)). The refinement process restricts the effects of CS activation to particular spinal motor circuits. *In vitro* studies in rats show that synapse elimination is *N*-methyl-D-aspartate receptor-dependent. Although the anatomy and physiology of this process have been studied, the functional logic of the final termination patterns of CS axons has yet to be elucidated.

During postnatal development, local CS axon branch growth and presynaptic bouton formation are abundant (Figure 6; see also Figure 4(b) and increasing termination density). When axon branch elimination is present (Figure 4(a)), local growth occurs concurrently and complements the refinement process. Local axonal branch growth leads to a remarkable increase in the strength of CS evoked responses during early development (Figure 5; note increase from 30 to 700 μV range). As CS axon terminals mature, they also are better able to recruit spinal motor circuits into action (Figure 7). This has been tested in the cat by stimulating CS axons in the pyramid and recording motor responses in peripheral motor nerves. Immature CS connections require stronger electrical stimulation of CS axons, and a greater number of electrical stimuli, to evoke a motor response (Figure 7(a)) compared with more mature animals (Figure 7(b)). While comparable spinal recordings in the developing monkey have not been done, TMS has been shown to be effective in evoking motor responses only after about 3 months of age. This correlates with the progressive late growth of CS axon terminals and is consistent with the finding in the cat (Figure 7) that CS connections with spinal circuits become more effective in evoking motor responses later in development. In the monkey,

Figure 4 The distribution of CS axon terminations is refined postnatally. (a)(1) Extensive dorsoventral and bilateral CS terminations in a 5-week-old cat. (a)(2) An adult cat, where terminations are predominantly contralateral and restricted dorsoventrally. Scale bar: 1 mm. (b) Increase in CS axon terminal density in monkeys at three different ages. These sections were taken from the rostral portion of the first thoracic spinal cord segment. Color codes the density of terminations, on a scale from 1 to a maximum of 100. The arrow marks the region of the lateral motor nucleus, where motor neurons innervating distal arm muscles are located. Note that at 2.5 months, very little of the nucleus is densely labeled (red), and there are areas without any label, whereas at 3 years, the entire nucleus is labeled, and labeling in the outer rim is dense. Figure 5 CS synaptic refinement. The amplitude of the monosynaptic CS evoked response is plotted at different depths (normalized; dorsal horn surface is zero and the ventral horn ventral surface, 100). Each graph overlies a schematic view of the distribution of terminations at that age. (a) The immature cat (5-week-old) shows small postsynaptic responses from the dorsal to the ventral surface. (b) By contrast, responses in the mature cat are restricted to the middle region, where the densest terminations are located. From Meng Z and Martin JH (2003) Postnatal development of corticospinal synaptic actions. *Journal of Neurophysiology* 90: 683–692.

TMS studies have also shown that there is an exponential increase in CV and decrease in TMS threshold within the first 1.5 years and a slower increase in CV and decrease in threshold later in development. Stronger connections between the motor cortex and spinal cord motor circuits are critical for the CS system's control over motor behavior.

Figure 6 Confocal images from (a) an immature cat (4-week-old) and (b) a mature cat ((a1), (a2), (b2), and (b3): 1 μm optical slices; (b1): 7 μm projection image). The top two images show CS axons labeled with the anterograde tracer BDA (green). The lower row of images shows staining for the synaptic vesicle protein synaptophysin (red), together with axon staining (green). Double labeled boutons are yellow and highlighted with the yellow arrow. (a1) CS axon terminal with sparse branches. (b1) Highly branched mature axon terminal. Scale bar = 25 μm (a1, a2), 50 μm (b1–b3). From Meng Z, Li Q, and Martin JH (2004) The transition from development to motor control function in the corticospinal system. *Journal of Neuroscience* 24: 605–614.

Electrophysiological studies in humans using TMS also point to an early period of transient ipsilateral and ventral CS terminations, as in the cat. TMS up to about 1 year evokes bilateral motor responses (Figure 8(a)), consistent with bilateral terminations. The amplitude of the ipsilateral response becomes reduced relative to the contralateral response during the first year (Figure 8(a)). This is similar to the early postnatal elimination of ipsilateral CS branches in the cat. The TMS threshold for evoking muscle contraction is lower in preterm and very young infants, only to become higher during the first 3 postnatal months. This could be due to the elimination of some ventral CS axon terminal branches, thereby reducing synaptic effects. Between about 1 and 15 years, TMS threshold systematically decreases (Figure 8(b)). This threshold reduction is due to several factors, including increased CS axon terminal branching in the spinal cord, stronger connections in the spinal gray matter, and increased myelination of CS axons, which results in more-synchronous activation of spinal motor circuits.

Activity-Dependent Refinement of CS Axon Terminal Connections

The basis for the CS system's motor control functions depends on a refined pattern of connectivity between zones in the motor cortex that integrate motor control signals from various sources and spinal motor circuits. What drives postnatal refinement of CS axon terminations in the spinal gray matter? Recent studies show an important role for the level and pattern of CS neuronal activity in shaping development of the regional distribution of their spinal terminations, consistent with activity-dependent synaptic competition. Activity of the CS system can be selectively reduced by intracortical infusion of the γ-aminobutyric acid agonist muscimol and augmented by electrical stimulation of CS axons. Unilateral activity reduction results in an aberrant pattern of contralateral spinal terminations. The axons populate more dorsal laminae (Figure 9(b); yellow). This defect reflects a failure of silenced axons to maintain connections established earlier during development as well as a failure to add new branches and presynaptic sites (Figures 9(c) and 9(d)). Animals with this aberrant pattern of CS terminations have significant arm control impairments (see section on motor skill development).

The contralateral active CS system not only develops the normal contralateral projection but also maintains significant ipsilateral terminations. Thus, the reduction in termination space of the silenced side is balanced on that side by maintenance of ipsilateral

Figure 7 Ability of immature cat CS tract to recruit threshold motor responses is much less than in the adult. Each trace is an average recording from the median nerve contralateral to pyramidal tract electrical stimulation. The arrows indicate the time of occurrence of pyramidal stimuli. Note that more pulses and higher currents are needed to evoke responses in the 4-week-old animal than in the adult cat. Calibrations: (a) 500 μV; (b) 300 μV. From Meng Z, Li Q, and Martin JH (2004) The transition from development to motor control function in the corticospinal system. *Journal of Neuroscience* 24: 605–614.

Figure 8 Transcranial magnetic stimulation (TMS) is used to activate the human CS system noninvasively. (a) Contralateral (red) and ipsilateral (blue) motor responses evoked by TMS over the motor cortex; 100% is maximal stimulus current. The amplitude of the ipsilateral response (blue) decreases with age. (b) The current for TMS to evoke a threshold motor response decreases from about the first to the 14th year. The *y*-scale of the graph plots current, as mean maximal current ±SD. Prior to 1 year of age, responses (blue) can be evoked at a lower threshold than at 1 year. (a) Modified from Eyre JA, Taylor JP, Villagra F, Smith M, and Miller S (2001) Evidence of activity-dependent withdrawal of corticospinal projections during human development. *Neurology* 57: 1543–1554. (b) From Nezu A, Kimura S, Uehara S, Kobayashi T, Tanaka M, and Saito K (1997) Magnetic stimulation of motor cortex in children: Maturity of corticospinal pathway and problem of clinical application. *Brain & Development* 19: 176–180.

terminations of the active system, which are the terminations that are normally eliminated. These topographic changes persist into maturity. The presence of ipsilateral terminations of the active side developing in parallel with the silenced CS terminations implies competition between the two sides during early development. Consistent with this idea is the observation that bilateral inactivation of the motor cortices produces a relatively normal pattern. This suggests that the changes in the laterality of CS terminals occurring after activity blockade are due to activity-dependent competition between developing CS terminals. The overall density of terminations after bilateral inactivation, however, is less than in controls, suggesting that the silenced CS terminations are less effective in competing with other spinal neural systems in securing terminations.

Another way to examine the role of activity of the two sides in shaping the mature pattern of terminations is to augment activity unilaterally. Electrical stimulation of CS axons in the medullary pyramid for several weeks during early postnatal life results in maintenance of substantial ipsilateral (and contralateral) terminations at 8 weeks (Figure 10(a)). Normally, there are predominantly contralateral terminations at this age. Projections from the nonstimulated side were displaced dorsally and laterally as a consequence of this CS system stimulation (Figure 10(c)). Both the maintenance of ipsilateral terminations and the displacement of nonstimulated axons are consistent with the activity-dependent competition model: The stimulated axons are more competitive at securing spinal synaptic space at the expense of the nonstimulated axons.

In hemiplegic cerebral palsy, the pattern of functional CS connectivity tested with TMS is similar to the anatomical distribution of CS axons in cats after unilateral CS system inactivation. TMS of the less impaired side evokes bilateral responses (Figure 11). TMS of the impaired side fails to evoke significant responses (not shown in figure). The aberrant ipsilateral effects are observed only after CS damage early in development, possibly before ipsilateral CS terminations are eliminated; in adults, stroke that produces hemiparesis does

Figure 9 (a) Normally there are overlapping CS terminations in the spinal cord at 1 month in the cat. These terminations are refined into predominantly contralateral terminations after 2 months. (b) After motor cortex inactivation between weeks 5 and 7, the silenced axons (yellow) failed to populate as much of the contralateral gray matter. In contrast, the active side (blue) has a bilateral termination pattern. The ipsilateral axons are largely maintained transient terminations. (c) Morphology of a normal CS axon terminal at 7 weeks, and (d) morphology after inactivation. Arrows in (d) point to presynaptic boutons. Presynaptic boutons were too many to label in (c). Scale bars: 100 μm. (e, f) Results of behavioral experiments in which animals were trained to reach and grasp a food reward located at the origin (0,0). The start of the reach is indicated by the filled circle. (e) Data from an animal that received unilateral saline infusion into the primary motor cortex. (f) Animal that received unilateral muscimol infusion to block activity. Each square indicates the location of the end point of a reach. The more end points at that spot, the darker the square. The ellipses enclose the end points of 95% of the reaches. The area and the location of the ellipses are measures of accuracy. Reaching accuracy for the control animal is normal for both limbs. By contrast, accuracy for the contralateral limb in the animal in which the motor cortex was inactivated was significantly worse than for the ipsilateral side, which was normal. The end points for the contralateral side were both overshot (i.e., farther from the origin) and more dispersed. AP, anteroposterior; M5–7, muscimol inactivation between postnatal weeks 5–7; ML, mediolateral. (a–d) From Friel K and Martin JH (2005) Role of sensory–motor cortex activity in postnatal development of corticospinal axon terminals in the cat. *Journal of Comparative Neurology* 485: 43–56. not augment the ipsilateral response. These findings are consistent with the hypothesis that during early development, the impaired side is rendered much less competitive in securing and maintaining spinal synaptic space than the normal or less impaired side is.

Use-Dependent Development of the CS Tract

Motor experience comprises both directed control of muscle by motor centers in the brain and spinal cord and sensory information received by the nervous system as a consequence of movement. To determine the role of motor experience on CS development, limb use can be prevented or curtailed specifically during key periods when the CS system is developing. Preventing limb use during early development has a profound effect on CS axon terminal development. One way to prevent limb use during development is to block contraction of selected forelimb muscles using botulinum toxin A. Like motor cortex activity blockade, preventing limb use prevents the growth of CS axon terminals and presynaptic sites (Figures 12(a) and 12(b)). When limb use is regained, axon branching and presynaptic site density remain significantly reduced compared with controls, which indicates that CS axon terminals do not recoup lost connections (Figures 12(c) and 12(d)); moreover, the regional distribution of CS axon terminations remains aberrant (Figures 12(e) and 12(f)). These findings are consistent with the synaptic competition model, similar to what is observed after CS neural activity blockade. However, there is an important distinction: Preventing motor experience changes the patterns of neural activity in the developing motor and somatic sensory system but does not eliminate activity, as in the blockade experiments. This suggests that the developing CS system uses forms of temporally specific activity-dependent plasticity, such as long-term potentiation and long-term depression, to shape connections and function.

Development of CS Control of Skilled Motor Behavior

What is the relationship between development of the CS system and development of skilled limb control?

Figure 10 (a) CS tract electrical stimulation during early development promotes maintenance of ipsilateral terminations (left). Axons were labeled with wheat germ agglutinin conjugated with horseradish peroxidase, which appears as bright bronze particles. Inset shows plane of section in (a) and (b). Distribution of CS axon terminals from (c) the nonstimulated side (i.e., ipsilateral to the side of stimulation) and (d) a control stimulation (reticular formation). The intra-axonal distribution of tracer used in parts (c) and (d) is shown as the solid black lines. The dotted lines mark the ventral boundary of lamina 6. Note that stimulation displaced developing CS terminals dorsally in (c). Scale bar = 1 mm (a–d). From Salimi I and Martin JH (2004) Rescuing transient corticospinal terminations and promoting growth with corticospinal stimulation in kittens. *Journal of Neuroscience* 24: 4952–4961.

Figure 11 Ipsilateral (solid line) and contralateral (dotted) motor responses (flexor digitorum indicis) evoked by TMS in (a) a control adult and in (b) a patient with spastic hemiplegia acquired as a consequence of a stroke during infancy (i.e., cerebral palsy). Note that there is an abnormally large-amplitude ipsilateral response in the patient. (c) Correlogram for simultaneous electromyographic recordings from the two sides. The *y*-scale of the graph plots probably of occurrence $\times 10^{-2}$, from 0 to 15, and the *x*-scale plots time lag in milliseconds (K). The peak at zero indicates likely activation of electromyogram on both sides by a common signal. This suggests bilateral CS axon terminations. From Eyre JA, Taylor JP, Villagra F, Smith M, and Miller S (2001) Evidence of activity-dependent withdrawal of corticospinal projections during human development. *Neurology* 57: 1543–1554.

In many species there is clear evidence of co-development of skills, the spinal terminations of the CS tract, and the cortical motor representation. Monkeys begin to develop relatively independent finger movements during the period when CS axon terminals become dense within the intermediate zone and when CS terminals establish synapses within the motor nuclei. Humans develop relatively independent finger movements after about 1–2 years, as the thresholds for evoking motor responses begin to decline. However, as the CS system matures, other motor systems develop, as do sensory and cognitive systems. All these changes are likely to contribute to the expanding motor repertoire. Thus, because many CNS systems are developing during these early periods, establishing causal links between CS system developmental milestones and development of skilled control is difficult. Another way to obtain insight into how the CS system contributes to developing motor skills is to perturb normal CS tract development by changing CS activity levels or motor experience and determine the effect of these manipulations on skilled limb control.

Early postnatal blockade of motor cortex activity, which alters the termination pattern of CS tract axons, has a profound effect on visually guided skilled limb control. After the blockade is removed, there is a permanent aiming error in reaching, in which the end point of the movement overshoots the target (Figure 9(e)). During visually guided locomotion, there is also a movement end point defect, in which the foot is placed too far forward on the substrate. The common hypermetric defect (i.e., overreach and overstep) suggests a common underlying mechanism, such as a deficit in recruiting a muscle synergy for stabilizing limb position at the end of the movement. There also is a grasping impairment. After animals' motor experience is prevented and they are then allowed to regain limb use, their aim of reaching movements is normal, but their digit coordination during grasping is impaired (Figure 12(g)), similar to the grasping defect after postnatal inactivation.

Development of the Cortical Motor Map

The CS tract carries the output from the primary motor cortex, as well as adjoining regions. In maturity, several characteristics of the motor representation in the primary motor cortex are thought to be critical for the normal expression of skilled movements, including a requisite size of the representation and the need for particular joints to be represented. In animals, the motor map can be assessed using microstimulation, whereby electrical stimulation through a microelectrode is used to excite a small population of cortical neurons. In development, the motor representation is first detected at 2 months in the cat; prior to this, motor cortex microstimulation does not evoke motor responses. The absence of a motor map before week 8 could be due to several factors, including weak intracortical synapses and weak CS synapses on spinal motor circuits (see **Figure 7**).

During the following month, there is an increase in the percentage of sites from which microstimulation evokes a motor response and a concomitant decrease in the current threshold (**Figure 13**). The threshold reduction suggests more-efficient activation of spinal motor control circuits, reflecting synaptic strengthening at both the cortical and the spinal levels (see **Figure 6**). The joints and muscles represented increases, from only proximal forelimb movements and muscles initially to both proximal and distal. In addition, as animals grow older, effects at multiple joints are produced at a higher percentage of sites. These multijoint sites are thought to play a role in encoding interjoint motor synergies. The role of experience and CS system activity in shaping motor map development is being studied in the cat: Training reduces the threshold for evoking responses and

Figure 12 Effects of preventing limb use in a cat between weeks 3 and 7. Morphological changes after preventing limb use persist into maturity. (a, c) Control micrographs of normal corticospinal axon terminals at 8 weeks and in maturity, respectively. (b) Micrograph of terminal at 2 months, which is immediately after the period of disuse. (d) Micrograph of terminal in a mature animal in which BTX was injected into forelimb muscles between weeks 4 and 7. Arrows in (b) and (d) mark axon varicosites (boutons). Calibrations in (a)–(d): 100 μm. (e) Regional distribution of contralateral CS terminals in a mature control and (f) in a mature animal in which BTX was injected into forelimb muscles between weeks 4 and 7. Calibration for (e) and (f) corresponds to the length of the bar in (c), but representing 500 μm. (g) Once the effects of BTX wear off, there is a permanent coordination impairment. The occurrence of coordinated digit flexion and forearm supination is plotted (mean ± SD) for the control side (red) and the side in which BTX was injected (blue). BTX, botulinum toxin, From Martin JH, Choy M, Pullman S, and Meng Z (2004) Corticospinal development depends on experience. *Journal of Neuroscience* 24: 2122–2132.

Figure 13 Development of the cortical motor map. The graph plots the percentage of sites from which microstimulation evoked a motor response at the various ages tested (solid line and dots; left scale) and the mean threshold for evoking the responses (dashed line; right scale). Each dot shows percentage data from a separate animal. Maps of the forelimb area at four selected ages are shown on the right. Color represents the amount of current needed to evoke a response. This threshold reduction can be seen on maps of the forelimb area of the cat motor cortex as a change from a preponderance of high-threshold (red) to low-threshold sites (blue). Red corresponds to a stimulation current of 100 μA, indigo to 1 μA. The general location of this area is indicated as the red box on the inset brain drawing. For the various maps, the lines indicate the cruciate sulcus, which roughly divides the rostral and caudal forelimb areas. E, elbow; M, multijoint responses; S, shoulder; W, wrist. increases the representation of coordinated muscle synergies, whereas preventing motor experience augments thresholds and reduces muscle synergy representation. These representational changes return to control levels several months after normal experience returns, reflecting plasticity that persists throughout the animal's life.

Conclusion and Implications for Rehabilitation

The CS system develops over a protracted pre- and postnatal period before achieving the mature distribution of spinal terminations. Activity-dependent synaptic competition between developing CS axon terminals, and possibly with other spinal synapses, shapes the formation of a complex set of stable connections between the motor cortex and particular spinal motor circuits. Both the level of CS neural activity and the pattern of activity, as reflected in the patterns of limb use, are critical to this system's development. The outcome is incorporation of the CS system into the developing motor systems and the expression of this system's contributions to skilled motor behavior.

Activity- and use-dependent development of the CS system assures that neural events and experience, as connections are being made, play an important role in forming the circuits for controlling movements that an individual makes throughout life. However, activity and use dependence also creates a vulnerability to deviations from an optimal functional state of the motor systems. It has been suggested that the vulnerability produced by activity-dependent competition between the developing CS tracts on the two sides of the brain could lead to a progressive worsening of the effects of a perinatal CS system lesion.

Can activity-dependent competition be harnessed to promote CS system function after early brain damage? Lessons can be learned from visual system development. It is well known that periods of monocular visual deprivation produced by cataracts or strabismus can lead to a worsening of sight as a child grows up. After correction of the ocular defect, vision is promoted in the impaired eye by periods of monocular deprivation of the normal-functioning eye. Visual acuity in the unimpaired eye is maintained at a normal level by permitting daily controlled visual experience. Work in the developing cat CS system points directly to overcoming functional impairment by rebalancing CS terminations later in development. There also is evidence in humans that rehabilitation strategies can be used to rebalance function in hemiplegic patients. A motor behavioral analog of monocular deprivation

is constraint-induced therapy, in which children with spastic hemiplegia have their unimpaired (or less impaired) arm physically restrained. Constraint-induced therapy forces them to use their affected arm exclusively during daily activities, which can lead to improvement in motor function. Convergence of animal research and human clinical studies leads to the optimistic view that some forms of developmental motor disorders might be significantly improved by harnessing activity-dependent processes shaping development of the CS system.

Corticothalamic Connections: Structure and Function

F Briggs and W M Usrey, University of California at Davis, Davis, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

For sensory systems, neurons in the thalamus provide the cortex with information about the external environment. The cortex, in turn, gives rise to feedback pathways terminating in the thalamus. As a result of this plan, neurons in the cortex not only respond to thalamic input but also help shape the nature of this input. This article summarizes the state of knowledge regarding corticothalamic circuits and their function on the basis of results primarily from studies of the visual system. Given the ubiquitous nature of corticothalamic connections, it seems likely that many of the fundamental properties of corticothalamic circuits are shared across sensory systems.

From Cortex to Thalamus: A Tale of Two Pathways

The corticothalamic pathway begins with neurons in the deepest layers of the cerebral cortex and ends in the thalamic nuclei serving that sensory modality. The two main types of corticothalamic projections are defined in part by their cortical layer of origin and in part by the thalamic targets they innervate. Corticothalamic projections from neurons in layer 6 typically target primary thalamic nuclei – subdivisions of the thalamus that receive ascending information from the periphery and relay that information to cortex. Axons of these corticothalamic cells are called type 1 axons. In contrast, corticothalamic projections from layer 5 neurons target secondary thalamic nuclei – subdivisions of the thalamus that receive mainly efferent cortical input and whose proposed function is to sort and relay information to various cortical targets, including higher-level areas. Axons of this type of corticothalamic neuron are called type 2 axons. One important feature distinguishing the two types of corticothalamic projections is the presence or absence of axonal branching within the reticular nucleus of the thalamus. Layer 6 corticothalamic axons (type 1) send axonal collaterals to the reticular nucleus whereas layer 5 corticothalamic axons (type 2) project few if any collaterals to the reticular nucleus. Instead, type 2 axons frequently send collateral projections that target a variety of nonthalamic structures. For the visual system, type 1 axons from neurons in layer 6 of primary visual cortex primarily terminate in the lateral geniculate nucleus (LGN) and the reticular nucleus, and type 2 axons from neurons in layer 5 terminate in the pulvinar nucleus (Figure 1).

Cortical Projections to the LGN

Layer 6 of primary visual cortex contains a myriad of morphologically and physiologically distinct cell types. In the macaque monkey, only about 14% of layer 6 neurons give rise to axons that target the LGN, although higher percentages have been found in carnivores and rodents. Layer 6 corticogeniculate neurons are generally short pyramids with basal dendrites restricted to layer 6 and apical dendrites that arborize in layer 4C – the primary target of ascending LGN input to cortex and analogous to layer 4 in carnivores and rodents. Such dendritic arborization allows corticogeniculate neurons to sample both intracortical activity and ascending LGN activity. Along these lines, physiological studies have shown that a subset of corticothalamic neurons receives direct thalamocortical input. Corticogeniculate neurons also give rise to local axons that synapse in layer 4C. As a result of this organization, corticogeniculate neurons are in a strategic position to influence the transmission of information from thalamus to cortex.

The primate LGN contains magnocellular, parvocellular, and koniocellular neurons that are distinct in their laminar location, visual physiology, and cortical projection patterns. Corticogeniculate axons provide synaptic input to all three classes of LGN neurons. In the macaque monkey, neurons in the upper tier of layer 6 have axons that target the parvocellular layers of the LGN, and neurons in the bottom tier have axons that project primarily to the magnocellular layers. In addition, a small percentage of corticogeniculate neurons in the lower tier of layer 6 provide input to either the parvocellular or the koniocellular layers. Although layer 6 neurons receive mixed intracortical input from both the magnocellular and parvocellular streams, there is evidence supporting a bias of magnocellular or parvocellular stream input to individual layer 6 neurons. Finally, although corticogeniculate projections to the LGN are topographically organized, the precision of these projections may not be as high as that of thalamocortical projections.

Corticogeniculate neurons share an intimate relationship with cells in the reticular nucleus. The reticular nucleus is a unique structure compared with its neighboring thalamic nuclei as it contains only γ-aminobutyricacidergic (GABAergic) neurons that provide inhibitory input to other thalamic nuclei, including the LGN. Because neurons in the reticular

Figure 1 Type 1 and type 2 corticothalamic axons. Type 1 corticogeniculate axons (blue, right side; dendrites are thick and axons are thin) originate from neurons in layer 6 of V1 and project to the lateral geniculate nucleus (LGN) and the reticular nucleus (RTN). RTN neurons (orange) make inhibitory synapses onto thalamocortical neurons. Thalamocortical axons (red, right side) display type 2 characteristics and project to specific compartments within V1. Type 2 corticothalamic axons (red, left side) originate from neurons in layer 5 of V1 and target the pulvinar and superior colliculus. IPul, inferior pulvinar; LPul, lateral pulvinar; MPul, medial pulvinar; SC, superior colliculus.

nucleus receive direct input from thalamocortical axons as well as corticothalamic axons, these neurons are well situated to play an important role in the transfer of information between thalamus and cortex, and vice versa.

Cortical Projections to the Pulvinar

Layer 5 of primary visual cortex contains a separate and distinct population of corticothalamic neurons. These neurons are tall pyramids with dendritic and local axonal arbors that extend into the superficial layers of cortex. As a result, these neurons are better positioned to sample local circuit input rather than direct thalamocortical input. Indeed, local circuit inputs impinging on layer 5 corticothalamic neurons originate from all the cortical layers, with particularly strong input coming from neurons in layers associated with the magnocellular stream.

Corticothalamic neurons in layer 5 have type 2 axons that project to the pulvinar nucleus rather than the LGN. Notably, these axons frequently give rise to collateral branches that target the superior

colliculus and other regions of the brain stem associated with motor function. Within the pulvinar nucleus, the specific subdivisions innervated by layer 5 axons include the lateral margin of the lateral pulvinar, the central inferior pulvinar, and the medial inferior pulvinar. Although corticopulvinar axons generally avoid the reticular nucleus, there is some evidence for weak input to this structure. Additional evidence indicating that type 1 and type 2 corticothalamic axons may not be entirely separable comes from findings that some neurons in deep layer 6 with type 1 axons provide weak input to the pulvinar.

Corticothalamic Physiology and Function

Conduction Latency

Some of the earliest physiological experiments performed on the corticothalamic pathway used electrical stimulation to identify corticothalamic neurons and to determine the time required for action potentials to travel from cortex to thalamus. These experiments were conducted in multiple species and systems and included different classes of corticothalamic projections. By providing electrical stimulation to the thalamic nucleus of interest, investigators measured the time required for action potentials to back-propagate to simultaneously recorded neurons in the cortex. These experiments frequently utilized a collision test to ensure that action potentials following stimulation were indeed caused by antidromic rather than orthodromic mechanisms. Results from these studies demonstrate diversity in the corticothalamic population as conduction latency among neurons can range from just a few milliseconds to more than 50 ms. Accordingly, across species and systems, corticothalamic cells are often categorized as fast-, medium-, or slow-conducting cells. It has further been suggested that these categories of neurons might also be distinct in their sensory response properties and the specificity of their input to specific regions of their target structures.

Synapses and Receptors

Corticothalamic neurons in layers 5 and 6 use glutamate as their neurotransmitter. Beyond sharing a common neurotransmitter, however, the anatomical and physiological properties of their synapses are quite different. In fact, the synaptic distinctions between type 1 and type 2 axons have led some to hypothesize that the two pathways serve distinct functions: those of modulators and drivers, respectively.

Type 1 axons from neurons in layer 6 are strikingly similar in appearance across modalities and species. These axons tend to be thin and sparsely branching with many short terminal sprouts containing small synaptic swellings that contain round glutamate-filled vesicles (termed 'RS profiles'). In the LGN, synapses are made onto the distal dendrites of excitatory relay neurons at extraglomerular sites. In addition to providing input to excitatory neurons, type 1 axons also provide input to inhibitory neurons, both within the relay nucleus (on dendritic shafts, outside glomeruli) and within the reticular nucleus. In the reticular nucleus, type 1 axons activate both ionotropic and metabotropic receptors on their postsynaptic targets. Relay neurons in the LGN also receive type 1 input via ionotropic and metabotropic receptors; however, local circuit neurons may receive input only via ionotropic receptors. Activation of non-NMDA ionotropic receptors causes a stereotypical fast Na^+-based excitatory postsynaptic potential (EPSP) in the target neuron. NMDA receptor activation is somewhat more complicated in that it requires a prior depolarization to remove the Mg^{2+} block before the ion channel can be opened. Once the channel opens, an EPSP results; however, the delay is longer than that of non-NMDA EPSPs. As for the metabotropic receptors, glutamate activation starts a series of second messenger cascades leading to release of intracellular Ca^{2+} and a reduced K^+ leak conductance, which depolarizes the cell and causes a slow and long-lasting EPSP. While ionotropic receptor activation should permit faster, perhaps higher-fidelity transfer of action potentials from pre- to postsynaptic cells, the long-term effects of metabotropic receptor activation likely impose a control over certain activity patterns through a sustained depolarization of postsynaptic cells.

In addition to corticogeniculate effects exerted directly onto LGN relay neurons through distal synaptic connections, relay cells are also affected indirectly by corticogeniculate activity through connections with local circuit neurons and neurons in the reticular nucleus. Local circuit neurons release GABA as their neurotransmitter, activating postsynaptic zones of relay neurons and other local circuit cells containing ionotropic $GABA_A$ receptors. These interactions cause fast inhibitory postsynaptic potentials (IPSPs) in target neurons. Neurons in the reticular nucleus exert their inhibition onto relay cells via $GABA_B$ receptors. These receptors are located on the distal dendrites of relay cells. As a result of this organization, corticogeniculate activity might influence the firing mode of LGN relay neurons through polysynaptic interactions with the reticular nucleus.

Thalamic relay cells tend to operate in one of two modes: tonic and burst. In tonic mode, the resting membrane voltage is around -60 mV with Na^+ and K^+ voltage-dependent conductances primarily active. Faster, short-term changes in membrane voltage associated with ionotropic receptor activation are

consistent with tonic mode operation. Additionally, the prolonged depolarization brought about by direct corticogeniculate activation of metabotropic glutamate receptors may serve to keep a relay neuron in tonic mode for a longer duration. A switch to burst mode requires a certain chain of events initiated by a prolonged period of hyperpolarization. Such hyperpolarization could be achieved by $GABA_B$ receptor activation, especially at more distal portions of thalamic relay cell dendrites. Once in the prolonged hyperpolarized state, T-type Ca^{2+} channels, which are also located at distal dendritic sites, are de-inactivated and can be activated by a depolarizing input. This input causes a low-threshold Ca^{2+} action potential, on top of which rides a burst of high-frequency Na^+ action potentials. Following the burst of action potentials and subsequent inactivation of the calcium conductance and other associated conductances, either the pattern can be repeated by another prolonged hyperpolarization, or the cell can depolarize toward −60 mV and return to tonic mode. In summary, the variety of receptor types and channels located at or near corticogeniculate synapses onto thalamic relay neurons allows this pathway to play a role in determining the firing mode of thalamic relay neurons. Based on these findings, the corticothalamic pathway has been suggested to modulate the mode of LGN activity and information transfer from thalamus to cortex (described further in the next section).

In contrast to type 1 axons, type 2 axons from neurons in cortical layer 5 tend to be thick and quite richly branched. Their terminal swellings tend to be larger and heterogeneously shaped. The synapses at these swellings tend to contact the more proximal dendrites of postsynaptic neurons in the pulvinar nucleus – often within glomeruli and often forming triads with other thalamic afferents and local circuit neurons, but also at extraglomerular regions. The presynaptic terminals of these neurons are large and contain round glutamate-filled vesicles ('RL profiles'). The postsynaptic receptors are ionotropic (likely both NMDA and non-NMDA). The resultant EPSP is similar to that described above for postsynaptic ionotropic receptors. However, the synapses of type 2 axons are more proximal to the cell body and are often combined with processes from other neurons in glomeruli, likely leading to different current outcomes at the postsynaptic cell's axon hillock compared with the current outcomes of type 1 axon activation. Based on these findings, type 2 axons have been suggested to serve as drivers, rather than modulators, of postsynaptic activity during sensory processing. It is not known whether synapses from type 2 axons can activate postsynaptic metabotropic glutamate receptors (or whether such receptors even exist). However, type 2 afferents from the retina to the LGN, another driver pathway, do not activate metabotropic glutamate receptors in their target neurons. When encapsulated within a glomerulus or as a portion of a triad, synapses from type 2 axons contact local circuit neurons in combination with thalamocortical neurons. The inhibitory contributions of the local circuit cells, as described above, could likewise exert a form of feedforward inhibition. However, the influence of inhibition at the microlevel within a glomerulus might have a profoundly different outcome at the postsynaptic cell body.

The Influence of Corticothalamic Feedback on Sensory Processing

Despite the anatomical strength of the corticothalamic pathway (e.g., individual LGN neurons receive two to five times more synapses from the cortex than from the retina), we know remarkably little about the function of this pathway during sensory processing. Nevertheless, a number of proposed roles have been assigned to the corticothalamic pathway, based mainly on studies of the pathway from cortex to the LGN. These proposed roles can be sorted into two broad categories: (1) the corticothalamic pathway serves to sharpen the receptive field properties of thalamic neurons, and (2) the corticothalamic pathway serves to enhance the transmission of sensory information from periphery to cortex. Although less is known about the functional properties of the corticopulvinar pathway, recent theories have been introduced that suggest a role for this pathway in relaying information from one cortical area to the next.

Past studies in the visual, auditory, and somatosensory systems have led researchers to suggest that corticothalamic feedback from neurons in layer 6 serves to sharpen the receptive fields and/or shift the tuning of thalamic responses to sensory input. In the visual system, the strength of the extraclassical or suppressive surround that extends beyond the classical receptive field has been argued to depend on corticogeniculate feedback. Because of the suppressive nature of this surround, stimuli restricted within the classical receptive field would elicit greater responses than would stimuli that extend into the surround. As a result, the extraclassical surround serves to sharpen the borders of the classical receptive field. The notion that corticothalamic feedback serves to sharpen receptive fields is also supported by work in the somatosensory and auditory systems. In most cases, these studies support the view that feedback enhances responses to stimuli within the center of the receptive field and diminishes responses to stimuli that extend into the surround. A variation on this theme is found in the auditory thalamus of echolocating bats. Here, a process referred to as

egocentric selection occurs in which cortical feedback appears to shift the tuning of thalamic neurons toward that of activated corticothalamic neurons. In the process, the transfer of stimulus-matched information is enhanced, and nonmatched information is weakened and ignored.

Corticothalamic feedback has been proposed to influence information transfer in a number of ways. As described above, corticothalamic feedback might serve to shift thalamic neurons between burst and tonic modes of firing. While no direct evidence for this hypothesis exists, the necessary machinery is present in the receptors and channels located at corticothalamic synapses. Determining the mode of LGN activity has significant ramifications for the transfer of information from LGN to cortex, as burst spikes are not only more effective than tonic spikes at driving cortical responses but also differ in subtle ways from tonic spikes in their visual response properties.

Distinct from burst and tonic activity, corticogeniculate feedback has also been proposed to synchronize the firing of LGN neurons. Although the source of this synchrony has been the subject of debate, separate studies have shown that near-synchronous spikes from two LGN neurons that provide convergent input to a common cortical cell are more likely to drive cortical responses than spikes displaced by little more than 10 ms. Thus, there appears to be a mechanism in place to preferentially detect synchronous inputs.

Finally, corticothalamic feedback has been suggested to gate the flow of information from periphery to cortex. In the most extreme case, corticothalamic connections are believed to contribute to the neuronal circuits that underlie sleep, an obvious case in which thalamocortical transmission is diminished or disrupted. At the other extreme, spatial attention has been argued to increase the activity of LGN neurons. If LGN activity is indeed influenced by attention, then it seems likely that the corticothalamic pathway plays a key role in mediating these effects. Last, somewhere in between these two extremes is the notion that corticothalamic feedback serves to increase the gain of LGN responses to otherwise weak stimuli, such as low-contrast visual stimuli.

Conclusion

Although we have a good understanding of the components of the corticothalamic pathway, our understanding of the function of this pathway during sensory processing is limited. This could be because the definitive experiment to determine corticothalamic function has yet to be conceived or the tools to study such an anatomically complex pathway have yet to be developed. Alternatively, we may not be thinking about the corticothalamic pathway in the right context. The brain does not function in separable pieces but as a flowing, dynamic whole. The key to understanding the corticothalamic pathway may thus lie in examining it within the context of a larger functional circuit including sensory afferents, thalamocortical afferents, corticothalamic efferents, and intrinsic circuits. A daunting task indeed, but perhaps the visual pathway of the future.

Corticothalamic Connections: Ultrastructure

Introduction

Corticothalamic (CT) connections are one of several major output systems to subcortical centers. In general, they are considered to reciprocate thalamocortical (TC) connections, and are numerically and functionally important. In the primary sensory thalamic nuclei, CT terminations have been thought to have a modulatory role, in contrast with inputs from the sensory periphery (retina, cochlea, or somatosensory systems), which are essential ('driving') for the receptive field response properties of neurons in the recipient nuclei. In associational thalamic nuclei, the anatomical organization is typically more complex, in that CT terminations originate from multiple cortical areas, and are composed of multiple subtypes. This has led to the suggestion that different subpopulations operate in modulatory or driving modes. This and other proposals about the role of CT connections are briefly discussed in the last section of this article.

CT connections were identified as fiber tracts as early as the end of the nineteenth century and were identified in finer detail at about the same time, in Golgi-stained preparations. During the twentieth century, major advances were made in defining neurons of origin in various cortical areas, terminal fields in the target thalamic nuclei, and basic synaptic microcircuitry. These three topics are developed later in this article. Overall, emphasis is on associational thalamic nuclei, which receive connections from associational cortical areas and are concerned with more integrative or multimodal processing. The lateral geniculate nucleus and other primary sensory nuclei might be considered something of a special case as regards CT terminations, and, moreover, are extensively discussed in textbooks and other source material. Finally, species-specific and nucleus-specific features have been largely neglected here (but see the section 'Further reading' for literature by Rouiller and Welker).

Cells of Origin

Layers

By injecting retrograde tracers into the thalamus, projection neurons can be visualized histologically in cortical areas. CT projecting neurons are found in the deeper cortical layers, in layers 5 and 6. These layers also contain other projection neurons, including some corticocortical neurons. Sublaminar location (i.e., layer 6A vs. layer 6B) and the proportion of neurons in layers 5 and 6 will vary, depending on the species of animal and the specific corticothalamic connection. Some nuclei, such as the lateral geniculate nucleus, receive connections only from layer 6, but most of the association thalamic nuclei receive CT connections from both layers 5 and 6. In that case, the population in layer 6 is much larger. When several cortical areas project to the same thalamic nucleus, terminations may originate from neurons only in layer 5 of one area, only from neurons in layer 6 of another area, or from a mixed population in yet another area (see 'Further reading,' Rouiller and Welker). In rats and cats at least, some nuclei receive bilateral connections.

Subtype Characteristics

CT neurons in layers 5 and 6 are distinguished by several distinct properties. (1) They have distinctive terminal morphology (see later). (2) They have distinctive extrinsic collateralization. At least some neurons in layer 6 send collaterals to the reticular nucleus of the thalamus (RTN). Layer 5 neurons, in contrast, frequently send collaterals to the superior colliculus or other brain stem regions, but not to the RTN. (3) They have distinctive intrinsic cortical collateralization. Layer 5 cells have extensive horizontal collaterals within layers 3 and 5; but intracellular fills of layer 6 corticothalamic neurons in cat auditory cortex have shown more confined recurrent collaterals, vertically oriented in the vicinity of the cell body. Further differences have been documented in the intrinsic collateralization of layer 6 neurons in monkey visual cortex, suggestive of additional subdivisions within the layer 6 population. (4) A physiological study in cat motor cortex demonstrated distinct spike trains for neurons in layer 5 and provided evidence of at least two subdivisions within the CT neurons in layer 6. CT neurons in layer 5 are fast conducting, show step-related activity, have sensory receptive fields, and are spontaneously active; one population of neurons in layer 6 is slow conducting, and shows none of the properties of the neurons in layer 5; and a second population of layer 6 neurons, distinguished as moderately conducting, has precisely timed step-related behavior.

Terminal Arbors

Light Microscopy

Background Terminal arbors can be visualized by Golgi stains of fixed tissue, by intracellular injection

of various tracers, or by extracellular injections of anterograde tracers such as biocytin, *Phaseolus vulgaris* leukoagglutinin, or biotinylated dextran amines. The most precise approach is intracellular injection of identified parent neurons in the cortex (*in vivo*), with subsequent complete visualization (in histology preparations) of the axon trajectory and terminations. As intracellular injections are technically demanding, most data have been derived from relatively large extracellular injections (diameter ~1.0 mm). These allow confident identification of thalamic terminations as having originated from neurons within the cortical injection site, but the exact cells of origin are obscured within the tracer injection.

Morphological subtypes Starting in the 1990s, several studies using high-resolution anterograde tracers reported multiple types of CT arbors at the light microscopic level. These have been grouped in two broad categories: type 1 and type 2 (Figures 1–4). Type 1 terminations consist of small, stalked terminations ('drumstick-like,' or *boutons terminaux*), which look very similar to dendritic spines. The axon is usually thin, and the terminal portion is very long (>1.0 mm). Type 2 terminations consist of predominantly large, beaded boutons (*boutons en passant*). The axon is slightly thicker (diameter ~ 1.0 μm) and

Figure 1 Light micrograph of lateral geniculate nucleus (parvocellular layer 4; macaque monkey). Corticothalamic terminations anterogradely labeled by an injection of biotinylated dextran amine in area V1. Note small terminations that are beaded (arrowheads) or stalked (arrows). Some thalamocortical neurons as well have been retrogradely labeled by the injection. Scale bar = 50 μm.

Figure 2 Light micrograph of medial pulvinar (macaque monkey). A segment of a corticothalamic axon, anterogradely labeled by an injection of biotinylated dextran amine in parietal cortex. This is a type 1 axon, characterized by an abundance of stalked ('drumstick') terminations. These occur in various patterns: singly, in clusters, in doublets (arrows), and intermixed with some beaded terminations. The overall configuration is more divergent than is seen in V1 axons in the lateral geniculate nucleus, and the stalked terminations are more pronounced. Scale bar = 50 μm.

Figure 3 Light micrograph of medial pulvinar (macaque monkey). A field of corticothalamic terminations anterogradely labeled by an injection of biotinylated dextran amine in parietal cortex. A small arbor with type 2, larger boutons (solid arrow) is visible in a field of type 1 terminations (hollow arrow). Scale bar = 50 μm.

Figure 4 Light micrograph of lateral pulvinar (macaque monkey). Cortical injections in temporal areas were made of adenovirus and biotinylated dextran amine. A thalamocortical neuron (brown) has been labeled with green fluorescent protein (reacted with anti-green fluorescent protein antibody and 3,3′-diaminobenzidine), after infection by adenovirus. Anterogradely labeled corticothalamic terminations (in black) are also visible. Curved arrow indicates a concentration of type 2, large boutons, targeting proximal dendrites of a thalamocortical neuron (soma not visible). Scale bar = 50 μm.

the terminal portion forms a well-defined arbor, frequently about 0.25 mm in diameter. Because of the distinctive shapes of the terminal field, an alternate terminology was proposed, of 'elongated' for type 1 and 'round' for type 2, but the classical terminology has so far been more popular.

The two broad types of connections have been associated with neurons in different cortical layers. Type 1 terminations are thought to arise from neurons in layer 6, while type 2 terminations arise from neurons in layer 5. This conclusion is based (1) on direct evidence from laminar-specific injections in auditory cortex of cat, and from a small number of single cell injections in rats and (2) on indirect numerical evidence. That is, there are large numbers of type 1 arbors and large numbers of retrogradely filled CT neurons in layer 6, and small numbers of type 2 arbors and small numbers of retrogradely filled CT neurons in layer 5.

In the primate association thalamus, further morphological subdivisions have been noted in both type 1 and type 2 CT terminations. On the basis of arbor shape, arbor size, and subtle differences in bouton size and shape, two further subdivisions have been proposed for type 1 terminations, and four subdivisions for type 2. This is consistent with ongoing characterization of subpopulations of layer 5 and layer 6 pyramidal cells, although the functional implications are still unclear.

In the visual system, CT connections to the lateral geniculate nucleus (LGN) are only type 1 (Figure 1). Type 2 large-bouton terminations do occur, but these belong to retinogeniculate terminations. In the LGN, this strong morphological dichotomy correlates with functional differences, where the type 2 retinogeniculate terminations have a driving influence (e.g., they are essential for normal visual response properties of LGN neurons), while the type 1 CT terminations are more modulatory. The driving type 2 versus modulatory type 1 distinction has been hypothesized to apply more generally. Thus, when the two types of CT terminations occur together, as in association thalamic nuclei, type 1 terminations are proposed to be modulatory and type 2 driving. Consistent with this distinction, type 1 terminations have been shown to use metabotropic receptors, associated with slow depolarization, while type 2 terminations are associated with the faster ionotropic receptors.

Electron Microscopy

Type 1 and Type 2 Boutons

Electron microscopic (EM) studies in the 1960s and 1970s reported the occurrence of large (type 2) and small (type 1) excitatory boutons. The positive identification of these boutons as CT required a prelabeling step, whereby anterograde tracer injections were made in cortical areas *in vivo*, followed by perfusion and histological processing. As early as 1979, this was achieved by intracortical injections of tritiated amino acids. Also used for this purpose were horseradish peroxidase conjugated to wheat germ agglutinin, or biotinylated dextran amine (Figure 5).

At EM magnifications, both small and large boutons were seen to contain round synaptic vesicles, characteristic of excitatory terminations, and were accordingly called LR ('large round,' up to 9.0 μm^2) and SR ('small round,' 0.2–2.0 μm^2). Both are associated with a postsynaptic density, but this is more pronounced for SR boutons. LR boutons contain mitochondria, but SR boutons often do not. LR boutons in addition have filamentous contacts (Figure 6). These are established with somata or dendrites of projection neurons. Their function is not known, but possibilities include an adhesive role (i.e., desmosomoid attachments), a role in the establishment and maintenance of precise connections, or a role in some form of energy-dependent intercellular communication. The extensive networks of agranular endoplasmic reticulum localized along both sides of filamentous contacts have been suggested to be sites for the storage and release of calcium ions.

Another particular feature identified by EM is that type 2, but not type 1, boutons frequently occur within glomeruli (also called 'synaptic islands'). These are large aggregations of excitatory and inhibitory synaptic terminals associated with a large central dendrite and encapsulated by astrocytic cytoplasm (Figures 6–8). The central element can sometimes be an LR terminal. The inhibitory terminations arise from external sources, such as the RTN or pretectal nucleus, or from local circuit neurons, and are identifiable by their flat synaptic vesicles Thalamic local circuit neurons have specialized dendrites which are both pre- and postsynaptic. The configuration and density of glomeruli vary with species and nuclei. In rats, except for the LGN, the glomeruli do not contain presynaptic dendrites of inhibitory neurons. Glomeruli, defined as aggregations of synapses wrapped by glia, occur in other areas besides the thalamus, such as the cerebellar nuclei.

Postsynaptic Target

EM verification of synaptic contacts is essential for specification of microcircuitry. The main postsynaptic targets in the thalamus are TC relay neurons and interneurons. Immunolabeling for γ-aminobutyric acid (GABA) is often used in discriminating between GABA-positive interneurons and GABA-negative relay neurons.

Figure 5 Electron micrographs of wheat germ agglutinin-conjugated horseradish peroxidase-labeled corticothalamic boutons in the lateral posterior nucleus, retrogradely labeled by an injection in parietal cortex (macaque monkey). (a) Examples of two labeled boutons. At the right, a large bouton with round vesicles (LR) is in close apposition with the proximal projection neuron dendrite (P). The medium-size bouton on the left forms two synapses (arrowheads): one with the proximal projection neuron dendrite (right-hand P) and another with a smaller diameter branch (left-hand P). (b) Two small, round vesicle-containing boutons (SR) with asymmetric synapses (arrowheads) on a distal projection neuron dendrite (P). (c) Example of a complex synaptic arrangement with a labeled LR bouton. It forms two asymmetric synapses (two arrowheads in the top left corner) on two vesicle-containing dendrites (labeled d), one of which forms a symmetric synapse (bottom left) with another vesicle-containing dendrite; the asterisk denotes a spinelike process, most likely belonging to a projection neuron dendrite, that protrudes into the LR bouton and has one continuous synapse encircling it. (d) An example of an LR bouton surrounded by vesicle-containing dendrites (labeled d) in a glomerulus. Arrowhead points to a synapse between the bouton and one of the vesicle-containing dendrites. (e) An example of an LR bouton forming long synapses (arrowheads) on a labeled projection neuron dendrite (P) and surrounded by two vesicle-containing dendrites (labeled d). All scale bars = 1 μm. Reprinted from Taktakishvili O, Sivan-Loukianova E, Kultas-Ilinsky K, et al. (2002) Posterior parietal cortex projections to the ventral lateral and some association thalamic nuclei in *Macaca mulatta*. *Brain Research Bulletin* 59: 135–150, with permission from Elsevier.

In primates and cats, but not rodents, thalamic nuclei contain 15–25% inhibitory interneurons. Both SR and LR boutons can synapse on inhibitory neurons, in variable proportions, depending on specific nucleus and species. (The LGN in all species, including rodents, contain a proportion of inhibitory interneurons.)

TC relay cells can be identified on the grounds of being GABA negative. They can also be identified by lack of the synaptic vesicles that occur in presynaptic dendrites of local circuit neurons. Relay cells can be labeled by intracellular tracers or, more commonly, by retrograde tracer injections in cortex, although these often fill only cell somata and very proximal dendrites. Proximal–distal location along a dendrite can be inferred on the basis of dendritic caliber.

Type 1 synapses tend to target distal dendrites, while type 2 synapses are usually located more proximally (Figure 4). In some nuclei, however, the distribution of LR and SR boutons is more even. Neurons in the centromedian interlaminar nucleus, for example, exhibit more intermingling of LR and

Figure 6 Micrograph 2: Part of a synaptic glomerulus in rat dorsal lateral geniculate. Two dendrites (D_1, D_2) are associated with two large axon terminal profiles (A_1, which is almost certainly a retinal afferent terminal, and A_2), and both dendrites establish asymmetrical filamentous contacts with A_1. Note that the excrescences (E) invaginating A_1 from D_1 make synaptic contacts (arrowheads) rather than filamentous contacts, and that neurofilaments (f) and agranular reticulum (arrows) are concentrated below the contact zones in both dendrites. Scale bar = 0.5 μm, ×24 000. Micrograph 3: extensive asymmetrical filamentous contact between a large presumptive lemniscal afferent axon terminal (A) and the primary dendrite (D) of a projection neuron in ventrobasal thalamus. A postsynaptic excrescence (E) protrudes from the dendrite. Scale bar = 1.0 μm, × 20 000. Micrographs 4a and 4b: differences between axodendritic filamentous and synaptic contacts. Note the clustering of vesicles and the continuous postsynaptic densities at the synaptic contacts (arrowheads) and the dendritic agranular reticulum (arrows) and neurofilaments associated with the filamentous contacts; 4a: ×80 000, 4b: Scale bar = 0.1 μm, × 120 000. Micrographs 5 and 5a: Tangentially sectioned asymmetrical filamentous contacts between lemniscal axon terminals (A) and projection cell dendrites (D) in ventrobasal thalamus. 5: Scale bar = 0.5 μm, ×35 000; 5a: Scale bar = 0.1 μm, × 50 000. Reprinted from Lieberman AR and Spacek J (1997) Filamentous contacts: The ultrastructure and three-dimensional organization of specialized non-synaptic interneuronal appositions in thalamic relay nuclei. *Cell and Tissue Research* 288: 43–57, with permission from Springer-Verlag GmbH.

SR boutons. Not known is whether there is any systematic difference in connectivity, depending on the type of relay neuron. TC relay neurons are all excitatory and glutamatergic, but they are further divisible, on the basis of dendritic morphology and depending on whether they contain parvalbumin or calbindin.

Examples of postsynaptic targets in five nuclei In the LGN, CT terminations are only type 1 (small), and type 2 (large) boutons are from the retina, but the synaptic topology is more complex in the auditory and somatosensory systems, each system consisting of several subnuclei. In association nuclei,

Figure 7 Electron micrographs from the rat mediodorsal thalamus. Large round axon terminals with reaction product after injections of wheat germ agglutinin-conjugated horseradish peroxidase into the basolateral amygdaloid nucleus. (a) A labeled large round terminal with round synaptic vesicles, an asymmetrical synaptic contact (arrowhead), and puncta adherentia (asterisks) on a dendritic shaft. Note the presence of glial enwrapment. (b) A labeled bouton that establishes an asymmetrical synaptic contact (arrowhead) on a dendritic spine. Puncta adherentia can also be seen (asterisks). Scale bar = 1 μm. Reprinted from Kuroda K, Yokofujita J, and Murakami K (1998) An ultrastructural study of the neural circuit between the prefrontal cortex and the mediodorsal nucleus of the thalamus. *Progress in Neurobiology* 54: 417–458, with permission from Elsevier.

Figure 8 Electron micrographs from the rat mediodorsal thalamus. Examples of labeled boutons following injections of wheat germ agglutinin-conjugated horseradish peroxidase into the piriform cortex. (a) A labeled large round axon terminal with numerous mitochondria and asymmetric synaptic contacts (arrowhead) on a longitudinally sectioned dendrite. (b) A labeled large round bouton synapsing with a dendritic shaft and spine. Note the round synaptic vesicles, the asymmetrical synaptic membrane specialization (arrowheads), and the glial ensheathment. The postsynaptic thickening is less pronounced than that seen in small round terminals. (c) A wheat germ agglutinin-conjugated horseradish peroxidase-labeled bouton identified as a small round terminal on the basis of the size and the absence of glial processes. All scale bars = 1 μm. Reprinted from Kuroda K, Yokofujita J, and Murakami K (1998) An ultrastructural study of the neural circuit between the prefrontal cortex and the mediodorsal nucleus of the thalamus. *Progress in Neurobiology* 54: 417–458, with permission from Elsevier.

CT terminations are both type 1 and type 2, but these can originate from different areas in different combinations. Type 2 boutons are also used by amygdala neurons, which project to the mediodorsal (MD) thalamus (Figure 7), and type 1 boutons can be from the brain stem, as is the case in the LGN. Thus, positive identification of CT terminations requires prelabeling with cortical injections of anterograde tracers. Cortical injections are also necessary to define the exact source area. This following five examples describe synaptic topology (different nuclear and species patterns are more extensively discussed elsewhere; see section 'Further Reading'):

Example 1: Cat ventral posterior (primary somatosensory) thalamic nucleus. The distribution of four types of synapses has been reported in detail on four physiologically identified relay neurons. In particular, this work provided an estimate of the total number of synapses per cell, calculated as 5584–8797. Of the total, LR synapses constituted approximately 15%; SR, approximately 50%; F ('flat vesicle,' inhibitory synapses), approximately 35%; and presynaptic dendrites, 35%. For all four cells, LR (from principal afferents) and F synapses were concentrated on proximal dendrites, and SR (from corticothalamic) were on distal dendrites, with variable proportions on intermediate dendrites. Some LR synapses occurred

distally as well, but sharply fewer than SR. Comparable studies have been carried out in the LGN and medial geniculate body (MGB).

Example 2: Cat pulvinar nucleus. Several EM studies have demonstrated that the cat pulvinar nucleus, as in the monkey, receives a mix of type 1 and type 2 CT terminations. The synaptic distribution in the neuropil was determined as 3.5% LR profiles, 84.2% SR profiles, 7.3% F profiles, and 5% presynaptic dendrites. For TC cells (identified on the basis of dendritic features, and being GABA negative), LR profiles were calculated to comprise 2.1% of the synapses and SR boutons were calculated to comprise 85.6%. For interneurons (identified as GABA positive), LR boutons represented 11.8% of the synaptic contacts, and SR boutons represented 75.6%. As compared with the cat LGN, the pulvinar nucleus received fewer LR boutons and significantly more SR boutons; the ratio of LR to SR synapses was given as 1:5 in the LGN (where LR are retinogeniculate and SR are at least partly corticogeniculate), and 1:24 for the pulvinar (where both LR and SR are CT). It is important to keep in mind that these are numbers in aggregate, and it is not known whether proportions differ significantly in relation to specific relay cells. When CT projections to the cat pulvinar were prelabeled by anterograde tracers in areas 5 and 7, LR terminations were found to target approximately equal numbers of GABA-positive and GABA-negative profiles, while SR synapses were mainly on small-caliber, GABA-negative dendrites, presumed to be distal dendrites of TC projection neurons.

Example 3: Cat lateral posterior (LP) nucleus. In contrast with the mixed type 1 and type 2 terminations in the pulvinar, terminations from area 17 (or area V1) are mainly or exclusively of type 2, from layer 5 neurons. These target large dendrites, presumably proximal dendrites of TC projection neurons, and, as well, presynaptic dendrites of interneurons within glomerular arrangements. SR terminations in the LP nucleus are not labeled from injections in area 17, but originate from other cortical areas.

Example 4: Inferior pulvinar nucleus in monkey. This subdivisions receives mainly type 2 terminations from area 17 (area V1), but receives a mix of type 1 and type 2 terminations from extrastriate areas.

Example 5: Mediodorsal nucleus. In the rat, CT terminations from prefrontal cortex are reported to be only type 1. LR terminations occur, but originate from neurons in the amygdala or piriform cortex (Figures 7 and 8). The organization of the MD nucleus in monkey is very different, and in this species, injections in frontal cortex label both type 1 and type 2 boutons. Type 2 terminations occur in glomeruli, where they target both dendrites of TC projection neurons and presynaptic dendrites of inhibitory interneurons. Projections from the amygdala are also large, and similar to type 2 CT projections.

RTN output The reticular nucleus of the thalamus is a key structure that participates in a three-way connectivity, receiving collaterals from TC neurons and from type 1 CT terminations. The RTN sends inhibitory connections to the thalamus. In the cat ventroposterior nucleus (Figure 9), tracer-labeled terminations from RTN are reported to target predominantly dendrites of relay neurons (82%), but also dendrites of interneurons (8.5%), and somata (9.3%). In the monkey, tracer injections in the anterior RTN produced terminations in four subdivisions of the motor thalamus. Synaptic contacts were mainly on distal dendrites of both projection and local circuit

Figure 9 (a, b) Views in two planes of focus of phytohemagglutinin-L-labeled terminal axons from reticular thalamic nuclei and their boutons, ending in the vicinity of a cell body in the ventroposterior lateral nucleus of cat. Cell body is identified by nonspecific staining. Scale bar = 12.5 μm. Reprinted from Liu XB, Warren RA, and Jones EG (1995) Synaptic distribution of afferents from reticular nucleus in ventroposterior nucleus of cat thalamus. *Journal of Comparative Neurology* 352: 187–202, Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

neurons. The proportion of synapses on local circuit neurons was noted to be higher (48%, 62%, and 65%, respectively) than what has been reported for sensory thalamic nuclei, although in range with previous reports of RTN terminations in the MD and the anterior ventral nuclei.

RTN cortical inputs For reticular neurons, the CT terminations are more numerous than are TC terminations (70% vs. 20–25% for thalamic synapses), and are evenly distributed over both proximal and distal dendritic locations. The TC synapses are larger, more proximally located, and have multiple vesicle release sites. CT terminations are associated with a higher number of glutamate receptors(GluR4) in reticular neurons than in the thalamus, and this has been proposed as a basis for differences in synaptic strength (Figure 10).

Convergence of Multiple Afferents

The quantification of specific inputs onto identified postsynaptic neurons has not yet been achieved, and it is not known how many thalamic neurons are contacted by how many different type 1 and type 2 CT axons. A representative type 2 axon might have 200 boutons, which are likely to contact portions of at least 10–20 neurons, lying relatively close together. At the light microscopic level, instances can sometimes be found of single neurons that are heavily entwined by numerous type 2 boutons, possibly from one arbor (Figures 4 and 11), and a serial reconstruction of large CT terminals in the mouse posterior nuclear group demonstrated that these encapsulate the postsynaptic dendrite, often near proximal branch points. Type 1 axons typically have more boutons (up to 2000) and extend over much wider territories. Thus, they clearly contact more postsynaptic neurons, possibly with only a few boutons (1–5?) per cell. Given the low ratio of LR to SR boutons, there are likely to be at least two distinct input patterns: cells with a mix of type 1 and type 2 inputs, and those with only type 1 inputs. These latter would derive from multiple type 1 axons, possibly even from different cortical areas. These questions need to be further addressed by continued EM analysis at the level of identified cells.

Finally, it is important to note that thalamic nuclei receive a variety of excitatory inputs. The LGN receives primary sensory input from the retina, CT

Figure 10 (a) Location and camera lucida drawing of a typical layer 6 corticothalamic cell from a mouse thalamocortical slice preparation. The axon branches to innervate both the reticular nucleus (RTN) and the ventral posterior (VP) nucleus (ST, corticothalamic synapses in the RTN). (b) Ten superimposed consecutive traces and their mean, showing excitatory postsynaptic currents recorded from a VP cell and an RTN cell in response to minimal stimulation of corticothalamic fibers. Minimal excitatory postsynaptic currents in RTN cells have approximately three times greater amplitudes than do those in VP cells. (c) Immunogold labeling for glutamate receptor (GluR4) subunits at corticothalamic synapses in the VP (RS synapse) and RTN (ST synapse), showing a larger number of particles in the RTN (D, dendrite). (d) Quantification of immunogold particles representing GluR4 and GluR2/3 receptor subunits at postsynaptic densities of four serially sectioned corticothalamic synapses in the VP and RTN. The number of GluR4 particles at corticothalamic synapses on RTN cells is approximately three times greater than at corticothalamic synapses on VP cells. Figure 11 Light micrograph of medial pulvinar (macaque monkey). An injection of biotinylated dextran amine in parietal cortex shows type 2 corticothalamic terminations wrapping proximal dendrites of a retrogradely labeled thalamocortical neuron. Although the arbor is spatially delimited, individual boutons appear to target multiple neurons (solid arrows), and one divergent branch is visible at left. Hollow arrow indicates type 1 terminations in the same field. Scale bar = 50 μm.

type 1 input from primary visual cortex and some other visual cortical areas, and cholinergic input from the brain stem. The retina input is numerically smallest, although it is known to have an essential (or 'driving') role. The medial pulvinar nucleus, a representative associational nucleus in the monkey, receives inputs from several cortical areas and, in selective patches, from the amygdala and superior colliculus. The convergence and interaction of these inputs, especially at the level of single cells, is only partially understood.

Reciprocity of CT and TC Connections

The reciprocal nature of the connections between thalamus and cortex has been well documented and is often considered a major characteristic of this network. The concept of reciprocity, however, is actually complicated. First, other connections play important roles. In the thalamus, these include the amygdala, brain stem nuclei, and, importantly, RTN. The bidirectional circuitry involving cortex, thalamus, and RTN may be better described as a larger, three-way connectivity loop. Second, connections between cortex and thalamus are not two-way, but occur as a fanout, where projections are among multiple areas and nuclei. Not all of these are directly reciprocal. Third, very little precise information is available at the cell-to-cell level. Do layer 5 neurons, which synapse on a small number of TC neurons, receive connections back from these same neurons, either directly or through an interposed synapse in layer 4? Similarly, concerning layer 6 neurons. But for these it seems likely that only some of the widely separated TC neurons contacted by a layer 6 arbor would actually project back to that same layer 6 neuron.

TC terminations from MD to prefrontal cortex in rats have been demonstrated to target multiple populations. These include presumptive CT pyramidal neurons in the deeper layers, but also neurons in layer 3, which do not project to the thalamus. This and other results clearly show that while some monosynaptic reciprocal loops may exist, these are only one component of rich connectivity networks

CT Terminations: Functional Roles

There has been much discussion of the function of CT terminations. One of the better understood roles has been the excitatory influence of cortical terminations (type 1) on RTN neurons, which in turn produce prolonged inhibitory postsynaptic potentials in TC neurons. This circuitry is crucial in the generation of sleep rhythms. More generally, large-scale interactions between cortex and thalamus have been proposed to recruit large constellations of neurons in synchronous activity appropriate to cognitive phenomena such as perceptual binding and directed attention.

As mentioned earlier in this article, the strong dichotomies of type 1 and type 2 CT terminations have been interpreted in the general framework of modulatory and driving influences. In this view, type 2 CT terminations are compared with primary sensory inputs and are proposed to have a similar essential role (driving, or feedforward) in receptive field properties, whereas the small bouton type 1 terminations would be more modulatory (feedback). When multiple areas are known to use different combinations of type 1 and type 2 boutons, this is proposed to reflect differential feedback or feedforward effects. This hypothesis has been very influential in emphasizing the importance and richness of CT terminations, but it has tended to overlook issues such as subtypes of CT terminations and of their postsynaptic TC neurons, convergence of multiple inputs, and the marked spatial difference in arbors, where type 1 CT arbors are widely divergent within a nucleus, in contrast with more spatially delimited type 2 arbors.

Another proposal is based on the differential collateral pattern of type 1 and type 2 CT terminations, and in particular, the fact that type 2 terminations typically branch to output centers of the brain stem or spinal cord. The thalamic terminations can thus be seen as transmitting information about both the environment and the body and concurrent instructions to motor centers.

Understanding the role of CT terminations, the anatomical substrates, and the network connectivity

is still at an early stage. As noted by Guillery, further work at the level of single cells will be important to resolve finer aspects of microcircuitry.

Discovery of CRF and Its Role in the Stress Response

Corticotropin-releasing factor (CRF) was identified in 1981 as the key hypothalamic factor to induce the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. This feat was accomplished by the purification of the peptide from sheep hypothalami. CRF is the most potent known stimulator of ACTH release, although other hypothalamic factors, most notably arginine vasopressin (AVP) and oxytocin, can synergize with CRF to augment the release of ACTH. Nevertheless, the observation that the release of ACTH from the anterior pituitary gland is almost completely blocked by administration of CRF antisera established that CRF is the predominant regulator of pituitary ACTH release. Mature bioactive CRF is a 41-amino-acid neuropeptide that is cleaved from a larger precursor protein lacking intrinsic biological activity (Figure 1). CRF is produced in the parvocellular neurons of the paraventricular nucleus (PVN) of the hypothalamus. These neurons project to the median eminence and release their neuropeptide content into the capillary bed of the hypophysial portal system. This portal system carries CRF to the anterior pituitary corticotropes, which respond by releasing ACTH into the general circulation to induce the release of glucocorticoids from the adrenal cortex. This endocrine axis, referred to as the hypothalamic–pituitary–adrenal (HPA) axis, controls reactions to stress. The stress response is an adaptive response aimed at maintaining or restoring homeostasis in the face of a plethora of potentially adverse stimuli from diverse origins. The glucocorticoids – cortisol in humans and corticosterone in rodents – that are released as a result of HPA axis activation are responsible for many of the hallmarks of the stress response, such as increased energy mobilization via enhanced liver glycogenolysis and the general inhibition of vegetative functions, including digestion, growth, reproduction, and immunity. Importantly, glucocorticoids engage in negative feedback at the level of both the pituitary gland and the hypothalamus to inhibit the synthesis and release of ACTH and CRF, aimed at a timely termination of the stress response. Many of the behavioral effects that are associated with stress, such as increased anxiety, improved cognition, increased depression, and reduced feeding behavior, are often the direct effect of the activation of central CRF circuits.

CRF: Founding Member of a Small Family of Neuropeptides

Shortly after the discovery of CRF in sheep, the CRF genes of humans, mice, rats, and other mammals were identified. Urotensin-I (UI), a peptide resembling CRF, was isolated from a fish species (*Catastomus commersonii*) following the discovery of CRF in mammals. This peptide was initially regarded as the fish ortholog (i.e., the same gene in a different species) of mammalian CRF, until a second peptide also resembling CRF was identified from the same fish species. As this second CRF-like peptide shared much higher similarity with mammalian CRF, it was clear that it represented the actual ortholog of mammalian CRF. The mammalian ortholog of fish UI was identified in 1995 with the isolation and characterization of urocortin 1 (Ucn1). Another peptide with resemblance to the Ucn1 of mammals and the UI of fishes was isolated from the skin of the waxy monkey tree frog (*Phylomedusa sauvagei*), a species from the Amazonian rain forest. This peptide was named sauvagine and although it is only known from the skin of a single amphibian species, sauvagine has been frequently used in the characterization of many aspects of CRF signaling. In recent years, two additional members of the CRF family of neuropeptides were independently discovered by two groups employing a bioinformatics approach. The current nomenclature for these peptides is urocortin 2 (Ucn2) and urocortin 3 (Ucn3), although one of the identifying groups initially named them stresscopin-related peptide and stresscopin, respectively. All members of the vertebrate CRF family have several characteristics in common with CRF. All are preprohormones that contain at their C-termini mature neuropeptides that are presumed to be liberated by cleavage at a mono- or dibasic cleavage site (Figure 1). In keeping with their discovery via bioinformatics, the existence of mature neuropeptides for Ucn2 and Ucn3 has been predicted, and their bioactivity following *de novo* synthesis has been established, but neither mature peptide has been directly isolated from an endogenous source.

CRF Family Neuropeptides Signal via One of Two CRF Receptors

Two receptors for CRF have been identified and are termed CRFR1 and CRFR2. Both are class B

Figure 1 Corticotropin-releasing factor (CRF) family ligands (Ucn1, Ucn2, and Ucn3; urocortins) are encoded as preprohormones. (a) The C-terminal mature neuropeptides are liberated from the prepropeptide sequence by cleavage at mono- or dibasic cleavage sites. At the amino acid level CRF and urocortins share moderate amino acid similarity. (b) Amino acids with similar biochemical properties are color-coded for clarity.

(secretin-like) seven-helix transmembrane G-protein-coupled receptors and consist of 395 to 440 amino acids. CRFR1 and CRFR2 share approximately 70% amino acid identity, with most of their amino acid differences concentrated in the N-terminal region. As the N-terminal domain (together with the extracellular loops) is responsible for ligand binding, this accounts for the substantial differences in the pharmacology of the receptors. CRFR1 is the principal receptor activating pituitary corticotropes during the stress response and has nanomolar affinity for CRF. CRFR1 binds Ucn1 with a similarly high affinity, but has no appreciable affinity for physiological doses of Ucn2 and Ucn3. The CRFR2 receptor has highest affinity for Ucn1 and also binds Ucn2 and Ucn3 with high affinity. The affinity of CRFR2 for CRF is about 10- to 30-fold lower than its affinity for the urocortins, but is still below 100 nM. This illustrates the redundancy of the CRF system, wherein multiple ligands share, and under certain circumstances may even compete for, two different receptors (Figure 2).

A further layer of complexity is added to CRF signaling by the observation that multiple transcripts can be generated from both CRFR genes. The CRFR1 gene (*CRHR1*, humans; *Crhr1*, rodents) consists of 14 exons in humans and 13 exons in rodents. More than one dozen alternative transcripts have been found that result from the skipping of one or several exons during gene transcription. The predicted proteins from some of these splice variants partially or completely lack the extracellular domain (ECD), or lack one or several transmembrane domains. Nevertheless, the mechanism responsible for these CRFR1 splice isoforms is unknown and the physiological roles played by CRFR1 splice variants remain presently unclear; direct evidence for the presence of corresponding CRFR1 proteins is lacking for most of these splice isoforms.

A clear example of how alternative splicing can generate functionally different receptor proteins is found in the mammalian gene encoding CRFR2. Two different receptor isoforms, CRFR2α and CRFR2β, are transcribed from the *CRFR2* gene by splicing alternative start exons onto a common set of downstream exons. A third isoform, CRFR2γ, is produced in a similar fashion in primates only. The resulting receptor proteins differ only at the extreme N-terminus of their ECD. As the majority of the ECD is encoded by exons four, five, and six, which are shared by all CRFR2 isoforms, their pharmacological properties do not differ substantially. Nevertheless, the different CRFR2 isoforms vary markedly in their central and

Figure 2 Corticotropin-releasing factor (CRF) and the urocortins (Ucn1, Ucn2, and Ucn3) signal through one of two CRF receptors (CRFR1 and CRFR2). Both CRF receptors differ in the repertoire of ligands that they bind. Furthermore, CRF and Ucn1, and to a lesser extent Ucn2, bind to CRF-binding protein (CRF-BP). The arrows pointing away from each ligand indicate the ligand potential targets. The thickness of the arrows indicates the approximate affinity for each of the ligands.

peripheral tissue distribution, as the transcription of each isoform is driven by its own unique promoter sequence. In rodents, the expression of CRFR2α is largely restricted to the central nervous system (CNS), with expression in the olfactory bulb, ventromedial hypothalamus (VMH), the lateral septum (LS), and the bed nucleus of the stria terminalis (BNST). In contrast, the expression of CRFR2β within the CNS is restricted to the choroid plexus. In the periphery of rodents, the situation is completely reversed. Expression of CRFR2β is widespread, with highest expression levels in skeletal muscle, heart, and skin. Interestingly, CRFR2α is the predominantly expressed isoform in the human periphery. By comparison, CRFR1 is expressed in brain and pituitary as well as in peripheral sites, including adrenal gland, spleen, testis, and skin.

Recently, several other splice variants were discovered that are generated from the CRFR2 gene. One particularly interesting splice variant stems from the deletion of exon six, resulting in a premature stop codon caused by a shift in the amino acid reading frame. The resulting 143-amino-acid protein consists of the complete ECD of CRFR2α followed by a unique hydrophilic 38-amino-acid C-terminal tail. The resulting soluble CRFR2α can abrogate the response to CRF and Ucn1 *in vitro* and may serve as a natural modulator of the actions of CRF and urocortins.

A two-step model has been proposed for hormone binding and receptor activation of CRF receptors. First, the C-terminus of the ligand binds the extracellular domain of the receptor, followed by the partial insertion of its N-terminus into the transmembrane region. This results in a conformational change that leads to exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) on the Gα subunit of the G-protein that is coupled to the third intracellular loop of the receptor. The activated Gα subunit dissociates from the G$\beta\gamma$ dimer, and both species can activate various downstream signaling pathways. In many cells, activation of the G-protein activates the adenylyl cyclase–cyclic adenosine monophosphate (cAMP)/protein kinase A (PKA) pathway. This pathway results in downstream modulation of target proteins by PKA as well as transcriptional regulation via cAMP response element-binding protein (CREB). Depending on the cell type that expresses CRF receptors, other signaling pathways can be activated downstream of CRF receptors via different G-proteins. These pathways include extracellular signal-regulated kinase/mitogen-activated protein kinase (ERK/MAPK), protein kinase C (PKC), nuclear factor-kappa B (NF-κB), and several others.

CRF-Binding Protein

A unique player in the network of CRF signaling exists in the form of a soluble 37 kDa protein that binds CRF with high affinity. This CRF-binding protein (CRF-BP) was initially discovered in late gestational maternal plasma, where it prevents activation of the stress response via the substantial amounts of CRF from placental origin that circulate prior to parturition. The CRF-BP gene consists of seven exons that encode a protein of 322-amino-acids, unrelated to the CRF receptors. In fact, its primary amino acid sequence bears no resemblance to that of any other known protein. CRF-BP is characterized by ten conserved cysteine residues that form five consecutive disulfide bridges, and a single N-linked glycosylation site. CRF-BP orthologs have been demonstrated for a number of vertebrate species and were recently

discovered in species of insects. In mammals, CRF-BP binds CRF and Ucn1 with an affinity that is several fold higher than the affinity of CRF receptors for either peptide. Human CRF-BP also binds mouse, but not human, Ucn2 with nanomolar affinity and does not bind Ucn3 (Figure 2). Interestingly, several peptide fragments, such as CRF(6–33) and CRF(9–33), which consist only of the core of the mature peptide hormone, retain the capacity to bind to CRF-BP with high affinity, but have lost the ability to activate CRF receptors. This indicates that different areas of the peptide hormone are involved in binding to the receptor and to the binding protein.

The high affinity of CRF-BP for CRF and Ucn1 suggests an antagonistic role by preventing these hormones from activating their receptors. Indeed, CRF-BP is expressed in anterior pituitary corticotropes and is capable of abrogating the CRF-induced release of ACTH from pituitary cells *in vitro*. CRF-BP is widely expressed within the CNS, including the cerebral cortex, the amygdala, BNST, olfactory bulb, and various nuclei within the brain stem and hypothalamus. Peripherally, complexes of CRF-BP and CRF are rapidly cleared from the circulation, supporting an antagonistic role for CRF-BP.

Central CRF Pathways Are Involved in Anxiety and Depression

Although initially discovered as an activator of the HPA axis, CRF is produced at many other sites in the brain outside of the parvocellular section of the PVN. Within the hypothalamus CRF is produced in several other nuclei, including the preoptic, supraoptic, and suprachiasmatic nuclei. Prominent sites of CRF localization outside of the hypothalamus include the cortex, the central nucleus of the amygdala (CeA), the BNST, the locus coeruleus (LC), and the parabrachial nucleus (PB). These nuclei are generally associated with autonomic function. Consensus is that within the CNS, CRF acts as a neurotransmitter by activating downstream neurons.

Central CRF pathways are involved in behavioral patterns that are commonly associated with stress, such as changes in arousal and anxiety. Several rodent models have been developed for the measurement and quantification of the behavioral manifestations of arousal and anxiety. Transfer of a rodent from a familiar nonstressful environment, such as its home cage, to a completely new environment is considered an acutely stressful event for the animal. This transition is immediately reflected in a series of behavioral changes that can be measured as a reduction in locomotor activity and reduced exploration of the novel environment, a reduction in rearing, and an increase in grooming and freezing. Injections of CRF (intracerebroventricularly; directly into the ventricles of the brain) can reproduce this panel of behaviors associated with novelty stress. Mice that lack CRFR1 display a marked reduction in anxiety-related behaviors in addition to blunted HPA activation. This suggests that the majority of the anxiogenic effects of CRF are mediated via CRFR1. Data regarding the role of CRFR2 in anxiety are less clear. Both anxiogenic (anxiety-promoting) and anxiolytic (anxiety-reducing) effects have been attributed to CRFR2, and the direction and magnitude of the effects mediated via CRFR2 may be dependent on the precise anatomical location of CRFR2 expression as well as on confounding factors such as gender.

Dysregulation of CRF pathways is implicated in the etiology of depression. CRF concentrations are significantly elevated in the cerebrospinal fluid of depressed patients, and reduction of these levels by electroconvulsive therapy correlates with alleviation of depression symptoms. Several rodent models have been developed that display behavior reflecting some traits associated with depression in human patients. In one of these models a mouse is suspended by the tail and the severity of depression is quantified as the fraction of the time the animal is immobile. In another test mice are subjected to involuntary swimming and depression is measured as a reduction in swimming and climbing behavior and increased immobility. In these animal models for depression, selective CRFR1 antagonists reduce immobility, implicating central CRF pathways that employ CRFR1 in the pathophysiology of depression. Recently, mice were generated that are deficient for the selective CRFR2 agonist Ucn2. One of the major findings in these Ucn2-deficient mice is their antidepression-like phenotype, as measured by reduced immobility in the forced swim test and the tail suspension tests. These experiments demonstrate a prominent role for CRFR1 and CRFR2 in the development of depressive disorders.

Feeding, Digestion, and Metabolism

Several CRF pathways are involved in the regulation of feeding and digestion. Central circuits employing CRF regulate key aspects of appetite control and feeding behavior, while peripheral CRF receptors relay signals that affect gastrointestinal motor functions. Much of the integration of central metabolic cues with peripheral indicators of nutrient status, such as circulating levels of leptin and insulin, takes place in the hypothalamus. It has long been known that injection of CRF and Ucn1 directly into the brain ventricle produces anorexic effects. Activation of either

CRF receptor produces anorexic effects, but with different kinetics. Intracerebroventricular injection of CRFR1-specific agonists results in a rapid inhibition of food intake, while the specific activation of CRFR2 results in prolonged anorexia that requires several hours to establish. These findings are supported by studies on CRF-deficient mice: mice lacking CRFR1 are insensitive to short-onset anorexia induced by a general CRF receptor agonist such as Ucn1, while CRFR2-deficient mice fail to mount prolonged hypophagia following Ucn1 administration. The arcuate nucleus has strong CRFR1 expression while the ventromedial hypothalamus features prominent CRFR2 expression. Both nuclei play key roles in the regulation of food intake and metabolism. The VMH receives abundant projections of Ucn3, and, to a lesser extent, Ucn1, while it is only sparsely innervated by CRF. Ucn2 and Ucn3 are also detected in the arcuate nucleus. These observations suggest that many of the anorectic effects of CRF family peptides are mediated via CRFR2 and that the urocortins constitute its endogenous ligands, modulating appetite control and feeding behavior. CRFR2 expression levels in the VMH drop during fasting and are correlated with circulating leptin levels, suggesting that plasma leptin levels directly or indirectly affect the level of CRFR2 expression in this nucleus. Direct stimulation of the VMH by CRFR2 agonist injection or electrical stimulation not only results in reduced food intake, but also activates the sympathetic nervous system. Via this route energy expenditure is increased through the stimulation of brown adipose tissue (BAT) thermogenesis. Thus, feeding behavior is enhanced and BAT thermogenesis is decreased during starvation, when plasma leptin and consequently VMH CRFR2 expression are low. During times of surplus body energy stores, increased leptin concentrations and CRFR2 levels drive increased BAT thermogenesis and inhibit food intake.

CRF signaling is involved in the regulation of gastrointestinal motor function. Although the inhibition of gastromotor function that is observed during stress is partially mediated via central CRFR2, CRF and urocortins have direct effects on the gastrointestinal tract. Peripheral administration of urocortins delays gastric emptying and inhibits gut motility. These inhibitory effects on gastromotor functions are blocked by selective CRFR2, but not CRFR1, antagonists. In contrast to the inhibition of gastric motility by central and peripheral CRFR2 activation, colonic motility can be stimulated during stress via CRFR1-mediated activation of the parasympathetic nervous system as well as via CRFR1 present in the colonic myenteric nervous system. The physiological relevance of the dichotomy in the activation of different stretches of the gastrointestinal tract is explained by adaptive value in times of stress. Inhibitions of gastric and gut activity and colon evacuation are different ways of inhibiting digestion, thus contributing to the maximal allocation of resources toward responding to stress.

Cardiovascular Effects of Urocortins via CRFR2

It has long been known that CRF influences cardiovascular function. During acute stress, heart rate, blood pressure, and cardiac output increase as the result of activation of the sympathetic nervous system. This overall stimulation of the cardiovascular system is an important adaptive response, assisting an animal to actively cope with a stressful event. Central injection of CRF mimics the cardiovascular effects that are normally observed following stress, provided that the sympathetic nervous system is intact. Since coadministration of a CRFR1-specific antagonist attenuates CRF-induced increases in heart rate, the CRF-induced activation of the sympathetic nervous system is, at least in part, mediated via CRFR1.

In contrast to the generally stimulatory effects of central CRF injections on the cardiovascular system, CRF delivered peripherally causes vasodilatation and a drop in mean arterial blood pressure. Systemic CRF and Ucn1 also increase cardiac contractility. These direct effects of systemically administered CRF and Ucn1 on the cardiovascular system suggest the presence of local CRF receptors. Indeed, CRFR2 is expressed in significant amounts in cardiac tissue, including myocardium, epicardium, arterioles of atrium and ventricle, and aorta. Its role in the cardiovascular system was elegantly demonstrated by comparing the hemodynamic properties of normal mice with mice lacking CRFR2. The latter mice have an elevated mean arterial blood pressure that is insensitive to systemic Ucn1 administration, whereas normal mice respond to Ucn1 with significant and prolonged (>1 h) hypotension. Ucn1 and Ucn2 are potential endogenous ligand(s) for CRFR2 in the cardiovascular system, as both urocortins are expressed in isolated cardiac myocytes. Alternatively, it is possible that CRF family peptides reach the heart via nerve terminals or through the general circulation to activate cardiac CRFR2.

In addition to the effects on blood pressure and cardiac contractility mediated via CRFR2 *in vivo*, urocortins display cardioprotective effects. The expression of Ucn1 and Ucn2 in cultured cardiomyocytes is increased after hypoxia followed by reoxygenation,

a model for cardiac ischemia. The presence of urocortin peptides in media reduces the percentage of cultured cardiomyocytes that can enter apoptosis and necrosis following hypoxia. CRFR2 is required for these cardioprotective effects, since Ucn2 and Ucn3 fail to rescue cardiomyocytes isolated from CRFR2-deficient mice from apoptosis. Moreover, the administration of Ucn2 and Ucn3 immediately following experimentally induced ischemia of the intact rat heart results in a substantial reduction of the infarct zone. These cardioprotective effects of urocortins acting through CRFR2 are of particular interest in the context of cardiac ischemia. In particular, the fact that Ucn2 and Ucn3 lack the affinity for CRFR1 required for HPA activation or induction of anxiety makes them promising targets in the quest for therapeutical interventions aimed at alleviation of the adverse outcome of cardiac ischemia in humans.

CRF and Pregnancy

CRF and Ucn1 as well as their cognate receptors and CRF-BP are expressed in different tissues of the female reproductive system. CRF plays a remarkably versatile role affecting pregnancy, from blastocyst implantation to parturition. Mammalian reproduction, in which the fetus is carried inside the womb, is an awkward phenomenon from an immunological point of view. The developing fetus is only 50% 'self': the paternal contribution to the fetus qualifies it as a foreign body and would as such subject it to attack by the maternal immune system. For obvious reasons, this would be incompatible with successful reproduction. CRF protects the fetus from attack by the maternal immune system and simultaneously prevents the developing fetal immune system from attacking maternal tissues. Around the time of blastocyst implantation into the uterus, CRF is produced in the embryonic trophoblast and the maternal decidua, the contact interface of maternal and fetal tissues. Locally, CRF increases the expression of an important proapoptotic factor, Fas ligand (FasL), via CRFR1. FasL induces apoptosis in cells carrying its cognate binding partner, Fas, which is expressed by many immune cells. As Fas only appears at the cell surface following leukocyte activation, CRF-induced upregulation of FasL at the site of implantation allows the specific deletion of only those immune cells that are activated at the maternal–fetal interface.

CRF is expressed in the placenta of primates, but not rodents, and CRF from placental origin is detectable in the maternal circulation beginning approximately halfway through gestation. Circulating CRF levels rise sharply toward the end of pregnancy and, close to term, reach levels equivalent to peak CRF levels measured in the hypothalamic–pituitary capillary bed during acute HPA activation. Yet, these high levels of CRF do not activate the HPA axis, because they are bound to a surplus of CRF-BP, which is also produced by the placenta. In the fetal circulation, increasing levels of CRF will activate the fetal HPA axis. This results in glucocorticoid release from the fetal adrenal gland, a process that drives the maturation of a number of fetal organs, including the lungs in preparation for delivery.

Throughout much of gestation, CRF in the placenta evokes quiescence of uterine smooth muscle cells via the CRFR1-dependent activation of the PKA pathway. In a series of intricate molecular switches that involve the oxytocin-dependent phosphorylation of CRFR1, CRFR1 is coupled to a different G-protein toward parturition. This causes a shift in the intracellular cascade that is activated upon ligand binding to CRFR1 from PKA to PKC. Instead of inducing myometrial relaxation, CRF now can assist in the induction of myometrial contractility and labor.

Summary

CRF was initially noted for its potent capacity to activate the stress response. In the decades that followed its discovery, three additional ligands related to CRF, as well as two receptors and a soluble binding protein, have been discovered. While CRF still has strong ties to 'stress,' we now know that CRF signaling is involved in a multitude of other central and peripheral processes. These include the regulation of anxiety, arousal, and depression, the modulation of food intake and sympathetic nervous system activation, control of cardiovascular output as well as cardioprotection, and a combination of fascinating roles in the regulation of human reproduction. Many of these processes are at the heart of human well-being, which has sparked widespread interest in CRF. The challenge that lies ahead will be the development of strategies to intervene in isolated CRF pathways without causing widespread activation of CRF receptors throughout the body.

Introduction

Corticotropin-releasing factor (CRF) is a neuropeptide that was first isolated from the hypothalamus on the basis of its capacity to stimulate the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. Its localization to parvocellular neurosecretory neurons of the paraventricular hypothalamic nucleus (PVH) defined the central limb of the hypothalamic–pituitary–adrenal (HPA) axis. It was recognized early on, however, that the central distribution of CRF is quite broad and includes aspects of the limbic forebrain associated with affective behaviors and brain stem cell groups involved directly in central autonomic control. The subsequent demonstration that the peptide could act within the brain to elicit stresslike behavioral (increased anxiety, arousal, decreased appetite) and autonomic (sympathomimetic) responses gave rise to the hypothesis that the central CRF system may act at multiple levels of the central nervous system to activate, and even integrate, complementary modes of stress adaptation. This notion has provided a dominant unifying framework guiding much contemporary work in the field of stress neurobiology.

The idea that individual signaling molecules may serve similar or complementary functions at diverse sites of expression has been entertained for some time. While this is not a universal generalization, certain catecholamines (epinephrine, norepinephrine) that serve as principal effectors of the sympathoadrenal system in the periphery are also prominently expressed, and situationally active, in aspects of central stress-related circuitry. In addition, there are a number of 'brain–gut peptides' (including CRF) whose expression in the peripheral autonomic and/or enteric nervous systems on one hand, and in the brain on the other, is associated with defined and complementary roles in digestive functions and appetitive control, respectively. Here we consider the functional and anatomical organization of the central CRF system and evaluate evidence bearing on its hypothesized role as an arbiter of multiple modes of stress adaptation.

The CRF Family of Signaling Molecules

CRF exerts its biological activities by binding G-protein-coupled receptors that activate adenylate cyclase. The type 1 receptor (CRFR1) is expressed by anterior pituitary corticotropes and can account for the neuroendocrine actions of the peptide. CRFR1 is expressed widely in brain (Figure 1), though its distribution is more suggestive of dominant roles in cortical, cerebellar, and sensory information processing than in the stress-related behavioral and autonomic functions for which CRF is better known. A structurally related type 2 receptor (CRFR2) exists in two principal forms; one variant (CRFR2β) is expressed in the periphery and the choroid plexus, while a second (CRFR2α) is expressed in brain, where its distribution is distinct from, and more limited than, that of CRFR1. The binding affinity of CRF for CRFR2 is relatively low. This information, coupled with the recognition that certain nonmammalian vertebrates express not only obvious CRF homologs but also other structurally related peptides such as sauvagine (from frog) and urotensin I (from fish) prompted an effort to identify new mammalian CRF family members, culminating in the cloning of three novel peptides, termed urocortins (Ucns 1–3). Ucn 1 binds both CRFRs with high affinity, while Ucn 2 and 3 are CRFR2-selective ligands. Each of the Ucns exhibits a distinctive and discrete expression pattern in brain (Figure 1), with variable potentials for interacting with cell groups expressing CRFR2 (e.g., Ucn 3) or both receptors (Ucn 1). There is a strong basis for considering these components of the central CRF system as functioning in a unified manner in stress adaptations. Shortly after the identification of Ucn 1, evidence was provided that this peptide can act centrally to mediate some stress-related functions originally attributed to CRF. Moreover, a substantial body of evidence supports an interaction of CRFR1- and CRFR2-dependent mechanisms in sculpting a variety of neuroendocrine, autonomic, and behavioral responses to stress.

In keeping with their binding affinities, a strong general correspondence has been found between the distribution of neurons that are activated in response to central administration of CRF and sites of CRFR1 expression, while central Ucn 1 activates both CRFR1- and CRFR2-bearing targets. The principal exceptions are robust activational responses provoked by either peptide in a set of interconnected cell groups that

Figure 1 Central distribution of corticotropin-releasing factor (CRF) signaling molecules. Schematic representation on a sagittal view of the rat brain of major sites of cellular expression of CRF-related peptides and receptors; major axonal projections of peptidergic neurons are indicated by arrows. In addition to being expressed by neurosecretory neurons of the paraventricular hypothalamic nucleus (PVH) that comprise the final common path for effecting stress-induced activation of adrenocorticotrophic hormone (ACTH) secretion, CRF (top) is broadly expressed in brain, including in limbic forebrain (BST, CeA) and central autonomic (NTS, VLM, PB, IML) cell groups. The expression of urocortins (Ucn 1–3; middle) is more restricted. The dominant seat of Ucn 1 expression is the Edinger–Westphal nucleus (EW), whose outputs include projections to central autonomic cell groups (PVH and NTS). Ucn 2 is weakly expressed in brain, and axonal projections immunoreactive for this peptide have not been demonstrated. Ucn 3 is expressed in a few discrete forebrain regions that project to some major sites of type 2 CRF receptor expression (medial amygdala, lateral septum and ventromedial hypothalamus). The two known CRF receptor subtypes (CRFR1 and CRFR2, bottom) are differentially distributed, with CRFR1 expression being more widespread. Receptor expression in demonstrated sites of peptide action in eliciting stresslike physiological and behavioral responses is limited mainly to the parabrachial nucleus (CRFR1) and NTS (CRFR2). comprise a core circuitry for central autonomic and neuroendocrine regulation – responses not readily explicable on the basis of CRFR distributions. These cell groups, collectively termed the central autonomic system (CAS), are of critical importance as most are implicated as principal sites of CRF action in eliciting stress-related responses but have been found to display limited capacity for CRFR expression or CRF binding. These include the central nucleus of the amygdala (CeA), which has been identified repeatedly as a site of CRF action relevant to behavioral (anxiety-like) and autonomic stress responses; the PVH, whose hypophysiotropic CRF neurons receive a CRF-immunoreactive input, defining a substrate for posited feedback and feed-forward effects on the central limb of the HPA axis, and which is otherwise a sensitive site for peptide effects on ingestive behavior and cardiovascular responses; and the nucleus of the solitary tract (NTS) and ventrolateral medulla (VLM), the linchpins of interoceptive information processing in brain and where CRF acts at low doses to elicit sympathomimetic effects on cardiovascular parameters. Many would include among this grouping the locus coeruleus, whose widespread noradrenergic output is thought to set levels of arousal and 'behavioral vigilance' and where unit activity is enhanced by local administration of CRF. Overall, the lack of an apparent basis in CRFR expression for the generalized CAS activation elicited by central peptide injection poses an unresolved challenge to the widely held view of CRF as a common arbiter of multiple modalities of stress responses.

The CAS and Its Role in Adaptive Responses to Stress

The basic organization of circuitry considered to compose the CAS is shown schematically in Figure 2. Integral components include aspects of the bed nucleus of the stria terminalis (BST), the PVH, the CeA, the lateral parabrachial nucleus, the A1 and C1 catecholamine cell groups of the VLM, and the medial division of the NTS. The NTS is the pivotal sensory structure in this system as it is the principal central nervous system recipient of primary visceral sensory input carried by the vagus and glossopharyngeal nerves and projects directly to all other components, which, in turn, are extensively interconnected with one another. Both the NTS and the VLM also receive noxious inputs by way of the marginal zone of the spinal dorsal horn, indicating a broader range of sensory control over this circuitry. Major effector arms of the CAS include the main cell groups governing the neural arm (sympathetic preganglionic neurons) and endocrine arm (CRF-expressing neurosecretory neurons) of the stress response. Equally direct access to the limbic forebrain (BST and CeA) provides a basis for invoking mechanisms involved in evaluating the emotional significance of environmental events and in effecting appropriate changes in behavior. Though less elaborately interwoven into this system, the locus coeruleus is considered here along with it as it is interconnected with other CAS components, mediates relevant arousal-like functions, is among the sites at which cellular effects of CRF are best characterized, and, like *bona fide* CAS components, receives a CRF and/or Ucn input that arises from other CAS structures.

The validation of inducible immediate-early genes such as *c-fos* and its protein product, Fos, to serve as markers with which to identify neurons that are activated in response to salient environmental events has enabled substantial progress to be made in unraveling central stress-related circuitry. This work has identified the CAS as being recruited to action in a nearly invariant manner in response to a wide variety of acute stressors, though the extent to which it may mediate adaptive responses may vary as a function of the nature of the challenge. Thus, in so-called physiological stress models (e.g., hemorrhage or immune challenges), core CAS structures are dominant seats of cellular activation, and evidence implicating projections originating from the sensory arm of these pathways in mediating HPA and other adaptive responses in these two models has been provided. Models of the other major, 'emotional' stress category (e.g., restraint, footshock) are also accompanied by widespread CAS activation, though the extent of this activation is variable and less pervasive than that seen in physiological models. The fact that the CAS is so generally called into play in response to diverse challenges is consistent with the view that it may constitute a system for reflexive mediation of generalized alarm responses, in a manner coarsely analogous to the sympathoadrenal system in the periphery. It must be noted, however, that for no emotional stress model

Ucn 1	+	+	+
Ucn 2	−	−	+
Ucn 3	−	−	+

Table 2 Effects of CRFR disruption on CRF-induced CNS responses

Disruption	*CRFR1-expressing cell groups*	*CRFR2-expressing cell groups*	*Central autonomic system cell groups*
CRFR antagonist	↓	−	↓
CRFR1 knockout	↓	−	−
CRFR2 knockout	−	−	↑
Double CRFR KO	↓	−	−

has the circuitry underlying CAS activation been identified, and for some such paradigms, the evidence supports a modulatory, rather than a mediating, role.

To what extent does the CRF signaling system participate in the brain's processing of stressful information? Central injections of CRF or Ucn 1 elicit patterns of cellular activation (e.g., Fos induction) that share substantial similarities with those elicited by various stressors, including recruitment of all cell groups of the CAS, as defined here. These responses can be blocked in a dose-related manner by coadministration of nonselective CRFR antagonists. But the evidence supporting an involvement of CRF signaling mechanisms in shaping the brain's response profile in stressful situations is less compelling. Studies involving central administration of CRFR antagonists have reported variable, and generally limited, effectiveness in mitigating stress-induced activation of CAS components. These issues are raised by recent studies of ligand- or stress-induced central nervous system activational profiles in mice genetically engineered to lack functional expression of either or both of the known CRFRs. Thus, central administration of CRF to mice lacking in CRFR1 expression gives rise to markedly reduced activation of cell groups in which CRFR1 is prominently expressed, including cerebral cortex and cerebellum, but CAS responses are unaffected relative to those of genetically intact mice (Table 1 and 2). Moreover, CRFR1-deficient animals display no alteration of CAS responses to acute physiological (intravenous endotoxin injection) or emotional (restraint) stressors relative to wild-type controls, while CRFR2-deleted animals showed exaggerated recruitment of some CAS cell groups in

Figure 3 Stress-induced cellular activation of central autonomic cell groups in wild-type and corticotropin-releasing factor receptor (CRFR)-deficient mice. Immunohistochemical localization of Fos protein (a generic marker of neuronal activation) induced in the paraventricular nucleus (PVH; top) in response to a physiological stressor (intravenous lipopolysaccharide (LPS)), and in the locus coeruleus (LC) in response to an emotional stressor (30 min restraint), as a function of CRFR status. None of the CRFR knockouts (KOs) disrupt stress-induced responses in central autonomic system, which are enhanced in the LC of CRFR2 mutants. MesV, mesencephalic trigeminal nucleus; V3, third ventricle.

response to the same challenges (Figure 3). Mice lacking both receptors display stress-induced response profiles like those of CRFR1 mutant animals.

These findings define a basic paradox. On one hand, studies employing functional assays strongly support an involvement of the central CRF system in modulating endocrine, autonomic, and behavioral responses to stress and point toward CAS structures as key sites of action in this regard. Yet on the other hand, these cell groups display limited capacity for CRFR expression, and their engagement in response to ligand administration or stress is not critically dependent on the integrity of either or both of the known CRFRs.

Issues in Understanding CAS Activation by Central Peptide Administration and Stress

Questions remain as to the basis for signaling by CRF-related peptides at demonstrated sites of action that are known to exhibit limited expression of cognate ligands and/or receptors and as to how these elements participate in the response of CAS components to central administration of ligand or stress. A number of possible means for reconciling the seemingly pervasive ligand–receptor misalignment in this system may be considered.

CRFR Protein Expression

The lack of a firm understanding of CRFR distributions at the protein level remains a major impediment for work aimed at pinpointing central sites and mechanisms of peptide action. Immunohistochemical studies using a variety of CRFR antisera have been published, but these often describe results at odds with the consensus of analyses at the messenger RNA level, and not one has been conducted to an unimpeachable standard of histochemical rigor. There is abundant evidence to document axonal transport of receptors, which may undergo differential trafficking to assume distinctive intracellular localizations in different cell types. Thus, 'presynaptic' receptor localization may define substrates for reconciling instances of apparent mismatch, such as recent electrophysiological evidence supporting presynaptic CRFR1-mediated effects in the CeA. Moreover, stress-inducible expression of CRFR1 has been described in the PVH, as has a capacity for modulation of CRFR2 expression. The range of sites and conditions under which such capabilities may be manifested as receptor protein expression remains to be determined.

Novel Receptors?

As noted above, CAS activation induced by central peptide injection can be blocked in a dose-related manner by coadministration of CRFR antagonists but is unabated in mice lacking either or both of the known CRFRs. These findings are consistent with the existence of a novel CRFR expressed in one or more CAS components. It may be noted that three distinct CRFRs have been cloned in a catfish species, with all three subtypes exhibiting distinctive distributions, including in brain. Arguing against the existence of a third receptor is the fact that recently isolated receptor isoforms in other G-protein-coupled receptor families have all displayed structural

similarities to existing receptors, and searches of human and mouse genome databases for genes related to sequences of various domains of the known CRFRs have failed to identify a gene with significant relatedness to CRFRs or other members of the secretin receptor family.

Receptor Cross-Talk

CAS activation observed in intracerebroventricular injection studies could be a result of interaction of CRF peptides with heterologous receptors. There are precedents for a degree of promiscuity among some subgroups of G-protein-coupled receptors, which may bind more than one structurally related ligand. While there appears to be no precedent for such cross-talk in the CRF system, several members of the secretin receptor family, including receptors for glucagon-like peptide 1, pituitary adenylate cyclase-activating peptide, and vasoactive intestinal polypeptide, are distributed in at least some CAS components and could comprise pharmacologic targets for CRF-related ligands. Further structural characterization of the ligand-binding domains of secretin receptor family members should help define potential participants in such interactions, and their involvement can then be tested using pharmacologic and genetic tools.

Interaction of CRFR- and CRFR2-Dependent Mechanisms

Whether or not the central CRF system proves to be indispensably involved in any given mode of stress adaptation, a growing body of evidence supports an interaction of CRFR1- and CRFR2-dependent mechanisms in shaping such responses. The generally hypo- and hyper-responsive phenotypes of CRFR1 and CRFR2-deficient mice, respectively, may be viewed as indicative of antagonistic interactions. However, there is evidence from both genetic and pharmacologic studies that the two receptors' influences on feeding suppression, anxiety, and HPA axis activation may be cooperative and exerted over distinct time domains. Studies of ligand and stress effects in CRFR-mutant mice provide ample evidence of receptor interplay in CAS sites of action for the above-mentioned responses. The anatomical organization that provides for convergent CRFR influences on a wide range of stress-related endpoints is completely obscure.

Other Ligand-Binding Proteins

A CRF-binding protein (CRF-BP) distinct from CRFRs was isolated as a circulating factor capable of binding and reversibly neutralizing CRF actions, thus preventing inappropriate pituitary–adrenal activation during pregnancy in primates. The CRF-BP is expressed prominently in brain, where its distribution suggests multiple potential sites and modes of interaction with CRF. The question of whether the CRF-BP may serve roles beyond its capacity to passively sequester peptide remains controversial. From synthetic CRF fragments that are bound with high affinity by the CRF-BP, but not either CRFR, evidence has been obtained to support an active role for the BP in signaling. This may be significant as the CRF-BP is more broadly expressed in the CAS than either known CRFR.

In a similar vein, a novel CRFR2α variant has been recently cloned and expressed, and its truncated form predicts that it exists as a soluble receptor (CRFR2α-S). Its abundance in brain rivals that of the membrane-bound form, raising the possibility that CRFR2α-S may serve a role in modulating signaling by CRFR2 agonists. The fact that the reported central distribution of the soluble receptor more closely mimics that of CRFR1 than CRFR2 is ostensibly at odds with this view.

Role of Ucns

Like other CRFR agonists tested to date, central administration of Ucn 2 or 3 strongly activates CAS cell groups; unexpectedly, though, sites of CRFR2 expression are unresponsive. Resolution of this paradox is needed to understand the basis for CRFR2-mediated signaling and its interaction with CRFR1-dependent mechanisms. At least three alternate explanations of this phenomenology may be considered: that CRFR2 activation may be CRFR1-dependent, that the naturally occurring form(s) of Ucn 2 and 3 may differ in activity from those predicted by complementary DNA sequences, and that access of centrally administered CRFR2 agonists may be limited by the actions of CRFR2α-S. Interest in the central functions of Ucns centers about their capacities to elicit stresslike anorexic and anxiolytic behavior, actions originally attributed to CRF, and, as putative endogenous CRFR2 ligands, to modulate a range of CRFR1-mediated activities. Each of the Ucns displays a restricted and unique central distribution (Figure 2). Only Ucn 1 pathways have been found to innervate CAS structures (mainly NTS) with any prominence. Ucn 3-containing projections are best aligned with major sites of CRFR2 expression in limbic forebrain (lateral septum, medial amygdala, ventromedial hypothalamus), which have the capacity to influence CAS mechanisms, albeit indirectly.

Significance

A wealth of evidence has implicated the central CRF system in the modulation of neuroendocrine, autonomic, and behavioral responses to stress, and CAS cell groups have been repeatedly implicated as

important sites of action in this regard. Studies involving repeated or chronic central administration of CRF have implicated elevated peptide levels in the genesis of stress-related physiological and behavioral disorders. Nevertheless, the relative paucity of evidence for cellular expression of CRFRs within the CAS and the general failure of pharmacologic or genetic disruption of CRFR signaling to mitigate stress-induced CAS activational responses pose stern questions as to mechanisms that provide for CRF system involvement in stress adaptations. Small-molecule CRFR1 antagonists are currently being evaluated in clinical trials for the treatment of major depression, other anxiety-related disorders, and at least one systemic condition, irritable bowel syndrome. Additional applications of drugs that target this signaling system in a range of stress-related illnesses are being explored avidly. Deeper understanding of the sites and mechanisms through which such agents act is essential to exploiting them in an informed and effective manner.

Cotransmission

G Burnstock, Royal Free and University College Medical School, London, UK

Early Background

For many years, the understanding of neurotransmission has been dominated by the concept that one neuron releases only a single transmitter, known as 'Dale's Principle.' This idea arose from a widely adopted misinterpretation of Dale's suggestion in 1935 that the same neurotransmitter was stored in and released from all terminals of a single neuron, a suggestion which did not specifically preclude the possibility that more than one transmitter may be associated with the same neuron. Several lines of evidence emerged which were inconsistent with the single transmitter concept, and it is now known that individual neurons contain and can release a large number and variety of substances which are capable of influencing target cells. This phenomenon of 'cotransmission' is widespread, involving virtually all known transmitter systems.

Early hints of cotransmission came in the 1950s with evidence for the involvement of both noradrenaline (NA) and acetylcholine (ACh) in sympathetic transmission. Koelle identified acetylcholinesterase in some adrenergic neurons in 1955, while Burn and Rand introduced the concept of a 'cholinergic' link in adrenergic transmission in 1959. Another line of evidence provided by Hillarp concerned the coexistence of adenosine 5′-triphosphate (ATP) with catecholamines, first in adrenal chromaffin cells and later in sympathetic nerves. Inconsistencies in the single transmitter hypothesis provided by these and other studies from the early literature were rationalized in an article by Burnstock in 1976 with the provocative title,"Do some nerve cells release more than one transmitter?" Today it is widely accepted that cotransmission is an integral feature of neurotransmission.

A role for ATP as a cotransmitter in sympathetic, parasympathetic, sensory–motor, and enteric nonadrenergic, noncholinergic (NANC) inhibitory nerves was supported by research from Burnstock and colleagues, while Hökfelt and colleagues focused on the co-localization, vesicular storage, and release of peptides from both peripheral and central nerves.

Furness and Costa introduced the concept of 'chemical coding' to describe the combination of potential neurotransmitters found in enteric nerves, and this concept has since been applied to other nerve types, in both peripheral and central nervous systems CNSs (see Figure 1). Co-localized substances are not necessarily cotransmitters; they can (especially peptides) act as pre-and/or postjunctional neuromodulators of the release and actions of the principal cotransmitters. The proportions of cotransmitters vary considerably between species and organs and show plasticity of expression during development and in pathological conditions. In general, classical transmitters are contained in small synaptic vesicles, whereas peptides are stored in large granular (dense-cored) vesicles (LGVs), although small molecule transmitters are sometimes stored together with peptides in LGVs.

Pharmacological studies of pre- and postjunctional neuromodulation provide evidence which is complementary to the concept of cotransmission. For example, parallel presynaptic modulation of transmitter overflow supports the concept of closely associated co-release, while postjunctional synergism between co-localized transmitters provides justification of cotransmission in terms of transmitter economy.

Sympathetic Nerve Cotransmission

There is substantial evidence to show that NA, ATP, and neuropeptide Y (NPY) are cotransmitters in sympathetic nerves, having differentially important roles as transmitters and neuromodulators, depending on the tissue, the species, and the parameters of stimulation. Most of the early studies establishing the model of cotransmission of NA and ATP were made on the vas deferens, a tissue with a high density of sympathetic nerves. Subsequently, numerous studies demonstrated that cotransmission of NA and ATP also occurs in other visceral organs and many different blood vessels in a variety of species.

The first indication that ATP might be released from sympathetic nerves was the demonstration that stimulation of sympathetic nerves by Su, Bevan, and Burnstock in 1971 led to release of tritium from taenia coli preincubated in [^{3}H]adenosine (which is taken up and converted to [^{3}H]ATP). Later Sol Langer and colleagues suggested that the substantial residual NANC response of the cat nictitating membrane observed after depletion of NA by reserpine was due to the release of ATP remaining in the sympathetic nerves. In retrospect, there was a good indication that the excitatory junction potentials (EJPs) recorded in the guinea pig vas deferens when the electrophysiology of sympathetic nerve smooth muscle transmission was first described by Burnstock and Holman in 1960 were due to ATP released as a cotransmitter from sympathetic nerves rather than to NA. It was puzzling at the time that adrenoceptor antagonists failed to block

Figure 1 Schematic diagram of the principal cotransmitters with ATP in the nervous system. Nerve terminal varicosities of (i) sympathetic, (ii) parasympathetic, (iii) enteric (NANC inhibitory), (iv) sensory–motor neurons, and (v) central nervous system (CNS). Reproduced from Burnstock G (2007) Physiology and pathophysiology of purinergic neurotransmission. *Physiological Reviews* 87: 659–797, with permission from The American Physiological Society.

the EJPs, although guanethidine, a drug that prevents the release of sympathetic transmitters, was effective. It was more than 20 years later that NANC EJPs were shown to be blocked by desensitization of the ATP (P2) receptors by α,β-methylene ATP and mimicked by ATP. After destruction of sympathetic nerves with 6-hydroxydopamine, purinergic nerve-mediated responses were abolished. ATP is co-stored with NA in small and large vesicles. Differential prejunctional modulation of the release of NA and ATP by various agents has been shown in the vas deferens, perhaps indicating that NA and ATP are stored in different vesicles.

Cotransmission of NA and ATP in perivascular sympathetic nerves supplying the rabbit aorta, portal vein, and saphenous, pulmonary and mesenteric arteries and the dog basilar artery has been demonstrated. Electrophysiological studies have shown that in a number of vessels, the electrical response to stimulation of perivascular sympathetic nerves is biphasic: an initial fast, transient depolarization or EJP of the vascular smooth muscle is followed by a slow, prolonged depolarization. The EJP and slow depolarization are mimicked by the effects of ATP and NA, respectively. Considerable variation exists in the proportions of NA and ATP utilized by sympathetic nerves. For example, in guinea pig submucosal arterioles, both vasoconstriction and EJPs, evoked in response to electrical stimulation of sympathetic nerves, are mediated exclusively by ATP, with NA assuming the role of a neuromodulator, acting through prejunctional α_2-adrenoceptors to depress transmitter release. At the other extreme, in rat mesenteric arteries, the purinergic component is relatively small. In addition, it has been noted that the purinergic component is optimal with short bursts of low-frequency stimulation, whereas longer durations of higher frequency favor adrenergic transmission.

NPY has been found to be present in LGV in most sympathetic nerves. The release of NPY, as well as

Figure 2 Schematic of sympathetic cotransmission. Adenosine 5′-triphosphate (ATP) and noradrenaline (NA) released from small granular vesicles (SGV) act on P2X and α_1 receptors on smooth muscle, respectively. ATP acting on inotropic P2X receptors evokes excitatory junction potentials (EJPs), increase in intracellular calcium ($[Ca^{2+}]_i$), and fast contraction while occupation of metabotropic α_1 adrenoceptors leads to production of inositol triphosphate (IP_3), increase in $[Ca^{2+}]_i$, and slow contraction. Neuropeptide Y (NPY) stored in large granular vesicles (LGV) acts on release both as a prejunctional inhibitory modulator of release of ATP and NA and as a postjunctional modulatory potentiator of the actions of ATP and NA. Nucleotidases are released from nerve varicosities and are also present as ectonucleotidases.

NA and ATP, in response to electrical stimulation of sympathetic nerve terminals is prevented by guanethidine. The major role of NPY in the vasculature, and in the vas deferens, appears to be that of a pre- and/or postjunctional modulator of sympathetic transmission since it has little direct postjunctional action or causes contraction only at high concentrations (see Figure 2). Direct vasoconstrictor actions of NPY have, however, been demonstrated in some vessels. At the prejunctional level, NPY has potent inhibitory

effects, reducing the release of NA and ATP from sympathetic nerves. Postjunctionally, NPY generally acts to enhance the actions of sympathetic nerve stimulation, NA, and ATP.

Although 5-hydroxytryptamine (5-HT) immunofluorescent nerves have been localized in a number of vessels, for the most part 5-HT is not synthesized and stored in separate nerves but is taken up, stored in, and released as a 'false transmitter' from sympathetic nerves. Enkephalins have been shown to coexist with NA in cell bodies and fibers of some postganglionic sympathetic neurons. Both NA and met-enkephalin are co-released by transmural stimulation in a guanethidine-sensitive manner. The functional significance of sympathetic coexistence of opioids is likely to be related to their prejunctional inhibitory effects on sympathetic transmission.

Parasympathetic Nerve Cotransmission

The classical evidence for cotransmission of ACh and vasoactive intestinal polypeptide (VIP) in certain postganglionic parasympathetic neurons comes from pharmacological studies performed by Lundberg in 1981 on cat salivary glands. ACh and VIP are released from the same parasympathetic nerve terminals in response to transmural nerve stimulation. During low-frequency stimulation, ACh is released to cause an increase in salivary secretion from acinar cells and also to elicit some minor dilatation of blood vessels in the gland. VIP is preferentially released at high frequencies to cause marked vasodilatation of blood vessels, and while it has no direct effect on acinar cells, it acts as a neuromodulator to enhance both the postjunctional effect of ACh on acinar cell secretion and the release of ACh from nerve varicosities via prejunctional receptors. Vasodilator nerves to the uterine arteries in the guinea pig contain immunoreactivity to VIP, which coexists with dynorphin, NPY, and somatostatin. NPY-like immunoreactivity has been reported in some of the choline acetyltransferase-/VIP-containing neurons of the parasympathetic ciliary, sphenopalatine, otic, and pterygopalatine ganglia with targets including the iris and cerebral vessels.

Autonomic control of penile erection, involving relaxation of the smooth muscle of the corpus cavernosum as well as dilatation of other penile vascular beds, has traditionally been attributed to the vasodilator effects of ACh and VIP released from parasympathetic nerves. More recently, nitric oxide (NO) released from nerves arising from nerves in the pelvic ganglia have been claimed to play a role in smooth muscle relaxation leading to penile erection. Fibers containing NO synthase, shown by lesion studies to arise from parasympathetic cell bodies in the sphenopalatine ganglia, have been localized in the adventitia of cerebral arteries, and many of these also contain VIP. A functional role for perivascular neuronal NO in cerebral arteries has been identified in studies showing that stimulation of adventitial nerve fibers causes vascular relaxation, which is attenuated by inhibitors of NO synthase.

Parasympathetic nerves supplying the urinary bladder utilize ACh and ATP as cotransmitters, in variable proportions in different species, and by analogy with sympathetic nerves, ATP again acts through P2X ionotropic receptors to produce EJPs and fast contraction, while the slow component of the response is mediated by a metabotropic receptor, in this case muscarinic. There is also evidence for parasympathetic, purinergic cotransmission to resistance vessels in the heart and airways.

Sensory–Motor Nerve Cotransmission

The neuropeptides substance P (SP) and calcitonin gene-related peptide (CGRP) are the principal transmitters of primary afferent nerves and have been shown to coexist in the same terminals. Furthermore, with the use of colloidal gold particles of different sizes, they have been shown to coexist in the same large granular vesicles. The motor (efferent) function of sensory nerves has been demonstrated in rat mesenteric arteries, where evidence exists for a role for CGRP as the mediator of vasodilatation following release from sensory–motor nerves. In contrast, SP is not co-released with CGRP by electrical stimulation, and SP has little or no vasodilator action on rat mesenteric arteries. While it is possible that SP released from nerves supplying the microvasculature could produce vasodilatation via SP receptors on endothelial cells, it is most unlikely to reach the endothelium without degradation in larger blood vessels. It may be that the role of the coexisting SP is either trophic or sensory (and not motor).

Other peptide and nonpeptide substances, including neurokinin A, somatostatin, VIP, and ATP, have been described in capsaicin-sensitive sensory neurons. Unmyelinated sensory neurons containing cholecystokinin (CCK)/CGRP/dynorphin/SP have been shown to project to cutaneous arterioles in guinea pig skin. Neurons from the same ganglia which contain CCK/CGRP/SP innovate arterioles of skeletal muscle, CGRP/dynorphin/SP nerve fibers mostly supply the pelvic viscera, and CGRP/SP fibers run mainly to the heart, large arteries, and veins. There is also evidence for a sensory role for ATP, and it has been proposed that ATP may coexist in sensory nerve terminals with SP and CGRP.

Intramural Nerve Cotransmission

Intrinsic neurons exist in most of the major organs of the body. Many of these are part of the parasympathetic nervous system, but certainly in the gut and perhaps also in the heart and airways, some of these intrinsic neurons are derived from neural crest tissue, which differs from that which forms the sympathetic and parasympathetic systems and appears to participate in local reflex actions independent of the CNS.

The enteric nervous system contains several hundred million neurons located in the myenteric plexuses between muscle coats and the submucous plexus. The chemical coding of these nerves has been examined in detail. A subpopulation of these intramural enteric nerves provides NANC inhibitory innervation of the gastrointestinal smooth muscle. It seems likely that three major cotransmitters are released from these nerves. ATP produces fast inhibitory junction potentials, NO also produces inhibitory potentials but with a slower time course, while VIP produces slow tonic relaxations. The proportions of these three transmitters vary considerably in different regions of the gut and in different species; for example, in some sphincters, the NANC inhibitory nerves utilize largely VIP, in others largely NO, while in nonsphincteric regions of the intestine, ATP is more prominent. In recent papers, evidence has suggested that ACh and ATP are fast excitatory cotransmitters to myenteric neurons and that there may be co-localization of ACh, ATP, and serotonin in enteric S neurons. Detailed studies have allowed a very complete mapping of the complex neuronal markers and projections of enteric neurons. Several peptidergic substances, including NPY, VIP, peptide histidine isoleucine, SP, and CGRP, have been identified in enteric neurons, often coexisting (up to five peptides in the same neuron) with the neurotransmitters NA, ACh, 5-HT, NO, and ATP. The precise roles of the coexisting substances, however, have not for the most part been established, except for the proposed combinations of ACh and SP in the excitatory nerves and ATP, NO, and VIP in the NANC inhibitory neurons involved in peristaltic reflexes.

Studies of intrinsic cardiac neurons in culture have shown that subpopulations of intrinsic nerves in the atrial and intra-atrial septum contain and/or release cotransmitters, including ATP, NO, NPY, Ach, and 5-HT. Many of these nerves project to the coronary microvasculature and produce potent vasomotor actions. NO and ATP have been shown to be the mediators of NANC vasodilatation of the rabbit portal vein.

CNS

Evidence for ATP's being a cotransmitter with established neurotransmitters in the CNS has been reported. In preparations of affinity-purified cholinergic nerve terminals from the rat cuneate nucleus, ATP and ACh are co-released. Co-release of ATP with catecholamines from neurons in the hypothalamus and locus ceruleus has been reported, and there is recent evidence for co-release of ATP with γ-aminobutyric acid (GABA) in dorsal horn and lateral hypothalamic neurons, and for ATP with glutamate in the hippocampus. Co-localization of functional nicotinic and ionotropic nucleotide receptors has been identified in isolated cholinergic synaptic terminals in the midbrain; ATP and dopamine (DA) are probably co-released from the terminals of ventral tegmental neurons in the nucleus accumbens.

Co-release and interaction of two fast inhibitory cotransmitters, GABA and glycine, in synaptic bouton preparations of the sacral dorsal commissural nucleus of the sacral spinal cord have been described. Earlier papers showed that glycine/GABA cotransmission occurred in brain stem motor neurons and spinal interneurons. Co-release of NA and DA from neurons in the cerebral cortex has also been reported. Neurons in the tuberomammillary nucleus in the posterior hypothalamus contain histamine, GABA, galanin, enkephalin, and SP as cotransmitters. GABA/somatostatin cotransmission has been reported at synapses in a subpopulation of amygdala projection neurons to the nucleus tractus solitarius, which might inhibit cardiovascular reflex responses to fear or emotion-related stimuli.

CCK is co-localized with DA in rat mesencephalic neurons, and with glutamate in corticostriatal neurons; released CCK appears to be involved in locomotor behavior. Synthesis and storage of glutamate, ACh, and GABA in basal forebrain neurons projecting to the entorhinal cortex have been reported. Galanin is co-stored with enkephalin, and often NPY, in some neurons of the substantia gelatinosa, whereas tachykinins and enkephalin, galanin, and SP are co-stored in neurons in deeper layers of the dorsal horn. Co-storage of galanin and neurotensin, as well as CGRP and SP, has been shown by postembedding immunocytochemistry to be present in LGVs. Reverse transcription polymerase chain reaction (RT-PCR) and *in situ* hybridization studies have shown co-storage of oxytocin and vasopressin mRNA in LGVs in hypothalamic neurosecretory neurons.

Physiological Significance of Cotransmission

Several major themes have emerged about the physiology of cotransmission (see Figure 3).

Fast and Slow Cotransmitters: Different Firing Patterns

Although single presynaptic action potentials release small molecule neurotransmitters, trains of impulses are needed to release neuropeptides. For sympathetic and parasympathetic cotransmission, release of ATP is favored at low-frequency stimulation, whereas NA and ACh are released at higher frequencies. There are instances where more than one fast cotransmitter is released (e.g., glutamate and ATP) together with one or more peptides. See Figures 3(a) and 3(b).

Different Cotransmitters Act on Different Postjunctional Cells

Neurons using multiple transmitters may project to two or more targets (Figure 3(c)). For example, ACh released at low-frequency stimulation from parasympathetic nerves supplying salivary glands acts on acinus cells to produce secretion and a minor dilatation of vessels, whereas at higher frequency stimulation, its cotransmitter VIP causes powerful vasodilatation of vessels in the glands and postjunctional enhancement of ACh-induced saliva secretion.

Presynaptic Neuromodulation of Cotransmitter Release

A cotransmitter can feed back on presynaptic receptors that increase or decrease its own release or that of its cotransmitter(s) (Figure 3(d)). For example, ATP released as a cotransmitter with glutamate from primary afferent fibers in lamina II of the spinal cord can act on prejunctional $P2X_3$ receptors to facilitate the release of its cotransmitter, glutamate, whereas adenosine resulting from ectoenzymatic breakdown of ATP acts on presynaptic P1 receptors to inhibit glutamate release. Both NA and ATP can prejunctionally modulate sympathetic transmission, NA via prejunctional α_2-adrenoceptors and ATP via P1 receptors following breakdown to adenosine. Modulation of cotransmitter release and presynaptic action by other agents also occurs and might provide a new level of synaptic flexibility, in which individual neurons utilize more than one transmitter but retain independent control over their synaptic activity.

Synergism

There are an increasing number of reports of the synergistic actions of cotransmitters (Figure 3(e)). ATP and NA released from sympathetic nerves have synergistic actions on smooth muscle of vas deferens and blood vessels, and ATP released with ACh from motor neurons facilitates the nicotinic actions of ACh at the skeletal neuromuscular junction. Cooperativity between receptors for ATP and *N*-methyl-D-aspartate (NMDA) in induction of long-term potentiation in hippocampal CA1 neurons has also been demonstrated. Thyrotropin-releasing hormone and serotonin have been reported to have synergistic actions in spinal cord neurons.

In view of the evidence for cotransmitter synergy, the reports that known nucleotide P2 receptor antagonists, such as suramin, have actions on nonpurinergic receptors need to be questioned. For example, the claims that suramin and reactive blue 2 have antagonistic actions on NMDA and GABA receptor channels in hippocampal neurons are probably explained by blockade of the P2 receptor-mediated responses of the cotransmitter ATP, thereby removing its synergistic potentiating effect.

The mechanisms underlying cotransmitter synergism are not well understood. However, it has been suggested that postjunctional synergism between the responses of vas deferens to NA and ATP is caused by the ability of NA to potentiate the contractile responses to ATP by sensitizing smooth muscle cells to Ca^{2+} via an inhibitory action on myosin light chain phosphatase, an action mediated by protein kinase C.

Negative Cross-Talk

Coapplication of nicotinic and P2X receptor agonists produces less than the additive responses predicted by independent receptor activation (Figure 3(f)). Inhibitory interactions between $5\text{-}HT_3$ and P2X receptors have been described in submucosal and myenteric neurons. Cross-inhibition of $GABA_A$ and glycine receptors has been demonstrated in rat sacral dorsal commissural neurons.

Cotransmitters and Trophic Factors

Some co-stored and co-released substances can act as long-term (trophic) factors, as well as neurotransmitters (Figure 3(g)). For example, ATP can act on P2 receptors, or P1 (adenosine) receptors after ectoenzymatic breakdown, to promote vascular cell proliferation, motility, differentiation, or death. NPY released from sympathetic nerves has cardiovascular trophic effects in end-stage renal disease. There is growing evidence that neurotrophic factors might be synthesized, stored, and released from nerve terminals together with fast neurotransmitters.

Excitatory and Inhibitory Cotransmitters

Although cotransmitters generally have similar actions on postjunctional cells, there are some examples of cotransmitters having opposite actions. For example, in the mammalian uterus, one or other cotransmitter dominates depending on the hormonal and/or tonic status of the postjunctional muscle cells

Figure 3 Spectrum of signaling variations offered by cotransmission (blue arrows = neurotransmission; red arrows = pre- or postjunctional neuromodulation). (a) Fast transmission is usually produced by small molecules (C1) released at low-frequency nerve stimulation acting on ionotropic receptors (R1), whereas slow transmission is usually produced by release of peptides (C2) or other

(Figure 3(h)). Brain-derived neurotrophic factor (BDNF) increases the release of ACh and reduces NA release from sympathetic nerves to cause a rapid shift from excitatory to inhibitory transmission.

False Cotransmitters

For example, it has been known for some time that sympathetic nerves take up 5-HT, which can then be released as a 'false transmitter' rather than a genuine 'cotransmitter.' A false transmitter is a substance actively taken up and subsequently released by a neuron that does not synthesize it (Figure 3(i)).

Coexisting Peptide Acting as a Neuromodulator

For example, NPY released from sympathetic nerves acts as a pre- and postjunctional modulator of ATP and NA release and postjunctional actions (Figure 3(j)).

Cotransmitter Plasticity: Control of Transmitter Expression

Cotransmitter plasticity occurs during development and aging, following trauma or surgery, and after chronic exposure to drugs, as well as in disease. There were some outstanding early studies of the factors influencing cotransmitter expression in sympathetic nerves, and a physiological role for neuropoietic cytokines in the control of VIP expression during the development of cholinergic sympathetic neurons was proposed. A more recent study presented evidence that cholinergic differentiation in sympathetic neurons is promoted by neurotrophic factors from three different protein families (glial cell line-derived neurotrophic factor, neurotrophin 3, and ciliary neurotrophic factor), whereas noradrenergic differentiation is promoted by nerve growth factor. In another study, BDNF was claimed to switch sympathetic neurotransmission to the heart from an adrenergic excitation to cholinergic inhibition; it was also shown that the action of BDNF was mediated by the P75 neurotrophic receptor. Histamine, galanin, and GABA acting as cotransmitters in neurons of the tuberomammillary nucleus (hypothalamus) have independent control mechanisms. Changes in chemical coding of myenteric neurons in ulcerative colitis have been reported, with a shift from cholinergic to more SP-positive cotransmission. In a study using primary cultures of neonatal rat spinal neurons, evidence was presented for the regulation of SP (NK1) receptor expression by CGRP.

CGRP-like immunoreactivity was found earlier than SP-like immunoreactivity in cerebrovascular nerves during development, and increased in old age, while the density of SP-like immunoreactive fibers did not change. NA and NPY also show different expression in cerebrovascular nerves during development. Direct evidence for changes in transmitter ratio in disease comes from a study of hypertension in which the purinergic component of sympathetic cotransmission has been claimed to be enhanced to the extent that it is the dominant component of the sympathetic response. In many isolated blood vessels, contractions produced by sympathetic nerve stimulation or due to vasoconstrictors including catecholamines and 5-HT are greater after the endothelium is removed or during antagonism of endothelium-derived relaxing factor. While part of this effect is likely to involve postjunctional mechanisms, evidence has been presented that substances released from the endothelium may act prejunctionally to influence neurotransmitter release from nerves. This may or may not involve endothelial-derived NO. ATP is also released from endothelial cells in response to physiological stimuli such as hypoxia or shear stress and may thus modulate the activity of perivascular nerves via prejunctional P1 receptors following breakdown to adenosine and diffusion through the vessel wall. Conversely, in the microvasculature, where neural-endothelial separation is small, cotransmitters released from nerves could act directly on endothelial cells to influence the release of endothelium-derived factors.

molecules at high frequency stimulation acting on G protein-coupled receptors (R2). (b) Cotransmitters C1 and C2 can both be fast messengers acting via ionotropic receptors (R1 and R2). (c) Cotransmitters C1 and C2 act on receptors (R1 and R2) localized on different postjunctional cells. (d) Cotransmitters C1 and C2 not only act postjunctionally via R1 and R2 receptors but can also act as prejunctional modulators to either inhibit (−) or enhance (+) the release of C1 and/or C2. (e) Cotransmitters C1 and C2 act synergistically to enhance the combined responses produced via R1 and R2 receptors. (f) Cotransmitters C1 and C2 act to inhibit the responses evoked via R1 and/or R2 receptors. (g) Cotransmitter C1 evokes neurotransmission via R1 receptors, while C2 evokes long-term (trophic) responses of postjunctional cells via R2 receptors. (h) Cotransmitter C1 produces excitation via R1 receptors when the postjunctional smooth muscle target has low tone, with C2 having little influence; however, when the smooth muscle tone is high, the dominant response might be relaxation produced by C2 via R2 receptors. (i) Substance C3 is taken up by nerve terminals rather than being synthesized and stored, as is true for the cotransmitters C1 and C2. C3 can then be released on nerve stimulation to act on postjunctional R3 receptors. In these circumstances, C3 would be known as a 'false transmitter.' (j) A coexisting substance C3 (often a peptide) can be synthesized and stored in a nerve but not act directly via a postjunctional receptor to produce changes in postjunctional cell activity. It could, however, act as a prejunctional inhibitor (−) of the release of the cotransmitters C1 and C2 or as a postjunctional enhancer (+) of the responses mediated by R1 and R2. Concluding Comments

To establish that compounds shown to be localized in nerves are actually cotransmitters, several criteria need to be satisfied:

1. The substance is synthesized and stored in the nerve.
2. The substance is released on nerve stimulation.
3. Specific receptors for the substance need to be identified on postjunctional sites that, when occupied, lead to changes in postjunctional activity.
4. A transport system needs to be present for the substance itself or its breakdown products, uptake of which leads to renewal of messenger storage in nerve terminals.

It has been particularly difficult to establish cotransmitter roles for the many peptides found in nerves, partly because specific receptors and physiological roles have not been established for some of these and partly because of the lack of selective antagonists. In some enteric neurons, up to five neuropeptides have been identified. It is important to distinguish between neuromodulator, neurotransmitter, and neurotrophic roles for released peptides.

It is becoming clear that ATP is a primitive signaling molecule that has been retained as a cotransmitter in every nerve type in both the peripheral and central nervous systems, although the relative role of ATP varies considerably in different species and pathophysiological conditions. ATP appears to become a more prominent cotransmitter in stress and inflammatory conditions. Most nerves contain and release ATP as a fast cotransmitter together with classical transmitters such as ACh, NA, glutamate, GABA, and one or more peptides. In view of this, it is recommended that the terms 'adrenergic,' 'cholinergic,' 'peptidergic,' 'purinergic,' 'aminergic,' and 'nitrergic' not be used when nerves are described, although adrenergic, cholinergic, peptidergic, purinergic, aminergic, or nitrergic transmission is still meaningful.

Cranial–Cervical Dystonia

Introduction and Definitions

Dystonia is a neurologic syndrome characterized by involuntary, sustained (tonic) or spasmodic (rapid or clonic), patterned, repetitive muscle contractions, which frequently cause twisting (e.g., torticollis), flexing or extending (e.g., writer's cramp, retrocollis), and squeezing (e.g., blepharospasm) movements or abnormal postures. Dystonia can involve skeletal muscles in any part of the body; distribution of symptoms may be focal, segmental, multifocal, unilateral, or generalized. Characteristic features include co-contraction of agonist/antagonist muscles and involuntary overflow contraction into adjacent muscle groups. Dystonic movements are typically action induced, although they may also occur at rest, particularly when severe or after peripheral injury.

Blepharospasm, an involuntary closure of the eye produced by spasmodic contractions of the eyelids and eyebrows (affecting the orbicularis oculi and corrugator muscles), is an example of focal dystonia, occurring particularly in adult women. An increased frequency of blinking, associated with a feeling of irritation or dryness in the eyes, usually precedes the sustained closure of the eyes. Only about 20% of patients with blepharospasm continue to have isolated (focal) blepharospasm, called essential blepharospasm. In the majority of patients, blepharospasm is associated with dystonic movements in the adjacent facial, oromandibular, laryngeal, and neck muscles. The disorder may vary from a slightly annoying condition to a disabling one that interferes with daily activities, such as reading, watching television, and driving. Bright light usually exacerbates blepharospasm. As a result, many patients wear sunglasses both outside and inside. The spasms may be transiently alleviated by pulling on an upper eyelid, pinching the neck, talking, humming, yawning, singing, sleeping, relaxing, reading, concentrating, looking down, and other maneuvers or sensory tricks ('geste antagonistique'). Blepharospasm may be confused with tic disorders or ptosis.

Oromandibular dystonia consists of involuntary spasms of jaw, mouth, and tongue muscles that produce trismus (jaw clenching); bruxism (tooth grinding); involuntary tongue movements; and opening, closure, or deviation of the jaw. These symptoms may interfere with chewing, speaking, and swallowing. Secondary complications of oromandibular dystonia include dental wear and temporomandibular joint (TMJ) syndrome. Involuntary contractions of the mouth and jaw muscles can cause disabling dysarthria and chewing difficulties, as well as severe discomfort and social embarrassment. Some patients with oromandibular dystonia have involvement of the pharyngeal and laryngeal musculature, resulting in dysphagia, strained voice (spasmodic dysphonia), respiratory difficulties, and involuntary vocalizations, such as humming, grunting, belching, and gasping. As in other forms of dystonia, alleviation of oromandibular dystonia may be attained by various sensory tricks (geste antagonistique), including touching the lips or chin, chewing gum, biting on a toothpick, talking, and applying pressure to the submental area. With this phenomenon unique to dystonia, touching a nearby body part ameliorates the abnormal posture temporarily.

Spasmodic dysphonia presents typically as focal dystonia induced by speech. Adductor dysphonia leads to overcontraction of the thyroarytenoid muscles causing a strained pattern of speech. Less commonly, abductor dysphonia causes dystonic contraction of the posterior cricoarytenoid muscles, resulting in a whispering or breathy voice. Spasmodic dysphonia may present in isolation or as part of a more diffuse dystonic disorder.

Cervical dystonia is a focal dystonia characterized by sustained, involuntary contractions of neck muscles that result in abnormal movements and postures of the head. Onset occurs typically between the third and fifth decade of life. The term spasmodic torticollis is commonly used to describe this form of dystonia. However, since the movement is not always spasmodic and may consist of abnormal postures other than torticollis (e.g., turning of the head), such as laterocollis (head tilt), antercollis (neck flexion), and retrocollis (neck extension), the term cervical dystonia is preferred as a generic descriptor of dystonic movements or postures involving the neck. Categorized as a focal dystonia, cervical dystonia is often seen in association with other movement disorders, such as dystonia of adjacent (and other) body parts and tremor. Head oscillation caused by cervical dystonia can be divided into two broad categories: essential tremor and dystonic tremor. Essential tremor usually has a higher frequency (>7 Hz) than the dystonic tremor (3–7 Hz). Dystonic tremor, a component of the dystonia, is most obvious when the patient attempts to maintain primary position of the head by resisting the dystonic 'pulling.' About

25% of patients with cervical dystonia have postural tremor in their hands that is phenomenologically identical to essential tremor, in addition to head tremor. A majority of patients (75%) note neck pain as a symptom of cervical dystonia.

The combination of blepharospasm, oromandibular dystonia, and cervical dystonia is sometimes referred to as Meige syndrome, but the term-cranial–cervical dystonia is more appropriate to describe this form of segmental dystonia. In most series of patients with cranial–cervical dystonia, women outnumber men by a ratio of 2:1, and the onset is usually in the sixth decade of life. The disorder is a lifelong condition, and spontaneous remissions are rare.

Causes

Since the muscle spasms of cranial–cervical dystonia are typically exacerbated by stress and relieved by relaxation, as well as by various sensory 'tricks,' the disorder is often incorrectly presumed to be mental or psychological. This misconception is fostered by the lack of diagnostic imaging or other laboratory tests for abnormalities, as the vast majority of these patients have 'idiopathic' dystonia.

Probably the second most common cause of cranial–cervical dystonia is tardive dystonia, which is similar to the more common tardive dyskinesia because it is caused by drugs that block dopamine receptors, such as the major tranquilizers and certain antiemetic drugs. In contrast to orofacial and other movements that are typically present in tardive dyskinesia, the movements in tardive dystonia are more sustained and resemble those of idiopathic dystonia. Patients treated for Parkinson's disease with levodopa may also experience cranial–cervical dystonia. Structural lesions in the upper brain stem, diencephalon, and basal ganglia, resulting from stroke, multiple sclerosis, thalamotomy, hydrocephalus, and other causes, have been reported to cause cranial–cervical dystonia. In addition, cranial–cervical dystonia can be seen in patients with Wilson disease and other metabolic and neurodegenerative disorders. Finally, trauma to the eyelids, jaw, or neck can trigger dystonic movements in the injured area, so-called peripherally induced dystonia. One example of peripherally induced movement disorder is hemifacial spasm. This form of segmental myoclonus must be differentiated from cranial–cervical dystonia. Hemifacial spasm consists of involuntary, recurrent twitches of the eyelids and perinasal, perioral, zygomaticus, platysma, and other muscles of one side of the face. The condition may be mild, causing only social embarrassment or psychological distress, but in some patients, it causes unilateral blepharospasm that can interfere with vision. Though rarely familial, hemifacial spasm is an example of a peripherally induced movement disorder in which the muscular contractions result from a compressive or irritative lesion of the ipsilateral facial nerve. Facial and jaw spasms, called oculomasticatory myorhythmia, can be a complication of central nervous system (CNS) involvement in Whipple disease. The rhythmic contractions of the eyelids, face, and mouth may be synchronous with convergent eye oscillations. Hemimasticatory spasm, consisting of unilateral jaw closure spasms and ipsilateral facial hemiatrophy, is another facial movement disorder that is clinically similar to cranial–cervical dystonia and hemifacial spasm.

Pathogenesis and Pathophysiology

Dystonia is characterized by impaired inhibition at multiple levels of the CNS. Overflow movements in adjacent muscles are thought to derive from a failure to suppress neuronal excitability in surrounding neural circuits (surround inhibition). No specific abnormality or lesion has been identified on brain imaging studies or at autopsy of the brain of patients with cranial–cervical dystonia. Electrophysiologic studies of patients with cranial–cervical dystonia have demonstrated abnormalities in the R2 component of the blink reflex, indicating increased excitatory of the brain stem interneuronal pathway. Presumably, impaired descending control of blink circuits is related to dysfunction of the cortico-striato-thalamo-cortical circuits. Functional magnetic resonance imaging (fMRI) studies show deficient activation of the primary motor and ventral premotor cortex along with overactivity in the somatosensory cortex and caudal supplementary motor area. Interestingly, botulinum toxin (BTX) partially reverses the overactivity of the somatosensory cortex and caudal supplementary motor area after treatment, exerting its clinical effects peripherally and centrally. Dystonia is generally regarded as a motor disorder, but the aforementioned overactivity of the somatosensory cortex implicates the sensory system as well. Furthermore, patients with blepharospasm often complain of sensory symptoms such as dry or itchy eyes which improve after BTX injections. The importance of tactile and proprioceptive input can be demonstrated at the bedside in dystonia using a sensory trick. Existing clinical and experimental lends support to the idea that sensorimotor integration is impaired in dystonia.

Clinical, pharmacologic, and biochemical studies have suggested dopaminergic and noradrenergic preponderance in some cases. This biochemical abnormality may be genetically determined, since family history of a movement disorder is present in at least one-third of patients with cranial dystonia. A familial form of young-onset cervical dystonia with a dramatic response to levodopa has been reported,

but the genetic mutation remains undiscovered. Adult-onset cervical dystonia may occur in families with the DYT7 locus localized to the short arm of chromosome 18 (18p) by linkage analysis; however, the molecular basis is poorly understood. Dystonia may also occur in individuals with deletions of the entire short arm of chromosome 18, thereby implicating a host of novel genes with unknown function and many others involved in important cellular pathways: GNAL, CIDEA, NDUFV2, TGIF, DAP-1, and AFG3L2.

Treatment

While the cause of cranial–cervical dystonia is still poorly understood, the treatment of dystonias has markedly improved in the past decade. Investigation should focus on potentially treatable causes of dystonia. If none can be identified, then strategies designed to provide symptomatic relief without side effects should be discussed with the patient. About one-third of patients benefit from some pharmacologic therapy with agents such as anticholinergics, benzodiazepines, or muscle relaxants (baclofen). Dystonic patients usually require high doses of anticholinergic treatment (trihexyphenidyl 6–80 mg/day) for noticeable improvement. Trihexyphenidyl should be administered at 1 mg/day and slowly titrated by 2 mg/week using a BID dosing schedule. The pediatric population tolerates these doses more readily than adults. Side effects may limit aggressive titration: dry mouth, blurred vision, and confusion. Baclofen reduces spinal cord interneuron firing by activation of presynaptic γ-aminobutyric acid (GABA) receptors. As with trihexyphenidyl, slowly titrated large doses may be required for amelioration of dystonia. Side effects include sedation, dizziness, and dry mouth. Tizanidine, a centrally acting muscle relaxant, improves dystonia and spasticity by stimulating noradrenergic α-2 receptors. Longer acting benzodiazepines such as clonazepam provide symptomatic relief with less concern of addiction. In some patients, tardive dystonia responds well to tetrabenazine, a dopamine-depleting drug. Dose-limiting side effects include sedation, akathisia, depression, and parkinsonism. Finally, reports exist of familial cervical dystonia that responds favorably to levodopa.

The most important advance in the symptomatic treatment of blepharospasm and other focal dystonias has been the introduction of BTX. Seven serotypes (A–G) exist in nature, two of which are available as commercial preparations (A and B). An injection of this complex protein into the contracting muscles inhibits acetylcholine release at the neuromuscular junction, resulting in a satisfactory, albeit temporary, relief of the dystonic spasms in a majority of patients. Specifically, BTX type A cleaves synaptosome-associated protein (SNAP-25), a protein required for synaptic fusion with the presynaptic membrane and eventual release of acetylcholine into the neuromuscular junction. A placebo-controlled trial, reported in 1987, provided support for and validation of encouraging reports from various open trials. In subsequent studies, BTX injections were reported to produce moderate or marked improvement in spasms and function in over 90% of patients with blepharospasm and cervical dystonia. The average latency from the time of the injection to the onset of improvement is 2–7 days, and the average duration of benefit is 3–4 months. A meaningful reduction in the mouth, jaw, and tongue spasms and an improvement in chewing and speech were noted in more than 70% of patients with oromandibular dystonia treated with BTX. Patients with dystonic jaw closure responded better than those with jaw-opening dystonia. Temporary swallowing problems, noted in about 10–15% of patients, were the most common complication of injections into the masseter, submental, and other oromandibular muscles. Other common side effects include excessive weakness or pain at the site of injection. BTX injections provide the most effective relief of oromandibular dystonia, and early treatment may prevent dental and other complications, including TMJ syndrome and oral and dental problems associated with oromandibular dystonia. Patients with jaw closure dystonia generally benefit from injections into the masseter and, occasionally, the temporalis muscles, and those with jaw-opening dystonia benefit from submental or lateral pterygoid injections. Patients with blepharospasm should be injected into the pretarsal portion of orbicularis oculi rather than the preseptal region to prevent ptosis. Adjacent muscles may also be involved in blepharospasm such as corrugator supercilii or procerus. Injections for blepharospasm can lead to dry eyes, tearing, or diplopia. A small subset of patients treated with BTX develop antibodies against BTX and no longer benefit from subsequent injections. Factors that predispose patients to antibody formation include large doses injected in intervals shorter than 3 months.

Treatment of cranial–cervical dystonia requires a detailed knowledge of the local anatomy and the individual's condition. When skilled clinicians use BTX therapy, side effects should occur less frequently, that is, in less than 15% of all treatment sessions. The potential side effects are related to the site of injection: an injection in the eyelids may cause ptosis, blurred vision, diplopia, tearing, or eyelid hematoma; an injection into the oromandibular muscles may cause chewing, speaking, and swallowing difficulties; and an injection into the cervical muscles can produce neck weakness and swallowing problems. Function is

impaired in less than 2% of the patients who experience these complications. Furthermore, the complications usually improve spontaneously within 3 weeks. The functional improvement, experienced by nearly all patients after a BTX injection, is difficult to express numerically. Many patients could not work, drive, watch TV, or read before the injections; after the injections, most can function normally as a result of reduced eyelid and eyebrow spasms. Similarly, after BTX therapy, patients with oromandibular dystonia can speak, chew, and swallow more easily, and those with cervical dystonia usually experience improved control of their head position and marked reduction in neck pain. BTX injection is now considered by many physicians as the treatment of choice for blepharospasm, oromandibular dystonia, cervical dystonia, and spasmodic dysphonia. While surgical microvascular decompression of the facial nerve has a high rate of success in the treatment of hemifacial spasm, this treatment is associated with potentially serious risks, such as permanent facial paralysis, deafness, stroke, and death. Therefore, a local injection of BTX into involved facial muscles offers a useful alternative to surgical therapy. Nearly all patients improve; the complications, consisting of mild facial asymmetry, are minimal and transient. The approach can be individualized by injecting only those muscles in which contractions are most disturbing to the patient. In the authors' experience with treating a large number of patients with hemifacial spasm, the average duration of improvement was 5 months, longer than in any of the other spasmodic disorders.

For patients unresponsive to conventional pharmacologic intervention, options include intrathecal baclofen, selective peripheral denervation, and deep brain stimulation (DBS). DBS is most appropriate for patients with disabling generalized dystonia rather than focal or segmental dystonia. To date, most investigators advocate targeting the globus pallidus interna (GPi) for the treatment of medically refractory dystonia. Patients with DYT1 dystonia appear to have the most robust response. Case reports and case series of cervical dystonia and cranial–cervical dystonia look promising, though reports of long-term follow-up are lacking. In contrast to essential tremor, the postoperative improvement of GPi-DBS may be delayed several months. Phasic dystonic movements tend to improve more rapidly than tonic movements. DBS parameters differ in dystonia when compared to essential tremor or Parkinson's disease in that the pulse width and voltage requirements are typically higher. DBS-related complications when targeting the GPi are infrequent but include intracerebral hemorrhage, infection, dysarthria, weakness, and numbness.

Cross-Modal Interactions Between Vision and Touch

K Sathian and S Lacey, Emory University, Atlanta, GA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Although this might seem heretical, it is now generally accepted that many extrastriate visual cortical areas are active during tactile perception, in both the sighted and the blind. Here we review the literature on such cross-modal recruitment of visual cortex during tactile perception. We consider the attempts that have been made to address a variety of issues that remain largely unresolved, including why such cross-modal recruitment of visual cortex occurs, whether the underlying reasons differ in the sighted and the blind, the nature of the underlying perceptual representations, and how they relate to performance differences between the blind and sighted.

Involvement of Visual Cortical Areas in Tactile Perception in the Sighted

Extrastriate visual cortical areas were first shown to be active during tactile perception in a positron emission tomography (PET) study conducted in our laboratory on normally sighted human volunteers. In this study, the experimental task was tactile discrimination of the orientation of gratings presented to the immobilized fingerpad. When this task was contrasted with a control task requiring tactile discrimination of grating groove width, activation was found at a focus in extrastriate visual cortex, close to the parieto-occipital fissure. This focus is in the vicinity of the human V6 complex of visual areas and had previously been found to be active during visual discrimination of grating orientation. The possibility that this cross-modal parieto-occipital activation might be merely epiphenomenal was ruled out in a subsequent study from our laboratory, using transcranial magnetic stimulation (TMS) to test whether disrupting the function of this cortical region was detrimental to performance. TMS applied directly over the parieto-occipital focus, and at sites close to it, significantly impaired discrimination of grating orientation when the magnetic pulses were appropriately timed with respect to the stimuli. However, TMS at or near the parieto-occipital focus did not affect discrimination of grating groove width, and when applied at more distant sites did not affect performance on either task. This pattern of results permitted the inference that the activation found in the earlier PET study was functionally meaningful.

Analogous findings were reported in a study using repetitive TMS (rTMS) at 1 Hz to decrease local cortical excitability. This study took advantage of a dissociation between subjective magnitude estimates of perceived interdot distance, which increase with physical interdot distance (up to 8 mm), and those of perceived roughness, which peak at intermediate values (around 3 mm). The main finding was that rTMS over the primary somatosensory cortex (S1) affected judgments of roughness but not interdot distance, whereas rTMS over the medial occipital cortex affected distance but not roughness judgments. Further, a congenitally blind patient who suffered a stroke that damaged the occipital cortex bilaterally was impaired on judgments of interdot spacing but not roughness. These observations, together with the studies of the grating orientation task reviewed in the previous paragraph, indicate that visual cortical involvement occurs in macrospatial (large-scale) tactile tasks but not in microspatial tasks in which the parameters of interest vary in the range of $\leq$3 mm. This conclusion is consistent with psychophysical studies suggesting that macrospatial tactile tasks are preferentially associated with visual processing and that vision seems to be better than touch for perceiving macrospatial features, the reverse being true for microspatial features.

Another example of visual cortical recruitment during tactile perception is offered by work showing that the MT complex, an area located in the dorsal (visuospatial) pathway and specifically involved in perception of visual motion, is also active during presentation of tactile motion stimuli, even in the absence of any task. Psychophysical studies suggest that both vision and touch may engage a common representation of motion; tactile motion perception can be used to disambiguate the direction of motion in an ambivalent visual motion display. Within the ventral visual pathway, which is specialized for form processing, the lateral occipital complex (LOC) is a region that is object-selective for visual stimuli. The LOC is also recruited cross-modally during haptic object recognition, as revealed by numerous functional magnetic resonance imaging (fMRI) studies. Further, activation has been reported in the LOC during tactile perception of two-dimensional forms presented to the immobilized right index fingerpad, and studies of patients with lesions involving the LOC suggest that it is necessary for haptic as well as visual shape perception. Multisensory object-selective activity in the LOC is stronger for graspable visual objects than for other visual stimuli and does not appear to

extend to the auditory modality. These studies, along with cross-modal priming effects observed in psychophysical and fMRI studies, cross-modal interference effects in memory tasks, and category-specific representations that overlap between vision and touch, imply that both visual and haptic shape perception may engage a unitary neural representation, as in the case of motion perception.

Visual Imagery and Multisensory Representations

The research reviewed so far has established that visual cortical processing is routinely involved in normal tactile perception in the sighted, especially during macrospatial tasks. Such processing is quite task-specific, so the extrastriate visual cortical areas known to be specialized for particular visual tasks are involved during performance of the same tasks tactually. An obvious question is whether visual imagery underlies this cross-modal recruitment of visual cortex into nonvisual tasks. Subjects in our laboratory consistently report mental visualization of tactile stimuli during macrospatial tasks such as discrimination of grating orientation or tactile form, which are associated with visual cortical recruitment, but not during microspatial tasks such as discrimination of grating groove width or gap detection, which do not tend to involve visual cortical activity. Visual imagery might be triggered by lack of familiarity with the tactile stimuli or tasks used; indeed, such cross-modal translation may be a general phenomenon, especially during complex information processing. Left-lateralized LOC activity has been found during mental imagery of shape generated from previous visual encounters in the sighted or from haptic encounters in the blind. An fMRI study from our laboratory found that inter-individual variations in the magnitude of haptic shape-selective activity in the right LOC (ipsilateral to the hand used for haptic perception) were strongly predicted by ratings of the vividness of visual imagery. In contrast, activation strengths in the left LOC were uncorrelated with these visual imagery scores, pointing to a role for factors other than visual imagery in cross-modal visual cortical recruitment. Despite the differences between these studies in the lateralization of imagery effects, they suggest that a role for visual imagery in cross-modal visual cortical recruitment cannot be ruled out.

However, some have argued that LOC activity during haptic perception is not due to visual imagery. Vision and touch can each encode object shape and motion, and visual cortical activation during tactile perception might reflect a multisensory representation rather than a specifically visual image, especially given the evidence reviewed earlier for common representations of motion and shape across vision and touch. That similar illusions can be experienced with both visual and tactile inputs support this idea. In the Müller–Lyer illusion, two lines of identical length and endcapped with fins that point either outward or inward are seen as shorter or longer, respectively, than the true length. This visual illusion has also been demonstrated in a haptic format and appears to be independent of visual experience because blindfolded, normally sighted individuals, those with low vision, late blind subjects, and congenitally blind individuals are all equally susceptible to the illusion. In the same vein, length distortion is an illusion that was first described haptically and subsequently found to occur in vision too. Length distortion refers to the overestimation of the distance between two points as a function of the increasing length of an indirect pathway between them. The same effect can be observed, albeit of a smaller magnitude, in the visual version of the task. These studies suggest a common visuo-haptic representation of space that may be based on body-centered reference points (e.g., the body midline or the positions of the hands relative to one another) because instructions to use these in judging Müller–Lyer line length virtually eliminated the illusion in both modalities whereas external reference points (a frame surrounding the illusion figure) had no effect. The use of these body-centered reference points may be a common mechanism for integrating spatial information from vision and touch.

The evidence for multisensory representations suggests the existence of direct, bottom-up somatosensory projections into the visual cortical areas that are implicated in tactile perception, as opposed to the top-down projections from the prefrontal into visual cortical areas that would be required to support a process such as visual imagery. These competing possibilities can be tested empirically by studying connectivity in experimental animals, by electrophysiological studies in animals or humans to pinpoint the timing of activity in different regions, or by analyzing fMRI data to reveal effective connectivity. A study from our laboratory using structural equation modeling of effective connectivity, based on the correlation matrix between the time courses of fMRI activity in various regions, revealed both bottom-up and top-down paths in a network of haptically shape-selective areas, including foci in the postcentral sulcus (corresponding to Brodmann's area 2 of S1), the intraparietal sulcus (IPS), and the LOC. This suggests that potential neural substrates exist for both visual imagery and multisensory representations, in relation to visual cortical involvement during haptic shape perception.

Neurophysiological and neuroanatomic studies in monkeys have also illuminated our understanding of the mechanisms involved in cross-modal visual cortical recruitment. Some neurons in area V4 (a nonprimary area in the ventral visual pathway) were found to be selective for the orientation of a tactile grating when it served as a cue for matching to a subsequently presented visual stimulus but not when it was task-irrelevant. The requirement for task-relevance implicates top-down, rather than bottom-up, inputs. Multisensory inputs have been reported in early sensory cortical areas that are traditionally considered unisensory, including the primary visual cortex (V1) and auditory association cortex. Analysis of the laminar profile of these projections suggests that both top-down and bottom-up inputs are present. Thus, the weight of evidence indicates the existence of multisensory representations that are flexibly accessible via both vision and touch, potentially involving interactions between bottom-up sensory inputs and top-down processes such as visual imagery. However, empirical studies addressing the format of such representations are in their infancy, and currently we cannot rule out as an alternative to unified multisensory representations that there might be independently derived spatial representations for vision and touch that can interact at later stages of processing (e.g., in cross-modal comparison).

If vision and touch produce separate representations, how do these affect one another? The classic work of Rock and Victor suggested that vision dominates touch; when the visual width of an object was distorted by a lens, individuals who both saw and felt the object were unaware of the cross-modal conflict and reported the distorted width perceived visually rather than the true width perceived tactually. Thus, this sensory conflict was resolved in favor of the visual percept. More recent research by Klatzky, Lederman, and their colleagues showed the situation to be more complex and to depend on the specific object property. For example, under neutral instructions the haptic salience of object properties is hardness > texture > shape; under haptically biased instructions this salience changes to texture > shape > hardness. But in combined visual and haptic perception, as well as in haptic perception with concurrent visual imagery, this saliency is reversed and changes to shape > texture > hardness/size. Visual imagery can therefore influence tactile perception in the absence of visual perception, and moreover, different modalities may be optimal for different object properties. Thus, there is not a simple dominance of visual over tactile perception.

Other approaches have also identified interactions between vision and somatosensory representations of the body. One line of work has demonstrated that noninformative vision of the body can improve tactile spatial acuity as measured using grating orientation discrimination, and that this cross-modal enhancement is abolished by TMS over the primary somatosensory cortex. Another line of research pertains to the rubber hand illusion – when a rubber hand is positioned in alignment with the subject's own concealed hand, if the subject sees the rubber hand being touched, he or she experiences illusory touch, indicating a feeling of ownership of the synthetic hand. Such a feeling of ownership is associated with activity in the ventral premotor cortex, a region where, in monkeys, neurons exhibit visual receptive fields that are anchored to the arm and move with it.

Tactile Perception in the Blind and Its Involvement of Visual Cortex

Despite the common belief that blindness is associated with superior nonvisual perception, research on this has not yielded uniform results. Some studies of haptic perception of three-dimensional shape have observed better performance in the blind, others have shown equal performance in sighted and blind individuals, and still others, even better performance in the sighted. It has been argued that superior performance of the blind on haptic tasks may stem not from heightened sensitivity but, rather, from using more efficient sensorimotor strategies or from practice in attending to cues that the sighted typically ignore. However, blind Braille readers out-perform the sighted on many tests involving tactile perception of two-dimensional patterns with the fingerpad. These include tactile recognition of Braille-like dot patterns, judging the orientation of bars or detecting gaps in them, discriminating grating orientation, and determining whether the central dot in a linear three-dot array is offset laterally by a small (<1 mm) distance. In contrast, blind individuals do not differ significantly from the sighted in their ability to discriminate bar length or laboratory textures such as gratings or real-world textures such as sandpapers or abrasive stones. There is some evidence that the superior tactile spatial performance of the blind (when it does occur) is due to practice. Thus, practiced sighted subjects do as well as the blind on the offset task and at discriminating patterns generated with the Optacon (a vibrotactile reading aid for the blind). They can also match the deaf-blind in decoding speech by the Tadoma method (feeling the speaker's face and neck). The role of specific practice with reading Braille is unclear; one study reported that the grating orientation discrimination threshold was lowest on the Braille-reading finger, whereas another study found no significant difference on this test between blind subjects who read Braille and

those who did not and that offset detection was no better on the hand used for reading Braille than the other hand.

Visual deprivation studies have investigated whether superior performance in the blind may be due to cortical reorganization. Following neonatal visual deprivation, rodents navigate a maze for a food reward faster than normal and demonstrate altered somatosensory cortical representations of the whiskers as well as novel somatosensory responsiveness in the anterior occipital cortex. In monkeys whose eyelids were sutured shut for the first year of life and opened later, the dorsal extrastriate visual cortex had lower visual but greater somatosensory responsiveness than in the controls, although this procedure did not affect haptic discrimination ability. The human somatosensory cortex also reorganizes after visual deprivation, probably as a consequence of increased hand use. Expansion of the representation of the Braille-reading finger has been reported in a study using evoked potentials and TMS. Others have found disordered cortical somatotopy as revealed by magneto-encephalography (MEG), and mislocalizations of touch on the reading fingers, in subjects who read Braille using multiple fingers. In an early report of cross-modal plasticity in blind humans, PET scanning was used to show that visual cortical areas in the occipital lobe were more active metabolically in the early blind than in the late blind or sighted. This was interpreted as an index of greater synaptic activity in the early blind, perhaps reflecting incomplete developmental pruning of synapses. Subsequently, many PET and fMRI studies found that the medial occipital cortical regions of blind subjects were recruited during tactile reading of Braille or embossed Roman letters. The medial occipital cortical activations were specific to early blind subjects, in contrast to late blind and sighted subjects, who deactivated these regions. Complementary rTMS studies demonstrated functional involvement of the medial occipital cortex in tactile identification of Braille or Roman characters by blind subjects but not in sighted subjects for Roman letters. As in the activation studies, the rTMS effects over the medial occipital cortex were found in the early blind but not the late blind, implicating cross-modal plasticity during a critical period of visual development. The functional role of the visual cortex in Braille reading is supported by the report of an early blind person who became unable to read Braille after a bilateral infarct of the occipital cortex.

Was the visual cortical activation observed during Braille reading in the blind due to sensory or higher-order cognitive processes such as attention and language? Most of the studies cited in the preceding paragraph could not resolve this because the tactile reading tasks were compared to low-level conditions. It turns out that visual cortical activity occurs in the blind during a variety of language tasks, including generating verbs in response to tactile or auditory input, and verbal recall in the absence of any sensory input. Such activity is more extensive in the early blind than the late blind. Its functional relevance is shown by its greater strength during semantic than phonological processing and by the correlation of its magnitude with semantic and syntactic complexity and with verbal recall ability.

The conclusion from these studies is that the visual cortex is clearly active during language processing in the blind. However, the extent of its involvement in tactile processing is still unclear, as is its potential relationship to performance differences between blind and sighted individuals. Compared to activity during Braille-reading, there was less activation in the medial occipital cortex of the blind during discrimination of angles or the width of grooves cut in homogeneous Braille fields. Vibrotactile frequency discrimination evoked extensive responses in the visual cortex in congenitally blind subjects, with less extensive responses in the late blind. Category-selectivity during haptic perception of three-dimensional form, similar to that noted in sighted subjects, was found in the inferotemporal cortex of blind subjects, although the category-selective voxels were located more ventrally in the blind than in sighted subjects. Unfortunately, most of these studies used rest controls, making it difficult to disentangle sensory from linguistic processing. A study of Braille-reading that did attempt to control linguistic processes, using an auditory word control, actually found medial occipital cortical activity in the late blind but not the early blind. Thus, more research is needed to address the extent to which tactile processing engages the visual cortex in the blind and its links with cross-modal recruitment in the sighted.

Cyclic AMP (cAMP) Role in Learning and Memory

T W Abrams, University of Maryland School of Medicine, Baltimore, MD, USA

Historic Background

From the time of the anatomical discovery of synapses in the later nineteenth century, microscopists such as Tanzi speculated that synapses would be modified as a result of experience. It was further proposed by Donald Hebb that synaptic modification during learning would be initiated by appropriately timed neuronal activity. However, prior to the mid-twentieth century, there was insufficient information about cellular signaling mechanisms to permit the development of hypothetical proposals for how activity might modulate synaptic strength. This changed in the late 1950s with the identification of cyclic adenosine monophosphate (cAMP) by Earl Sutherland and Theodore Rall as the intracellular signal responsible for the modulatory effects of hormones such as epinephrine and glucagon. According to the classical model of cAMP signaling, receptors for hormones or neurotransmitters stimulate the enzyme adenylyl cyclase (AC), which synthesizes cAMP from adenosine triphosphate (ATP). cAMP exerts its modulatory effects primarily by activating cAMP-dependent protein kinase, known as protein kinase A (PKA), which transfers the tertiary phosphate group from ATP to specific serines or threonines in consensus sequences within target proteins. PKA was also identified in the 1950s by Edmond Fischer and Edwin Krebs. By stimulating the phosphorylation of target proteins, which vary depending on the cell-type, cAMP initiates modulatory effects that are cell-type specific. The understanding that cAMP regulates the activity of enzymes and other effector proteins by stimulating their phosphorylation gave rise to a general model of intracellular signaling. Although these early discoveries initiated a period of rapid progress in analyzing cAMP signaling, some of the other proteins that participate in the cAMP pathway would not be characterized for several decades.

The cAMP signaling model was highly influential. Neurobiologists interested in modulation of synaptic connections began to explore the possibility that cAMP might be involved in the experience-dependent alteration of synaptic strength. Strikingly, in the mid-1960s, Sutherland, Eduardo De Robertis, and their colleagues found that AC activity is enriched in brain homogenates that contain synaptic terminals, as is phosphodiesterase, the enzyme responsible for hydrolyzing cAMP and terminating its actions. Within a few years, Paul Greengard and colleagues had found that both PKA and phosphoproteins regulated by cAMP are also enriched in fractions containing presynaptic terminals. Greengard began to characterize a few of the most abundant cAMP-dependent phosphoproteins in synaptic terminals, including a presynaptic protein that was later named synapsin. During the same period, initial biochemical evidence suggested that in neurons, cAMP might mediate some slow modulatory effects of neurotransmitters.

In 1972, Seymour Kety published an essay discussing the possible involvement of noradrenergic signaling in associative learning, which he proposed is mediated by the modification of synaptic connections. He speculated that this noradrenergic modulation of synapses during learning might involve cAMP. However, it was not yet possible to conduct cellular studies on synaptic modulation in the mammalian brain. The first physiological evidence for the importance of cAMP at synapses came at the end of the 1960s from recordings at the mammalian neuromuscular junction. Analogs of cAMP or inhibitors of phosphodiesterase caused an increase in the amplitude of the synaptic response. In the 1970s, Eric Kandel, James Schwartz, and Vincent Castellucci studied short-term synaptic modulation during sensitization in the marine mollusk *Aplysia*; sensitization is a nonassociative form of behavioral plasticity in which a noxious stimulus increases the magnitude of a defensive withdrawal reflex. They showed that the noxious stimuli that caused behavioral sensitization increased cAMP levels in the central nervous system (CNS) and that this effect was mimicked by the modulatory neurotransmitter serotonin. Both serotonin and cAMP increased the strength of the direct synaptic connections between sensory neurons and motor neurons in the circuit for the defensive withdrawal reflex. Collaboratively with Paul Greengard, they demonstrated that this strengthening of the synaptic connections of sensory neurons to motor neurons was mediated by PKA.

It is noteworthy that the groundbreaking studies of the cAMP signaling pathway were recognized by three independent Nobel Prizes: for the discoveries of cAMP and the mechanism of hormone action (to Sutherland in 1971), for discoveries concerning protein phosphorylation (to Fischer and Krebs in 1992), and for the discovery of G-proteins, which were first identified in studies of the regulation of AC (to Gilman and Rodbell in 1994). In 2000, Greengard and Kandel received the Nobel Prize for physiology or medicine (which was shared with Carlsson) for research on signal

transduction in the nervous system; a substantial portion of the seminal work by these two investigators involved their studies of cAMP-dependent signaling at synapses.

This article summarizes the present understanding of the molecular mechanisms by which AC, cAMP, and PKA act to modulate synapses during learning. Before synaptic plasticity is discussed, the central elements of the cAMP signaling system are briefly reviewed.

The cAMP Signaling Pathway

In animals, AC enzymes contain two transmembrane domains, each with six membrane-spanning α helices. Between the two sets of six α helices is a large C1 cytoplasmic loop. A second cytoplasmic domain (C2) forms the C-terminus. Enzymatic activity of AC, catalyzing the synthesis of cAMP from ATP, requires both of these cytoplasmic domains. In mammals there are nine isoforms of membrane-bound AC. In addition, there is a cytoplasmic AC isoform that may be important in neuronal development. Metabotropic receptors that are positively coupled to AC interact with the enzyme via stimulatory, guanine nucleotide-binding G-proteins (G_s; known generally as G-protein-coupled receptors). These heterotrimeric G regulatory proteins consist of an α subunit and tightly associated $\beta\gamma$ subunits. In the inactive state, guanosine diphosphate (GDP) is bound to $G_{s\alpha}$, and $G_{s\alpha}$ is associated with $G_{\beta\gamma}$. When the AC-coupled receptor binds to a transmitter, guanosine triphosphate (GTP) is exchanged for GDP, and $G_{s\alpha}$ dissociates from $G_{\beta\gamma}$. The free GTP-bound G_s now stimulates AC. AC isoforms are also regulated by specific isoforms of $G_{\beta\gamma}$; whether the regulation is stimulatory or inhibitory depends on the specific type of AC. Moreover, several AC isoforms are inhibited by the α subunit of the inhibitory G-protein, G_i.

cAMP directly activates certain ion channels and also interacts directly with some other signaling proteins, such as specific GTP exchange factors, which facilitate the activation of G-proteins by GTP. However, most cAMP effects are mediated via PKA. PKA is a tetramer complex with two catalytic (C) subunits and two regulatory (R) subunits. In the tetramer, the R subunits inhibit the catalytic site of the C subunits. When cAMP concentrations are elevated, two cAMP molecules bind to each R subunit, which causes the dissociation of the C subunits. There are two classes of regulatory subunit, each of which has two isoforms: RIα, RIβ, RIIα, and RIIβ. There are two isoforms of the catalytic subunit, Cα and Cβ. The specificity of action of PKA depends on the substrate proteins expressed in different cells and the localization of PKA (discussed in the section titled 'Localization of PKA via A kinase anchoring proteins is necessary for cAMP-dependent synaptic plasticity').

Interactions among Intracellular Signaling Systems

cAMP is traditionally considered the prototypical intracellular messenger, in part because cAMP was the first intracellular messenger to be recognized. However, by the 1950s, another cytoplasmic signal, calcium, was known to be important for initiating key physiological processes in excitable cells. The earliest evidence for the possible role of calcium in triggering muscle contraction was obtained years before the identification of cAMP. Moreover, it had also begun to be appreciated that calcium plays a central role in both triggering and regulating the release of neurotransmitter at the synapse. By the 1960s, it was generally believed that cAMP was a universal intracellular messenger, whereas calcium was thought to be involved in a few specific roles, and only in excitable cells. It is now understood that calcium is also a ubiquitous intracellular signal. It is interesting that some of the earliest evidence suggesting that calcium is an important intracellular signal that participates in diverse cellular mechanisms was obtained in studies of the cAMP pathway. Particular forms of phosphodiesterase (the enzyme that degrades cAMP) were found to be activated by calcium. In the early 1970s, it was discovered that this activation by calcium occurred via a small, 17 kDa, heat-stable calcium regulator protein, which had been purified from brain. This calcium regulator protein, later named calmodulin, is highly conserved throughout evolution. Calmodulin binds four calcium ions; in the calcium-bound state, calmodulin activates a wide variety of calmodulin-dependent proteins. By the mid-1970s, calcium–calmodulin was found to stimulate some forms of AC. It is now widely appreciated that in general, multiple signaling pathways interact within single cells, as occurs with the calcium–calmodulin and the cAMP pathways. (Yet another example of interactions between signaling cascades, involving PKA and mitogen-activated protein (MAP) kinase, is discussed in the section titled 'How does the cAMP pathway initiate synaptic modifications during learning?'.) Although the calcium–calmodulin-sensitive AC was first identified in mammalian brain, its central role in synaptic plasticity and learning in mammals was not appreciated until after this AC isoform had been demonstrated to be involved in learning in invertebrates.

Genetic Evidence for the Role of cAMP in Learning

During the 1970s, a number of learning mutants were isolated in *Drosophila* by screening for deficits in an olfactory conditioning task. The first mutant that was successfully analyzed at the biochemical level was *dunce*. The *dunce* gene codes for an isoform of phosphodiesterase, and the learning deficit in the mutant appears to result from the tonic elevation of cAMP. When cAMP is tonically increased, cAMP modulatory effects may be chronically activated, occluding any modulatory changes initiated during learning. In addition, the tonically activated cAMP pathway in *dunce* has been shown to result in altered synaptic physiology in these flies and altered synaptic morphologies. Thus in *dunce*, developmental changes and changes in synaptic physiology may also contribute to the learning deficit.

The Role of Calmodulin-Sensitive AC

In the early 1980s, a second *Drosophila* learning mutant, named *rutabaga*, was found to have a lesion in calmodulin-sensitive AC. In *Aplysia*, calmodulin-sensitive AC, which is also regulated by the serotonin receptor and G_s, was proposed to act as an associative integrator during classical conditioning of the defensive withdrawal reflex. Mammals express nine types of membrane-bound AC; two of these expressed in the brain, AC1 and AC8, are stimulated by calcium–calmodulin. The cloning of calmodulin-sensitive ACs from mammals has allowed for exploration of the roles of these specific AC isoforms in learning. Daniel Storm and colleagues have examined the learning deficits resulting from knockout of AC1 and AC8. When placed in a bright chamber and given the choice, mice normally move into a darkened chamber. Pairing of shock with entry into the darkened chamber results in inhibition of the normal behavioral preference; that is, the animals learn to avoid the shock, which is known as inhibitory avoidance learning. In a mutant mouse in which the genes for both AC1 and AC8 were knocked out, inhibitory avoidance learning was normal when tested at 5 min after training; however, in the double-knockout mouse, memory at 30 min, 1 day, and 8 days was greatly impaired. These double-knockout mice were also tested in a fear-conditioning paradigm, in which animals learn to fear either a distinctive context or a conditioned stimulus (such as a tone) that is paired with a shock. In context-dependent conditioning, mice that are exposed to a shock delivered in a distinctive conditioning chamber display freezing behavior when they return to that chamber. This type of learning about the context involves the hippocampus, as well as the amygdala. The double-knockout mice showed normal context-dependent conditioning at 24 h but displayed reduced freezing compared with wild-type mice when tested at 8 days. In cue-dependent fear conditioning, when a shock is paired with a tone, animals learn to freeze on presentation of the tone. Cue-dependent conditioning involves the amygdala but not the hippocampus. Cue-dependent fear conditioning was normal in the double-knockout mice at both 24 h and 8 days. As in the fly mutants, it is difficult to know whether the impairment in learning is not at least partially due to developmental abnormalities when synapses form in the absence of normal cAMP signaling. Hippocampal synapses appeared normal in terms of synaptic strength and very shortterm synaptic plasticity, but certainly more subtle changes could have contributed to a learning deficit. Storm and colleagues also evaluated transgenic mice that overexpress AC1 in a memory task in which mice pay particular attention to novel objects. Compared with wild-type mice, mice overexpressing AC1 as adults showed improved memory, that is, enhanced preference for the novel object, at both 1 day and 5 days. In contrast, the double-knockout mice lacking AC1 and AC8 showed no memory for the novel object when tested at 1 h. Based on the deficits in the double-knockout mice, calmodulin-sensitive AC appears to be important for memory as early as 1 h after the initial exposure to objects, but not in the first 5 min.

The evidence from *Drosophila* and mouse strongly implicates calmodulin-sensitive AC in learning. However, the importance of convergent activation of calmodulin-sensitive AC is still uncertain in these two systems, and in *Aplysia*. In particular, in mammalian brain, much of the activation of AC1 appears to be mediated via calcium–calmodulin, and the role of any dual activation involving neurotransmitter remains unclear.

cAMP-Dependent Signaling Plays a Central Role in Long-Term Learning

Memory mechanisms must function over dramatically different time periods. Short-term memory lasts for minutes to tens of minutes. In contrast, long-term memory lasts hours to days or even months or years. These two forms of memory are mechanistically distinct in that long-term memory requires gene transcription and protein synthesis, whereas short-term memory does not. Undoubtedly, there are multiple molecular mechanisms with different durations that overlap to provide a continuous, relatively stable memory.

One approach to addressing the question of the role of cAMP in learning is to study transgenic mice

that express dominant negative R subunits of PKA in hippocampus and forebrain. Mice were tested with the Morris water maze spatial learning task. In this paradigm, mice are placed in a circular pool, and they learn to escape the water by finding a hidden platform located just below the surface. With repeated trials, the mice learn the location of the hidden platform using spatial cues. Training was conducted over 14 days, and the animals' searching behavior was tested on the following day, when the submerged platform was removed. Wild-type mice spent more than twice as much time searching in the quadrant where the platform was previously located as they spent searching in the other three quadrants; in contrast, mice expressing dominant negative R subunits showed little preference for the previous platform location. These dominant negative-PKA mice were also tested with fear conditioning. With cue-dependent fear conditioning, the amygdala-dependent task, no deficits were observed either 1 h or 24 h posttraining. With context-dependent fear conditioning, the dominant negative-PKA mice showed normal learning when tested 1 h after training but displayed a dramatic memory deficit when tested 24 h after training. Although these studies with transgenic mice did not implicate either calmodulin-sensitive AC or PKA in cue-dependent fear conditioning, studies by Joseph LeDoux and colleagues demonstrated that a PKA inhibitor delivered into the lateral amygdala blocked memory at 24 h but not at 1 h. Thus, cAMP-dependent signaling may also be involved in memory for amygdala-dependent fear conditioning. One general conclusion from these behavioral experiments on transgenic mice with deficits in the cAMP pathway is that AC and PKA are particularly important in longer-term memory. The precise time frame in which cAMP-dependent signaling is critical seems to vary depending on the learning task and also on the how the cAMP cascade is altered. Mechanisms by which the cAMP pathway modifies synaptic connections during activity-dependent plasticity are considered below.

How Does the cAMP Pathway Initiate Synaptic Modifications during Learning?

By the 1970s, it had been demonstrated that cAMP can cause strengthening of synapses, and one PKA-dependent, synapse-associated phosphoprotein, synapsin, had been identified. Nevertheless, understanding of the molecular mechanisms by which cAMP exerts its effects is still modest. The incompleteness of understanding of cAMP-dependent regulation of synaptic strength is at least partly because multiple mechanisms are involved, depending on the type of synapse. This heterogeneity of mechanisms of synaptic plasticity that are initiated by cAMP will be evident below.

In any analysis of an alteration in the strength of a synaptic connection, the fundamental initial question is whether the underlying change takes place presynaptically or postsynaptically. The former type of mechanism involves changes in calcium handling or the vesicle release apparatus, whereas the latter type involves changes in properties or numbers of receptors. The issue of pre- versus postsynaptic contributions has been analyzed in a number of examples of synaptic plasticity that are believed to occur during learning. (Synaptic plasticity is defined simply as a change in the strength of a synaptic connection.) Two of the most extensively studied systems are long-term potentiation of the synaptic connections between CA3 and CA1 pyramidal cells in hippocampus and serotonin-induced facilitation of synaptic connections of sensory to motor neuron in *Aplysia*. Both 'potentiation' and 'facilitation' refer to an enhancement of synaptic strength; in contrast, 'synaptic depression' refers to a decrease in synaptic strength. At the CA3-to-CA1 pyramidal cell synapse, most recent attention has focused on postsynaptic mechanisms of plasticity and primarily on pathways other than cAMP, particularly calmodulin-dependent kinase II, protein kinase C, and MAP kinase. At the *Aplysia* synapse of sensory to motor neuron, most analysis since the 1970s has focused on presynaptic mechanisms of facilitation, and the PKA pathway has received the greatest emphasis. This has led to the widespread impression that learning in mollusks utilizes presynaptic mechanisms of plasticity involving cAMP and that learning in mammals utilities postsynaptic mechanisms for altering synaptic strength that are largely independent of cAMP. This dichotomy reflects the history of the research on plasticity at the *Aplysia* synapse of sensory to motor neuron and the hippocampal CA3-to-CA1 synapse rather than fundamental differences between the phyla. Indeed, both within *Aplysia* and within mammalian CNS, learning involves a diverse array of pre- and postsynaptic mechanisms. (A substantial number of recent studies of *Aplysia* synapses have focused on the contribution of increases in postsynaptic calcium to the strengthening of these synaptic connections. These mechanisms are discussed here, as cAMP has not yet been implicated in these postsynaptic processes.) The diverse examples discussed in the next section illustrate some of the ways that cAMP contributes to plasticity during learning. It is also important to emphasize that this discussion of cAMP-initiated synaptic plasticity should not be interpreted as suggesting that other signaling pathways do not also play important roles in these same forms of plasticity.

Presynaptic Modulation by cAMP

Evidence for Effects of cAMP That Enhance Transmitter Release during Long-Term Potentiation at Mammalian CNS Synapses

Long-term potentiation (LTP) is a persistent strengthening of synaptic connections induced by a brief period of high-frequency presynaptic activity. Many central synapses display LTP, though the required patterns of stimulation for induction vary depending on the synapse. In the cerebellum, synapses between the granule cells and the Purkinje neurons undergo LTP when the granule cell axons, called parallel fibers, are stimulated at 2–8 Hz for $\geq$10 s. Modulation of the strength of these parallel fiber synapses is believed to contribute to at least some types of motor learning. Parallel fiber LTP is initiated by presynaptic calcium influx through voltage-activated calcium channels. cAMP is known to be involved because bath-applied inhibitors of PKA block LTP induction. Linden and Storm and their colleagues have analyzed the contribution of AC and cAMP to parallel fiber LTP. They found that knockout of calmodulin-sensitive AC1, which is expressed in cerebellum, completely eliminated parallel fiber LTP. To assess the relative contributions of pre- and postsynaptic PKA, inhibitors of the kinase were delivered pre- and postsynaptically. Unexpectedly, neither pre- nor postsynaptic delivery of PKA inhibitors blocked LTP. This suggested that inhibitors might not adequately diffuse from the soma where they were injected to the synaptic terminals. Subsequent experiments attempted to improve delivery by transiently expressing an endogenous PKA inhibitor protein, using a viral vector. Expression of the PKA inhibitor in the presynaptic granule cell, but not in the postsynaptic Purkinje neuron, blocked LTP induction. By the use of extracellular application of antibodies against the intravesicular domain of the synaptic vesicle protein synaptotagmin, it was possible to directly demonstrate that cAMP increases the rate of vesicle fusion. Together, this evidence suggests that activity in the presynaptic parallel fiber terminals, and the accompanying increase in intracellular calcium, results in calmodulin-dependent activation of AC1. The increase in cAMP somehow initiates facilitation of transmitter release.

A similar form of cAMP-dependent LTP occurs in hippocampus at the synapse between dentate granule cells and CA3 pyramidal cells. LTP, elicited by 1 s of 100 Hz stimulation of the dentate granule cells' axons, called mossy fibers, may also involve a postsynaptic contribution by PKA. However, there is substantial evidence that mossy fiber LTP can occur with a similar or identical mechanism as parallel fiber LTP in cerebellum. Mossy fiber LTP is largely eliminated in mutant mice in which AC1 has been knocked out. Presynaptic injection of a PKA inhibitor results in comparable elimination of most of the mossy fiber LTP. It should be pointed out that as of yet, no deficits in hippocampal-dependent learning have been identified that result from mutations that impair mossy fiber LTP. This lack of a deficit may be a consequence of which specific learning tasks are routinely evaluated rather than a reflection of a lack of relevance of plasticity at the mossy fiber synapses for behavioral plasticity in general. Other central synapses, including corticothalamic synapses, undergo LTP that appears to involve a similar presynaptic, PKA-dependent mechanism.

Presynaptic Targets of PKA That Contribute to LTP or Synaptic Facilitation

It has been difficult to identify the active-zone proteins that are the critical targets for PKA during facilitation of transmitter release. This is in part because the active zone includes more than two dozen proteins that participate in regulating synaptic vesicle trafficking, including docking (initial interaction of vesicles with proteins associated with the plasma membrane at the active zone), priming (the prefusion step that makes the vesicle competent for exocytosis), and fusion (the final step in transmitter release). Two proteins that have been implicated in PKA-dependent enhancement of transmitter release are RIM1α and synapsin.

Phosphorylation of RIM1α Plays a Necessary Role in PKA-Dependent LTP at Mossy Fiber and Parallel Fiber Synapses

Rab3A is a small G-protein that binds GTP. When in the GTP-bound state, Rab3A attaches to synaptic vesicles and influences the probability of vesicle release. Knockout of Rab3A had only subtle effects on transmitter release, perhaps because there are three Rab3 isoforms. The most striking phenotype that was observed in the Rab3A knockout mouse was that LTP is lacking at mossy fiber synapses. The importance of Rab3A in PKA-dependent mossy fiber LTP was initially puzzling because Rab3A is not a substrate for PKA. However RIM1α, with which Rab3A interacts, is phosphorylated by PKA. Like Rab3A, RIM1α is required for mossy fiber LTP. RIM1α is a scaffolding protein that interacts with a number of active-zone proteins, including munc13 and synaptotagmin, as well as Rab3A. RIM1α may participate in vesicle priming, and it also influences release probability. Knockout of RIM1α eliminates LTP at both mossy fiber and parallel fiber synapses. This has been explored in the most detail by Sudhof and Linden and their colleagues at

Figure 1 Presynaptic mechanisms of short-term, protein kinase A (PKA)-dependent synaptic enhancement: two alternative mechanisms by which PKA acts to enhance transmitter release. (a) Phosphorylation (P) of RIM1α enhances vesicle priming and increases the probability of vesicle release. PKA, containing two regulatory and two catalytic subunits, is shown above, with cyclic adenosine monophosphate (cAMP) bound to the regulatory subunits. The dissociated catalytic subunit phosphorylates RIM1α at serine 413 near the N-terminus. RIM1α interacts both with Rab3A, which is coupled to synaptic vesicles (SVs), and with munc13. The RIM1α–Munc13–Rab3A complex participates in vesicle priming. Munc13 is shown interacting with syntaxin. (b) Phosphorylation of synapsin (red) recruits vesicles from the reserve pool. Synapsin is shown attached to actin and synaptic vesicles, tethering the vesicles in the reserve pool to the cytoskeleton. Phosphorylation by activated PKA catalytic subunit results in dissociation of synapsin from the vesicle, enabling the vesicle to be mobilized into the readily releasable pool of vesicles. In both (a) and (b), the synaptosome-associated protein (SNAP) receptors (SNAREs; VAMP, syntaxin, and SNAP-25) are shown participating in vesicle priming. (Numerous other presynaptic proteins that do not participate in these specific modulatory mechanisms are omitted from the figure; moreover, proteins participating in one modulatory mechanism are omitted from the other panel. Nevertheless, these omitted proteins play critical roles in vesicle trafficking at these synapses.)

the cerebellar synapses of granule cells to Purkinje neurons (i.e., in parallel fiber LTP). PKA phosphorylates RIM1α at two serine residues, at the 413 and 1548 positions. Mutation of serine 413 to the nonphosphorylatable amino acid alanine blocked parallel fiber LTP; a similar mutation of serine 1548 had no effect. This suggests that phosphorylation of RIM1α at a single residue may mediate the increase in the probability of vesicle release during LTP at both parallel fiber synapses and mossy fiber synapses (Figure 1(a)).

Phosphorylation of Synapsin by PKA Regulates the Readily Releasable Pool of Vesicles

Despite the identification of synapsin a decade or more before other active-zone proteins, it has been difficult to delineate unambiguously its role either in normal exocytosis or in synaptic plasticity. This is, in part, because synapsin does not directly contribute to the exocytosis processes or influence release probability. Synapsin knockout animals do not show striking deficits in synaptic transmitter release. The primary role for synapsin may be the regulation of vesicle availability from the reserve pool of synaptic vesicles at the active zone. Synapsin binds to synaptic vesicles and also to actin filaments, as well as to other cytoskeletal proteins. Through these interactions, synapsin has been proposed to tether the reserve pool of synaptic vesicles to the cytoskeleton. In the absence of synapsins, localization of the reserve pool of synaptic vesicles at the active zone is impaired. Synapsin-dependent regulation of vesicles in the reserve pool is particularly important during high-frequency activity; with long periods of activity, excitatory synapses from synapsin knockout mice display more-severe synaptic depression and impaired recovery from synaptic depression. The interaction of synapsin both with vesicles and with actin depends on phosphorylation, though at different amino acids. Phosphorylation of synapsin at serine 9 either by PKA or by calmodulin-dependent kinase I or IV results in dissociation from synaptic vesicles; phosphorylation at another site by calmodulin-dependent kinase II or MAP kinase triggers dissociation from actin.

Analysis of the role of synapsin is also complicated because there are three synapsin isoforms in mammals. In contrast, *Aplysia* expresses only a single synapsin isoform, and it is in this marine snail that the clearest role for synapsin in learning has been identified. In addition to behavioral sensitization and classical conditioning, the defensive withdrawal of *Aplysia* reflex undergoes habituation. During repeated stimuli, the synaptic connections from the sensory neurons to postsynaptic motor neurons of the reflex circuit become progressively weaker. In a habituated animal, noxious stimuli cause a recovery of the behavioral response called dishabituation. Like sensitization, dishabituation involves the release of serotonin, which acts to enhance transmission at the previously depressed synapses of sensory neurons to motor neurons. John Byrne and colleagues have studied the regulation of synapsin during this serotonin-initiated reversal of synaptic depression. The PKA and calmodulin-dependent kinase I/IV phosphorylation site at the N-terminus of synapsin is highly conserved throughout evolution, suggesting it is central to this synaptic protein's function; the PKA consensus sequence, including serine 9, is also present in *Aplysia*. Exposure to serotonin resulted in the dissociation of synapsin from the main pool of synaptic vesicles at the active zone, as evidenced by immunocytochemistry. The dispersal of synapsin from

the active zone depended on PKA. It is believed that by phosphorylating synapsin and thereby releasing vesicles in the reserve pool that are tethered to the cytoskeleton, PKA increases the availability of vesicles for release in the active zone (Figure 1(b). This increase in vesicle availability triggered by PKA phosphorylation of synapsin may be an important step in the serotonin-induced facilitation of previously depressed synapses of sensory neurons to motor neurons. The full mobilization of vesicles into the readily releasable pool requires docking and priming, which involve other active zone proteins; these steps are likely to be regulated by other protein kinases, including protein kinase C. (Synapsin was recently found to also interact with Rab3A and may participate in docking, but regulation of this interaction by PKA has not been demonstrated.)

The importance of phosphorylation of synapsin at serine 9 was explored using hippocampal pyramidal cells that expressed a mutant protein in which this serine was changed to alanine. Vesicle release was monitored by preloading vesicles with the fluorescent dye FM4-64, applied extracellularly, and then measurement of the disappearance of the fluorescence, which is indicative of the rate of release. Extended periods of release were elicited with prolonged depolarization stimulated by high potassium saline. The decline in fluorescence at presynaptic terminals stimulated by depolarization was dramatically reduced in neurons expressing synapsin with the serine-to-alanine substitution. On the other hand, the mutant synapsin did not affect release triggered by single action potentials. Phosphorylation of serine 9 that was induced by depolarization depended primarily on PKA, as opposed to calmodulin-dependent kinase. This suggests that calcium influx during presynaptic activity activates cAMP-dependent kinase, probably via calmodulin-sensitive AC; phosphorylation by PKA of serine 9 in synapsin mobilizes vesicles from the reserve pool, contributing to the maintenance of transmitter release during high-frequency firing.

Postsynaptic Modulation by cAMP: Regulation of Glutamate Receptors during LTP

In contrast to modulation of vesicle release by PKA, which has been difficult to analyze due to the large numbers of presynaptic proteins that participate in vesicle trafficking, modulation of postsynaptic responses to neurotransmitter have been relatively easy to characterize. At the synapse, postsynaptic receptors are directly modulated by phosphorylation. PKA-dependent modulation of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors occurs during LTP at the CA3-to-CA1 pyramidal cell synapse in hippocampus. High-frequency stimulation of the CA3 axons (e.g., with trains of 100 Hz for $\leq$1 s) results in synaptic potentiation that persists for tens of minutes or longer, depending on the details of the induction protocol. As is the case for most fast excitatory synapses in the mammalian CNS, these synapses utilize glutamate as their neurotransmitter. At these CA3-to-CA1 pyramidal cell synapses, changes in localization of AMPA-type glutamate receptors (GluRs) have been demonstrated to play a central role in the early phase of LTP. AMPA receptors are composed of combinations of GluR subunits. The GluR1 subunit of the AMPA receptor is phosphorylated both at serine 845 by PKA and at serine 831 by calcium–calmodulin-dependent kinase II. Typically, at naive synapses, serine 845 of GluR1 is already phosphorylated. Long-term depression (LTD) is initiated by low-frequency synaptic activation and involves the dephosphorylation of serine 845 by a phosphatase (depending on the protocol, one of several serine/threonine phosphatases may be involved). The loss of the phosphate at serine 845 triggers the endocytic removal of the GluR1-containing receptor from the membrane. Phosphorylation by PKA is therefore required for stabilizing GluR1-containing AMPA receptors at the synapse (Figure 2). Phosphorylation of serine 845 in GluR1 by PKA also increases the open probability of the AMPA receptor, which increases the postsynaptic current elicited by the neurotransmitter glutamate. The dephosphorylation of GluR1 that occurs during LTD has the opposite effect: reducing the current through the AMPA receptor, as well as destabilizing the AMPA receptors. At CA3-to-CA1 synapses that have undergone LTD, high-frequency stimulation initiates potentiation that reverses the effect of LTD (de-depression). In addition to maintaining normal AMPA receptor localization and function, PKA plays a key role in restoring synaptic strength during de-depression. Thus, when GluR1 subunits have been dephosphorylated, reversal of depression is mediated by PKA in the postsynaptic dendritic spines. The activation of PKA during high-frequency presynaptic activity is triggered by calcium influx through *N*-methyl-D-aspartate (NMDA) receptors, probably via activation of calmodulin-sensitive AC (AC1 and AC8) in the dendritic spines.

Localization of PKA via A Kinase Anchoring Proteins Is Necessary for cAMP-Dependent Synaptic Plasticity

For coupling among proteins in signaling cascades, including the cAMP cascade, the co-localization of interacting proteins is critical. Anchoring and scaffolding proteins mediate the assembly of protein

Figure 2 Protein kinase A (PKA) acts postsynaptically to increase α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor response to glutamate. PKA is co-localized with AMPA receptors by binding to A kinase anchoring protein (AKAP) 79/150. AKAP79/150 and AMPA receptors are brought together through their mutual interactions with the scaffolding protein SAP97. Under basal conditions at CA3-to-CA1 pyramidal cell synapses, PKA phosphorylation of glutamate receptor (GluR) 1 at serine 845 (indicated by P) increases the AMPA receptor open probability and stabilizes the receptors in the postsynaptic membrane. During long-term depression (LTD), dephosphorylation of serine 845 by protein phosphatase (PP) decreases the open probability and promotes endocytic removal of the GluR1-containing AMPA receptors from the membrane. When moderate levels of calcium influx through the *N*-methyl-D-aspartate receptor (not shown) initiate LTD, PKA is displaced from the postsynaptic density, shifting the kinase–phosphatase balance in favor of dephosphorylation of serine 845. The protein phosphatase responsible for regulating serine 845 is not specified, though calcineurin is activated by calcium influx during initiation of LTD. When higher-frequency presynaptic stimulation initiates potentiation of synapses that have undergone LTD, de-depression involves phosphorylation of serine 845 to increase AMPA receptor current and to promote AMPA receptor stabilization. Cat, catalytic subunit of PKA; Reg, regulatory unit of PKA.

complexes, including the enzymes that produce intracellular messengers, the channels that mediate calcium elevation (e.g., NMDA receptors), protein kinases, phosphatases, and the target proteins that are regulated by phosphorylation. This localization of signaling proteins within microdomains achieves both specificity and efficiency of the modulatory cascades. Because the co-localization of signaling molecules within a microdomain varies among cell types, co-localization also contributes to the cell specificity of the effects of each signaling cascade. Localization of PKA is achieved through A kinase anchoring proteins (AKAPs), which have been extensively characterized by John Scott. AKAPs anchor the regulatory subunits of PKA, localizing the protein kinase via the targeting domains of each particular AKAP. One such AKAP, AKAP79/150, targets both PKA and the phosphatase calcineurin to the postsynaptic density by interacting with two scaffolding proteins, PSD-95 and SAP97. SAP97 binds to AMPA receptors, whereas PSD-95 binds to NMDA receptors. The RII subunit of PKA binds to AKAP79/150, positioning the kinase proximal to both NMDA and AMPA GluRs. AKAP localization of PKA is required for the normal PKA phosphorylation of GluR1 at serine 845 and for the stabilization of GluR1-containing AMPA receptors in the postsynaptic membrane (Figure 2). During LTD and de-depression, the initiating signal for the plasticity is calcium influx through NMDA receptors. Therefore the AKAP complex localizes PKA close to both the source of the initiating signal, the NMDA receptor, and the target protein, the AMPA receptor. There must be similar co-localization of calmodulin-sensitive AC with the channels that mediate calcium influx, the NMDA receptors, to enable PKA activation during de-depression. With LTD, there is loss of GluR1-containing AMPA receptors from the surface of the postsynaptic membrane, as described above (Figure 2). Activation of calcium influx through NMDA receptors by low levels of activity, which induce LTD, displaces the PKA that contains RIIβ from the postsynaptic density. The importance of co-localization of PKA can be tested by means of the Ht31 peptide, which corresponds to the PKA-binding domain of an AKAP; this peptide can be used experimentally to disrupt the PKA–AKAP association. When the Ht31 peptide was injected postsynaptically, both GluR1 and GluR2 were lost from the membrane, presumably through endocytosis, as during LTD. Thus, it seems that part of the mechanism of LTD is

to displace PKA from the postsynaptic density, thereby eliminating the PKA-dependent stabilization of AMPA receptors.

AKAP-dependent localization of PKA is also critical for presynaptic mechanisms of synaptic plasticity. Serotonin-dependent initiation of long-term synaptic facilitation of the connection of sensory neurons to motor neurons in *Aplysia* requires the RII subunit of PKA. Injection of the Ht31 peptide into the presynaptic *Aplysia* sensory neuron to disrupt PKA–AKAP coupling completely blocked long-term synaptic facilitation tested at 24 h after exposure to serotonin.

A clear link between AKAP-mediated localization of PKA and learning has been demonstrated in amygdala-dependent fear conditioning by LeDoux and colleagues. PKA in the lateral amygdala is required for both context-dependent and cue-dependent fear conditioning, when learning is evaluated at 24 h after training. Injection of a membrane-permeant form of the Ht31 peptide into the amygdala disrupts formation of stable memory for fear conditioning evaluated at the 24 h test point. Thus AKAP-mediated localization of PKA is essential for cAMP-dependent presynaptic and postsynaptic mechanisms of plasticity, and also for formation of long-term memory.

Role of cAMP and PKA in Initiating Long-Term Synaptic Plasticity

Synaptic plasticity that is initiated by transient increases in an intracellular messenger typically lasts only minutes or tens of minutes, ending when the intracellular signal disappears. In the case of cAMP, when AC is no longer activated, cAMP levels drop as a result of hydrolysis by phosphodiesterase; protein phosphatases then rapidly reverse the phosphorylation of proteins that had been targets of PKA. The initiation of more-persistent alteration of synaptic strength requires gene transcription and protein synthesis, much as is true for long-term learning (see the section titled 'cAMP-dependent signaling plays a central role in long-term learning'). Thus, long-term synaptic plasticity involves mechanisms distinct from the mechanisms that mediate short-term synaptic plasticity, which typically depends on covalent modification of existing proteins. One of the early steps in the initiation of stable long-term synaptic changes and long-term learning is the transient expression of immediate early genes. These immediate early genes code for transcription factors and other proteins important for the transition from short-term to long-term plasticity. These proteins then initiate a later wave of transcription and protein synthesis which contributes more directly to stable synaptic changes.

cAMP-Dependent Phosphorylation Plays an Important Role in Initiating Stable Transcription-Dependent Long-Term Synaptic Plasticity in Both *Aplysia* and Mammals

In *Aplysia*, repeated brief exposures to serotonin result in long-term facilitation of the synaptic connections of sensory neurons to motor neurons, lasting 24 h or more. Initiation of long-term facilitation at these synapses depends on cAMP and PKA. In hippocampus, LTP at CA3-to-CA1 pyramidal cell synapses lasts either tens of minutes or hours depending on the pattern of high-frequency stimulation. Stable late-phase LTP that lasts several hours is initiated when the presynaptic Schaeffer collateral axons from the CA3 pyramidal cells are stimulated with repeated trains of high-frequency stimuli, whereas single trains elicit only short-lasting LTP. Initiation of late-phase LTP involves cAMP, similar to long-term facilitation in *Aplysia*. Storm and colleagues examined mice in which both of the calmodulin-sensitive ACs, AC1 and AC8, had been knocked out; the CA3-to-CA1 pyramidal cell synapses in these animals displayed no late-phase LTP, measured 80 min after the end of high-frequency presynaptic stimulation (Figure 3). Injection of an inhibitor of PKA into the postsynaptic CA1 pyramidal neurons similarly

Figure 3 Contribution of adenylyl cyclase (AC) and protein kinase A (PKA) to late-phase long-term potentiation (LTP) at CA3-to-CA1 pyramidal cell synapses. Blue curve illustrates typical stable, late-phase LTP. Late-phase LTP was initiated by a series of four high-frequency 100 Hz stimulus trains (arrows), which activated the presynaptic CA3 pyramidal cell axons. Depending on the study, the train duration was 200 ms or 1 s and the interval between trains was 6 s or 5 min. The late phase of LTP was almost completely eliminated by postsynaptic injection of a PKA inhibitor or by knockout (KO) of the calmodulin-dependent ACs (AC1 and AC8; red curve). Graph is illustrative of the effects of blockade of the cyclic adenosine monophosphate pathway observed by Wong et al. and Duffy and Nguyen. Note the partial decrease in LTP with blockade of the PKA pathway even at early time points, which is before the transcription-dependent phase of LTP first appears. This suggests that PKA may also contribute to early-phase LTP, at least with some protocols; a PKA-dependent contribution to early-phase LTP could be mediated by modulation of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor open probability or trafficking (see Figure 2).

blocked the late phase of LTP. Furthermore, Kandel and colleagues found that a dominant negative form of the regulatory subunit, which reduced PKA activity by as much as 50%, completely eliminated the late phase of LTP. Thus, even in regions of the mammalian CNS where short-term synaptic plasticity is independent of cAMP, long-term synaptic potentiation requires phosphorylation by PKA.

Presynaptic Contributions to Late-Phase LTP at CA3-to-CA1 Pyramidal Cell Synapses

Induction of late-phase LTP at CA3-to-CA1 pyramidal cell synapses is believed to be initiated by postsynaptic calcium influx through NMDA-type GluRs and calmodulin-dependent activation of AC. Siegelbaum and Kandel and colleagues examined the effects of treatment with cell-permeant cAMP analogs on presynaptic release sites at these same synapses. To monitor exocytosis at active release sites, they applied the lipophilic dye FM1-43, which labels vesicles during fusion with the plasma membrane. They found, 2 h after exposure to the cAMP analog, a sixfold increase in the number of active release sites without any change in total number of synaptic sites. This dramatic increase in functional release sites reflects conversion of preexisting silent release sites to active release sites (or conversion of release sites of very low probability to release sites of high probability). Because this increase in functional release sites depended on protein synthesis and because this change developed gradually, appearing at 2 h but not at 30 min, this enhancement of release must correspond to a component of long-term synaptic potentiation. The induction of the increase in active release sites initiated by the cell-permeant cAMP analog required functional postsynaptic GluRs that responded to the neurotransmitter released from the CA3 pyramidal cell terminals. This suggests that the mechanism for initiating the change in release involves the postsynaptic CA1 neuron and must reflect transsynaptic signaling. As discussed above, late-phase LTP at these same synapses involves postsynaptic activation of calcium–calmodulin-dependent AC and postsynaptic protein synthesis. Although these experiments in which increases in active release sites were imaged involved pharmacologically induced plasticity initiated by a cAMP analog, it likely that this coordinate interaction of pre- and postsynaptic cells in producing stable synaptic changes is a general phenomenon.

Persistently Activated Protein Kinase Contributes to Initiation of Long-Term Synaptic Facilitation

In order to understand how transient changes in synaptic connections initiated by intracellular messengers might be converted to more stable changes, James Schwartz and his colleagues explored the possibility that a specific protein kinase might be modified so as to upregulate phosphorylation. During the mid-1980s, they obtained evidence for persistent activation of PKA during induction of long-term synaptic facilitation in *Aplysia*; this persistent activation of PKA results from proteolysis of the regulatory subunit, removing the inhibitory regulation of the catalytic (C) subunit. Schwartz and his colleagues also observed that calmodulin-dependent kinase II can be persistently activated; since then, the persistent activation of calmodulin-dependent kinase II in mammalian hippocampus has been analyzed in detail. More recently, during LTP in hippocampus, protein kinase C was found to be expressed in a truncated form that lacks its inhibitory domain and is therefore autoactive. Thus, the persistent activation of serine/threonine protein kinases appears to be a general mechanism contributing to persistent synaptic plasticity.

How do serotonin and cAMP initiate degradation of the PKA regulatory subunits? Analogous to the requirements for induction of the late phase of LTP, initiation of stable long-term facilitation of *Aplysia* synapses of sensory neurons to motor neurons requires repeated exposures to serotonin spanning tens of minutes. PKA then triggers long-term facilitation of synapses of sensory neurons to motor neurons, a process that depends on both transcription and protein synthesis. One of the early steps in initiation of long-term facilitation is the proteolysis of the RI isoform of the regulatory subunit of PKA. This degradation of RI is mediated by the ubiquitin–proteasome pathway. Ubiquitin is a small, 76-amino-acid protein; proteins that are targeted for degradation are covalently labeled via the attachment of a chain of individual ubiquitin monomers. The proteasome is a large multiprotein proteolytic complex that cleaves ubiquitinated proteins into polypeptides. The ubiquitin-mediated degradation of RI subunits of PKA requires two steps. First, cAMP binding to both sites on RI initiates a conformational change that makes the subunit vulnerable to ubiquitination. Second, one of the immediate early genes that is induced in the presynaptic sensory neuron by repeated exposures to serotonin is a ubiquitin hydrolase; this hydrolase disassembles ubiquitin chains, accelerating the processing of proteins through the ubiquitin–proteasome pathway and the recycling of ubiquitin. Normally, RI subunits persist for 2 weeks, but with serotonin exposure, a percentage of RI subunits is degraded in less than 2 h. This degradation of the R subunits results in a population of PKA C subunits that are not bound to R subunits and therefore are tonically active. In a series of elegant experiments, Schwartz and Kandel and their colleagues found that blocking

the proteasome pathway in the presynaptic sensory neurons prevents induction of long-term facilitation. Injecting an excess of C subunits overcomes this effect, initiating substantial long-term facilitation. Thus, the ubiquitin-mediated degradation of the R subunits and the resulting reduction in the inhibitory regulation of C subunits are critical for the induction of stable long-term synaptic facilitation by serotonin. The RI subunits are primarily localized to the cell body, which suggests that the primary role of the autoactive PKA catalytic units is to initiate the transcription cascade that results in long-term facilitation. This process represents a positive feedback loop in which serotonin and cAMP initiate transcription of immediate early genes; the transcription of ubiquitin hydrolase then results in degradation of RI, which enhances PKA activity, potentiating further activation of the transcription cascade. The necessity for a subsequent increase in cAMP, which binds to RI and enables its degradation after ubiquitin hydrolase has been expressed, may be one reason that long-term learning requires repeated training and that long-term synaptic plasticity requires repeated exposure to the initiating stimulus, serotonin.

Initiation of Long-Term Plasticity by cAMP Involves Phosphorylation of Transcription Factors, Including CREB: Interactions between PKA and MAP Kinase

Many of the genes induced by cAMP have an upstream control region that contains a specific DNA consensus sequence, known as the cAMP responsive element (CRE). Activation of transcription of CRE-regulated genes occurs via phosphorylation of transcription factors, including the CRE binding protein (CREB), which then bind to the CRE. The role of the CRE in initiating long-term plasticity in *Aplysia* was tested by injecting into the nucleus of the presynaptic sensory neuron short DNA dimers that include the CRE sequence. These oligonucleotides should bind any activated transcription factors that interact with the CRE, including CREB, and should therefore block activation of the native CRE. Indeed, this 'transcription factor decoy' completely blocked long-term facilitation, measured 24 h after treatment with serotonin. In *Aplysia* and *Drosophila*, CREB has been demonstrated to play a central role in long-term synaptic facilitation and long-term learning, respectively. For example, in *Drosophila*, long-term memory was blocked by overexpression of an endogenous inhibitory isoform of CREB, which inhibits CREB activation of CRE-mediated transcription. In mammals, the situation is more complex because there are two other CREB-related genes, CREM and ATF1, which code for transcription factors that also bind to the CRE. Manipulations of the CREB gene in mammals have produced limited effects on long-term plasticity, perhaps because of compensatory increases in the expression of these other CREB family members.

The analysis of the role of CREB in long-term plasticity is also complicated because CREB can actually be phosphorylated by more than half a dozen protein kinases. In *Aplysia* CNS and in mammalian brain, it has been found that MAP kinase is required for CREB activation by cAMP. The interaction between the two signaling cascades has been most thoroughly analyzed by Storm and colleagues using CRE-regulated transcription of a reporter gene. Although PKA does not directly phosphorylate CREB in hippocampal neurons, PKA is required for the activation of CRE-mediated transcription triggered by calcium influx and cAMP synthesis. MAP kinase was also required for the initiation of CRE-mediated transcription. During exposure to an activator of AC, paired with calcium influx produced by membrane depolarization, MAP kinase is translocated to the nucleus. Both the activation and the translocation of MAP kinase depend on PKA (Figure 4). A second kinase, RSK2, is translocated to the nucleus along with MAP kinase. RSK2 is activated by MAP kinase, as is MSK1. Both RSK2 and MSK1 are CREB kinases that directly phosphorylate CREB. Thus, PKA participates in translocating and activating other kinases, which in turn are responsible for activation of CRE-mediated transcription.

Summary

cAMP and PKA play central roles in synaptic plasticity and learning. Because of interactions among signaling cascades, it is often difficult to analyze the contributions of one pathway in isolation. At some specific synapses, cAMP-dependent protein phosphorylation contributes to short-term synaptic plasticity and short-term learning. Postsynaptically, short-term modulatory mechanisms involve the regulation of neurotransmitter receptors. Receptor open probability or conductance may be modulated, as well as the stability of receptors in the plasma membrane. Presynaptically, because the vesicle trafficking apparatus involves more than 30 participating proteins, there are many possible targets for modulation by PKA; it is likely that these mechanisms have not yet been fully characterized. PKA-dependent phosphorylation of two presynaptic proteins, synapsin and RIM1α, is known to contribute to synaptic plasticity. Synapsin primarily regulates trafficking between the reserve pool and the readily releasable pool of vesicles, whereas RIM1α influences vesicle priming and the probability of release. One important interaction between cascades is the activation of calmodulin-sensitive AC by calcium influx. The AC–cAMP–PKA pathway depends on co-localization

Figure 4 Interactions between protein kinase A (PKA) and mitogen-activated protein (MAP) kinase in activation of cyclic adenosine monophosphate (cAMP) responsive element (CRE)-mediated transcription. Calcium influx, via either voltage-sensitive calcium channels (shown here) or *N*-methyl-D-aspartate-type glutamate receptors, acts via calmodulin (CaM) to stimulate adenylyl cyclase (AC). cAMP (yellow triangles) binds to the regulatory subunit of PKA, releasing the catalytic subunits. PKA activates the mitogen-activated protein kinase (MAPK) cascade via the small G-protein Rap1. Small G-proteins are regulated by guanosine triphosphate (GTP) exchange factors (GEFs), which increase the rate of exchange of GTP for guanosine diphosphate (GDP). Phosphorylation of a Rap1-specific GEF activates Rap1, which in turn stimulates the protein kinase Raf. Raf phosphorylates the kinase MEK, which phosphorylates MAPK. The translocation of MAPK from the cytoplasm to the nucleus depends on activity of PKA via an unknown mechanism. In the nucleus, MAPK activates one of two CRE binding protein (CREB) kinases, RSK2 or MSK1, which phosphorylates CREB. Phosphorylated CREB binds to CRE, activating transcription of CRE-regulated genes. A specific activation pathway based on results from several studies is illustrated here, but depending on the specific cell type, the co-localization of these signaling proteins varies. Thus, there can be additional pathways for the activation of MAPK, including Ras. cAMP also binds to a subclass of GEFs called exchange proteins directly activated by cAMP (EPACs), not shown; however, because of a lack of appropriate co-localization, EPACs do not appear to mediate the activation of the MAPK cascade.

of these signaling proteins with upstream regulators, such as calcium channels, and with downstream target proteins. Co-localization of PKA with target proteins is mediated by AKAPs. The binding of the regulatory subunit of PKA to specific AKAPs and the resulting co-localization of PKA with target proteins is necessary for induction of PKA-dependent plasticity. Initiation of long-term synaptic plasticity and long-term learning involve activation of transcription cascades. cAMP and PKA play a central role in this process by activating transcription of genes regulated by the CRE, a DNA regulatory element. Activation of CRE-mediated transcription by PKA is indirect. The signaling between PKA and the CRE involves a cascade of interacting proteins, including MAP kinase and downstream CREB kinases that directly activate the transcription factor CREB in the nucleus.

Structural Features of Cyclic Nucleotide-Gated and Hyperpolarization-Activated Cyclic Nucleotide-Gated Channels

Cyclic nucleotide-gated (CNG) and hyperpolarization-activated cyclic nucleotide-gated (HCN) channels are members of an extended superfamily of cation channels that is characterized by a principal building unit containing six transmembrane helices (S1–S6) and an reentrant pore-loop (ion selectivity filter) between S5 and S6 (Figure 1). Four channel subunits are assembled around the central ion conducting pore to form a tetrameric complex. CNG channels pass monovalent cations, such as Na^+ and K^+, but do not discriminate between them. Ca^{2+} is also permeable but at the same time acts as a voltage-dependent blocker of monovalent cation permeability. By providing an entry pathway for Ca^{2+}, CNG channels control a variety of cellular processes that are triggered by this cation. HCN channels conduct Na^+ and K^+ with permeability ratios of approximately 1:4 and are blocked by millimolar concentrations of Cs^+. Despite this preference for K^+ conductance, HCN channels carry an inward Na^+ current under physiological conditions. HCN channels can also conduct Ca^{2+}, but not CNG channels. At 2.5 mM external Ca^{2+}, the fractional Ca^{2+} current of HCN2 and HCN4 is approximately 0.5%, whereas for native CNG channels it is 10–80%.

Native CNG channels are heterotetramers composed of homologous A subunits (CNGA1–CNGA4) and B subunits (CNGB1 and CNGB3). The subunit stoichiometries have been determined for the channels expressed in rod photoreceptors (3 CNGA1:1 CNGB1a), cone photoreceptors (2 CNGA3:2 CNGB3), and olfactory neurons (2 CNGA2:1 CNGA4:1 CNGB1b). The HCN channel family comprises four members (HCN1–4). In contrast to CNG channels, the exact subunit composition and stoichiometry of native HCN channels has not been determined experimentally. However, there is evidence for the presence of both homo- and heterotetrameric channels *in vivo*.

CNG and HCN channels differ from each other with regard to their mode of activation. CNG channels are typical ligand-gated channels. Their activation obligatorily requires binding of cAMP or cGMP to a cyclic nucleotide-binding domain (CNBD) in the C-terminus. This domain is homologous to CNBDs of other cyclic nucleotide-binding proteins, such as cAMP- and cGMP-dependent protein kinases or cAMP-regulated guanine nucleotide exchange factors. In contrast to CNG channels, HCN channels are principally operated by membrane hyperpolarization. Sensitivity to voltage is conferred by a positively charged voltage sensor motif (S4) in the channel core. HCN channels also contain a CNBD in the C-terminus that shows strong homology to the CNBD of CNG channels. Unlike in CNG channels, binding of cAMP to the CNBD is not sufficient for HCN channel activation. However, it affects the voltage dependence of channel activation and, hence, modulates the voltage range where HCN channels can operate. The extent of regulation by cAMP varies between different HCN channels. It is profound in HCN2 and HCN4 (shift of $V_{0.5}$ by +10 to +20 mV) but weak in HCN1 and HCN3 (shift of $V_{0.5}$ by −5 to +7 mV). The crystal structure of the proximal C-terminus of HCN2 containing the CNBD and the short linker sequence that connects the CNBD with the S6 helix (the C-linker) has been determined. Together with results from functional studies, the structural data indicate that in the absence of cAMP the proximal C-terminus assembles into a twofold symmetry (dimer of dimer) that inhibits HCN channel gating, probably via an interaction between the C-linker and the channel core. Binding of cAMP to the CNBD promotes a conformational change to a fourfold symmetry and relieves this inhibition. Differences in the magnitude of the response to cAMP among the four HCN channel isoforms are largely due to differences in the extent to which the CNBD inhibits basal gating.

Functional Roles of CNG Channels in Visual and Olfactory Transduction

CNG channels are molecular switches converting alterations of cellular cAMP and cGMP levels into changes in the membrane potential. In outer segments of rod and cone photoreceptors, the CNG channel is opened in the dark by high cGMP concentrations. The resulting inward current depolarizes the cell and triggers synaptic glutamate release. Light-induced hydrolysis of cGMP leads to the closure of the CNG channel and, hence, to cessation of synaptic transmission. Olfactory transduction takes place in the cilia of olfactory receptor neurons. It relies on odorant-induced synthesis of cAMP and subsequent activation

Figure 1 (a) Phylogenetic tree of human CNG and HCN channel subunits. (b) The membrane topology of CNG and HCN channel subunits (top). The native channels are homo- or heterotetramers (bottom). 1–6, transmembrane segments 1–6; C, C-terminus; cA, cyclic AMP; cG, cyclic GMP; CNBD, cyclic nucleotide binding domain; N, N-terminus.

of a CNG channel. Influx of Na^+ and Ca^{2+} depolarizes the membrane and triggers action potentials. Depolarization is amplified by an outward Cl^- current that is activated by Ca^{2+} entering the cell through the CNG channels.

Channelopathies and Knockout Models of the Rod Photoreceptor CNG Channel

CNGA1 Subunit

Mutations in the CNGA1 gene (Table 1) have been found in patients suffering from retinitis pigmentosa (RP). RP comprises a genetically diverse group of progressive degenerative diseases affecting the photoreceptors of the retina. The most common symptoms of RP include night blindness, progressive concentric reduction of the visual field, an abnormal accumulation of pigmentation in the retina, and blindness. At the cellular level, the disease is characterized by a primary impairment or total loss of rod function and structure followed by a secondary degeneration of the cones. RP has been mapped to more than 30 genes encoding proteins involved in the visual transduction pathway (e.g., rhodopsin) or required for the maintenance of rod architecture (e.g., peripherin). Mutations in CNGA1 lead to an autosomal recessive form of RP that accounts for approximately 1% of cases of RP. Three of the five mutant alleles identified are null mutants (E76Stop, K139Stop, and deletion of most or all of the CNGA1 transcription unit) because they would encode proteins that are lacking essential channel domains. The remaining two alleles (S316F and R654DStop) encode channels that, in heterologous expression systems, fail to reach the plasma membrane. To date, mice lacking the CNGA1 subunit are not available. However, transgenic mice revealing an approximately 50% reduction of CNGA1 transcript levels due to the overexpression of a CNGA1 antisense mRNA have been produced. These mice show some histological features reminiscent of RP (e.g., reduced number of photoreceptors and apoptotic death of retinal cells).

CNGB1a Subunit

The CNGB1 gene locus consists of at least 33 exons encoding several splice variants. Rods express a 240-kDa isoform (CNGB1a) containing a long cytosolic N-terminus that is also translated as a separate cytosolic protein (glutamic acid rich protein (GARP)). Shorter variants of the subunit lacking the GARP part are present in the native olfactory CNG channel

Table 1 Overview of diseases associated with CNG channels

Type	*Subunit*	*Animal model*	*Human disease*
Rod channel	CNGA1	CNGA1 antisense expressing mice: retinal degeneration	Retinitis pigmentosa
	CNGB1a	CNGB1-deficient mice: impaired rod function and retinal degeneration	Retinitis pigmentosa
Cone channel	CNGA3	CNGA3-deficient mice: loss of cone function, cone degeneration, enhanced hippocampal LTP, impaired cued fear conditioning	Achromatopsia, progressive cone dystrophy
	CNGB3	Canine models (null deletion or missense mutation): cone degeneration	Achromatopsia, progressive cone dystrophy
Olfactory channel	CNGA2	CNGA2-deficient mice: impaired olfaction, impaired hippocampal LTP	
	CNGA4	CNGA4-deficient mice: impaired odor adaptation, impaired olfaction	
	CNGB1b	CNGB1-deficient mice: impaired odor adaptation and impaired olfaction	

LTP, long-term potentiation.

(CNGB1b) and have been identified in sperm cells and other tissues. A CNGB1-deficient mouse model covering all potential CNGB1 splice variants was generated by deleting exon 26, which encodes the pore-forming region and the S6 segment. These mice show an impairment of both vision and olfaction. In this section, we describe the retinal phenotype; the olfactory phenotype is described later.

CNGB1-deficient mice (Table 1) show a slow-progressing degeneration of the retina caused by apoptotic death and concurred by retinal gliosis. The degeneration primarily affects rod photoreceptors and is detectable in these cells as early as postnatal day 15. Cones are quite unaffected up to 6 months of age but start to degenerate subsequently. At the age of approximately 1 year, the retina of CNGB1-deficient animals is essentially devoid of both rods and cones. The principal structure of the inner retina is unaffected by the deletion of CNGB1. However, rod bipolar cells and horizontal cells reveal some morphological alterations (e.g., sprouting extensions, retraction of processes, and misplacement of cell bodies). CNGB1-deficient mice show no detectable rod-mediated responses in electroretinograms (ERGs), whereas at up to 6 months of age, cone-mediated responses are normal. Later, the cone responses also decrease, and at the age of 12 months knockout mice are legally blind. In agreement with the ERG measurements, the vast majority of isolated rod photoreceptors of young mice (postnatal day 17) fail to respond to light. Only in a few cells can a tiny dark current be detected. The severe retinal phenotype of CNGB1-deficient mice was unexpected given that CNGB1 was considered to be a modulatory subunit not needed for principal channel formation. This conundrum could be solved by Western blots and immunohistochemistry showing that in CNGB1-deficient mice, only trace amounts of the CNGA1 subunit are present on the rod outer segment. Thus, in contrast to cell lines used for heterologous expression (e.g., *Xenopus* oocytes or HEK293 cells), rod photoreceptors are not capable to produce substantial amounts of the homomeric CNGA1 channel and/or cannot target homomeric channels to the rod outer segment. It is not known why photoreceptors, unlike *Xenopus* oocytes or HEK293 cells, cannot efficiently target homomeric CNGA1 channels to the plasma membrane. It is tempting to speculate that the requirement of CNGB1 for targeting CNGA1 to the outer segment may have evolved to ensure that only heteromeric channels reach the outer segment membrane.

The total loss of CNG channel expression explains why the retinal phenotype of CNGB1-deficent mice is very similar to that found in RP patients with null mutations in the CNGA1 gene. Interestingly, RP patients have been identified who carry a point mutation in the CNBD of CNGB1. The functional consequences of this mutation, G993V, which involves a highly conserved residue in the CNG channel family, have not been determined in expression systems. Importantly, it is not known whether the mutant protein is targeted to the plasma membrane of rod outer segments. If the mutant protein is not targeted, the disease mechanism in CNGB1-deficient mice would be equivalent to that leading to human CNGB1-related RP. Alternatively, if the mutant CNGB1 is produced and assembled with CNGA1, it might impair the cGMP-dependent activation of the channel.

Taken together, the genetic data imply that photoreceptors degenerate in response to the absence (or downregulation) of functional CNG channels in outer

segments. The molecular pathways leading to the initiation of cell death in CNGA1/CNGB1-deficient rods are unknown. One possible mechanism refers to the 'equivalent light' hypothesis. According to this hypothesis, the absence of functional CNG channels is equivalent to the permanent closure of channels occurring under continuous bright light conditions. Continuous exposure of experimental animals to light has been shown to result in photoreceptor degeneration. In support of the equivalent light hypothesis, mutations of several other genes leading to constitutive activation of the visual cascade (e.g., null mutants of the guanylyl cyclase and activating mutants of rhodopsin) have been identified in RP patients. It is unclear, however, how constitutive activation of phototransduction leads to retinal degeneration. Low Ca^{2+} levels resulting from the loss of Ca^{2+} influx through CNG channels as well as toxicity induced by reactive oxygen species may play roles in this process.

Channelopathies and Knockout Models of the Cone Photoreceptor CNG Channel

CNGA3 Subunit

Mutations in the CNGA3 subunit cause achromatopsia (total colorblindness or rod monochromacy) (Table 1). CNGB3 and GNAT2 (which encodes cone-specific transducin) have been identified as additional achromatopsia genes. Achromatopsia is a rare autosomal recessive disorder (incidence of approximately 1 in 30 000), in which functional cones are absent from the retina. Affected individuals show a total loss of color discrimination, photophobia, nystagmus, and poor visual acuity. Electroretinography reveals absent photopic (cone) responses and normal scotopic (rod) responses. Individuals with incomplete achromatopsia retain some color vision. Approximately 50 mutations have been identified in the CNGA3 gene of patients suffering from achromatopsia. Most of the mutations are amino acid substitutions compared with a few stop codon mutations and deletions or insertions. The effect of several mutations on channel function was examined in heterologous expression systems. CNGA3 subunits carrying mutations in the S1 region (Y181C, N182Y, L186F, and C191Y) failed to be targeted to the plasma membrane, indicating that the folding and/or subunit assembly was disturbed in these mutants. Impaired channel targeting may also explain the loss of function induced by several other mutations. Alternatively, mutations may alter the biophysical properties of the channels. For example, the N471S and R563H mutants were found to have an increased cGMP affinity which may prevent complete closure of the channels in response to light stimulation. Consequently, these 'gain-of-function' mutations may lead to a sustained and potentially toxic elevation of intracellular Ca^{2+} levels in cone outer segments. A T369S mutation in the pore region of CNGA3 has been linked to incomplete achromatopsia. When co-expressed with the CNGB3 subunit, this mutant induced robust currents. However, the channel revealed a lower efficacy of Ca^{2+} blockage at physiological membrane potentials which tentatively would lead to a lower signal-to-noise ratio of the light response and, hence, explain the lower light sensitivity observed in the patients.

CNGA3-deficient mice display the principal hallmarks of achromatopsia described previously. As the only exception, deletion of CNGA3 has no obvious effect on visual acuity. This finding may be explained by the fact that mice lack the cone-enriched macula that confers high-acuity vision in humans. CNGA3-deficient mice reveal a complete loss of cone function. By contrast, the rod photoreceptor system remains fully intact (structurally and functionally) over the life span of the animals. Cones of CNGA3-deficient mice show a delayed postnatal migration behavior, form irregular synapses, and reveal a progressive degeneration. Interestingly, dorsal cones expressing medium-wavelength sensitive opsin survive significantly longer (up to 22 months) than ventral cones expressing mostly short-wavelength sensitive opsin (<3 months). The reason for this difference remains to be determined. CNGA3-deficient cones fail to transport opsins into outer segments, downregulate various proteins of the phototransduction cascade, and induce apoptotic death. As discussed previously for CNGA1/B1-deficient rods, cones of CNGA3-deficent mice may degenerate as a result of the constitutive activation of the visual cascade.

The CNGA3 subunit has been identified in a number of tissues different from retina, including a subpopulation of oligoribonucleotides (ORNs), sperm, kidney, and brain. CNGA3-deficient mice reveal normal fertility, indicating that CNGA3 is not essential for sperm function. There is evidence that CNGA3 may be involved in the modulation of long-term potentiation (LTP) in some brain regions and the formation of amygdala-dependent memory.

CNGB3 Subunit

A missense mutation in the CNGB3 gene (S435F) was identified in colorblind individuals originating from the Pingelap Atoll of Micronesia. On this small island, achromatopsia is very frequent and it affects nearly 10% of the native population. Several other mutations of the CNGB3 gene have been identified, most

of which lead to truncated proteins. Overall, mutations in the CNGB3 gene account for approximately 50% of all cases of achromatopsia. A missense mutation in exon 6 of the CNGB3 gene (D262N, corresponding to human D267N) and a CNGB3 null deletion were also identified in two canine inbred strains (Table 1) with cone degeneration.

The S435F mutation has been functionally characterized in *Xenopus* oocytes. CNGA3/CNGB3$_{S435F}$ heteromeric channels exhibited a more than fourfold increase in cAMP affinity and a modest increase in apparent affinity for cGMP. In addition, the mutant channel had a slightly higher open probability in the presence of saturating cyclic nucleotide concentration than wild-type channels. It is unclear whether these subtle effects can account for the severe clinical phenotype of the patients. Alternatively, it is possible that the mutation prevents correct protein folding and/or assembly with the CNGA3 subunit *in vivo*. The finding that null mutations of the CNGB3 gene induce achromatopsia strongly suggests that the CNGA3 subunit (like the CNGA1 subunit) is not able to form homomeric channels *in vivo*.

Knockout Models of the Olfactory CNG Channel

CNGA2 Subunit

Unlike all other CNG channel genes, the CNGA2 gene is localized on the X chromosome. Mutations of this gene have not been identified in humans. However, four different CNGA2-deficient mouse lines have been generated to define the physiological role of this subunit. CNGA2-deficient mice display elevated neonatal lethality due to their inefficiency to locate the mother and suckle milk. Indeed, initial electroolfactogram (EOG) recordings showed that the mice exhibit no detectable responses to odorants. Moreover, in perforated patch experiments, ORNs of CNGA2-deficient mice did not respond to odors or activators of the cAMP system. Together, these findings indicate that olfaction is conferred by a cAMP/CNGA2-mediated signaling pathway. In addition, the results strongly argue against a major contribution of other signaling cascades which have been suggested in the past (e.g., IP3-mediated olfaction). Studies have confirmed this principal conclusion and also uncovered that CNGA2-deficient mice are not totally anosmic. Very small but reproducible EOG responses to a variety of odorants were found in CNGA2-deficient mice. In behavioral tests, CNGA2-deficient mice could detect and discriminate several odorants. The molecular components conferring this residual olfaction remain to be determined. Pharmacological blockers suggest that the respective signaling pathway(s) is cAMP independent. There is evidence that a small subgroup of ORNs projecting to the so-called necklace glomeruli could be involved in non-cAMP-mediated olfaction. These neurons do not express CNGA2 but, rather, express the CNGA3 channel and several other components that support a cGMP signaling pathway.

In addition to its key role in olfactory transduction, CNGA2 is required for normal development of the olfactory epithelium and olfactory bulb. In comparison to wild-type mice, CNGA2 knockouts display a thinner olfactory epithelium and show lower expression of an olfactory marker protein. Moreover, the olfactory bulb is smaller, and tyrosine hydroxylase expression is reduced in the majority of periglomerular neurons but is retained in necklace glomeruli.

The olfactory CNG channel was identified in murine and rat hippocampus, suggesting a role of this protein in memory formation. In support of this hypothesis, hippocampal LTP evoked by a theta burst stimulation protocol was reduced (Table 1) in CNGA2-deficient mice. By contrast, several measures of basal synaptic activity as well as LTP induced by high-frequency stimulation seemed to be similar in wild-type and knockout mice. Behavioral tests to determine the memory performance of CNGA2-deficient mice have not been reported, leaving the question of whether or not the observed alterations of the hippocampal LTP are physiologically relevant unanswered.

CNGA4 and CNGB1b Subunits

Mice deficient for the CNGA4 subunit are fertile and show no obvious morphological differences with respect to wild-type mice. Moreover, the olfactory epithelium and the olfactory bulb are normally developed in these mice. Maximal EOG responses induced by 3-isobutyl-1-methylxanthine (IBMX), an inhibitor of the phosphodiesterase, are comparable in both genotypes. However, the dose–response curves of the response are shifted to approximately threefold higher IBMX concentrations in the CNGA4-deficient mice, suggesting that the mutant CNG channel is less sensitive to cAMP. Indeed, the apparent cAMP affinity of the CNG channel as determined from excised patch recordings is approximately tenfold lower in the knockouts than in wild-type mice. Thus, CNGA4 is clearly required to confer high cAMP affinity to the olfactory channel. CNGA4-deficient mice also show a defect in odor adaptation (Table 1). The decay time of the EOG in response to an odorant stimulus is profoundly slower in knockouts than in wild-type mice. Electrophysiological recordings in excised patches from ORNs clarified why CNGA4 is needed

for odor adaptation. The recordings revealed that in the absence of CNGA4, the kinetics of Ca-calmodulin-dependent inhibition are profoundly slower than in its presence. Thus, CNGA4 is required for fast feedback inhibition of channel activity by Ca-calmodulin. The results also suggested that the Ca-calmodulin binding site identified in the CNGA2 subunit is probably not involved in Ca-calmodulin-mediated inhibition *in vivo*. Another study confirmed this notion by demonstrating that apocalmodulin is preassociated with an IQ motif present in the C-linker of CNGA4. The authors also showed that another IQ motif present in the N-terminus of the CNGB1b subunit is necessary for inhibition. It was speculated that one apocalmodulin molecule binds to both sides, thereby cross-linking the CNGA4 and the CNGB1b subunit. If Ca^{2+} flows through the channel pore, it interacts with the preassociated apocalmodulin and induces a conformational change in the channel that decreases its cAMP sensitivity. As a consequence, the CNG channel closes and the olfactory transduction pathway is switched off.

RP patients carrying the G993V mutation were reported to show no olfactory impairment. In contrast, CNGB1-deficient mice that lack both the retinal CNGB1a and the olfactory CNGB1b subunit reveal a profound olfactory phenotype (**Table 1**). As reported for CNGA2-deficient mice, CNGB1 knockouts show an increased postnatal mortality that is probably due to a deficit in locating their mother's nipples to suckle milk. The knockout mice have a decreased olfactory performance and their EOG responses are significantly smaller than those of wild-type littermates. Moreover, fast odor adaptation is impaired, confirming that CNGB1 is absolutely necessary for Ca^{2+}-calmodulin-dependent inhibition. Interestingly, protein levels of the CNGA2 and the CNGA4 subunits are dramatically reduced in the cilia of CNGB1 knockout mice. Similarly, ciliary expression levels of CNGB1b and CNGA2 are extremely low in CNGA4-deficient mice. These findings show that ORNs have evolved a mechanism to control the composition of the CNG channel in the cilia to ensure that only channels containing all three subunits are available for olfactory signal transduction.

Introduction

Intercellular communication at chemical synapses occurs via exocytosis of neurotransmitter-containing synaptic vesicles in presynaptic nerve terminals. In the synaptic vesicle cycle, neurotransmitter-filled synaptic vesicles translocate (dock) to the presynaptic plasma membrane, where they are transformed into a fusion-competent primed state, ready for exocytosis. After a suprathreshold depolarization (usually an action potential), voltage-gated Ca^{2+}-channels open and the resulting Ca^{2+} influx triggers the completion of the final fusion event and neurotransmitter release. After exocytosis, synaptic vesicle membrane is retrieved and recycled for a new round of the synaptic vesicle cycle. The synaptic vesicle cycle is the result of extremely fast, precisely timed, and highly regulated cascades of protein–protein interactions. The assembly and disassembly of protein–protein complexes relies on the proper folding and native conformation of the participating proteins. Presynaptic nerve terminals work as largely autonomic subcellular units that are often separated by large distances from the biosynthetic machinery of the cell body. Consequently, dysfunctional proteins cannot be immediately replenished. This suggests that nerve terminals are equipped with first-aid mechanisms that protect them from the consequences of malfolded or denatured proteins (aged in the course of duty during continuous activity in the synaptic vesicle cycle).

Chaperone proteins are important components of the cellular rescue machinery. They ensure the proper folding of proteins, participate in the refolding of damaged or aged proteins and the untangling of protein aggregates, and aid in the stabilization and restructuring of protein conformations. Chaperone proteins typically bind to short stretches of hydrophobic amino acids that are exposed on partially or completely unfolded proteins and stabilize them until they are translocated into the hydrophobic interior of the protein or covered by other protein–protein interactions. Many protein–protein interactions involve hydrophobic stretches of amino acids which eventually need to be shielded from the aqueous surrounding if the protein–protein complex is disassembled. Obviously, the maintenance of correct protein folding is particularly important in presynaptic nerve terminals, where many protein–protein interactions are assembled and disassembled.

CSPα is an essential part of the chaperone system in presynaptic terminals. The importance of this chaperone protein was initially appreciated in *Drosophila* and *Drosophila* mutants and was recently highlighted by several studies analyzing CSPα-deficient knockout mice. Important properties of the (CSP) based chaperone system, including insights that emerged from the analyses of these CSPα-deficient mice, are summarized in this article.

Molecular Anatomy of CSPs: J-Domain Proteins Highly Conserved in Evolution

CSP genes, cDNAs, and proteins have been characterized in a variety of species and are highly conserved in evolution (Figure 1(a)). Invertebrates (e.g., *Drosophila*) have a single CSP gene, whereas mammals have three CSP genes (CSPα, CSPβ, and CSPγ). CSPα is the main isoform in the brain; CSPβ and CSPγ transcripts are absent from the brain as indicated by northern blot analyses. Hair cells from the inner ear express both CSPα and CSPβ; the testis expresses all CSP isoforms. CSPβ and CSPγ have same domain structure as CSPα, but their function is entirely unknown.

CSPs are characterized by distinct domains (Figure 1):

- An N-terminal Dna-J domain, the signature domain of Hsp40-type co-chaperones. J domains comprise a stretch of approximately 70-amino-acids which is highly conserved from bacteria (Dna-J protein) to humans.
- A central string of multiple cysteine residues. In mouse CSPα, 13 cysteine residues are found within a 22-amino-acid stretch present in the central portion of the protein.
- The linker region (L region) between the J domain and the cysteine-string region. The linker domain of CSP is highly conserved in evolution and has been implicated in regulating exocytosis.
- A variable C-terminus. The C-terminus is subject to differential splicing and generates C-terminally truncated proteins in *Drosophila* and mammals (named CSP1, CSP2, and CSP3; Figure1(a)).

The J domain of CSP mediates binding to Hsp70-type chaperone proteins. Hsp70-type chaperone proteins are a large family of evolutionary highly conserved proteins that includes the constitutively expressed

Figure 1 Primary structure of vertebrate and invertebrate CSPs: (a) general domain structure (top) and sequence alignment of CSPs (bottom); (b) the CSP–Hsc70–SGT complex. In (a), the amino acid sequences of human (Hs), mouse (Mm), *Drosophila melanogaster* (Dm), and *Caenorhabditis elegans* (Ce) are aligned for maximal homology using the single-letter amino acid code. The three mammalian CSPs are identified on the left as CSPα, CSPβ, and CSPγ; the single CSP genes in *Drosophila* and *C. elegans* are Dm CSP1 and Ce CSP, respectively. Residues that are identical in > 50% of the sequences are highlighted in blue, and residues that are similar or identical in 50% of the sequences are in red. The initiator methionines are shown in white on a black background, and the cysteine repeats are highlighted in yellow. Sequence in empty boxes at the C-terminus indicate alternatively spliced regions. The protein topology is illustrated by a colored horizontal bar above the sequence, with the Dna-J domain indicated by green and the linker region in black. Asterisks at the C-termini of the sequences indicate stop codons. Genbank accession number for the sequences analyzed are NP_079495 (Hs CSPα), NP_149096 (Hs CSPβ), NP_775921 (Hs CSPγ), AB87080 (Mm CSPα), Q9UF47 (Mm CSPβ), Q8N7S2 (Mm CSPγ), Q03751 (Dm CSP1), and NAAK39254 (Ce CSP). As shown in (b), CSP binds via its J domain to the ATPase domain of Hsc70. The TPR repeats of SGT bind to the C-terminus of Hsc70 as well as to the cysteine-string region and the C-terminus of CSP. Thus, binding of Hsc70 to CSP is secured by two different molecular connections. ATP, adenosine triphosphate; CSP, cysteine-string protein; SBD, substrate-binding domain; SGT, small glutamine-rich tetratricopeptide; TPR, tetratricopeptide repeat.

heat-shock cognate protein Hsc70, the stress-induced Hsp70, and many other Hsp70-type members. Hsp70 proteins bind to short, strongly hydrophobic stretches on proteins. These hydrophobic stretches are often found on denatured proteins or on disassembled protein complexes which are mediated by hydrophobic interactions.

Hsp70 proteins contain a N-terminal adenosine triphosphatase (ATPase) domain and a C-terminal substrate-binding domain (SBD). The ATPase domain binds ATP/adenosine diphosphate (ADP) with distinct affinities. The intrinsic ATPase activity of Hsp70 is low, but it can be strongly activated by the binding of the J domain to the ATPase domain of Hsp70 and probably, although to a lesser extent, also by the binding of client proteins to the SBD.

In the ATP-bound form, the affinity for client proteins is low. Nevertheless, ATP-Hsp70 does bind client proteins; however, binding is transient and release occurs rapidly. Binding of the J domain and subsequent ATP hydrolysis locks Hsp70 into its high-affinity conformation in which the refolding of malfolded proteins probably takes place. Subsequent binding of a novel ATP promotes the release of renatured client proteins, making Hsp70 ready for a new round of the chaperone cycle (Figure 2). In addition to the activation of ATPase activity by CSP binding, the ATPase activity of Hsp70 is further enhanced by the simultaneous binding of the small, glutamine-rich tetratricopeptide repeat (TPR) protein small glutamine-rich tetratricopeptide (SGT) (Figures 1(b) and 2). SGT binds to the cysteine-rich region of CSP (in cooperation with the CSP C-terminus). Previously, SGT had also been shown to bind to the C-terminus of Hsc70, and thus it represents a bridge molecule between CSP and Hsp70. SGT is ubiquitously expressed. Recently, a brain-specific isoform of SGT, called SGTβ, has also been described.

The cysteine residues in the cysteine-rich central portion of CSP are heavily palmitoylated and

Figure 2 Mechanistic model of the CSP–Hsp70–SGT chaperone complex at the synapse. CSP is anchored via its acylated cysteine residues in the cysteine-string region to the synaptic vesicle membrane. Then, a complex formed by Hsc70 and denatured client protein recruits the TPR protein SGT. The binding of CSP to Hsc70 induces ATP hydrolysis and a conformational change of Hsc70, which provides the energy for the refolding of the denatured client protein. The subsequent binding of ATP releases the renatured client protein and induces the disassembly of the trimeric complex. ADP, adenosine diphosphate; ATP, adenosine triphosphate; CSP, cysteine-string protein; Pi, inorganic phosphate; SGT, small glutamine-rich tetratricopeptide.

responsible for membrane targeting. Vesicle-bound CSP recruits Hsp70 to synaptic vesicles (Figure 1(b)). The trimeric complex consisting of CSP, Hsp70, and SGT is formed *in vivo* on the surface of synaptic vesicles and is able to refold denatured luciferase *in vitro*.

CSP Is Localized to Synaptic Vesicles and Secretory Granules

CSP proteins are associated with the membrane of synaptic vesicles. Originally, CSP was assumed to be brain-specific. Further studies clarified that CSP is also expressed outside the brain, in the endocrine, neuroendocrine, and exocrine tissues. In exocrine and endocrine glands, CSP has been localized to various secretory granules: the chromaffin granules in chromaffin cells, zymogen granules in exocrine pancreatic cells, insuline-containing secretory granules of neuroendocrine β-cells, hormone-containing secretory granules of the rat neurohypophysis, and secretory granules in secretory epithelia (e.g., the mammary gland). The localization in synaptic vesicles and secretory granules indicates an importance of CSP for secretion. CSP was also found in some nonsecretory tissues (e.g., the heart, kidney, spleen, testis, and adipose tissue), although in lower amounts. The significance of CSP at the latter localizations is not well understood.

Insights from CSP-Deficient Flies

The deletion of the CSP gene in *Drosophila* using transposon techniques is semi-lethal. The majority of flies without a functional CSP gene die. Only a minor fraction (4%) survives. These suffer from uncoordinated motor behavior and die prematurely. Interestingly, they become totally paralyzed and die within hours when the temperature is increased. At the cellular level, motor deficits result from a presynaptic defect in neurotransmission. Initially, it was believed that the recycling of vesicles in the presynaptic terminals would be the prime defect in CSP-deficient flies because Hsc70 (in cooperation with the J domain protein auxilin) mediates the uncoating of clathrin-coated vesicles. Further analyses, however, showed that the endocytotic pathway is not impaired in CSP-deficient flies. Instead, CSP is necessary for normal, evoked neurotransmitter release in flies. Characteristically, the presynaptic secretion defect in mutant flies was temperature dependent. Neurotransmitter release and evoked postsynaptic responses were already strongly reduced at 22 °C; at higher temperatures (29 °C or 32 °C), evoked responses were nearly completely lost. The temperature-dependent block of synaptic transmission is consistent with an increase in protein instability or unfolding in the absence of the CSP chaperone function. The temperature-sensitivity of the defects and the existence of escapers are untypical for a distinct and uniform loss-of-function effect, but are more compatible with a main role of CSP as a chaperone that works on denatured synaptic client proteins. Although a very useful and important model system was available with the CSP-deficient flies, pinpointing the precise molecular function of CSP and explaining the molecular defect in secretion in CSP mutant flies remained difficult.

Studies of CSP Interactions with Voltage-Dependent Ca^{2+} Channels and Other Presynaptic Proteins

Several studies suggested that voltage-dependent presynaptic Ca^{2+} channels (VDCCs) and their modulation are main targets of CSP. Early studies on CSP function described that the expression of Torpedo N-type VDCCs in oocytes was inhibited on injection of CSP antisense RNA. Later, the putative connection between CSP and VDCCs was supported by imaging studies of exocytosis in nerve terminals of *Drosophila* CSP mutants. Those studies showed that neurotransmitter release of CSP mutants was normalized on the application of Ca^{2+} ionophores that bypassed VDCC activation but not on the application of depolarizing solutions. Biochemical studies with vertebrate CSP led researchers to propose that CSP directly binds VDCCs by a direct interaction of CSP with the synaptic protein interaction (synprint) site of P/Q-type and N-type VDCCs and indirectly via G-protein subunits that regulate N-type VDCCs. Nevertheless, other observations challenged the CSP–Ca^{2+} channel hypothesis. Patch-clamp measurement of L-type Ca^{2+} currents at peptidergic nerve terminals of *Drosophila* CSP mutants showed no differences from wild-type flies. In addition, direct measurements of cytosolic Ca^{2+} levels in synapses of *Drosophila* CSP mutants revealed that Ca^{2+} influx elicited by depolarization was even higher than normal, ruling out that a deficit in Ca^{2+} influx through VDCC caused the impairment in neurotransmitter release. Instead, CSP appeared to more directly influence the synaptic vesicle exocytotic machinery. This notion was supported by experiments of CSP overexpression in neuroendocrine cells that showed altered exocytosis but had no effect on Ca^{2+} channel activity, arguing against a major importance of CSP in regulating VDCCs.

In conclusion, the reported heterogeneous abnormalities of VDCC function did not prove there is a major role for CSP as a physiological regulator of VDCC function. The observed multiple, and partly controversial, observations can be well explained by context-dependent activation of the CSP chaperone system induced by partially unfolded and/or aged proteins. Such an argument is particular relevant in overexpression experiments in which transfected cells are forced to overexpress proteins that might be difficult to fold (e.g., membrane proteins with multiple membrane-spanning regions) and which – if unproperly folded – will activate the CSP chaperone system. Also overexpression of CSP constructs could generate unphysiological side effects due to the sequestration of the physiological interaction partner of CSP and/or due to an overload of the cellular palmitoylation system.

Further studies proposed the interaction of CSP with key proteins implicated in synaptic vesicle fusion. Using CSP fusion protein as a bait protein, synaptotagmin 1 was identified as a potential interacting protein for CSP in rat brain homogenates. The interaction has been described to be phosphorylation dependent. A genetic and biochemical interaction between CSP and syntaxin in *Drosophila* has been controversially reported. Syntaxin was suggested as a possible target of CSP because the overexpression of syntaxin 1A compensated for the loss of CSP in *Drosophila*. A direct interaction between CSP and syntaxin was observed in some studies but not in others. Synaptobrevin 2 and CSP were found to co-immunoprecipitate from rat brain homogenates, although a direct interaction between these proteins was not found *in situ*. Only in cell-culture experiments that employed an overexpression of proteins as CSP reported to directly interact with synaptobrevin 2.

Recently, the vesicular γ-aminobutyric acid (GABA) transporter (VGAT) was found in a complex with CSP, Hsc70, and glutamate decarboxylase (GAD), suggesting an involvement of CSP in neuratransmitter synthesis and filling of synaptic vesicles with the neurotransmitter GABA. Also, Rab-α-guanosine diphosphate (GDP)-dissociation inhibitor (GDI), which recognizes GDP-complexed rab proteins and solubilizes rab-proteins from synaptic vesicle membranes after vesicle fusion, has been found in a complex that contained Hsc70 and CSP. This finding might indicate that either particular proteins of the complexes or the stability of the complex itself need to be chaperoned to maintain the required enzymatic activity. Yet these observations are still based on biochemical experiments, and the physiological relevance has not yet been determined.

Elucidating the Biological Function of Cysteine-String Proteins in CSPα-Deficient Mice

Recently, CSPα knockout mice (CSPα KO mice) were generated in which the CSPα gene was inactivated by homologous recombination, allowing a detailed molecular and functional analysis of CSPα in mouse. CSPα is the only CSP isoform in brain.

Immediately after birth, CSPα-deficient animals were normal and did not show any obvious defects. The synapse structure and function of CSPα-deficient mice was analyzed at different postnatal stages. Although the defects were initially inconspicuous, CSPα-deficient mice started to suffer from progressive muscle weakness and a severe deficiency in locomotive behavior that began between the second and third postnatal weeks of life. Locomotor defects in CSPα-deficient mice (e.g., delay in righting time (the time it took to get into the upright position after mice have been laid on their back)) dramatically increased with age. Parallel to the developing muscle weakness and deficits in locomotor performance, CSPα-deficient mice showed abnormal, decreased mean compound muscle action potentials (CMAPs) at postnatal day (P)45 but – most interestingly – not at P13 or P23. Thus, defects in CSPα-deficient mice were prominent in older animals but not yet present in young mice. These physiological defects in muscle strength and CMAPs correlated with a morphological degeneration in the presynaptic nerve terminal of the neuromuscular junction (NMJ), indicating a presynaptic defect.

Certain fast synapses in the mouse, which are absent in *Drosophila*, are enormously useful for the quantitative analysis of Ca^{2+} currents and neurotransmitter release. In particular, giant presynaptic terminals of the calyx of Held synapse in the auditory pathway of the brain stem are ideal for measuring VDCCs because the presynaptic terminals are directly accessible for patch-clamp recordings. Interestingly, detailed measurements of P/Q- and N-type Ca^{2+} currents performed at the calyx of Held did not reveal any abnormalities in CSPα KO mice compared to control littermates. The absence of any defects in VDCC function cannot be explained by compensation of the CSPα-deficiency by other CSP isoforms because CSPα is the only CSP isoform in the brain. Similarly, also L- and T-type VDCCs in ribbon synapses of the inner ear were found to be normal in CSPα KO mice. These findings indicate that in the physiological context CSPα is not essential for regulating voltage-gated Ca^{2+} channels.

Synaptic transmission was measured in the calyx synapse by using afferent fiber stimulation and by

Figure 3 Use-dependent loss of function and presynaptic degeneration in CSPα-deficient mice, revealing the consequences of the loss of the chaperone activity *in vivo*: (a) at 4 weeks of age, CSPα-deficient mice (CSP$^{-/-}$) are significantly smaller and show severe defects in the motor system compared to control littermates (CSP$^{+/+}$); (b) asynchronous, delayed, and amplitude-decreased EPSCs in the calyx of Held of CSP mutants (CSP$^{-/-}$) compared to control littermates (CSP$^{+/+}$) at postnatal day (P)20–P23, indicating alterations in neurotransmitter release (note the different scales in the wild-type and knockout graphs); (c) presynaptic calyx terminals in wild-type animals (CSP$^{+/+}$); (d) presynaptic calyx terminals in CSPα-deficient knockout mice (CSP$^{-/-}$); (e) electroretinogram (ERG) activity in wild-type and CSPα-deficient knockout mice; (f) wild-type photoreceptor ribbon synapses; (g, h) degenerated presynaptic photoreceptor ribbon terminals of CSPα-deficient mice. The asterisk in (b) indicates postsynaptic currents of extra-calycal origin. As shown in (c, d), the functional defects observed by electrophysiology are accompanied by a morphological degeneration of the presynaptic calyx terminals. In wild-type animals (c), the typical large, cup-shaped presynaptic terminal can be observed, which is filled with synaptic vesicles and mitochondria. In CSPα-deficient mice (d), the presynaptic terminal shows a pathological translucent appearance with few synaptic vesicles and condensed mitochondria (M). As shown in (e), at P45, CSP$^{-/-}$animals are completely blind and show no electrical activity in the electroretinogram (ERG); both the b-wave and the a-wave of the ERG (present in the wild-type animals) have disappeared. The loss of vision is accompanied by a morphological degeneration of the presynaptic ribbon photoreceptor terminals; the wild-type photoreceptor ribbon synapses (f) are characterized by large presynaptic terminals which are filled with synaptic vesicles and which contain a synaptic ribbon (sr) anchored to the active zone. As shown in (g and h), the degenerated presynaptic photoreceptor ribbon terminals of CSPα-deficient mice have a strongly decreased density of synaptic vesicles, an increased number of coated vesicles (cv), and an abnormal architecture of the presynaptic terminal. Remarkably, in the active zone of CSPα-deficient mice omega-shaped exocytotic figures could be occasionally observed. These exocytotic figures are hard to capture via conventional electron microscopy due to the high speed of exocytosis and the slow velocity of chemical fixation. The visibility of exocytotic fusion events and, in addition, rows of synaptic vesicles docked to the active zone waiting for exocytosis ((g) indicated by the solid line next to the arrowhead) could

parallel, paired recordings of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor-mediated postsynaptic responses. At early stages (P9–P11), measurements of evoked excitatory postsynaptic currents as response to presynaptic fiber stimulation did not reveal any alterations in the amplitude and kinetics of postsynaptic responses. This indicates normal coupling of Ca^{2+} channels and the exocytotic machinery, as well as a normal performance of exocytotic machinery, ruling out significant defects in exocytosis at that time. In addition to evoked postsynaptic responses, spontaneous miniature excitatory postsynaptic currents (mEPSCs) were also found to be normal in terms of kinetics and amplitude in CSPα-deficient mice.

In contrast to the normal synaptic function at P9–P11, synaptic function at P20 showed severe defects in the calyx synapses of the brain stem. Evoked EPSCs were asynchronous and lower in amplitude than in the wild-type animals (Figure 3(b)). Interestingly, in wild-type animals, the calyx synapses showed synaptic depression after repeated stimulation; in contrast, the calyx synapses of CSPα-deficient mice at P20 showed a synaptic facilitation instead of synaptic depression. Such an increase in synaptic facilitation is consistent with a decrease in release probability. In contrast to the decreased evoked postsynaptic responses, amplitudes of the spontaneous mEPSCs were increased, which might be due to a compensatory upregulation of postsynaptic receptors. These physiological changes in CSPα-deficient mice were accompanied by a structural degeneration of the presynaptic terminals.

Progressive synaptic defects and neurodegeneration were also observed in the retina and particularly affected the tonically active photoreceptor ribbon synapses. Initially, after eye opening at P14, electroretinogram (ERG) analyses demonstrated that vision was only slightly affected in CSPα KO mice but vision faded completely away by P45 (Figure 3(e)). This loss of vision correlated with a morphological degeneration of the photoreceptor ribbon synapse (Figures 3(g) and 3(h)). Neurodegeneration started in the presynaptic ribbon synapses and initially spared other synapses, indicating that neurodegeneration starts in synapses which are particularly active. These data indicate that CSPα is necessary to keep synapses running for extended periods of time and to prevent neurodegeneration. Interestingly, tonically active ribbon synapses from inner-ear hair cells were spared from structural and functional defects because of their expression of an additional CSP isoform, CSP*β*.

These findings of CSPα support a major role of CSP as a synaptic chaperone protein because defects were initially small and then dramatically increased with age. Consistently, synapses that are heavily used are the first ones that degenerate in a principally ubiquitous degeneration of presynaptic nerve terminals. CSPα-deficient mice finally died after 2–3 months.

Recent studies by the Südhof group demonstrated that synaptosomal-associated protein of 25 kDa (SNAP-25) is an important substrate of CSPα. In CSPα-deficient mice, SNAP-25 levels and the formation of the soluble *N*-ethylmaleimide-sensitive factor attached protein receptor (SNARE) complex of exocytosis are decreased. The assembly and dissociation of the SNARE complex require hydrophobic interactions, which probably need protective shielding in the nonassembled form. It is conceivable that CSPα is a chaperone that maintains the SNARE complex during multiple rounds of exocytosis. This hypothesis is further supported by recent findings demonstrating that the protein α-synuclein, a protein whose gene is mutated in cases of familial Parkinson's disease, enhances SNARE complex formation and, by this means, is able to compensate for the defects generated by CSPα-deficiency. The neuronal overexpression of α-synuclein in transgenic mice prevented the neurological and lethal phenotype of CSPα KO mice. Furthermore, the analysis of KO mice lacking both CSPα and α-synuclein accelerated the neurological phenotype of CSPα KO mice. These experiments convincingly showed that α-synuclein functionally cooperates with CSPα to prevent synaptic degeneration. Remarkably, the rescue occurs only if α-synuclein is able to bind phospholipids because transgenic expression of the A30P mutant of α-synuclein, a Parkinson-associated point mutant not able to bind phospholipids, did not rescue early lethality in CSPα KO mice. Synuclein itself does not interact with Hsc70 or SGT but, rather, acts downstream of CSPα. However, the cooperative action between α-synuclein and CSPα in

indicate delays in the exocytotic fusion process. Such a delay has been documented by electrophysiology (b). neuroprotection involves chaperoning of the SNARE complex in a reaction that requires phospholipids binding.

Interestingly, SNAP-25 levels were already present in decreased amounts at early stages (P5), before signs of neurodegeneration were obvious. This further indicates that SNARE proteins are particularly important synaptic substrates of CSP-containing chaperone complexes. Initially, the remaining SNAP-25 might be sufficient to allow core complex formation. But prolonged activation of the synaptic vesicle cycle probably provokes irreversible and cumulative ageing that can no longer be compensated for and which leads to the observed nerve terminal degeneration.

Concluding Remarks and Perspectives

The analysis of the CSP-dependent chaperone system in CSPα-deficient mice has shown that this system is essential to prevent use- and age-dependent degeneration of presynaptic terminals. These findings further put chaperones at center stage for neurodegenerative diseases of the human brain. The hallmark of many neurodegenerative diseases is malfolded proteins that subsequently generate harmful aggregates, for example, in Alzheimer's disease, Huntington's disease, spinocerebellar ataxia, and Parkinson's disease. Transgenic approaches demonstrated that the activation of the Hsp70-chaperone system is able to improve to some extent the neurological symptoms of neurodegenerative diseases in mouse model systems. Therefore, the knowledge and further analysis of chaperone systems in the brain are of crucial importance to understanding neurodegeneration in humans. Elucidating the cross-talk between the Hsp70-based chaperone system and the ubiquitin proteasome system (UPS) will be highly relevant to understanding the mechanisms of protein quality control in neurons. Hsp70-binding proteins such as the TPR-protein CHIP can probably shuttle (triage) proteins from the chaperone system to the proteasome degradation system if malfolded proteins cannot be recovered. Candidate proteins to be chaperoned by CSPα and Hsp70 are just beginning to be elucidated. Future studies aiming to complete the list of CSPα substrates will be very important in identifying sensitive target molecules that lead to synaptic failure in neurodegenerative disorders.

Cysticercosis: Cerebral

M A Goldberg, Washington University School of Medicine, St. Louis, MO, USA

This article is reproduced from the previous edition © 2004, Elsevier B.V.

The invasion of the central nervous system by the larva of the pork tapeworm, *Taenia solium*, results in a neurological disorder known as 'cerebral cysticercosis.' Until recently, this condition was primarily encountered in Third World countries, but improved diagnostic methods and changing migration patterns have resulted in recognition of this disease in developed countries. Cerebral cysticercosis is common in Mexico, Central and South America, Southeast Asia, South Africa, and in parts of Eastern Europe. In some undeveloped countries it is the most common cause of epilepsy. The parasite spreads through unsanitary porcine agricultural conditions, and in many countries its eradication follows the adoption of simple sanitary measures. The primary infection in humans is an intestinal infestation by the adult tapeworm resulting from ingestion of contaminated pork. This condition is relatively benign, producing only mild gastrointestinal symptoms. Mature segments from the adult worms contain eggs which pass out with human feces into the soil. Pigs, usually living in close association with humans, become infected by consuming food contaminated with these eggs. Human infestation with larva occurs through autoinfection by anal–oral transfer or fecal contamination of food. Ingestion of the eggs results in the development of the larval form which then invades tissues. Skeletal muscle and the central nervous system are the primary sites for this organism. In tissue, the larva develop into a cystic structure typically 1–2 cm in diameter or larger and with a characteristic scolex and three-layered membrane. They may survive in the CNS for up to 15 years.

Five clinical syndromes of cerebral cysticercosis can be defined: (1) intraventricular, (2) meningitic, (3) parenchymal, (4) spinal, and (5) mixed. The clinical manifestations depend largely on the anatomical site of encystment.

Cysts in the 3rd or 4th ventricle obstruct the flow of cerebral spinal fluid (CSF) and can result in obstructive hydrocephalus. The cyst may move within the ventricular cavity and produce a ball-valve effect resulting in intermittent symptoms. Sudden death may occur in these patients, occasionally without prior symptoms.

In the parenchymal form, symptoms are closely related to the site of encystment. Cortical cysts frequently give rise to partial seizures, and epilepsy due to this disease is quite common. Persistent motor or sensory loss or ataxia from cerebellar cysts occurs less frequently.

The meningitic form is common, and may be the result of the rupture or death of an arachnoidal cyst or its transformation into the racemose form of the organism which lacks a scolex and can enlarge within the basal cisterns. Symptoms of meningeal involvement vary from mild headache to a syndrome of chronic meningitis with communicating hydrocephalus. Spinal involvement may occur and evolve into complete spinal subarachnoid block.

The diagnosis should be considered in individuals who have resided in endemic areas and have epilepsy, meningitis, or increased intracranial pressure. Computerized tomography is useful in evaluating such patients but MRI is more sensitive. Hydrocephalus may be observed and the exact site of obstruction determined; parenchymal cysts are often calcified, and the presence of small calcifications which may be surrounded by a lucent area, either singly or scattered diffusely, is helpful in suggesting the diagnosis. Specific clinical diagnostic criteria have recently been proposed.

Viable cysts appear as small, lucent areas that do not enhance after the intravenous infusion of contrast material. CSF examination is usually normal at this stage. The longtime survival of these cysts suggests a lack of immunological or host responses, supporting the view that the brain is an immunologically privileged site. When the larva dies, proteins leak out of the cyst and an immunological response takes place. A more severe meningitis with many white blood cells, elevated protein, and low glucose in the CSF may occur. The histological appearance of the lesions at this time shows a chronic inflammatory response with lymphocytes and plasma cells, and the surrounding brain will enhance when contrast material is given prior to CT or MRI scan (Figures 1 and 2). In addition to the cellular response there may be a significant antibody response. Specific immunoglobulins to cysticercosis have been identified in serum and in CSF using enzyme-linked techniques and immunoblots and may be of diagnostic assistance. The apparent discrepancy

Figure 1 Axial T1-weighted, postcontrast MRI of the brain demonstrating a cysticercus (arrows) within the trigone of the right lateral ventricle.

Figure 2 Coronal T1-weighted, postcontrast MRI of the brain demonstrating a cysticercus (arrows) within the trigone of the right lateral ventricle.

between the immunological response seen in symptomatic patients and the long survival of cysts has led investigators to suggest that it is usually the death of the organism that produces most of the clinical features of this disorder, as well as the greatest inflammatory and immunological response.

Treatment of cerebral cysticercosis is usually symptomatic with anticonvulsants and anti-inflammatory agents. Two antihelminthics, praziquantel and albendazole, have been reported to be effective in the treatment of cysticercosis. The role of these agents in treatment and the long-term outcome remains controversial as they are associated with serious toxicity, and there is considerable evidence that many cases of CNS cysticercosis undergo spontaneous resolution and healing. Intraventricular cysts can be removed surgically, and newer endoscopic techniques are quite safe.

Cytokine Receptors in Glia

H W G M Boddeke, U Eisel, and K Biber, University of Groningen, Groningen, The Netherlands

Introduction

Cytokines and chemokines are secreted, soluble proteins that are involved in cell survival, proliferation, differentiation, and a range of specific cellular activities. They act through transmembrane receptors and thus initiate a variety of complex intracellular signaling cascades. In the central nervous system, a number of cytokines are essentially involved in neurodevelopment and homeostasis and also play a role in neuroinflammatory processes and neurodegenerative pathology. Particularly glial cells, including astrocytes and microglia, are the primary source of cytokines in the nervous system. Astrocytes, microglia, and oligodendroctyes express a specific repertoire of cytokine receptors, allowing them to react properly on cytokines released from surrounding glia and infiltrating immune cells. In the following sections the various groups of cytokine receptors, their signaling, and their possible functions in glia are addressed.

The Interferon/Interleukin-10 Receptor Family

Interferon (IFN) and interleukin-10 (IL-10) receptors are related structurally. IFN receptors have been categorized as type I and type II receptors. Type I receptors bind IFN-α and IFN-β, whereas type II receptors bind interferon-γ. Both type I and type II receptors are heterodimers consisting of the transmembrane protein chains IFN-αRI and IFN-αRII, and IFN-γRI and IFN-γRII, respectively.

Signaling of type I receptors is initiated by phosphorylation of the receptor-associated proteins tyrosine kinase-2 (TYK-2) and Janus kinase (JAK), which subsequently phosphorylate IFN-αRI. IFN-αRI then binds to signal transducer and activator of transcription 2 (STAT2), which is then tyrosine phosphorylated and associates with STAT1α. The STAT1α–STAT complex dissociates from the receptor and binds the interferon-regulating factor IRF-9. The resulting trimer translocates to the nucleus and binds to IFN-stimulated regulatory element responsive elements (ISREs). ISREs are found in the promoters of all IFN-regulated genes and activate a specific pattern of gene expression.

In the brain, IFN-α has direct effects on neurosecretory hypothalamic neurons and regulates the hypothalamic–pituitary–adrenocortical axis. Generally, IFN-β induces anti-inflammatory activity and thus is used for the treatment of multiple sclerosis. Type I IFN receptors have been localized in astrocytes, microglia, and oligodendrocytes, which respond to IFN-β by suppression of the production and release of proinflammatory cytokines, induction of anti-inflammatory cytokines such as IL-10, downregulation of class II major histocompatibility complex (MHCII) expression, and suppression of matrix metalloprotease activity.

The IFN-γ receptor subunits RI and RII are constantly associated with JAK-1 and JAK-2, respectively. After dimerization and activation of JAK-1 and JAK-2, IFN-γRI is phosphorylated, which leads to phosphorylation of STAT1α. Subsequently, homodimerized STAT1 translocates to the nucleus and binds gamma activation sites (GASs) in the promoter of IFN-γ-inducible genes, thus regulating their transcription. In general, IFN-γ is produced by T helper (Th1) cells and natural killer cells and produces a proinflammatory (Th1-like) response. Type II IFN-γ receptors are expressed by astrocytes, microglia, and oligodendrocytes. Thus, IFN-γ is a potent activator of microglia and astrocytes, resulting in expression of MHCII, CD40, and B7. Furthermore, INF-γ induces upregulation of a variety of proinflammatory cytokines. In oligodendrocytes, IFN-γ induces apoptosis.

The IL-10 receptor has structural similarity to the IFN-γ receptor and is composed of an IL-10R1 and -R2 subunit. After binding IL-10, the IL-10R1 subunit associates with IL-10R2. The receptor complex then activates the JAK–STAT pathway, including phosphorylation of the receptor-associated proteins TYK and JAK-1, ultimately leading to activation of STAT3, STAT1, and STAT5, which regulate the expression of IL-10-responsive genes, including c-*myc*, *bcl-2*, and *bcl-xL*.

IL-10 is generally considered an anti-inflammatory cytokine that inhibits the production and secretion of a variety of inflammatory cytokines. Furthermore, IL-10 suppresses the expression of MHCII, CD40, and B7 molecules. Astrocytes and microglia produce IL-10 and express high-affinity IL-10 receptors under pathological conditions. Activation of IL-10 receptors in astrocytes leads to decreased expression of intercellular cellular adhesion molecule-1 (ICAM-1) and enhances the release of nerve growth factor (NGF). IL-10 suppresses cytokine and chemokine expression in both astrocytes and microglia. Furthermore, IL-10 has a protective effect on microglia and oligodendrocytes.

Interleukin-6-Type Receptors

IL-6 belongs to the family of cytokines (IL-6-type cytokines) which also includes ciliary neurotrophic factor (CNTF), leukemia inhibitory factor (LIF), oncostatin M (OSM), IL-11, cardiotrophin-1 (CT-1), and the recently discovered IL-27 and cardiotrophin-like cytokine (CLC); CLC is also known as novel neurotrophin 1 (NNT1) or B cell-stimulating factor-3 (BSF-3). IL-6-type cytokines bind to specific receptors that share as a common feature the use of glycoprotein 130 (gp130) in their signaling cascade. Various variants of signaling complexes have been described for different cytokines from this family. IL-6 and IL-11 bind to α receptor subunits (IL-6R or IL-11R) that recruit two gp130 subunits (gp130/gp130 homodimer) for signaling. NNT1/BSF-3/CLC/LIF and CNTF also bind to their corresponding α receptor subunits, which recruit a dimer of a LIF receptor (LIFR) and a gp130 (gp130/LIFR heterodimer). The same signaling complex can also be activated by OSM that signals through either gp130/LIFR or gp130/OSMR heterodimers.

Two forms of IL-6R, a membrane bound and a soluble extracellular form, are known. The soluble IL-6R either results from proteolysis (shedding) of membrane-bound IL-6R or from alternative splicing. Since the membrane-bound IL-6R does not contain any signaling domains in its short cytoplasmic part, both membrane-bound IL-6R and soluble IL-6R have very similar effects. Thus, soluble IL-6-like receptors bound to an agonist ligand act as agonist in any gp130-expressing cell, independent of the presence of IL-6R, a process that is called trans-signaling. Indeed, this has been described in astrocytes and neurons. Cytokine-activated gp130 complexes do not contain intrinsic kinase domains, but are known to associate with JAKs. Upon cytokine binding and dimer formation, JAKs phosphorylate several tyrosine residues in the cytoplasmic domain of gp130. These tyrosine residues are essentially involved in the activation of various intracellular signaling cascades, such as the mitogen-activated protein kinase (MAPK) pathway, or in the activation of STAT.

The co-receptor gp130 is expressed ubiquitously and is thus also found in the major glia types. There is, however, limited information concerning the receptor expression for IL-6-type cytokines in glia cells. Evidence for the expression of IL-6-type cytokine receptors in glia cells is mostly based on functional studies showing effects of these cytokines in glia cells. Among the members of the IL-6 family, IL-6 has been intensively studied in glia cells. There is convincing evidence that glia cells are main producers of IL-6 in brain pathology; however, contradictory findings have been published concerning the expression of IL-6 receptor in astrocytes. Trans-signaling most likely enables astrocytes to respond to IL-6, although several reports suggest astrocytic expression of IL-6R. In unchallenged astrocytes, expression levels of CNTF receptors are rather low. CNTF and its receptor are clearly upregulated in the central nervous system (CNS) following lesions, when CNTF is suggested to be involved in the regulation of astrogliosis. Little is yet known about effects of CNTF in oligodendrocytes and microglia. LIF is an important regulator of astrocyte differentiation and is crucial for the expression of glial fibrillary acidic protein (GFAP). Accordingly, LIF-deficient mice display less astrogliosis in response to neuronal injury. Therefore, a regulation of astrocytic activity (astrogliosis) after CNS lesion is also suggested for LIF. Recent results, moreover, indicate a similar function for LIF in the regulation of microglia activity. Exciting findings have been published concerning the effects of LIF in oligodendrocytes: LIF has been found to enhance the survival of oligodendrocytes and stimulated myelination of axons. Accordingly, LIF is now discussed as a potential therapeutic agent in multiple sclerosis. OSM is currently being discussed as a means to control the growth of glioblastoma cells, but little is yet known about OSM-dependent effects in other glia cell types.

The Interleukin-2 Receptor Family/γC

Of the IL-2 receptor family, the cytokine receptors for IL-2, IL-4, and IL-15 have been found to be expressed in glia. These cytokine receptors contain a ligand-binding subunit (also designated as the α chain) and a commonly shared γC chain. Particularly, IL-2 and IL-15 cytokine receptors contain a third chain. IL-2 and IL-15 cytokine receptors mediate signal transduction by activation of STAT5. IL-4 cytokine receptors use STAT6 for signal transduction.

The IL-2 receptor consists of two to three receptor subunits: the α chain, the β chain, and the common γ chain. The high-affinity receptor is composed of all three subunits; the intermediate affinity receptor only contains the IL-2β and IL-2γ subunit. The IL-2α subunit is not required for signal transduction but confers high affinity to the receptor complex. Furthermore, it has been suggested that the oligomeric receptor complex consisting of the receptor subunits IL-2β, IL-2γ, and IL-15α serves as a receptor for the cytokine IL-15 in microglia.

After IL-2-dependent oligomerization of the IL-2 subunits, leading to either high- or intermediate-affinity receptors, JAK-3, which is associated with the IL-2γ subunit, activates the IL-2β-associated

JAK-1. Both JAKs phosphorylate tyrosine residues in β chain-associated lymphocyte-specific protein tyrosine kinase ($p56^{lck}$), as well as tyrosine residues in both the β and γ chains. This leads to activation of secondary signaling molecules, including STAT5 and STAT3 and SH2 domain-containing protein tyrosine phosphatase (SHP-2), ultimately leading to induction of cell-specific genes and cell proliferation.

IL-2 is a potent T cell growth factor and has a variety of neuromodulatory activities. Thus, IL-2 may be involved in memory function, regulation of sleep, and modulation of the neuroendocrine axis. In the brain, IL-2 synthesis has been described for astrocytes, neurons, and possibly micoglia. Expression of IL-2R has been found in microglia, astrocytes, and oligodendrocytes. In microglia, IL-2 activity has been associated with the production of nitric oxide. Furthermore, IL-15 signaling in microglia has been associated with activation of JAK-1, cell proliferation, and inhibition of nitric oxide production. In astroctyes, IL-2 increases astrogliosis. IL-2 has been shown to promote oligodendrocyte proliferation, and maturation inhibition of IL-1-induced oligodendrocyte progenitor proliferation has been reported as well.

Phosphorylation of JAK-1 and JAK-3, which are stably associated with the α chain and with the γC chain, respectively, occurs after binding of IL-4 to its receptor. Subsequently, phosphorylation of STAT6 takes place; STAT6 then binds to N4 STAT binding elements and interacts with a variety of transcription factors, including nuclear factor-kappa B (NF-κB), CCAAT/enhancer binding protein (C/EPBα), and cAMP response element-binding protein (CBP). IL-4 receptors are found in astrocytes and microglia and oligodendrocytes. IL-4 is an anti-inflammatory cytokine that also effectively suppresses production of tumor necrosis factor-α (TNF-α), IL-1β, and nitric oxide (NO) in glial cells, as well as the expression of MHCII and CD40.

Tumor Necrosis Factor Receptor Family

TNF receptors are activated by cytokines and growth factor molecules of the TNF ligand family. Based on the presence or absence of a death domain, members of the TNF receptor family have been divided into two groups. Death domain-containing receptors (e.g., Fas) are solely potent inducers of cell death. Despite the presence of a death domain, TNFR1 activation mostly activates a multitude of signaling responses, whereas apoptosis is induced only under certain conditions. Receptors lacking the death domain, such as TNFR2 and CD40, play a role in gene transcription, differentiation, or cell survival.

The most abundant and best-described TNF ligand in the brain is TNF-α, which acts upon TNFR1 and TNFR2, with TNFR1 mediating most of the TNF-α effects. After TNF-α-induced trimerization of TNFR1 subunits, a TNFR1-associated death domain (TRADD) protein is recruited. The TNFR1–TRADD complex can bind TNFR-associated factor 2 (TRAF2) and receptor-interacting protein (RIP) in order to activate c-Jun N-terminal kinase (JNK) and NF-κB. Additionally, the TNFR1–TRADD complex can recruit Fas-associated death domain protein (FADD), which ultimately initiates caspase activation and apoptosis. TNFR2 was for a long time considered to be a modulator of TNFR1 or even only a 'ligand-passing molecule' because of its low affinity for soluble TNF-α. However, after it was shown that the TNF-α membrane precursor acts as the prime activator for TNFR2, independent signaling pathways were described for also TNFR2. TNFR2 is known to be capable of binding TRAF2 and to induce NF-κB. Co-signaling of both receptors in some cell types leads to a modulation of TNFR1 signals.

TNF-α is primarily produced not only by microglia, but also, to a certain extent, by astrocytes and neurons. TNF-α is a pleiotropic and proinflammatory cytokine and induces a variety of cellular responses, including proliferation, differentiation, gene transcription, and apoptosis. TNF-α is a major activator of microglia and astrocytes and both TNFR1 and TNFR2 have been found in astrocytes, microglia, and oligodendrocytes. Both receptors become strongly upregulated in glia upon cellular stress. Although TNF-α is directly toxic to oligodendrocytes, and transgenic mice overexpressing TNF-α clearly exhibit marked white-matter lesions, other studies show that TNFR2 signaling is important for remyelination. In ischemia, TNFR2 antagonizes TNFR1 effects and induces cell survival signals mediated via protein kinase B (PKB)/Akt phosphorylation and NF-κB activation. Upon ischemia, TNF-α and TNFRs become upregulated for hours in both neurons and glial cells. Mice without TNFR1 (TNFR1 knockout mice) show a strong resistance to ischemia and have high levels of phoshorylated PKB/Akt, whereas TNFR2 knockout mice are highly sensitive. Interestingly, NF-κB activation by TNFR1 does not induce neuroprotection and is not activated by the same signaling pathway as seen in TNFR2-mediated NF-κB activation. TNFR2-mediated and NF-κB-dependent protection may be a result of the long-lasting activation kinetics. TNF-α-induced activation of the transcription factor NF-κB is crucial for production of various cytokines and chemokines, adhesion molecules, and acute-phase proteins. NF-κB also activates regulators of apoptosis and cell proliferation.

Interleukin-1 Receptors

IL-1 receptors belong to the Toll/IL-1 receptor superfamily, as defined by the presence of a so-called Toll/IL-1 receptor (TIR) domain. Besides IL-R1, this family includes IL-1 receptor accessory protein (IL-1AcP; which is essential for IL-1 signaling), a number of Toll-like receptors, and the putative IL-18/IL-1-γ receptor IL-1Rrp (IL-1 receptor-related protein). After binding IL-1α/β, IL-R1 heterodimerizes with IL-1AcP. The TIR domains of the IL-R1–IL-1AcP complex interact with a number of adapter molecules, including the IL-1 receptor-associated kinases IRAK1 and IRAK2. Activation of NF-κB occurs by association of the death domain-containing cytosolic protein MyD88 to both IL-1RAcP and IRAK2, which leads to binding of tumor necrosis-associated factor 6 (TRAF6) to the signaling complex and subsequent activation of NF-κB-inducing kinase (NIK).

The regulators of IL-1 signaling, IL-1 receptor antagonist (IL-1Ra) and type 2 IL-1R (IL-1R2), are present in the brain. IL-1Ra is an IL-R1 antagonist; IL-1R2 is a membrane-bound IL-1 binding protein, incapable of signal transduction, which is also situated in glial cells. Astrocytes, microglia, and oligodendrocytes express IL-1R1, which can be activated by IL-1α and IL-1β. Glia-derived IL-1 is a potent inducer of proinflammatory effects in chronic degenerative diseases and traumatic or toxic lesions. Resting microglia constitutively express IL-1Ra, which may contribute to the 'immune-privileged' state of the central nervous system. The relative levels of IL-1 and IL-1Ra most likely contribute to the overall state of reactivity toward immunological challenges. IL-1β induces astrogliosis and the expression of cell adhesion molecules (ICAM-1 and VCAM-1), as well as astrocytic expression of various cytokines and chemokines, including TNF, IL-6, CCL2, CXCL8, and CXCL10.

IL-1 expression is induced rapidly in response to CNS injury and is a key mediator of experimentally induced neuronal damage. However, IL-1-mediated neuronal death requires co-culturing of neurons and glia. IL-1-induced neuronal cell death can be prevented by pretreatment with IL-1 receptor antagonist and caspase inhibitors. It is assumed that IL-1 activates IL-1R1 receptor in astrocytes to induce caspase-dependent neuronal death, which is dependent on the release of free radicals and may contribute to neuronal cell death in CNS diseases.

Transforming Growth Factor-β Receptors

Transforming growth factor-β (TGF-β) belongs to the TGF-β superfamily, a large family of structurally related cytokines and growth factors. In mammals, three TGF-β isoforms (TGF-β1, TGF-β2, and TGF-β3) are known. The effects of all TGF-β isoforms are mediated by a transmembrane serine/threonine kinase receptor complex consisting of TGF-β type I and TGF-β type II receptors. Since these receptors function as heterodimers, both receptor types must be expressed in order to allow TGF-β-dependent effects. Upon TGF-β binding and heterodimer formation, type II receptor phosphorylates the type I receptor kinase domain, which subsequently activates intracellular Smad proteins (vertebrate homolog of the *Drosophila* gene 'mothers against decapentaplegic' (MAD)). Two different receptor-regulated Smads (R-Smads), Smad2 and Smad3, are known to interact with type I TGF-β receptors. Upon activation, these R-Smads associate with the common-partner Smad (Co-Smad), Smad4, to form heterooligomers, which enter the nucleus and induce gene transcription.

TGF-βs regulate a variety of cellular functions, including cell survival, apoptosis, proliferation, and cellular differentiation. It is known today that TGF-βs act in a highly contextual manner, meaning that the outcome of TGF-β signaling greatly depends on the cell type and environment. A large body of evidence shows the presence of all three TGF-β isoforms in the CNS. Whereas TGF-β2 and TGF-β3 are found under physiological conditions, TGF-β1 expression is rapidly induced in damaged nervous tissue. The cellular source of TGF-β isotypes is widespread; thus, all major cell types in brain, including astrocytes, microglia, and oligodendrocytes, show expression of TGF-β isotypes.

The expression of TGF-β receptors in brain cells is less clear. Few reports show TGF-β receptor (mRNA or protein) expression in brain or cultured neurons and astrocytes. However, despite a less clear characterization of the TGF-β receptor expression pattern in glia cells, it has been convincingly shown that all major glia cell types (astrocytes, oligodendrocytes, Schwann cells, and microglia) functionally respond to TGF-β stimulation, strongly indicating that they functionally express TGF-β receptors. In astrocytes, TGF-β1 treatment downregulates the expression and release of various proinflammatory cytokines (IL-1β or TNF-α) and induces the expression of various extracellular matrix molecules (ICAM-1 or VCAM-1). Similarly, an anti-inflammatory role of TGF-β1 in microglia has been described; TGF-β treatment disrupts endotoxin signaling, controls MHCII expression, and induces and changes the expression pattern of microglia inflammatory genes toward an anti-inflammatory phenotype. The importance of TGF-β in downregulating microglia activity has been corroborated in TGF-β1-deficient mice, which

display increased microgliosis and neuronal death in response to excitotoxic injury.

Chemokine Receptors

Chemokines are small-sized proteins that are able to induce migration of cells; currently, approximately 50 chemokines and 20 receptors are known. Based on the position of four conserved cysteine residues in the N-terminal region of the protein, the chemokine family has been divided into four groups. The two largest groups are CXC (or α) and CC (or β), in which the first two cysteines are either separated by one amino acid residue or are adjacent to each other respectively. The two small groups are the C chemokines (or γ), with only one cysteine in the N-terminal region, and the CX3C chemokines (or δ), in which the first two cysteines are separated by three amino acid residues. Chemokine receptors are named after the types of chemokines they preferentially bind. Thus, CC receptors bind CC chemokines, and so on. Functionally, only one exception has been reported in the literature, the CC chemokine CCL21, which, in addition to its primary receptor CCR7, also activates the CXC receptor CXCR3. Chemokine receptors all belong to the family of G-coupled protein coupled receptors (GPCRs). A majority of chemokine-induced responses are inhibited by pertussis toxin (PTX), indicating that G_i proteins mediate these effects. Chemokine receptors activate several intracellular targets, such as adenylcyclase, phospholipases, and molecules like Rho, Rac, and Cdc42. They are also able to activate signaling cascades of major kinases, such as MAPK and phosphatidylinositol 3-kinase (PI3K) pathways. The actions of chemokines are not restricted to chemoattraction but are very diverse. Chemokines are important in early development, formation of secondary lymphoid organs, wound healing, angiogenesis and angiostasis, regulation of expression of adhesion molecules, and development of Th1/Th2 profiles, and they have also been implicated in certain aspects of tumor growth and metastasis.

Glial cells (astrocytes and microglia) are the primary cellular source of chemokines in the CNS under various conditions and these cells also express a large variety of chemokine receptors. In Table 1 a summary of the chemokine receptors expressed in glia is given. An induction of chemokine receptor expression in glia cells has been described in various brain diseases such as multiple sclerosis, HIV infection, infarcts/stroke, and neoplastic disease.

Various chemokines have been shown to induce astrocyte proliferation and/or migration *in vitro*. Similarly, microglia express a large number of chemokine receptors and respond to chemokine stimulation with chemotaxis. Since endangered neurons express and release chemokines that recruit microglia and CXCL10, a role of chemokines in neuron–microglia signaling has been proposed. This assumption is mainly based on *in vitro* findings, though recent studies using chemokine receptor-deficient mice indeed show significant changes in microglia behavior in response to neuronal injury.

Table 1 Summary of the chemokine receptors expressed in glia and their chemokine ligands expressed in brain

Chemokine receptor	*Ligand*	*Glial cell type*
CCR1	CCL3	Microglia
	CCL5	Astrocytes
	CCL6	Oligodendrocytes

Cytoskeletal Interactions in the Neuron

A Adebola and R K H Liem, Columbia University College of Physicians and Surgeons, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

The cytoskeleton is a dynamic arrangement of interconnected actin filaments, microtubules (MTs), and intermediate filaments (IFs) that extends throughout the cytoplasm. This structure plays a vital role in the development and maintenance of cell and tissue structure. Due to the complex nature of the cytoskeleton, early studies focused on identifying mechanisms that governed the organization and function of individual filament networks. Although these studies ascribed distinct functions to each, it has become increasingly clear that many dynamic cellular processes, such as cell migration, cell polarization, cell division, growth cone guidance, and intracellular transport, require the cooperative activity or cross-talk of multiple filament networks. In recent years, there has been tremendous focus on identifying and characterizing the structural and regulatory components required for facilitating such cytoskeletal cross-talk. Studies have revealed that proteins once thought to associate specifically with actin, MTs, or IFs are indeed capable of associating with more than one cytoskeletal network and thus may be involved in mediating cytoskeletal cross-talk. One such class of proteins is the plakins. Plakins were originally identified as IF-binding proteins that functioned to cross-link IFs to adhesion complexes of epithelia. Advancements in molecular cloning, whole-genome sequencing, and gene-targeting technologies have revealed that plakins are not limited to their capacity to associate with IFs. Instead, newly identified plakin genes and alternatively spliced isoforms have been shown to interact with other cytoskeletal elements, namely, actin and MTs. Interestingly, many of the newly identified proteins are highly expressed in the nervous system. This article provides an overview of plakin cross-linking properties from both nonneuronal and neuronal model systems.

Plakins

Plakins are giant-sized (200–800 kDa) modular proteins that link cytoskeletal elements to each other and to specialized sites at the plasma membrane. Maintaining such linkages lends mechanical strength to cells and tissue structures and ensures proper cellular development. The importance of plakins as cytolinkers is evident by the fact that mutations in several plakins are linked to a diverse array of diseases in humans and mice, in which cell and tissue integrity is compromised.

The plakin family is composed of the mammalian plakins desmoplakin, plectin, bullous pemphigoid antigen-1 (BPAG1), microtubule cross-linking factor 1 (MACF1), envoplakin, periplakin, and epiplakin and the invertebrate plakins *shortstop* (shot) and *vab-10* (Figure 1). Analysis of the genomic organization of plakins reveals that various protein modules are encoded by the gene loci of plakins. These modular interaction units, which allow for interaction with different cellular elements, are alternatively combined to produce distinct proteins with unique functions that are expressed in a tissue-specific manner (Figure 1). The modules include a calponin-type actin binding domain (ABD), a plakin domain, a coiled-coil rod domain, a plakin (plectin) repeat domain (PRD), a PRD associated linker (L) subdomain, a spectrin repeat-containing rod domain, two EF-hand motifs, a Gas2-related homology domain (GAR), and a domain containing a series of glycine–serine–arginine (GSR) repeats. The function of these modules is discussed in further detail later.

Because plakins were first identified as components of adhesion complexes in epithelia, most of our knowledge concerning plakin function stems from epithelial cell biology. Autoimmune and inherited disease states, such as plakin-associated skin-blistering disorders, provided insight into the function of these molecules. As additional cDNAs of plakins were cloned, they were found to be more complex than epithelial plakins, and their expression profiles were not limited to epithelia. Many of the new plakins were highly expressed in the nervous system. Their functions as linkers in the nervous system are just beginning to become clear. We therefore first describe the known functions of plakins in epithelial cells and proceed to their roles in the nervous system.

Connections between the Cytoskeleton and Cell Junctional Complexes

Cell-anchoring junctions are cytoskeleton-associated sites of cell–cell and cell–extracellular matrix (ECM) adhesions. In epithelial cells, three types of cell–cell junctions are identified: tight junctions, adherens junctions, and desmosomes (Figure 2). Cell–ECM adhesions include focal adhesions and hemidesmosomes (Figure 2). The formation and stabilization of these adhesion complexes are essential for molecular events that govern how tissues acquire and maintain proper architecture. In general, anchoring junctions are composed of transmembrane adhesion molecules of the cadherin (cell–cell adhesions) or integrin (cell–ECM adhesions) families and an electron-dense submembrane

Figure 1 Schematic diagram of mammalian and invertebrate plakins. The plakin family is composed of several interaction modules that include calponin-type acting binding domain (ABD), plakin domain, coiled-coil rod domain, spectrin repeat-containing rod domain, plakin repeat domain (PRD), Gas2-related (GAR) domain, and glycine–serine–arginine (GSR) repeat-containing domain. The calponin-type ABD is composed of two calponin homology domains, CH1 and CH2, arranged in tandem. Although not shown here, there is extensive alternative splicing of the ABD. Such splicing alters the actin binding capacity of these proteins. The plakin domain is common to all but one of the plakin proteins. The coiled-coil rod domain is present in several of the epithelial plakins and is thought to mediate homo- and hetero-dimerization of plakins. The spectrin repeat-containing rod domain is present in MACF1, BPAG1, Shot, and VAB-10 isoforms. These proteins (asterisks) are sometimes referred to as spectraplakins because they share similarities with members of both the spectrin and the plakin families. The PRD is composed of plakin repeat motifs. It is important for binding to intermediate filaments. For some plakins, the presence of a linker (L) subdomain aids in interactions with intermediate filaments. PRDs based on sequence similarity are divided into subgroups called A, B, and C. For MACF1-b, the PRDs labeled 'a' and 'b' are equivalent to half of the A and B PRDs. The number of spectrin repeats and PRs drawn here are descriptive and may not reflect the actual number that exists in reality. EF-hand motifs appear in several plakins; however, it is not known if this domain can bind Ca^{2+}. The microtubule binding domain of BPAG1 and MACF1 isoforms is composed of a GAR domain, which binds microtubules, and a GSR domain that bundles microtubules. The GSR domain of plectin is also able to bind microtubules; however, its presence in desmoplakin functions to regulate desmoplakin's intermediate filament binding activity. In *Drosophila* Shot and *C. elegans* VAB-10 the GAR domain serves as the microtubule binding region. The existence of Shot III is still controversial. This figure is not drawn to scale. Adapted from Jefferson JJ, Leung C, and Liem RKH (2004) Plakins: Goliaths that link cell junctions and the cytoskeleton. *Nature Reviews Molecular Cell Biology* 5: 542–553, with permission.

Figure 2 Mammalian cell adhesion complexes. The schematic illustrates adhesion complexes present in mammalian epithelia. Epithelial cells are polarized cells with an apical surface that is exposed to the environment and a basal surface that contacts the underlying extracellular matrix (ECM). Cell junctions, sites of cell–cell and cell–ECM contact, are generally composed of transmembrane adhesion proteins and an electron-dense submembrane plaque made up of signaling proteins that contribute to the transduction of intracellular signals and adaptor proteins that tether the junctional complex to the cytoskeleton. There are five different types of cell junctions illustrated in this figure. First, tight junctions or zona occludens (ZO) are selective permeability barriers that seal adjacent cells together. At these junctions, claudins and occludins are adhesive transmembrane proteins that are linked to the actin cytoskeleton through ZO proteins. Second, adherens junctions are cell–cell junctions composed of classical cadherins linked to the actin cytoskeleton through adaptor proteins such as vinculin and catenins. Third, desmosomes are cell–cell junctions that are formed by homotypic interactions between desmosomal cadherins, termed desmocollins and desmogleins, and are linked to intermediate filaments (IFs) through desmoplakin dimers. The armadillo proteins plakoglobin and plakophilin mediate interactions between desmoplakin and the desmosomal cadherins. Desmoplakin can also bind directly to the juxtamembrane region of desmocollin. Fourth, focal adhesions are cell–ECM junctions that are formed by cell adhesion proteins of the integrin family. These junctions are linked to actin filaments by adaptor proteins such as talin, filamin, and vinculin. Fifth, hemidesmosomes are cell–matrix junctions composed of the transmembrane proteins $\alpha_6\beta_4$ integrin and BPAG2 (bullous pemphigoid antigen-2). These transmembrane proteins, which interact with components of the ECM, are linked to cytoplasmic IFs through interactions with the plakin proteins, plectin and BPAG1-e (the epithelial form of bullous pemphigoid antigen-1). Adapted from Jefferson JJ, Leung C, and Liem RKH (2004) Plakins: Goliaths that link cell junctions and the cytoskeleton. *Nature Reviews Molecular Cell Biology* 5: 542–553, with permission.

plaque made up of signaling proteins that contribute to the transduction of intracellular signals and adaptor proteins that tether the junctional complex to the cytoskeleton. Several members of the plakin family serve as essential adaptor proteins for desmosomes and hemidesmosomes (**Figure 2**). Desmosomes are specialized intercellular junctions present in epithelia and cardiac muscle, where IFs are linked to desmosomal cadherins through interactions with desmoplakin. At hemidesmosomes, specialized cell–ECM junctions present in epithelia, BPAG1-e (the epidermal isoform of BPAG1), and plectin provide links between IFs and the transmembrane hemidesmosomal proteins $\alpha_6\beta_4$ integrin and BPAG2, a type XVII collagen. In the absence of these plakins, links between adhesion complexes and IFs are compromised and tissues under mechanical stress are subject to shearing.

The ability of plakins to connect cell adhesion targets at the plasma membrane with cytoskeletal elements is mediated through interactions with the various protein modules that make up these cytolinkers. Generally, epithelial plakins exhibit a tripartite architecture defined by a central rod domain flanked by globular N- and C-terminal domains, whereby each globular domain is composed of protein modules that can interact with distinct cytoskeletal or cell adhesion targets. At the N-terminus of all plakins (except for an unusual plakin called epiplakin) is a protein module called the plakin domain (**Figure 1**). This domain has been shown to interact with transmembrane components of desmosomal and hemidesmosomal junctions. The crystal structure of an N-terminal segment of the plakin domain of BPAG1 has been solved. It consists of a pair of three α-helical bundles aligned in an antiparallel array that are connected by a helical linker region. This structure is analogous to the secondary and tertiary structure that defines spectrin repeats found in spectrin family members, although plakin domains are more similar to each other than to spectrin-repeat regions found in spectrin proteins. Although the crystal structure of the entire plakin domain has not been solved, protein domain prediction programs suggest that the complete domain may consist of an SH3 domain flanked by two or more pairs of spectrin repeats. The presence of a putative SH3 domain suggests that plakins may serve as molecular scaffolds that recruit signaling proteins to sites of cell–cell contact, cell–ECM contact, or cytoskeletal activity. In addition to the plakin domain, some plakins also have a calponin-type ABD preceding the plakin domain at its N-terminus. This domain is described in more detail later.

Whereas the plakin domain mediates connections with cell–junctional complexes, it is the C-terminal end of several epithelial plakins that mediates connections with IFs. Connections to the IF network are mediated through a region at the C-terminus composed of plakin repeat motifs. Plakin repeats are described as repeats of 38 residues that form a β-hairpin followed by two antiparallel α-helices. Four and a half of these repeats form a globular PRD. PRDs based on sequence similarity are divided into subgroups termed A, B, and C. The PRDs have been shown to function as IF binding domains. For some plakins, IF binding also requires the presence of a linker (L) subdomain. The number of PRDs varies among different plakins. For example, the desmosomal protein desmoplakin contains three PRDs, whereas hemidesmosomal proteins plectin and BPAG1-e contain six and two, respectively. Although it is thought that the primary function of plakin repeats is to mediate binding to cytoplasmic IFs, there is evidence that they may have additional functions. First, there are plakin isoforms in which the plakin repeat motifs are not arranged as the 4.5-repeat PRD that is seen in mammalian epithelial plakins. Second, plakin homologs present in *Drosophila* contain plakin repeats, yet the *Drosophila* genome lacks genes encoding cytoplasmic IFs. The plakin repeats in both *Drosophila* and *Caenorhabditis elegans* are not arranged as PRDs. In fact, invertebrate plakins are quite different in structure from the epithelial plakins described so far. Although their N-terminal region contains a plakin domain, the remainder of the invertebrate plakins diverges from the epithelial plakins (**Figure 1**). In addition to the plakin repeats, some *Drosophila* and *C. elegans* plakin isoforms contain a series of spectrin repeats which is thought to confer some flexibility to the molecule as well as serve as a site for protein interaction. These isoforms also contain a C-terminal region that consists of EF-hand motifs and an MT binding region in turn composed of a GAR domain.

The *Drosophila* plakin homolog is called *Shortstop* or Shot (also referred to as *kakapo*). As mentioned previously, the domain architecture of Shot diverges from mammalian epithelial plakins. However, it is quite similar to mammalian plakins that are expressed highly in the nervous system. These plakins include BPAG1-a (neuronal BPAG1 isoform) and MACF1-a (neuronal MACF1 isoform). Insights into the function of Shot came from studies concerning position-specific (PS) integrins. In *Drosophila*, PS integrins, which are similar to mammalian β_1 integrins, have been shown to be important for integrin-mediated adhesions between dorsal and ventral wing surfaces and between muscle and epidermis (hemiadherens junctions). Mutations of PS integrins result in defects in epidermal integrity and epidermal muscle attachment. A genetic screen for mutants that produce

similar phenotypes led to the identification of Shot. Shot behaves similarly to mammalian plakins in that it anchors integrin-mediated adhesion complexes to cytoskeletal elements. However, since *Drosophila* lack cytosplasmic IFs, Shot anchors the junctional complex to MTs, through interactions with its GAR domain. In *Drosophila*, MTs seem to have taken on the role of IFs as the filaments that stabilize cells subject to mechanical stress.

In *C. elegans*, muscle cells are mechanically linked to the cuticle through electron-dense structures similar to mammalian hemidesmosomes called fibrous organelles (FOs). FOs consist of an IF array anchored at the basal surface to the underlying basement membrane and associated muscle and at the apical surface to the cuticle. VAB-10, the plakin homolog in *C. elegans*, functions similarly to hemidesmosomal plakins. However, unlike hemidesmosomes, FOs do not contain integrins or a BPAG2 homolog; instead, other transmembrane proteins (myotactin, MUA-3, and MUP-4) that might function analogously are present. Two VAB-10 isoforms have been identified – VAB-10A, which localizes to FOs, and VAB-10B, which localizes to bands between FOs. Loss of both VAB-10 isoforms results in epidermal detachment from the cuticle and muscle and perturbation of IFs and circumferential actin bundles. The role of VAB-10 in the nervous system has not been elucidated.

Thus far, our discussion on the role of plakins as key integrators of plasma membrane components and the cytoskeleton has been restricted to epithelia and muscle, tissues that are subject to substantial mechanical stress. Are plakins involved in the formation and/or maintenance of adhesive connections between neurons or between neurons and the underlying ECM? Such connections would have important implications for development and maintenance of neural structures. Several reports hint that indeed plakins may be involved in events that require neural adhesion. For example, mutations in *Drosophila* Shot affect sensory and motor axon growth, terminal arborization at the neuromuscular junction (NMJ), the assembly of presynaptic specializations at the NMJ, and the formation of neuronal dendrites in the central nervous system (CNS) – all cellular events that require cell adhesion.

In mammals, the plakin domain of BPAG1 interacts with the LAP protein erbin. LAP proteins, which include erbin, scribble, and densin-180, are PDZ binding proteins that are involved in the clustering of receptors at synaptic junctions. Erbin interacts with ErbB2, a mammalian epidermal growth factor receptor that in turn interacts with neuregulin. Neuregulin is a signaling protein that is essential for the formation and maintenance of the NMJ. Erbin has been found to localize to postsynaptic sites at the NMJ and sites of ErbB2 localization in the CNS. Thus, BPAG1 in conjunction with erbin may play an important role in the regulation of neuregulin signaling and subcellular organization of ErbB proteins, which in turn could play an important role in the formation and maintenance of NMJs. Despite these connections to NMJ integrity, there is no direct evidence that shows that plakins link the cytoskeleton to junctional complexes in the nervous system.

Cytoskeletal Cross-Linking

Intermediate Filament and Actin Connections

Disruption of IF organization due to pharmacological perturbations of actin function illustrates the interdependence of these two cytoskeletal filament networks. In epithelia, initiation of keratin IF formation is thought to be dependent on a functional actin-rich cortex. *In vitro* studies with *Xenopus laevis* egg extracts suggest that actin cables act as templates upon which cytoplasmic keratin IFs assemble after transition into the first mitotic interphase. A role for actin in IF motility has been identified from studies that compare the difference in motile properties of keratin and vimentin IFs in epithelial cells. These studies show that in the absence of MTs, keratin squiggles (short filaments) continue to move, whereas vimentin squiggles do not, suggesting that actin might be the alternative mode of transport for keratin. Additional evidence supporting actin-based IF motility includes reports that more than half of the total myosin Va (actin-associated molecular motor protein) in the CNS associates with neuronal IFs. Deletion of myosin Va, which is abundant in nerve fiber tracts of brain and spinal cord, results in altered distribution of IFs within axons.

Members of the plakin family may be mediators of IF–actin interactions involved in IF organization and IF motility. Several plakins are able to interact with both actin and IFs. These interactions are mediated by the IF-interacting PRD described previously and an N-terminal ABD composed of two calponin homology (CH) domains arranged in tandem (Figure 1). CH domains are protein modules of approximately 100 residues that are present in a number of structural and regulatory actin binding proteins, such as α-actinin, calponin, filamins, dystrophin, and spectrins. Although similar in secondary structure, CH domains are divided into several subtypes based on their primary sequence. Studies show that although the CH1 subtype has the ability to bind actin and the CH2 subtype does not, it is the combination of both CH1 and CH2 arranged in tandem that constitutes a functional ABD. Transfection and *in vitro* binding

assays demonstrate that the CH1–CH2 motifs of mouse BPAG1, MACF1, plectin, and *Drosophila* Shot serve as functional ABDs that bind directly to actin and co-localize with actin filaments.

The possible importance of plakin-mediated IF–actin cross-linking is seen in disease states in which plakin function has been perturbed. For instance, deletions within the BPAG1 gene are linked to a mild skin blistering phenotype and severe sensory neuron loss in the dystonia musculorum (*dt*) mouse mutant. *Dt* mice display dystonic movements and usually die before weaning. Those animals that survive past the weaning stage exhibit lower motor neuron degeneration due to sensory neuron loss. The degenerating sensory neurons display abnormal accumulation of neuronal IFs and disorganization of the MT network. The observed skin blistering phenotype seen in *dt* mice is due to the absence of BPAG1-e. This results in disruption of connections between hemidesmosomes and IFs, leaving epithelial cells vulnerable to shearing due to mechanical stress. Disorganization of the neuronal cytoskeleton is linked to the absence of several neuronal BPAG1 isoforms. One such isoform is BPAG1-n, which has the capacity to connect actin and IFs and is thought to be important in anchoring neuronal IFs to the axonal actin cytoskeleton. Loss of this connection could contribute to the abnormal accumulation of neuronal IFs seen in *dt* mice. However, it is important to note that BPAG1-n is a minor neuronal isoform and that cytoskeletal defects seen in *dt* mice likely involve other neuronal BPAG1 isoforms, especially BPAG1-a.

As described previously, plectin, another member of the plakin family, also has a functional ABD and a C-terminal PRD-containing region that can interact with IFs. Plectin has many alternate promoters that allow for its tissue-specific expression. One particular isoform (plectin 1C) has been reported to be expressed in neurons and can link actin filaments and IFs. However, elucidation of the importance of plectin in the nervous system may require the isoform-specific knockout of this plakin. Plectin may play a role in regulating the dynamics of actin because cultured plectin null fibroblasts display perturbations in cell motility and Rho/Rac/Cdc42-mediated actin rearrangements.

Intermediate Filament and Microtubule Connections

It has long been known that IFs also associate with MTs. Evidence for this association comes from electron microscopy studies that reveal IF–MT are linked at the ultrastructural level. Pharmacological perturbation studies also show that inhibition of MT function results in reorganization of IFs as well as impairment of intracellular transport. For instance, cultured sympathetic neurons treated with nocodazole exhibit profound inhibition of neurofilament (NF) transport.

NFs were traditionally thought to undergo slow axonal transport. However, observations of living sympathetic neurons expressing GFP-tagged NFs reveal that transported NF structures move at rates similar to those seen for fast axonal transport, although the movements are frequently interrupted by prolonged pauses. It has been shown that during anterograde transport in mature sensory neurons, NFs pause 99% of the time. Molecules that are responsible for the transport of NFs include motor proteins of the kinesin and dynein families that regulate anterograde and retrograde transport of NFs, respectively.

Plakins may play a role in mediating NF–MT interactions given that mutations in the plakin gene BPAG1 lead to disorganization of MT and neural IF networks. Several reports suggest that the primary function of BPAG1 is to stabilize the MT network. Once the integrity of this network is perturbed, many MT-based functions such as intracellular transport may be impaired. BPAG1-a and BPAG1-b isoforms associate with MTs via their microtubule binding region, which is composed of a GAR domain that binds MTs and a C-terminal tail that contains GSR repeats, which is thought to be important for MT bundling. BPAG1-b also has a PRD, which could interact with IFs, but there are no published reports of this interaction. Furthermore, there is little BPAG1-b present in the brain.

In addition to associating with and stabilizing MTs, one report has revealed a potential interaction of a component of the minus-end-directed dynein motor with a region of BPAG1 that encompasses a portion of the spectrin-repeat rod domain. Although this would implicate BPAG1 as a participant in retrograde transport, it is important to note that there have been conflicting reports concerning the role of BPAG1 in axonal transport. The discrepancies may be due to the fact that several plakins are expressed in the nervous system and so may compensate for one another.

Some BPAG1 isoforms may have the ability to cross-link IFs with MTs. This cross-linking could serve as a molecular brake against rapid transport of IFs and thus contribute to the frequent IF pausing that is observed during NF axonal transport. The plakins may also contribute to the stabilization of cytoskeletal networks in specific regions of the cell experiencing mechanical stress.

The other major plakin expressed in the nervous system is MACF1. MACF1-a has a similar domain structure as BPAG1-a and is the primary isoform of MACF1 in the nervous system. However, it has no

obvious IF binding domains. Another isoform, MACF1-b, has a series of PRDs that could bind to IFs. However, MACF1-b is expressed primarily in muscle tissues, and there is no evidence that it functions in the nervous system to link MTs and IFs.

Actin and Microtubule Connections

As mentioned previously, the cytoskeleton plays a vital role in dynamic cellular processes such as neuronal pathfinding. Proper development of the nervous system as well as functional recovery after insults to the brain due to disease or injury are dependent on mechanisms that guide the processes of developing neurons to their correct target. Mediating this guidance behavior is a highly dynamic sensorimotor structure at the distal ends of axons and dendrites called the growth cone. While surveying the extracellular environment, growth cones sense guidance cue information and integrate it into cytoskeletal changes that result in directed movement toward a specific target. It is well documented that the dynamic behavior of the growth cone is dependent primarily on the organization of the actin and MT cytoskeletons. Advances in high-resolution time-lapse imaging have made it possible to directly visualize cytoskeletal changes that underlie growth cone behaviors and in recent years have sparked an explosion of research examining the role of cooperative cytoskeletal activity in growth cone guidance.

The growth cone cytoskeleton is divided into three major domains: an actin-rich peripheral (P) domain, a central (C) domain predominated by MTs, and a transition (T) domain at the interface of the P and C domains (Figure 3). The P domain is characterized by filopodia, which are thin finger-like structures present at the leading edge of the growth cone, and lamellipodia, which are veil-like structures situated between filopodial protrusions. Filopodia are composed of actin bundles and extend forward to survey the environment, whereas lamellipodia make contact with the ECM and are composed of a dense actin meshwork. The actin cytoskeleton is arranged in a polarized manner such that the plus ends of actin filaments, sites of polymer growth, are directed toward the leading edge. A dense array of stable, polarized MT bundles in the axon shaft extend into the C domain, where they defasciculate and exhibit complex dynamic behaviors that include looping, bending, splaying out, and extension

Figure 3 Neuronal growth cone. The schematic illustrates the organization of the growth cone cytoskeleton. The peripheral region (dark gray) consists of two different actin filament populations: actin bundles (pink) present in filopodial structures and an actin meshwork (orange) present in lamellipodial structures. Microtubules (blue) which are bundled in the axon shaft enter the central domain (light gray), where they defasciculate. Microtubules can also be seen extending into peripheral regions of the growth cone. The transition domain (gray) is at the interface of the peripheral and central domains and is composed of actin arcs (green) and intrapodia (purple) that co-localize with microtubules extending into the periphery.

into more peripheral regions of the growth cone (through probing with their plus ends). This domain is also packed with intracellular membrane structures such as vesicles and organelles. The T domain, a site of active membrane ruffling and actin–MT interaction, contains MT-associated actin arcs (contractile actin bundles) that are positioned perpendicular to filopodia and intrapodia, motile actin and β_1 integrin-rich protrusive structures.

Early studies of the growth cone suggested that the actin and MT filament systems are interdependent. For example, application of actin filament depolymerizing drugs results in robust MT advancement into the P domain, whereas inhibiting MT activity results in the formation of lamellipodial and filopodial structures along the length of the axon shaft. The suggestion that the two filament networks are physically linked is supported by imaging studies that show that myosin-driven actin retrograde flow in filopodial structures aids in the rearward movement of MTs. This retrograde transport contributes to MT clearance from the P domain. Retrograde flow also contributes to the formation of MT loops, which signifies growth cone pausing and MT buckling and breakage. The breakage creates new minus ends that quickly depolymerize and new plus ends that can elongate into peripheral regions. Thus, this transport mechanism, which contributes to the cycle of MT clearance and MT advancement in the P domain, reflects the interdependence of actin and MT networks of the growth cone.

Whereas retrograde transport serves to regulate the spatial distribution of cytoskeletal elements in the growth cone, it is clear that the molecular machinery required for eliciting growth cone turning responses is dependent on factors that control stabilization of actin and MTs. Studies show that focal application of MT-stabilizing drugs on one side of the growth cone results in directed growth toward the side in which MTs have been stabilized. Interestingly, this also enhances lamellipodial protrusion on that side before turning occurs. Conversely, when MTs are pharmacologically destabilized on one side of the growth cone, the growth cone turns away from this region and instead grows in the direction containing stabilized MTs. Focal disruption of stable actin bundles with actin depolymerizing agents inhibits actin–MT interaction in that region and consequently results in directed growth toward the side of stabilized filopodia, where MTs are still able to extend. Factors involved in this process include cytoskeletal-associated proteins that function to stabilize the actin and MT cytoskeletons, as well as proteins that serve to physically link the two cytoskeletal systems. Such factors include members of the plakin family.

As mentioned previously, plakins are able to cross-link different cytoskeletal elements to each other. Genetic studies in *Drosophila* suggest that the cytoskeletal cross-linking activity of plakins is involved in several processes that underlie growth cone activity. Reduction in the activity of the *Drosophila* plakin homolog Shot, which localizes throughout the growth cone, results in defects in axon extension, dendrite formation, and axonal terminal arborization at the NMJ. The activity of Shot is dependent on its ability to interact with both actin and MTs. Interestingly, Shot and its mammalian counterparts, MACF1-a and BPAG1-a, interact with the microtubule plus-end protein EB1, which has been localized to the growth cone. EB1 is important for MT capture events at the cell cortex. However, its role in growth cone function has not been clearly defined. Defects in BPAG1 result in severe sensory neuron degeneration, in which affected neurons exhibit abnormal accumulation of neuronal IFs in axon swellings and disorganization of MT network. BPAG1 is expressed in axonal and dendritic processes and has been shown to stabilize MTs; it may therefore be involved in stabilization of MTs required for growth cone activity. However, a role for BPAG1 in the growth cone has not been elucidated. Cultured MACF null endothelial cells show defects in MT activity. In these cells, MTs no longer stabilize at the actin-rich cortex and they no longer grow along actin bundles. This suggests that in the context of the neuron, MACF may function in stabilizing actin–MT interactions. Further studies are needed to establish definitive conclusions.

Concluding Remarks

Cross-linking cytoskeletal elements to each other and to specialized sites at the plasma membrane is important for many dynamic cellular processes. This article focused primarily on members of the plakin family, key facilitators for such linkages. Because plakins were initially identified as key structural components in epithelia, most of our knowledge centered on their role in ensuring proper development and maintenance of epithelial structures. Further analysis of the gene loci of plakins indicated that plakins are complex molecules that contain numerous interaction modules that are alternatively combined in a tissue-specific manner. This analysis led to the identification of several plakin proteins that are highly expressed in the nervous system. Current studies suggest that the presence of these complex molecular

goliaths is critical for proper neuronal function. This is seen with mutations in the BPAG1 gene in mice, which result in severe sensory neurodegeneration, where degenerating neurons exhibit disorganization of NF and MT networks. It is also seen in invertebrate systems, in which reduction in the activity of plakins leads to defects in axonal growth, axonal and dendritic arborization, and defects at the NMJ. Although it is likely that plakins are important for neuronal function, definitive evidence to support this claim is lacking. Because there are multiple plakins that are expressed in the nervous system, conditional knockout of tissue-specific isoforms will be useful in elucidating the roles of plakins in neurons.

In addition to plakins, there are a host of other proteins that play essential roles in mediating the dynamics and physical connections between different cytoskeletal elements. Proteins once thought to exclusively associate with one filament system have now been shown to interact with multiple networks. For example, microtubule-associated proteins have been shown to interact with the actin cytoskeleton and with NFs. Motor proteins of the kinesin, dynein, and myosin families are involved in multiprotein motor complexes that operate along multiple cytoskeletal tracks to transport common cellular cargo. In addition to proteins that function to physically link cytoskeletal networks, there is a plethora of signaling proteins that regulate the dynamics of cytoskeletal elements. The best examples of such regulatory elements are members of the Rho family of GTPases. Once thought to play a role in actin organization and dynamics, these molecules are also known to regulate MT dynamics. It is an exciting time in the field of neuronal cell biology, in which it is hoped that insights into the structural and regulatory components of cytoskeletal connections will provide a better understanding of the molecular events that govern the development and maintenance of neuronal structures.

Overview

Neurons are connected to each other and to their target cells via highly specialized structures called synapses. Morphologically, the synapse resembles an asymmetrical intercellular junction, with a presynaptic compartment specialized for neurotransmitter release and a postsynaptic side attuned to the reception of released neurotransmitters and signal propagation. Functionally, the synapse serves one in 10^{14} internodes in a very complex network, and modulating the efficacy of synaptic transmission – the synaptic strength – is central for the coordination of multiple activities in our body. Despite the plasticity of synaptic strength, historically, the synapse was regarded as a stable, static structure. In recent years, particularly with advances in imaging technology, experimental evidence has revealed a dynamic nature of the synapse that encompasses its morphology.

This article focuses on the relationship between the neuronal cytoskeleton and its changes during synaptic plasticity, particularly in dendritic spines. We concentrate mostly on the actin cytoskeleton because it is the major cytoskeletal component present at the synapse and the best studied. We describe the morphological characteristics of a synapse at pre- and postsynaptic terminals, and will also discuss the different forms of synaptic plasticity and the possible intracellular signaling pathways involved in coordinating functional and structural changes. Finally, the importance of actin regulation is highlighted through some examples of human diseases. All the data and information reported in this article comes from studies on excitatory synapses, where the synapse structure–function relationship has been actively investigated.

The Cytoskeleton at the Synapse

Structurally, synapses in the central nervous system (CNS) represent strongly adhesive junctions that are similar to adherens junctions in nonneuronal cells. Conserved properties between these two types of intercellular contacts include (at synapses) (1) Ca^{2+}-dependent homophilic cell adhesion molecules (the cadherin–catenin complex), (2) electron-dense material at both sides of the cellular membrane (the postsynaptic density (PSD) and the active zone), and (3) the intercellular distance between the opposite membranes (~25 nm; the synaptic cleft). In a speculative view, the physiological role of the synapse could have been refined during evolution, over a simple junction by the addition of the molecular machinery specific to conveying information across the intercellular gap. On the presynaptic side, the machinery is involved in the organization of synaptic vesicles (SVs) – such as their clustering, docking, fusion, and retrieval, which are needed for regulated neurotransmitter release. On the postsynaptic side, the assembly of neurotransmitter receptors modulates intracellular signaling and controls the excitability of the cell.

The Presynaptic Terminal

In the late 1980s the first electron microscopy (EM) structural reports on the presynaptic organization were published from various preparations. Strikingly, the presynaptic cytoarchitecture shared a high degree of homology, from insects to fish and rodents. The presynaptic cytomatrix consists mainly of fibrillar structures that extend from the specialized presynaptic plasma membrane, called the active zone, deep into the presynaptic bouton. Among the high molecular weight proteins, piccolo and bassoon and other cytomatrix proteins are thought to provide the framework along which SVs are guided toward the active zone, where SVs fuse to release their contents, neurotransmitters. The major components of the presynaptic cytoskeleton are filamentous actin (F-actin), synapsin, fodrin, and, at some synapses, microtubules. F-actin is enriched throughout the synaptic bouton and colocalizes partially with synapsin. Synapsin has been suggested to regulate the availability of SVs for neurotransmitter release by sequestering the reserve SV pool to the F-actin scaffold.

The Postsynaptic Terminal

The postsynaptic compartment represents a cellular specialization where neurotransmitter receptors are enriched by being anchored to the PSD. In electron micrographs, the PSD is highly electron dense, which reflects the fact that it is extremely protein rich, and is roughly 20 nm thick and 200–400 nm long. More than 200 different proteins have been reported to be associated with the PSD, including receptors, scaffolding proteins, and other proteins involved in signal transduction and receptor trafficking. The PSD has a crucial role in mediating signals from the glutamate receptors to intracellular pathways, and, therefore, in modulating activity-dependent responses. For instance, scaffold proteins such as postsynaptic density-95 (PSD-95) protein physically link the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors

Table 1 Key actin regulatory proteins and actin effectors

Protein	*Function*	*Phenotype*
ADF/cofilin	Actin-binding protein	Inhibition leads to defective LTP late phase
Cdc42	Small Rho-GTPase	Inhibition causes increased filopodia and decreased spine formation
Cortactin	Actin-binding protein	Overexpression increases spine length and inhibition decreases spine number
Eph4	Receptor tyrosine kinase	Knockout shows increased spine density and elongation
Gelsolin	Actin-binding protein	Knockout shows impaired LTD and increased NMDAR current
Intersectin	Cdc42 guanosine exchange factor (GEF)	Inhibition leads to less spine formation and increased filopodia
Kalirin	Rac guanosine exchange factor (GEF)	Positively regulates spine density
LIMK	ADF/cofilin regulator	Knockout shows spines with wider heads and thinner necks, enhanced LTP, synaptic depression, and miniature excitatory postsynaptic currents (mEPSCs) frequency
N-WASP	Interacts with ARP2/3	Downstream effector of Cdc42; its first blockade leads to increased filopodia
Oligophrenin	Rho-activating protein (GAP)	Inhibition leads to decrease in spine length
PAK	Rac effector	Upstream of LIMK, inhibition causes increased spine head size with reduced spine length. Increased LTP, decreased LTD
PIX	Cdc42 and Rac guanosine exchange factor (GEF)	Inhibition results in reduced spine and synapse number
Profilin	Actin-binding protein	Inhibition causes spine elongation and spine head loss
Rac	Small Rho-GTPase	Activation leads to increased filopodia and lamellipodia; inhibition leads to decreased spine number
Rho	Small Rho-GTPase	Its activation leads to reduced spine length and density, decreased branching

to regulators, which in turn couple to the different signaling cascades that impact the postsynaptic cytoskeleton. Such pathways include Rac/Cdc42, Ras/MAPK, or Rho/Rap (see Table 1 for a summary of representative proteins involved).

Dendritic Spines

Dendritic spines are distinct protrusive structures that decorate the main shaft of the dendrite and harbor the postsynaptic terminals. A majority of excitatory synapses are formed on spines, whereas inhibitory synapses have a smooth appearance. The dendritic spines were first described by Ramón y Cajal toward the end of the nineteenth century. Cajal insightfully postulated that morphological plasticity of spines might have an important role in brain function. It was only in the middle of the twentieth century that EM studies performed by Gray established spines as the reception sites for neurotransmitters, thereby mediating neurotransmission at most excitatory synapses. Spines are formed of two distinct compartments: one is the neck, which connects the spine to the dendritic shaft, and the second, the body of the spine, called the spine head, is an enlarged structure attached at the end of the spine neck housing the main PSD and structural proteins of the spine. The spine head diameter can range from ~0.6 to ~1.1 μm, and comes in various shapes, such as thin, stubby, mushroom, cuplike, or branched, as identified by Cajal. The heterogeneity of spine shapes might represent their functional diversity.

An important function of spines is Ca^{2+} regulation and signaling. Accordingly, the common feature of all spines is the presence of endoplasmic reticulum (ER) compartments that are interconnected to the ER in the dendrite, and the presence of inositol triphosphate (IP3) receptors and Ca^{2+}-ATPase. Upon neurotransmitter release from the presynaptic terminal and activation of postsynaptic receptors, Ca^{2+} influx into the dendritic spine can occur through the NMDA receptors and voltage-gated Ca^{2+} channels. The extent to which Ca^{2+} level rises in the dendritic spine and the time window in which it occurs are critical parameters that regulate the extent and directionality of synaptic plasticity. The physical structure of the spine has been suggested to play a key role in Ca^{2+} compartmentalization where the neck restricts Ca^{2+} movement between the spine head and the dendritic shaft. In general, small and thin spines show higher relative increases in Ca^{2+} and a higher degree of plasticity and motility. On the contrary, larger mushroom-shaped spines might experience smaller changes in Ca^{2+} levels and are more stable. The contribution of different spine types to particular forms of synaptic plasticity remains to be clarified.

Dendritic Spines: Cytoskeleton

The actin filaments and actin regulatory proteins have an essential role in conferring the unique spine shape and driving spine motility. Microtubules, which are present in the dendritic shaft, are usually absent from dendritic spines. As a major component of the

Figure 1 Dynamic interactions with actin modulators regulate the balance of F- and G-actins. Adapted from Carlisle HJ and Kennedy MB (2005) Spine architecture and synaptic plasticity. *Trends in Neuroscience* 28: 182–187, with permission from Elsevier.

scaffold structure of the spine, actin forms a dense lattice around the ER in the spine neck and head. Activity modulates actin dynamics and the balance between monomeric G-actin and filamentous F-actin. Moreover, interfering with the functional activity of actin modulators, in turn, impairs synaptic plasticity.

F-actin is a double-stranded filament composed of G-actin, and is a dynamic structure that undergoes continuous turnover, where monomers are added at the 'barbed' end and removed from the 'pointed' end (Figure 1). Growth of filaments depends on the availability of ATP-bound G-actin versus ADP-bound G-actin, because only the ATP-bound G-actin is added onto a growing filament. As the filament 'ages,' ATP is exchanged for ADP, whereupon G-actin is lost from the filament. Various proteins regulate actin turnover. Actin-depolymerization factor (ADF)/cofilin binds preferentially to ADP-bound actin to promote actin depolymerization, and it can also sever filaments. Profilin promotes actin growth by exchanging ADP with ATP on G-actin monomers and, therefore, maintains the supply of ATP-bound G-actin pool needed for F-actin growth. Other actin-interacting proteins include ARP2/3, which initiates the nucleation of new actin filaments and/or branching of preexisting actin filaments, and gelsolin, which is an actin-capping protein that prevents addition of new G-actin to the barbed growing end of F-actin filaments. Calmodulin also interacts with actin and modulates the activities of fodrin, myosin, and the microtubule-associated protein (MAP-2) and Ca^{2+} signaling. These properties of calmodulin serve to couple the structure of the spine to functional synaptic plasticity involving Ca^{2+}-regulated events.

Forms of Synaptic Plasticity

Two major and best-studied forms of synaptic plasticity are long-term potentiation (LTP) and long-term depression (LTD), which represent the adaptability of synapse to variable activity regimes. The balance between the two phenomena is thought to regulate experience-dependent processes such as learning and memory storage in the brain and control the dynamic range of neuronal network activity. Synaptic strength changes during LTP and LTD are mirrored by structural plasticity of synapses.

LTP and Activity-Dependent Actin Remodeling

LTP was first described in the early 1970s as an increase in synaptic strength mediated by coincident activation of pre- and postsynaptic neurons. By increasing synaptic strength of coactive inputs, LTP is thought to play a role in shaping and consolidating neuronal circuit activity for the encoding of specific experiences. LTP induction involves presynaptic activation, for example, by brief tetanic bursts (50–100 Hz). There are several forms of LTP that are either dependent or independent of NMDA receptor activation. In both cases, its induction requires a local rise in postsynaptic Ca^{2+} that must reach a certain threshold to activate specific kinases, such as calmodulin-dependent protein kinase II (CaMKII), protein kinase C (PKC), and protein kinase A (PKA). The signaling culminates in the increase in the number of functional α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) subtype of glutamate receptors, either by rapid insertion of receptors into the PSD and/or by phosphorylation of the receptors already present at the PSD, thereby enhancing the postsynaptic response to presynaptic glutamate release.

It has been long postulated that such physiological alterations in synaptic strength might be reflected by structural changes in the synapse. Early ultrastructural studies showed correlation between high-frequency stimulation, PSD remodeling, and spine duplication, which suggested that morphological changes could

contribute to the increase in synaptic efficacy associated with LTP. In one study, active synapses were marked based on their increased Ca^{2+} level. Subsequent three-dimensional reconstruction of EM serial sections demonstrated that LTP induces an increase in the number of spines adjacent to a mature spine that shared the same presynaptic terminal, with an overall effect of increasing the number of activated synapses.

In recent years it has been possible to visualize in real time the morphology of dendritic spines undergoing LTP induction by using fluorescently labeled dendrites. Following LTP induction, the spine head is enlarged and the spine neck appears to thicken. After repetitive stimulation, spines can split to give rise to two new spines. Time-lapse studies of green fluorescent protein (GFP)-tagged actin have permitted following the live behavior of the pre- and postsynaptic actin cytoskeleton in response to different stimulation protocols aimed at inducing synaptic plasticity. LTP induction by high-frequency stimulation caused an increase of F-actin content. Fluorescence resonance energy transfer (FRET) experiments also showed in real time, upon tetanic stimulation, a shift in the balance between G-actin and F-actin toward F-actin in the dendritic spines, with a net elongation of actin filaments and an increase in their stability. In addition, an *in vivo* study elegantly showed, after LTP induction in the dentate gyrus, an increase in F-actin in the spines, as identified by phalloidin staining. Such an increase was dependent on NMDA receptor activation, actin polymerization, and ADF/cofilin inactivation, but not on *de novo* protein synthesis, which suggested that F-actin increase occurred in the early phase of LTP. Indeed, the increase was apparent within 20 min after LTP induction and lasted for at least 5 weeks.

Long-Term Depression

LTD is the phenomenon by which synapses become less efficient in transmitting neuronal signals. As a counterpart to LTP, it is also important for adapting neural networks to physiological activity requirements. LTD has been characterized in various systems and brain areas, including the cerebellum, the hippocampus, the cerebral cortex, and the striatum. Experimentally, LTD induction requires low-frequency stimulation (e.g., 1 Hz) over a prolonged time period (i.e., 5–15 min). In the cerebellum, LTD plays an important role in the trial-and-error motor learning processes, and it has been most thoroughly characterized at the synapses formed between parallel fibers and Purkinje cells. In the hippocampus, LTD has been primarily investigated at the CA3 to CA1 connections, in association with spatial learning in rodents.

Similar to the differences in the polarity of synaptic strength changes between LTP and LTD, actin cytoskeletal dynamics behave in the opposite direction during LTD, compared to LTP. In the FRET experiments using fluorescently labeled actin, low-frequency stimulation to induce LTD shifted the balance between G-actin and F-actin toward G-actin in the dendritic spines, leading to a net loss of postsynaptic F-actin. These changes were accompanied by the shrinkage of the spine and, sometimes, by spine disappearance.

Postsynaptic Signaling Pathways

What are the possible biochemical signaling pathways that mediate actin remodeling and structural plasticity at the synapse? Intracellular signaling pathways involve different protein families that act in a coordinate manner, interact with each other, and form specific complexes in order to exert their final effect on actin dynamics, and, therefore, on spine morphology and turnover. At the spine, the following classes of proteins participate in signaling: (1) neurotransmitter receptors, which initialize the signal at the cell membrane, (2) scaffold proteins, which physically link interacting proteins in specific complexes, (3) the Rho-GTPases, which execute changes in actin dynamics, (4) GEFs (guanine exchange factors), which activate Rho-GTPases, (5) GAPs (GTPase-activating proteins), which inactivate Rho-GTPases, and, finally, (6) various adaptor proteins, which ensure signal specificity by bringing specific scaffold proteins into contact with its mediators (Table 1). As the effector of actin dynamics, major players in spine remodeling are the Rho family GTPases, such as Ras, Rap, Cdc42, and Rac. Although these actin effectors represent independent pathways, there is a high degree of cross-talk between them. Signal specificity is therefore facilitated by spatial localization of effectors and coeffectors via scaffolding proteins.

Upon LTP or LTD induction, NMDA receptor activation triggers a number of signaling cascades. These include activation of GEFs for Ras (RasGRF) and therefore Ras activation, CaMKII activity modulation, interaction with SynGAP, and inhibition of Ras. In addition, indirect pathways modulate activities of gelsolin and profilin, which are proteins that regulate actin dynamics by F-actin capping and ADP–ATP exchange on G-actin.

Some activity-dependent changes involve spine formation, in which EphB receptors (EphBRs) might have a role. EphBRs are activated through ligand binding, and lead to kalirin-7 tyrosine phosphorylation. Kalirin-7 is a Rho-GEF with a Rac1 GEF domain, and upon activation, it translocates to the spine head. Overexpression of a kalirin-inactive mutant or of a Rac1-dominant negative mutant blocks the effect of EphB ligand on spine formation. Signaling downstream of EphBR–kalirin is mediated by Rac,

p21-activated kinases (PAK), and LIM motif-containing kinase (LIMK), which modulate ADF/cofilin activity, to exert changes in actin dynamics. An alternative pathway engaged following EphBR activation involves intersectin. Intersectin is a scaffold protein that interacts with several signaling proteins, among which is Cdc42. A large complex composed of intersectin, Cdc42, and a Wiskott-Aldrich syndrome protein, N-WASP, nucleates new F-actin branches via activation of ARP2/3 by N-WASP.

Other examples of receptor-mediated postsynaptic intracellular signaling are represented by glutamate receptor interacting protein (GRIP), which binds to AMPA receptors, and homer, which binds to IP3 receptors and to metabotropic glutamate receptors (mGluRs). Both GRIP and Homer link to the actin cytoskeleton via Shank, and, either via cortactin or via fodrin. The ability of high molecular weight proteins such as GKAP and Shank to interact with three postsynaptic scaffold proteins, PSD-95, GRIP, and Homer, completes the link between the different classes of glutamate receptors (NMDA, AMPA, and mGluR). Scaffold proteins, therefore, can modulate interactions between signals originating from different sources. Collectively, the postsynaptic scaffold has a dual function: shaping the postsynaptic organization and the signaling responses elicited by it. Despite the extensive interconnectivity, the ability of each receptor subtype to mediate and/or respond to distinct signaling suggests that the PSD might be segregated into substructural domains.

Mental Retardation and Dendritic Spines

The importance of a proper synapse assembly and its morphological regulation is exemplified by a class of human cognitive disorders involving mental retardation (MR). MR, which is reflected by an abnormally low IQ (usually <70), affects 2–3% of the population, and has its onset early during postnatal development. Golgi staining studies of brains of MR patients performed in the 1970s revealed abnormalities in dendritic structures. In particular, dendritic spines were predominantly long and thin, with few mushroom and stubby spines. Since elongated spines resemble filopodia-like structures typical of immature synapses, the etiology of MR could be attributed to the failure of the nervous system to wire correctly. This is due to either genetic or environmental factors, and consequently leads to a suboptimal network performance. The link between disease and spine structure is substantiated by the identification of specific genetic loci, in particular, of genes coding for modulators of actin cytoskeleton. An example is X-linked mental retardation (XLMR). At least 13 genes have been implicated in the pathogenesis of XLMR, and many of the proteins encoded by them are involved in the regulation of Rho family GTPases. The best characterized of such proteins thus far are: oligophrenin 1, PAK3, and ARHGEF6 (also called αPix).

Oligophrenin 1 negatively regulates Rho-GTPases such as RhoA, Rac, and Cdc42 via its GAP domain. The gene encoding oligophrenin 1, *OPHN1*, was first identified as a translocation on chromosome X in a female patient affected by XLMR. Subsequently, other familial forms of the disease associated with a mutation in the *OPHN1* gene have been described. A more direct link between oligophrenin 1 and aberrant spine morphology has been established by recent interference RNA (RNAi) studies. Knocking down of oligophrenin 1 expression in hippocampal slice cultures significantly reduces spine length in the CA1 region. Oligophrenin 1 also interacts with Homer, a postsynaptic scaffold protein for glutamate receptors. This indicates that oligophrenin 1 might be important not only for spine formation and maintenance, but might also have a more direct role in modulating synaptic transmission to regulate cognitive processing.

PAK3 belongs to the family of PAK and acts downstream of Rac and Cdc42. So far, three point mutations of PAK3 have been described in XLMR families: R419X, R67C, and A365E. R419X abolishes the kinase activity of the enzyme, R67C disrupts the interaction with Rho-GTPases, and A365E lies within a highly conserved motif in the catalytic domain that probably affects its kinase activity.

Another MRX gene is *ARHGEF6*, which encodes a GTP exchange factor. In its monomeric form, ARHGEF6 can bind to both Cdc42 and Rac with the same affinity. As a homodimer, however, its affinity for Rac is higher, and it therefore functions as a specific Rac GEF. ARHGEF6 also interacts with PAK, thereby regulating its activity. Mutations in *ARHGEF6* comprise translocations and frame shifts, resulting in a protein that lacks either exon 2 or a portion of exon 10 and exon 11. This could affect the integrin-mediated signaling that leads to activation of Rho-GTPases. ARHGEF6 has been shown to interact with the complex that localizes to the focal adhesions to regulate integrin clustering, including β-parvin (PARVB) and the integrin-linked kinase (ILK).

Concluding Remarks

Advances in molecular and imaging techniques have facilitated a better understanding of the importance of dendritic spine heterogeneity. Current evidence indicates that spines are highly plastic, and they undergo complex changes in both shape and number over time in an activity-dependent manner. A bewildering array of postsynaptic signaling pathways can

be activated by synaptic activity, and this in turn is reflected in the complexity of protein interactions in the PSD. A key future goal will be to understand in quantitative terms how these various postsynaptic mechanisms are coupled to synaptic activity, including neurotransmitter release from the presynaptic terminal, how different signaling systems cross-talk with each other, and how specific patterns of synaptic activity manifest in particular forms of cytoskeletal remodeling.

Deafness

J E Hawkins, Ann Arbor, MI, USA

© 2009 Published by Elsevier Ltd.

This article is a revision of the previous edition article by Joseph Hawkins, © 2004 Elsevier B.V. All rights reserved.

Deafness (anacusis) is the complete inability to hear speech and other sounds, however much they may be amplified. Persons with partial deafness (hypoacusis, dysacusis) are described colloquially as being hard of hearing, or clinically as having a hearing loss. Such deficiencies are all too common, especially in developed countries, with their overcrowded cities, excessive environmental noise and other forms of pollution, and their 'diseases of civilization.' In the United States alone, more than 20 million persons over 3 years of age have trouble hearing. Thus, some 8% of us are, like Chaucer's Wyf of Bathe, 'som-deel deef.' As our population ages and noise levels continue to rise, these figures can only increase. Moreover, some 4.8 million persons are deaf in the proper, absolute sense of that word. Comparable estimates are available for the UK, where the total number of deaf persons has been calculated to be 1 774 000. This figure includes 15 000 deaf mutes; 30 000 totally deaf; 70 000 'deaf to all natural speech' (who could hear speech amplified by hearing aids); and 1 659 000 persons who are hard of hearing.

Assessment of Hearing

The degree of auditory impairment, or hearing loss, is usually estimated by subjective audiometry, using pure tones and speech at precisely measured intensities. Thresholds, that is, sound pressure levels at which tones are just audible, or speech barely intelligible, are compared with established average normal values. The difference in decibels (dB) is the patient's hearing level. The audiogram (Figure 1) shows hearing levels for tones over a range of about six octaves, including the frequencies between 125 and 4000 Hz, which are most important for speech and music. Hearing levels between 0 and 20 dB ISO (i.e., based on the audiometric calibration of the International Standards Organization) are generally considered normal; those between 20 and 40 dB represent a mild hearing loss. Between 40 and 55 dB the loss is regarded as moderate, between 55 and 70 dB as moderately severe. Hearing levels between 70 and 90 dB indicate that the loss is severe and, above 90 dB, that the loss is profound. In these terms, deafness can be defined as a hearing level of 92 dB or more.

Other types of screening tests are used for identifying neonates who are at risk for hearing problems. One important test is based on otoacoustic emissons (OAEs) measured from the external ear canal with a microphone. Normal OAEs indicate normal middle-ear function and normal function of the inner ear at least for the outer hair cells, which are the likely generators of OAEs. Brain stem response measures are also used for hearing screening. The neuronal potentials of the brain stem, as elicited by brief sounds, are recorded with one electrode on the skin over the mastoid process and another on the scalp at the vertex. Normal brain stem responses indicate normal function of the middle ear, inner ear, auditory nerve, and certain important pathways within the brain stem. In electrocochleography (EcoG), the responses of the inner ear (cochlear microphonics and nerve action potentials) are recorded from the cochlea with a fine needle electrode piercing the tympanic membrane to make contact with its bony wall at the promontory. Pain is minimal for the adult, but for children sedation or anesthesia is advisable. On occasion, measurement of the threshold for the acoustic reflex, the brief contraction of the stapedius muscle of the middle ear in response to sudden sounds of high intensity, can be informative.

Causes of Impaired Hearing

When deafness is congenital, as it is in 1 or 2 in 1000 births, it is generally of genetic origin. The majority of such cases of hereditary hearing loss are nonsyndromic, that is, not accompanied by other structural or functional anomalies. Others may be the result of one or another of a large number of genetically determined syndromes involving malformation of the external or middle ear, or degenerative changes in the cochlea. The loss may be associated with visual defects, as in retinitis pigmentosa (Usher syndrome); musculoskeletal malformations, as in mandibulofacial dysostosis (Treacher–Collins syndrome) and osteogenesis imperfecta; pigmentary abnormalities, as in the Waardenburg syndrome; renal disease, as in the Alport syndrome; metabolic disorders such as goiter, as in Pendred's syndrome; various neurological conditions; or trisomy 13, 18, and 21. Also, maternal disease during pregnancy (e.g., rubella and syphilis) or perinatal conditions (e.g., jaundice, anoxia, and trauma) may be responsible. When hearing impairment is acquired, it may be attributable to one or more well-recognized causes, including viral or bacterial disease (e.g., mumps, measles, herpes zoster oticus, meningitis, and

Figure 1 Audiogram showing moderate, symmetrical, sensorineural hearing loss in an octogenarian subject of the NIDCD-sponsored 'Old Time Ears Project' (a functional and histopathological study of presbycusis by CI Berlin and JB Nadol). Speech reception thresholds (SRT) for spondees are 40 and 30 dB. In addition to presbycusis, the hearing loss suggests the lasting effects of numerous experimental exposures some 50 years ago to intense tones and noise and possibly those of still earlier quinine treatment for malaria. Nowadays the subject finds binaural hearing aids of help in the theatre and lecture room, but not essential for ordinary conversation. Published with permission.

syphilis), or head injury with temporal bone fracture. Other causes include ototoxic medications, in particular the aminoglycosidic antibiotics such as neomycin or gentamicin (especially when used with a loop diuretic), the antitumor agent cisplatin, the antimalarial quinine, or even aspirin in large doses. Occupational or recreational exposure to high levels of noise sooner or later produces hearing loss, not least among today's youth. In adults, otosclerosis and Meniere's disease can be causes of impaired hearing, with the aging process itself the most common cause of all. In presbyacusis, which may have a genetic, an environmental, or a temporal basis, both ears tend to be equally affected (Figure 1). In Meniere's disease and sudden deafness, the loss is often confined to one ear. In Meniere's there may also be evidence of an autoimmune condition. In sudden deafness a viral infection may be responsible, or possibly occlusion of a small artery supplying the membranous labyrinth. Infection with cytomegalovirus can also be a cause of adult deafness, especially in AIDS.

Sites and Types of Abnormality

The site of hearing impairment is usually peripheral rather than central, that is, in the outer, middle, or inner ear rather than in the brain stem or higher centers. If the cochlea is normal but sounds are prevented from reaching it by malformation or blockage of the external canal or injury to the drum membrane or the chain of ossicles, the hearing loss is said to be of the conductive type. Thresholds for airborne sounds tend to be reduced more or less equally at all frequencies, but the loss is not complete. Hearing by bone conduction, that is, with a vibrator held against the mastoid process, the forehead, or the teeth, may be normal. For such a patient, a hearing aid to amplify sounds is often of great help. Surgical repairs, as in Wullstein's and Zöllner's types of tympanoplasty, can restore sound conduction by the ossicular chain and thus give significant hearing improvement. In otosclerosis (more appropriately called otospongiosis, as

in French usage), the impairment is most often of the conductive type. Sounds are prevented from reaching the cochlea because the stapes footplate is unable to vibrate, being sealed in the oval window by deposits of newly formed, abnormal bone. Fortunately, an effective surgical treatment is available. In this stapedectomy, the fixed and immobile stapes are removed from the oval window and the opening into the vestibule is covered with a membrane consisting of vein, fascia, or other suitable material. As a substitute for the stapes, a short length of wire or plastic is attached to the long process of the incus to make contact with the new membrane. Like tympanoplasty, stapedectomy has proved to be a dramatic advance in surgery for the betterment of hearing in patients with conductive hearing loss.

Sensorineural Impairment

In sensorineural hearing impairment, there are usually pathological changes in both the cochlea and its nerve, but the middle ear may be intact. Most often, extensive loss of the sensory hair cells and supporting cells of the organ of Corti has occurred, with secondary degeneration of at least some of the cochlear nerve fibers and spiral ganglion cells. This most prevalent type of hearing loss occurs with aging and after injury by intense noise or ototoxic medications. The changes tend to occur first in the basal turn of the cochlea, which responds to the higher frequencies of sound, but they may spread to involve the upper turns and thus affect hearing for lower frequencies as well. A slow progression of this type of change is commonly observed in presbyacusis, the hearing loss associated with aging and earlier in life with certain genetic disorders. During treatment with an ototoxic antibiotic, especially in combination with a loop diuretic, a similar but rapidly progressive loss of hearing can occur. The sensory epithelium of the cochlea may also degenerate in the wake of viral diseases such as mumps; in the late stage of Meniere's disease; in sudden deafness; and in the destructive capsular form of otosclerosis, which is not limited to the oval window and stapes but may extend so far as to violate the periosteal lining of the bony labyrinth and injure Corti's organ as well (Figures 2 and 3). Because the resulting impairment is both conductive and sensorineural in character, it is called mixed. In man and other mammals, sensorineural loss is permanent because the hair cells do not regenerate. Ongoing studies in several laboratories have shown that in birds the sensory cells can reappear after noise or ototoxic injury. There is a hope that gene transfer or stem cell treatment may eventually be devised to encourage human hair cells to regenerate and replace their losses after injury. Because sensorineural change tends to diminish hearing for the higher frequencies, presbyacusic and other patients with this form of impairment have difficulty in understanding sibilant and fricative speech sounds and in distinguishing among unvoiced stop consonants. They are at a particular disadvantage when trying to converse in noisy surroundings and in groups. A hearing aid may be helpful in a church, theater, or lecture hall, but the results are often disappointing because of the user's inability to resolve the spectral details of speech sounds, especially in the presence of noise, despite amplification.

Figure 2 A case of deafness in a 73-year-old woman with capsular otosclerosis who had also received ototoxic aminoglycosides for sepsis following surgery. Top, Otic capsule, right ear, thinned by drilling and with stapes removed, showing otosclerotic focus surrounding both oval window (OW) and round window (RW). Bottom, Basal turn of cochlea. The organ of Corti (OOC) is clearly absent from most of the basal half-turn. The auditory-nerve fibers (AN) coursing across the osseous spiral lamina.were stained with osmium; their density is less than normal in most of the basal half-turn. At black arrow, Endosteum (Eo) is thickened and connective tissue has grown onto the basilar membrane as a result of the otosclerosis. From Johnsson LG, Hawkins JE Jr. et al. (1982) Cochlear and otoconial abnormalities in capsular otosclerosis with hydrops. *Annals of Otology, Rhinology and Laryngology* 91(supplement 97): 3–15.

Sensorineural impairment of hearing may be accompanied by the sometimes distressing symptom called tinnitus, a subjective ringing in the ears that may also take the form of a buzzing or roaring noise.

Figure 3 Corresponding cytocochleogram of the same ear as **Figure 2**. The *x*-axis plots the length of the basilar membrane from the cochlea's basal end (0 mm) to the apex (36.3 mm). There is a loss of outer hair cells from the basal turn (below 13 mm), attributable to ototoxic agents, and from the second turn (18–25 mm) in the region of the thickened endosteum, attributable to the capsular otosclerosis. Inner hair cells are present except for the most basal 3 mm of Corti's organ, where nerve fibers have also degenerated. Reprinted from Johnsson LG, Hawkins JE Jr., et al. (1982) Cochlear and otoconial abnormalities in capsular otosclerosis with hydrops. *Annals of Otology, Rhinology and Laryngology* 91(supplement 97): 3–15, with permission.

Tinnitus often accompanies attacks of Meniere's disease, in which the acuity of hearing tends to vary (fluctuant hearing loss). It also occurs during quinine treatment for malaria and salicylate treatment for arthritis. Furthermore, tinnitus may also be present after injury by noise, and unless the impairment is symmetrical, sounds may produce an unpleasant sensation of dissimilar pitch in the two ears (diplacusis). Unilateral tinnitus when hearing thresholds are near normal may indicate a problem with the auditory nerve. Such a retrocochlear lesion may be produced by a tumor such as an acoustic neuroma, which can interrupt conduction in the auditory nerve. A final characteristic symptom of sensorineural hearing loss is an unusually rapid increase in the perceived loudness of sound as its intensity level is increased: a phenomenon known as the recruitment of loudness.

Animal Models for Deafness

Animal models are very important tools for the study of normal hearing and disease processes. Genetic forms of deafness and their underlying otopathology have historically been studied in certain types of domestic and laboratory animals that are either born deaf or become deaf at an early age. Among these are blue-eyed white cats; waltzer, shaker, and other strains of mice; Dalmatian dogs; and Hedlund mink. The changes seen in the inner ear can resemble closely those occurring in certain types of congenitally deaf patients. Molecular biological techniques can be used to knock out (or overexpress) a protein in mouse models. The resulting loss of function can lead to important knowledge of the role of that protein in the normal ear. Noise-induced and ototoxic hearing losses have been studied experimentally in a variety of species to understand why humans who are exposed to such conditions lose their hearing. Presbyacusic changes in the cochlea vary with the species examined. In the dog they more nearly resemble those found in aging human ears, whereas those seen in the largely vegetarian rhesus monkey tend to be milder and less extensive.

The Cochlear Prosthesis

In deafened patients, even with extensive degeneration or absence of cochlear hair cells, it is often possible to restore a significant degree of useful hearing by surgically implanting a cochlear prosthesis. This device consists of a microphone, a speech processor, and an array of up to 24 tiny metal electrodes inserted through the round window of the cochlea into scala tympani. These electrodes stimulate the remaining nerve fibers, bypassing the missing hair cells. Most patients who have received an implant have emerged from a world of silence. Many are able to carry on a normal conversation. Lip-reading ability is usually enhanced. Over 60 000 implants have been placed over the past 20 years. In the past, the prosthesis scored its greatest successes in patients who had become deaf after learning to speak. Now, striking results are being obtained even in congenitally deaf infants and children, provided they receive the implant during the optimal period for language learning. Many such operations are now performed around the age of 12 months. In some patients, a cochlear implant will not work because there is no functioning auditory nerve. In these patients, an auditory brain stem implant (ABI) is placed in the

cochlear nucleus in the brain stem. ABI users have not generally had speech perception as good as that possible with a cochlear implant One challenge of the future will be to improve such devices to allow speech perception for all forms of deafness.

Decision Theory in Economics

Decision theory as developed in economics is an axiomatic analysis. The theory proceeds by first defining a set of choices that a subject (the decision maker, DM) faces. A choice is a finite set of options that are offered to the DM; a decision is the selection of one of these options. These are the observed data: it is in principle possible to collect them by explicitly asking a real DM to choose among the options, under the condition that the object selected is actually delivered to him. No speech acts (that is, statements like "I prefer this option to this other option") are necessary or allowed among the potential observations.

The method and the main results of the theory are best illustrated in a simple and concrete example of choice environment, choice under risk. In this environment the options are lotteries. A common lottery ticket provides an example: a winning number is drawn at random, and with such a ticket, a person is entitled to a payment if the winning number is the one he has, and he receives no payment otherwise. In general, a lottery is a contract specifying a set of outcomes (the payments made to the subject in our example) and a probability for each of these outcomes. The probability is typically specified in advance and precisely known to the subject.

For example, a lottery with two outcomes can be formally described with a pair $(x, p, y, 1-p)$, to be interpreted as this lottery gives the outcome x with probability p, and the outcome y with probability $1-p$. With this notation, a lottery with monetary payments (\$10, 1/2, \$0, 1/2) gives a 50/50 chance of a payment of 10 dollars and nothing otherwise. Lotteries do not need to award a monetary amount: the theory applies also to situations where x is an expensive jewel and y is a night in jail (if, for example, you are contemplating robbing a jewelry store and considering the risk of getting caught in the act). For simplicity of exposition we confine ourselves mostly to lotteries with monetary amounts in the rest of the article.

Revealed Preferences

The only feature that we can observe of our subject is the decisions he makes. We do not, of course, observe his preferences directly. However, we may interpret his choices as a 'revelation' he makes of his preferences: if when he is presented with a choice between lottery L_1 and L_2 he chooses L_1, we may say that he reveals he prefers L_1 to L_2. It is in this sense and in this sense only that we can say that the DM prefers something. The two descriptions of his behavior, one with the language of decisions and the other with that of preferences, are by the definition we adopt perfectly equivalent. Since the language of preferences seems more intuitive, it is the one used typically by decision theory, and is the one used here. But how do we describe the behavior or preferences of our subject?

Axioms

Even with simple lotteries with two monetary outcomes, by varying the amounts and the probabilities we can obtain an infinite set of possible lotteries, and by taking pairs of these lotteries we can obtain infinitely many choices. So to completely describe the behavior of a subject we should in principle list the infinite set of decisions he makes. The theory considers instead subjects whose decisions can be described by a short list of simple principles or axioms.

The first axiom requires that the preferences are complete: for every choice between the two lotteries L_1 and L_2, either L_1 is preferred to L_2 or L_2 is preferred to L_1. The occurrence of both possibilities is not excluded: in this case, the subject is indifferent to the two lotteries. When the subject prefers L_1 to L_2 but does not prefer L_2 to L_1, then we say that he strictly prefers L_1 to L_2. The second axiom requires the preferences to be transitive: if the DM prefers L_1 to L_2 and L_2 to L_3, then he prefers L_1 to L_3.

The next two axioms are also simple, but have more of a technical nature. Suppose we have two lotteries, $L_1 = (x, p, y, 1-p)$ and $L_2 = (z, q, w, 1-q)$. Take any probability r, a number between 0 and 1. Imagine the following contract. We will run a random device, with two outcomes, *Black* and *White*, the first with probability r. If *Black* is drawn, then you will play according to the lottery L_1; if *White* comes out, you will play according to the lottery L_2. This new contract is a lottery as well. If you do not care about how you get the amounts of money, then this is the lottery with four outcomes described as $(x, rp, y, r(1-p), z, (1-r)q, w, (1-r)(1-q))$. We write this new lottery as $rL_1 + (1-r)L_2$. The two axioms that we mentioned are expressed using this new concept.

The next axiom, third in our list, requires that if you strictly prefer L_1 to L_2, then for some number r, you strictly prefer $rL_1 + (1-r)L_2$ to L_2. This seems

reasonable: when r is close to 1, the composite lottery is very close to L_1, so you should strictly prefer it to L_2 just like you strictly prefer L_1.

Finally, suppose that you strictly prefer L_1 to L_2. Then for any lottery L_3, you also strictly prefer $rL_1 + (1-r)L_3$ to $rL_2 + (1-r)L_3$. Again, this seems reasonable. When, in the description we gave above, *White* is drawn, then you get in both cases L_3; when *Black* is drawn, you get in the first case L_1 and in the second L_2. Overall, you should prefer the first lottery, $rL_1 + (1-r)L_3$.

Representation of Preferences

A fundamental result in decision theory (due to von Neumann and Morgenstern (vNM)) is that subjects having preferences that satisfy these four axioms behave as if they had a simple numerical representation of their preferences. A numerical representation of a preference is a function that associates to a lottery a single number, called the utility of the lottery, that we can write as $U(L)$. This function is called a representation of the preferences if whenever L_1 is preferred to L_2, then the utility of L_1 is larger than the utility of L_2, that is, $U(L_1) > U(L_2)$.

It should be clear that the existence of such a function restricts the preferences of the subject. For example, suppose that L_1 is preferred to L_2 and L_2 to L_3. If such a function exists, then $U(L_1) > U(L_2)$ and $U(L_2) > U(L_3)$. It follows that $U(L_1) > U(L_3)$, and since the utility is a representation of preferences, L_1 is preferred to L_3. That is, preferences with a utility representation must be transitive.

The vNM theorem also states that the preference order satisfies the four preceding axioms if and only if there exists a utility function with a very simple form that represents the preference. The form is simple because it is the expectation of the utility of each outcome, according to some function u of outcomes. For example, the expected utility of the lottery $L = (x, p, y, 1-p)$ is

$$U(L) = pu(x) + (1-p)u(y). \qquad [1]$$

Cardinal and Ordinal Utilities

For neuroeconomics, and any research program that tries to determine how decisions are implemented, the utility function is probably the most interesting object. This function ties observed behavior with a simple one-dimensional quantity, the utility of the option, and predicts that the decision between two options is taken by selecting the option with the highest utility. If one is interested in determining the neural correspondents of the objects we have introduced, he must first know whether these objects are unique. For example, we may formulate the hypothesis that the decision is taken depending on some statistics of the firing rate of a group of neurons associated with each of the options. We may also consider that this firing rate is proportional to the utility we determine from observed choice behavior. Then we need to know whether this utility is uniquely determined. This introduces us to a fundamental distinction in decision theory, that between cardinal and ordinal representation.

An ordinal representation of a preference is any utility function such that $U(L_1) > U(L_2)$ if and only if L_1 is strictly preferred to L_2. There are clearly many such functions. For example, if M is any increasing function, then $M(U(L_1)) > M(U(L_2))$ if and only if L_1 is strictly preferred to L_2. So we say that an ordinal representation is unique only up to increasing (or monotonic) transformation, like the one we have used from U to $M(U)$.

Consider now the function u is eqn [1], and take two numbers $a > 0$ and b. Replace the u function in (1) with the new function v defined for any value z by $v(z) = au(z) + b$. If we replace the u in eqn [1], we obtain a new function on lotteries which also represents preferences and has the form of expected utility. Since these transformations leave the observed choices and preferences unchanged, the u in [1] is not unique. However, these are the only possible transformations we can apply. A second remarkable part of the vNM theorem is that if two functions u and v represent the preferences of a subject as expected utility (that is, as in [1]), then it must be that $v(z) = au(z) + b$ for some positive number a and some number b. In this case, the two functions are said to be linear transformations of each other, and representations like these are said to be cardinal representations. A different but equivalent way of saying this is that if we consider functions on a range of monetary prizes between a minimum of 0, say, and a maximum value M, and we agree to normalize the utility function u to $u(0) = 0$ and $u(M) = 1$, then there is a unique such function that, once substituted in eqn [1], represents the preferences of the DM.

However, the observed decision between two choices is determined by the function U, and this is unique only up to monotonic transformations. So even if we agree to normalize $U(0) = 0$ and $U(M) = 1$, still there are infinitely many such Us. Can we do better than this? We can, if we agree to extend the set of observed data to include errors and time in the decision process.

Stochastic Choice

The next step in our survey brings us closer to the models and results currently applied in neuroscience: the theory of stochastic choice.

To illustrate and motivate this new point of view, we begin with an interesting finding, discovered in the 1940s by an Iowa researcher, D Cartwright. He asked subjects to pick one of two alternatives. In keeping with our previous exposition, one may think of these alternatives as lotteries, although the original experiments were based on cognitive tasks, such as discriminating among geometric shapes or angles of different width. By changing the parameter appropriately, the experimenter could make the choice more or less difficult. For example, setting the width of two angles to be more similar would make choosing the wider angle a more difficult task. Also, by asking the subject to make the same choice repeatedly, at some time distance, he could test the frequency of the choice of one or the other of the alternatives in different decision problems. He could then construct what we can call the empirical random choice: the frequency of choice of each of the options from a given set of alternatives.

He had, however, also measured the response time for each choice (that is, the time that passed between the moment the choice was presented and the time the choice was made by the subject), and he then plotted the average response time for each decision problem against the minimum frequency of any of the two choices in that same problem. The key finding was that the longest response time was observed when the minimum frequency was approaching 50%. In other words, those problems in which the subject was more likely to select, over time, both options were also those in which he was taking more time to decide.

The result is robust and has been replicated since in many different environments. A related test is the measure of the response time measured as function of the distance between the two options, when a measure of distance is natural, for example, the distance between two numbers when the subject has to pick the largest. A robust finding is that the response time decreases with the distance (typically the log of the time is linear in the log of the distance). This is the 'symbolic distance' effect.

The finding of Cartwright suggests a model of decision in which two opposing forces push in the direction of each of the options. When the difference between these two forces is large, the decision is frequently in favor of the favored option, and the decision is taken quickly. When they are the same, the frequency of choice of the two options becomes closer, and the response time becomes longer.

For our purposes of outlining a theory of the decision process when the decision considers economic choices, it is important to note that for economic choices the same result holds. Suppose we determine the utility of a subject from the observed choices, that is, the quantity $U(L)$ for every lottery L. We can now measure the distance between the utility of any two lotteries in a choice and conjecture that the analog of the Cartwright results hold in this situation: the closer the two options in utility, the longer the time to decide, and the higher the minimum probability of choosing any of the two. This conjecture has been confirmed in several studies. There is one last hurdle: we have just seen that the U in [1] is not unique; in fact, even after normalization we have infinitely many such functions. So how can we measure in a meaningful way the distance in utility between two options?

Economic Theories of Stochastic Choice

The experimental evidence reviewed in the previous section suggests that when faced with a choice between two options many times, the subject may not always choose the same option in each instance. This is the opposite of what the utility theory we have reviewed so far predicts: in that theory, if the utility of one of the two is larger, it should always be chosen. Still, a large body of experimental and empirical evidence suggests that at best we can determine the frequency according to which one option is chosen, and that this frequency is not necessarily (in fact, is typically not) concentrated on one option. The key idea of the stochastic theory of choice is that the relative frequency of the choice of one option over the other gives a way to get a better measure of the utility of the two options.

The method of analysis is again axiomatic. Let $p(L_1, L_2)$ denote the frequency according to which lottery L_1 is chosen out of the set $\{L_1, L_2\}$, that we called the empirical random rule. Thus, it gives us evidence on whether L_1 is preferred to L_2: for example, this is plausible if that frequency is larger than 1/2. But it tells us more. If we compare the same frequency of choices out of two other lotteries $\{L_3, L_4\}$, and we observe that $p(L_1, L_2) > p(L_3, L_4)$, then we may say that the difference in utility between L_1 and L_2 is larger than the difference between L_3 and L_4. An appropriate set of axioms on the new evidence (the frequency of choice) guarantees that there is a utility

function (that we denote V to distinguish it from the very different object U) such that

$$p(L_1, L_2) > p(L_3, L_4)$$

if and only if

$$V(L_1) - V(L_2) > V(L_3) - V(L_4) \qquad [2]$$

This function is a cardinal object: that is, if a different function W also satisfies [2], for the same p, then W is a linear monotonic transformation of V. That is, there are two numbers $a > 0$ and b such that $W = aV + b$. Another way of stating this delivers us the unique object that we were looking for: if we normalize V to $V(0) = 0$ and $V(M) = 1$, then this function is unique. This is the object we were looking for: a unique summary, entirely constructed from behavioral observations, of the value that the DM attaches to different options.

In the plan of determining the neural basis of decision, we have now two final steps. First, we have to produce a reasonable model of the decision process that produces a stochastic choice with the required coherence expressed formally by the axioms underlying the representation in eqn [2]. Second, we have to specify and test the neural basis implementing this process. Let us begin with the first.

The Random Walk Model of Decision

The random walk model is a model of the decision process, originally formulated by Ratcliff. The process was originally thought of as an explanation of memory retrieval. In this task, a subject is presented with an object and is asked to decide whether it is the same he saw some period earlier. The model describes the two objects (one in front of the subject, the other in his memory) as a vector of characteristics. The decision is taken by marking, for each characteristic, whether it is the same in the two objects (in this case mark a score of 1) or not (and then mark -1). When the sum of the evidence in favor and against the conclusion that the two objects are the same reaches a critical threshold, then the decision is taken.

The process provides the basis for a general model of decision. Let us consider for simplicity the case in which the DM has to choose between two alternatives. The essential elements of the model are a space of evidence, a stochastic process on this space, and two barriers. In the memory retrieval example, the space of evidence is the set of integers, where a number is the number of agreements minus the number of disagreements. The process on the space is a random walk: as the DM proceeds to consider the next characteristic in the list, he can add or subtract one unit to the current evaluation state, depending on whether he finds an agreement or a disagreement. Finally, the process stops and the decision is taken when a barrier (high or low) is reached. The decision process has been reduced to a random walk on a space and a stopping time described by two barriers. At the stopping time, the decision corresponding to the barrier is taken.

The Predictions of the Model

The model has several parameters: first, those describing the process, for example, the mean and the variance of the random walk. The other parameters are the barriers. The model yields two observed variables: the probability that one of the two decisions is taken, and the time needed to reach the decision. Of course, an important qualitative aspect of this model of the decision process is that choice is not deterministic: when the subject is presented with the same choice, he may sometimes choose one option, and sometimes the other. The connection between the theory of stochastic choice in economics and the random walk model is clear: the probability of choice of each option studied in the model of stochastic choice is the same object induced by the random walk model when the latter hits the barrier.

The model gives sharp predictions on the two variables. For example, if the drift in favor of one of the two options is stronger, then the probability that that option is chosen increases. Also, when the difference in drift between the two choice is small, then the time to take a decision increases. The model provides a good fit with the observed data on choice and on response time in a variety of situations. The question is: do we have any evidence that suggests a neural basis for this?

Decision Theory in Neuroscience

Intense research on the neural foundation of the random walk model of decision has been developed in the past years. To illustrate the method and the findings, we begin again with a classical experiment.

In the experiment, the subject (for example, a rhesus monkey) observes a random movement of dots. A fraction of the dots is moving to the left and a fraction to the right. The monkey has to decide whether a larger fraction of dots is moving to the right or to the left, being instructed to do this after intensive training. If it makes the right guess, it is compensated with a squirt of juice. Single neuron recordings of neurons show that the process of deciding on the direction is the outcome of the following process. Some neurons are associated with the movement to the left, and others to the right. The overall firing rate of the 'left' and 'right' neurons is of course roughly proportional to the number of dots moving in the two directions.

The decision is taken when the difference between the cumulative firing in favor of one of the two alternatives is larger than a critical threshold.

We suggest that the mental operation that is performed when the subject has to choose between two economically valuable options consists of two steps. First, the individual has to associate a utility to each of the two options. Second, he has to decide which of these two computed quantities is larger. This second step is a simple comparison of quantities. The first is completely new and is specific to economic analysis. Note two important features of this model: first, even if the DM assigns (somewhere in his brain) a strictly larger utility to one of the two options, he still does not choose for sure that option; he has only a larger probability of doing so. Second, the DM has a single utility or preference order over outcomes. The choice outcome is not deterministic, because the process from utility evaluation to choice is random.

What is the evidence supporting this view? Let us begin from the step involving comparison of quantities. There are experiments involving comparison of numbers, run with human subjects, that confirm the basic finding that the response time is decreasing with the distance between the two quantities that are being compared. For example, if subjects have to decide whether a number is larger or smaller than a reference number, then the response time is approximately decreasing exponentially with the distance between the two numbers. So there is experimental evidence that suggests that the operation of comparing quantities follows a process that is close to that described by the random walk model.

The last missing element is this: do we have evidence that there are areas of the brain where neurons fire in proportion to the utility of the two options?

The Computation of the Utility

Building on previous results, we examine the neural basis of the computation of the utility. In this experiment, a monkey is offered the choice between two quantities of different food or juices, for example, three units of apple or one unit of raisin.

By varying the quantities offered of juice of each type, the experimenter can reconstruct, from 'revealed preferences', the utility function of the monkey. This function can be taken to be, for the time being, an artificial construct of the theorist observing the behavior. The choices made by the subjects have the typical property of the random choice. For example, between any amount less than or equal to 2 units of apple-tea and 1 unit of raisin, the monkey always chose the apple juice. With 3 units of tea and 1 of apple, the frequency of choice was 50/50 between the two. With 4 units of tea, the monkey always went for the tea. This is the revealed preference evidence.

At the same time, experimenters can collect single neuron recordings from areas that are known to be active in evaluation of rewards (for example, area 13 of the orbito-frontal cortex). They could then plot the average firing rate over several trials (on the y-axis) against the estimated utility of the option that was eventually chosen on the x-axis. One then obtains a clear, monotonic relationship between the two quantities.

A Synthesis

We have now the necessary elements for an attempt to provide a synthesis of the two approaches, one based on economic theory and the other on neuroscience.

Consider a subject who has to choose between two lotteries. When a subject considers each of them, he can assign to it an estimate of the expected utility of each option. This estimate is likely to be noisy. When he has to choose between the two lotteries, he can simply compare the (possibly noisy) estimate of the two utilities, so the choice between the two lotteries is now determined by the comparison of these two values. At this stage, the choice is reduced to the task of comparing of two numerical values, just as the task that the random walk model analyzes.

In summary, this model views the decision process as the result of two components. The first reduces the complex information describing two economic options to a numerical value, the utility of each option; the second performs the comparison between these two quantities, and determines, possibly with an error, the larger of the two. The comparison in this second step is well described by a random walk model of decision.

Risky and Ambiguous Choice

In this final section we illustrate how this theory can provide a simple explanation of the choice behavior of subjects facing a special type of uncertainty: ambiguity. We begin with a precise definition of this idea. Our simple examples of lotteries were meant to illustrate the uncertainty that individuals face in real economic life: any choice is typically between options that promise not certain, but rather random, outcomes. In our examples, the probability over the outcomes was clearly defined: the description of a simple random device (for example, a toss of a coin) would not leave any doubt. But in common real choices, the outcomes do not come with clearly defined probabilities attached. For example, a car insurance is a contract stipulating payments depending on events

(car accidents) for which we do not know the exact probability of their occurrence, although we can formulate a subjective estimate of it, or perhaps gather information from actuarial data. When the situation defining the probability of an option is not familiar, the ambiguity of the option may be particularly troubling. For example, an investor considering two different assests may look very different at those of a US company compared to those of a company in Malaysia: the confidence that he has on his forecasts may be fundamentally different in the two cases.

Ambiguity can be produced in experiments by reducing the information available to the subject on the likelihood of the outcomes. For example, he may be told that a lottery L will pay an amount x if a white ball is drawn from an urn containing 90 balls and y if a black one is drawn. He is not told, however, the proportion of black and white balls.

The barrier in the random walk model of choice that we have considered can be interpreted in the case of economic choices as expressing the level of satisfactory evidence which is considered necessary to make a decision. If this level is independent of the quality of the information, then the prediction on response time is clear: when the information is inferior, it would require a longer time to reach the same level of satisfactory evidence. We argue that the information-processing device (the brain) should also consider that inferior information gives a smaller incentive to wait and see. In the random walk model of decision, the trade-off between waiting and the accuracy of the information translates into different distances of the barrier from the initial point of the decision process: a barrier which is farther will require, all else being equal, more time and will allow more accurate evaluation. How should the barrier be set? This depends on the quality of information that the *DM* has. Consider, for example, the case in which the signal observed provides no information at all. Then clearly it is optimal to decide immediately, since observing the signal is not going to improve the quality of the decision. In this case the barrier is very close to the initial starting point of the process. Let us apply this to choices involving risky or ambiguous lotteries. For example, let us compare the situation in which a subject has to choose between a risky lottery and a certain amount to be paid for sure with a similar choice in which the lottery is ambiguous.

In these two types of choice, the quality of the information is different. When the quality is inferior (as in the case of ambiguous choices), the barrier should be closer to the initial point than in the risky choice because the evidence gathered is less useful. So a less informative signal has the effect of reducing the level of evidence considered necessary before the information processing stops and a decision is reached.

The main hypothesis we derive is that the choices made with a less informative signal (an ambiguous lottery compared to a risky one) may induce a shorter response time. Correspondingly, we should observe a weaker activation than those found during choices made with a more informative one. This is exactly what we find in several experimental analyses of choice.

Decision-Making and Vision

Introduction

Vision involves more than processing the light information received through the eyes. It involves interpreting information, classifying it, drawing inferences, and making decisions about its meaning in the context of goals, plans, and attitudes. The study of visual processing dovetails with the study of cognitive function. When we approach the study of vision from the 'processing' perspective, we tend to ask questions about the mathematical transformations of low-level features, such as contrast contours, to more complex entities, such as depth, motion energy, curvature, texture, objects, and faces. When we approach the topic from the cognitive perspective, we tend to ask questions about how information leads to a behavioral response, inference, or decision. Thus, a central question in the study of both vision and cognition is how the brain processes information to select among different behavioral alternatives. In this article we exploit knowledge about the neurobiology of vision to gain insight into the neurobiology of decision making.

A decision is a commitment to a particular choice or proposition at the expense of competing alternatives. It is usually based on evidence bearing on the likelihood of the alternatives and on the costs and benefits associated with the choices. This blanket formulation applies to complex decisions, like for whom to vote or what car to buy, and to simple ones, like whether to stop or go or whether a note is sharp or flat. The latter type of decision can be studied using the tools of neuroscience, especially those developed to study perception. We think understanding these simple decisions opens a window onto higher brain function in general.

Many decisions involve contingency and deliberation. By contingency, we mean that the process can occur without necessitating a particular outcome. Contingencies defy an 'if A then B' recipe. Instead we are inclined to use the language of probability to describe the outcome, or at least to predict it: if A then probably B, but maybe C or D. Of course, sometimes decisions are based on such overwhelming evidence that one outcome is guaranteed. We might view such decisions as diminutive examples, especially if they are part of a continuum. How we classify such easy decisions is not so important, but as objects of study, they are of limited utility to the neurobiologist. This is because the decision process is hard to separate from the cause and consequence – stimulus and response in the laboratory setting.

By deliberation, we mean that process is guided by more than one piece of information that is acquired from the environment or retrieved from memory over time. Again, not all decisions contain this element, but from a purely practical point of view, if the process of deciding is drawn out over time, it is easier to study. In short, decisions that do not necessitate immediate action can be peeled away from the evidence and outcome of the process. Decisions that incorporate deliberation also necessitate a stratagem for terminating the process. Thus many decisions are really double – they are a decision about the alternatives and a decision to commit based on the current state of knowledge.

The combination of these elements – contingency, deliberation, and a rule for termination – has led to the idea that many decisions are accomplished by a mechanism that accumulates evidence until some criterion level has been achieved. The neurobiology of decision making exploits this condition because it permits exposure of neural responses associated with the decision process and dissociated at least partially from the immediate representation of evidence or the outcome of the decision, typically a motor act. This separation of motor response from sensation – both temporally and logically (via contingency) – is a basic element of higher cognition.

The Basic Accumulator Model for Decisions

In the laboratory, stimuli can be configured so that the evidence for each alternative is present but sometimes weak. These kinds of stimuli are ideally suited to accumulation of evidence. We will describe work from a number of laboratories that have created stimuli of this kind to encourage animals to accumulate evidence over time. However, we are confident that this kind of decision making is not constrained to artificial laboratory situations. As we will detail at the end, a number of ecological situations are well suited to this kind of strategy also.

The premise behind the accumulator model for decision making is that evidence accumulates to better inform the decision. This is not always the case. Which decisions benefit from accumulation of evidence? A reasonable benchmark is the improvement

in accuracy expected from an accrual of independent samples of evidence. The simplest example of when accumulation of evidence is beneficial is a process that adds a series of independent values in time. Suppose that a series of independent samples with mean μ and standard deviation σ arrive at rate kt. The accumulated signal at $t = T$ would have a mean μkT and standard deviation $\sigma\sqrt{kT}$. (Recall that the sum of two independent random numbers has mean and variance equal to the sum of the their means and variances, respectively.) Thus the signal-to-noise ratio should improve as $\sqrt{t}$.

If accumulation is truly benefiting the subject in a psychophysical experiment, we might expect the threshold stimulus intensity that is required to achieve some level of accuracy to fall by the square root of the stimulus duration. The graph in **Figure 1** shows results, which conform reasonably well to this prediction. Note that slope of threshold versus viewing duration is very close to -0.5. It is often the case that performance improves at a rate substantially less than what is predicted from the $\sqrt{t}$ relationship. That could be a sign that the samples of evidence (in time) are not independent, or that not all are used, either because there is some forgetfulness (e.g., a leak of an integrator) or that some samples are ignored (e.g., because the process has terminated before all the samples were counted). In other words, a departure from $\sqrt{t}$ does not rule out accumulation.

Formal models of the process just described are termed accumulator models. In these models, a decision variable reflects the evidence accumulated over time (**Figure 2(a)**). Models of this kind are also known

Figure 1 Accuracy improves as a function of viewing time in the motion discrimination task. Each point in the graph was obtained by measuring the monkey's accuracy as a function of motion strength for one viewing duration. From these data, we estimate a threshold: the motion strength required to reach 81% correct. The graph shows that when given extra viewing time, the monkey achieves this level of accuracy with weaker motion strength (coh, coherence). The best fitting line has a slope of –0.46 (95% confidence interval is –0.59 to –0.33). Adpted from Gold JI and Shadlen MN (2003) The influnce of behavioral context on the representation of a perceptual decision in developing oculomotor commands. *Journal of Neuroscience* 23(2): 632–651.

as sequential sampling models because new evidence is added at each moment in time. The rate of accumulation (k) might depend on a number of factors, including the salience of the sensory stimulus being evaluated to make the decision. When a sufficient amount of evidence has been accumulated, the decision variable reaches a threshold value, known as a bound, and the decision process is terminated. The bound provides a reliable way to determine when to cease accumulating evidence and commit to a course of action. When decisions are among two alternative courses of action, the process might be modeled by two accumulators, each accumulating evidence for one alternative (**Figure 2(b)**). And if the evidence for one alternative is evidence against the other, then the race can be conceived as a single process/accumulation terminating in an upper or lower bound, for the two alternatives, respectively (**Figure 2(c)**).

This last scenario is termed a diffusion or random walk to bound model. It has special status in the field of statistical decision making because, under appropriate assumption, it offers the most efficient algorithm for deciding between two alternatives. It also played a key role in Alan Turing's scheme to break the German enigma cipher during World War II. In all cases, a higher bound requires more evidence before the decision process is terminated, while a lower bound requires less evidence. As we will describe, bound height may be somewhat flexible and slowly change depending on the demands of the decisions being made. A variety of accumulator models have been proposed on theoretical grounds or to explain different data sets. Some restrict accumulation to positive quantities, some to positive or negative values drawn from normal distributions; some contain leak and some involve strong interactions between accumulators. Though the details of the models differ, they share a common theme, which is that they attempt to describe both the content of a decision and the time it takes to reach it with a single mechanism. Further, by using a bound to terminate the decision process, accumulator models collectively describe a process that is controlled by internal signals in the brain, rather than by external sensory cues. Here, we highlight differences between kinds of accumulator models only as needed.

We focus on a number of different kinds of decisions that appear to rely on the accumulation of evidence. We begin with perceptual decisions whereby individuals are required to make judgments based on visual stimuli. Next, we describe a simpler kind of decision to act or not. Last, we outline decisions that may be well-described by the accumulation of evidence, but require some key changes to the models described elsewhere in this article.

Figure 2 Accumulator models. (a) Basic accumulator model. Samples of momentary 'evidence' are accumulated into a decision variable. The process terminates when the decision variable reaches a bound. The momentary evidence is modeled as a probability distribution with mean μ and variance σ^2 (insert). The decision variable has the appearance of a random walk. The jagged trace shows one example. The average of many such traces would have a slope equal to μ and a variance equal to $n\sigma^2$, where n is the number of samples drawn in time. (b) Race model for decisions between two alternatives. Conventions are the same as in a except that there are two races, one for each possible outcome. Each decision variable is the accumulation of momentary evidence for one of the outcomes. (c) Diffusion model. In a two-choice decision, if the evidence for one choice is evidence against the other, then the two decision variables are identical except for a sign change. The accumulation can be drawn on a single graph with an upper and a lower bound. Horizontal line labeled 'A' reflects the bound for one choice; horizontal line labeled 'B' reflects the bound for the other choice. (d) The LATER (linear accumulation to threshold with ergodic rate) model for decisions to 'go' or not. The decision signal rises linearly from a starting point until the bound is reached. The rate of rise during this time varies from trial to trial and can rise slowly (thin, shallow line), at an intermediate rate (medium line), or quickly (thin, steep line). The variability in slope explains reaction time variability. The linear rise approximates the accumulation of a fixed value, which is drawn from a normal (Gaussian) distribution on each trial. The slopes are therefore normally distributed and so are the reciprocals of the reaction times.

Simple Perceptual Decisions

Behavioral Observations

Considerable behavioral evidence suggests that both humans and monkeys suffer more errors when they make decisions quickly. In a recent study by our group, humans performed a random-dot motion-discrimination task. Individuals viewed a dynamic random-dot kinematogram and decided the net direction of motion of the dots. Some of the dots moved together, in the same direction, while the remaining dots moved randomly. On each trial, the percentage of dots moving in the same direction, termed the coherence, was set to make the trial easy or more difficult. In our version of the task, individuals terminated the dot motion when they were ready with a decision by making an eye movement to one of two choice targets (Figure 3(a)). Accuracy (percentage of trials whereby the individual correctly reported the direction of motion) and speed (reaction time) were measured

Figure 3 A neural correlate of a decision variable. (a) Reaction-time (RT) direction-discrimination task. A random-dot motion task is used to study decision making in humans and monkeys. The task begins with the appearance of a fixation point and two choice targets. After a random interval, a patch of moving dots appears. Some of the dots in the stimulus move coherently in the same direction while the remaining dots move randomly. When the individual is ready with a decision, he terminates the trial by making a saccade to one of two choice targets. When monkeys are performing the task, they are rewarded for correct responses with a drop of juice or water. (b) Average response from 54 lateral intraparietal area neurons on the direction-discrimination task. The firing rates (sp/s, spikes/second) of neurons in the lateral intraparietal area were measured while the monkey performed a RT version of the random-dot direction-discrimination task shown in (a). In each experiment, one of the choice targets was in the neuron's response field. Responses are grouped by motion strength (line color) and the choice the monkey made at the end of the trial in favor of the direction associated with the target in (T_{in}; solid) or out (T_{out}; dashed) of the neuron's response field. The responses are aligned to two events in the trial. On the left, responses are aligned to the onset of stimulus motion. Response averages in this portion of the graph are drawn to the median RT for each motion strength and exclude any activity within 100 ms of eye movement initiation. On the right, responses are aligned to initiation of the eye movement response. Response averages in this portion of the graph show the buildup and decline in activity at the end of the decision process. Only correct choices are included in these graphs for motion coherences >0%. Arrow indicates the approximate time at which responses to different coherences coalesce for T_{in} choices. From Roitman JD and Shadlen MN (2002) Response of neurons in the lateral intraparietal area during a combined visual discrimination reaction time task. *Journal of Neuroscience* 22: 9475–9489.

both when individuals were given no instructions about reaction time and when they were instructed to aim for a specified reaction time on the most difficult trials. Both individuals were able to comply with the instructions, and their reaction times changed accordingly. Changes in accuracy accompanied the changes in speed: when a fast reaction time was specified, both responded quickly, but both made more errors and hence had reduced accuracy.

An accumulator model described the individuals' behavior well, and also helped explain how both speed and accuracy changed with instruction. Because the model was required to account for both speed and accuracy with a single mechanism, it provided a stringent test of accumulator models. The model successfully described the behavior; further, changes in each of the model's three parameters were examined to see whether the model could produce the behavioral effects that were observed: rate of accumulation and bound height (both described previously) as well as residual time (an additional contributor to response latencies meant to encompass sensory and motor delays that are not part of the decision process). There was little change to drift rate and residual time when the speed–accuracy trade-off changed. Instead, changes in the speed–accuracy trade-off were best explained by changes in bound height. Specifically, when the individuals had fast reaction times and low accuracy, they had a low bound height, and when they had slow reaction times and high accuracy, they had a high bound height. Intuitively, this makes sense: increasing the bound height can be thought of as raising one's standards for how certain one has to be in order to make a decision. Raising one's standards improves performance, but it also takes more time. Similar findings have been obtained by BA Reddi and colleagues.

Notice that the rate of evidence accumulation – that is, the average drift rate of the decision variable – is governed by the intensity of stimulus motion. In contrast, the level of the bounds is controlled by the brain. J Palmer and co-workers showed that this level governs the trade-off between speed and accuracy. That may yield important insights into why performance may be different among individuals or even for the same individual under different circumstances. Unless decision time is measured, it is possible that the reason

for poor performance is a low level for the bound. Put simply, the decision maker might ignore useful information because the brain has already come to the end of the decision process. This also accounts for improvements in performance that fall below the expected $\sqrt{t}$ improvement.

The brain might employ deeper principles to set the bound. For example, it has been suggested that the bound could be set to maximize the overall rate of harvesting reward. RY Cho and colleagues tested this using a variant of the choice-reaction-time (RT) motion task. Reaction time as a function of error rate for a number of different task difficulties (coherences) was measured and was observed to be very close to that of an optimal estimator for some individuals. The estimator took into account the overall reward rate, which depended on the individual's reaction time, error rate, and the intertrial interval. Although not all of the individuals tested appeared to have adopted an optimal strategy, the close match between the optimal estimator and the best 30% of individuals suggests that neural systems may invest in trying to find the speed–accuracy trade-off that maximizes reward.

Taken together, these behavioral studies provide evidence for accumulators by demonstrating that the time it takes to reach a decision is linked to the accuracy of that decision. The model is not without its drawbacks. For example, in its simplest form, it fails to account for the RT on error trials, and it tends to overestimate the degree of skew seen in the distribution of RTs measured experimentally. A variety of extensions have been proposed to remedy these failures. In our view, they should not allow us to lose sight of the essential computational principle. The appeal of the accumulator model is that it provides an explanation for both choice and decision time, using a single mechanism – hence their success in a wide variety of decision tasks, including brightness discrimination, letter discrimination, and lexical decisions.

Physiological Observations

The key features of the accumulator model have been observed in neural recordings obtained from awake monkeys while they performed the choice-RT direction-discrimination task. Monkeys perform this task almost identically to the way humans do. Just as in the Palmer experiments with humans, monkeys indicated their decisions about direction by making a saccadic eye movement to a 'choice target.' By recording from neurons that encode one of the choice targets – its salience, importance, or the fact that it will be a target of an upcoming eye movement – it is possible to observe a neural correlate of an evolving decision during the period in which it is formed. Recordings from several brain areas have shed light on the process, but only one area has been studied during the choice-RT version of the random-dot motion task.

Neurons in the lateral intraparietal (LIP) area are candidates for providing evidence for the neural basis of accumulator models. Area LIP receives input from sensory areas (middle temporal (MT) and medial superior (MST) areas) that are sensitive to the motion stimulus used in the task. Further, it projects to areas known to play a role in the generation of saccadic eye movements. The position of area LIP in a sensory-motor middle ground suggests it is suited to participate in decisions that use incoming sensory information to make choices about outgoing movements. LIP neurons are selective for the direction of a saccade, so they respond more vigorously on decisions when the choice target is in the neuron's response field relative to when the choice target is in the opposite hemifield. In other words, their firing rates indicate the outcome of the monkey's decision on the motion task. However, the dynamics of the LIP response in the period leading up to the saccade suggest that these neurons play a role in the formation of the decision.

There is a gradual change in firing rates of LIP neurons in the period between onset of random-dot motion and the end of the decision process signaled by an eye movement. These changes are depicted by the traces in Figure 3(b). These traces are averages from many neurons over many trials. All of the solid traces correspond to trials that ended with an eye movement to the target in the neuron's response field (T_{in}). All of the dashed traces correspond to trials that ended with an eye movement to the opposite target (T_{out}). Not surprisingly, at the end of the decision, when the monkey is about to make an eye movement, the responses are clearly larger for T_{in} choices than for T_{out} choices (compare solid to dashed curves). In fact, the responses look like they reach the same firing rate, regardless of motion strength for all of the T_{in} choices (arrow). At the beginning of the trial, when the motion is first turned on, the responses are nearly identical for all choices and for all motion strengths.

What is happening in area LIP between the onset of random-dot motion and the eye movement response? In the first 100 ms after the dots appear there is a dip in the firing rate. This dip does not depend on the direction and strength of the motion, and it is the same regardless of the choice. It seems to signal the beginning of the decision process, but there is no sign yet of an accumulation of evidence for the T_{in} or T_{out} choice. The first sign that the neurons are affected by the direction of motion occurs ~200 ms after onset of the motion, when the solid and dashed

curves begin to separate. From this point forward, the trajectories represent the accumulation of evidence for and against the T_{in} choice. When the motion is strong and toward T_{in} (solid orange), the evidence from the visual cortex is overwhelmingly positive: the accumulation has a large positive slope. When the motion is strong and toward T_{out} (dashed orange), the evidence is overwhelmingly negative: the accumulation has a large negative slope. When the motion is weak, the evidence is less definitive and the accumulation has a smaller positive (for T_{in} choices) or negative (for T_{out} choices) slope.

Consider the case when the motion is entirely ambiguous (0% coherence motion). From moment to moment, the direction-selective neurons in the visual cortex are providing evidence that is sometimes positive and sometimes negative, but whatever the sign, the evidence is weak. The accumulation of such evidence is a random walk that meanders away from its starting point in either the positive or the negative direction. The average of all such random walks would be a flat line with zero slope. But we have sorted the responses in accordance with the monkey's choices. According to the accumulator model, the trials that end in a T_{in} choice (**Figure 3(b)**; solid dark blue) are those random walks that happen to wander to high firing rates – high enough to reach the bound (threshold) that terminates the decision process. The average of this half of the data should have a positive slope, and that is exactly what we see in **Figure 3(b)**. The other half of the trials ended in a T_{out} choice. According to the accumulator model, these are the random walks that never wandered far enough in the positive direction to cause a T_{in} choice. Instead, the decision terminated when the LIP neurons with the other target in their response field (our neurons' T_{out}) reached a high firing rate. Accordingly, this half of the data should appear to meander in a somewhat negative direction. That is exactly what we see in the dashed dark blue curve. The intermediate motion strengths (light blue) can be understood in much the same way.

The hallmarks of evidence accumulation and bound crossing just described are present in LIP neurons. First, as the monkey watches the motion stimulus, LIP neurons undergo ramplike changes in firing rate (**Figure 3(b)**, left panel). Importantly, responses to motion that is in the direction of the monkey's response field ramp up progressively at a buildup rate that is dependent on the quality of the evidence – the motion coherence. Around the time of the saccade, neural responses that have diverged, as a function of motion strength, coalesce to a common firing rate. About 70 ms after the responses come together, the saccade is executed (**Figure 3(b)**, right panel). This is a signature of the bound: when the firing rate of the LIP neurons reaches a critical value, the decision process ends with a decision in favor of the direction associated with the choice target in the neuron's response field. On the other hand, when the monkey chooses the opposite direction, the responses do not achieve a stereotyped level (**Figure 3(b)**, right panel, dashed curves). This observation suggests that these choices do not occur when the spike rate reaches a lower bound. Rather, the absence of a stereotyped termination value suggests that another process terminates the decision, presumably neurons with the chosen target in their response field. The observation thus supports a race between accumulators, like LIP neurons with each of the choice targets in their response fields, rather than the diffusion model in **Figure 2(c)**.

An accumulation to threshold model is able to reproduce the firing rate dynamics of LIP neurons well. Further studies have suggested that the momentary evidence that is accumulated in area LIP comes from a difference signal in area MT, that the accumulation represented in area LIP appears to be through a process resembling integration, and that LIP activity appears to be causally linked to the monkey's choice and response time.

Decision-related activity resembling the patterns in **Figure 3** have been observed in a number of brain areas for a variety of tasks. A gradual rise and decline in firing rates during decision making has been reported in the superior colliculus (SC), frontal eye field (FEF), and dorsolateral prefrontal cortex in studies using the random-dots task, although these studies did not measure reaction times. There is some evidence from human functional magnetic resonance imaging (fMRI) studies that a similar process underlies decision making in the human brain. In the SC, where neurons are associated with saccade-related and preparatory activity, responses of monkeys performing a two-choice position-identification task are related to reaction times and perhaps accuracy. And, in premotor cortex, responses appear to reflect different stages of the decision process when monkeys are engaged in a somatosensory discrimination task. Whether an accumulation to threshold model can explain the neural responses and behavior in all of these systems is not yet known.

Deciding to 'Go'

The behavioral and physiological observations thus far have been about perceptual decisions. However, accumulator models have been successful at describing even simpler decisions: whether to make a particular movement or not. These decisions arise when the

evidence is overwhelming for one choice, or in which there is only one possible choice. In that case, the only real decision is whether to go or not. Such decisions take more time than one would expect based on simple sensory and motor latencies. Even a simple eye movement to a single target takes ~200 ms to initiate, and there is a lot of variability in this response time from trial to trial. RHS Carpenter has championed the idea that this variable latency furnishes contingency – the possibility of doing something else – thereby imbuing even a simple motor act with the seeds of higher brain function.

A simple accumulator model has been proposed to describe these kinds of decisions. In this model, known as LATER (linear accumulation to threshold with ergodic rate), a decision signal rises linearly from a starting point until it reaches a threshold. Because (1) these decisions take very little time and (2) the accumulation is mainly positive, the process can be described very simply as a ramp with variable slope (Figure 2(d)). It is very easy to see from the geometry in Figure 2(d) that the distribution of decision times will have its median where the mean accumulation ramp intersects the bound. The distribution of decision times will be skewed to the right. Indeed, if the distribution of ramp slopes is Gaussian, then the reciprocals of decision times will also obey a Gaussian distribution.

Because the LATER model primarily describes reaction times (i.e., how long it takes to reach the bound) rather than accuracy, it is well suited to decisions about when and whether to 'go.' The simple model has been exploited to study the role of prior probability (i.e., bias), urgency, and stimulus strength on the decision process. Bias might arise when there is some uncertainty about which action is about to be instructed. Urgency refers to a time pressure on initiation after an instruction to go. Stimulus strength might be something like the intensity of the instruction or the ease of its interpretation, much like the coherence of random-dot motion. These studies exploit the change in the median reaction time and the shape of the distribution to gain insight into the process. It seems that bias and urgency affect the height of the bound in Figure 2(d), whereas stimulus intensity affects the rate or rise – what we would term the evidence accumulation.

This simple idea has been elaborated slightly to incorporate a race between two processes. As we have already noted, when there are two or more options, it may be sensible to conceive of two or more accumulators that reach a decision point, thus committing the organism to acting and selecting. In our view, the LATER type of accumulation makes sense when a single random number can effectively characterize the rate of accumulation. This will tend to be true when decision times are short and/or when the momentary evidence is the same at each moment in time. These conditions do not hold in the motion experiments reviewed earlier, but they do hold in some circumstances.

The countermanding task is a case in point. In countermanding, a second 'stop' signal instructs an individual to cancel a movement in the period between the onset of any eye movement target and movement initiation. When the stop signal is presented a long time before the individual is to make a saccade, the movement is easily withheld. However, when the stop signal occurs close to the time when the individual makes his saccade, the individual is sometimes unable to withhold the movement. The decision to go or cancel is well described by a race between a go and a stop signal.

There is physiological support of the kind of simple rise of a decision variable to a threshold, as postulated by LATER, to explain decisions to go. DP Hanes and JD Schall showed that movement neurons in the FEF exhibit a rapid rise in firing rate just before eye movement begins. These neurons, which are known to project to brain stem oculomotor structures, undergo a linear rise in firing rate after a target appears to instruct an eye movement. Hanes and Schall showed that the saccadic reaction times measured in monkeys could be explained by the rate of this rise in firing rate (Figure 4). Moreover, the firing rate reached a common value ~10–20 ms before the eye movement began, consistent with the presence of a threshold for initiation (Figure 4).

In countermanding, Hanes and Schall showed that these movement neurons also fail to achieve a critical level of discharge rate on trials in which the monkey successfully cancels a saccade. When the 'stop' signal comes too late and the saccade ensues, the FEF movement cells discharge as they do for saccades. This provides partial evidence for the type of race model hypothesized to underlie the decision process in countermanding. Indeed, a putative neural correlate of the other race – the stop signal – has been observed in the FEF and SC. However, the evidence for an accumulator-race model is still preliminary. It rests on the observation that fixation cells fire more and movement cells fire less when an eye movement is canceled. This is hardly surprising: by definition, the fixation cell responds when the animal does not make an eye movement. Thus, the argument that these cells participate in a race rests on subtle comparisons of firing rates in epochs predicted by the computational theory.

It seems secure that a rise in firing rate to a threshold level will account for the variable interval between

Figure 4 A neural correlate of a decision to go. Responses from a neuron in the FEF were recorded while a monkey made saccadic eye movements to a peripheral target. The three responses accompanied saccades to the same visual target in the response field of the neuron. Eye position traces (gray traces, top) show that the eye movements were nearly identical in amplitude, duration, and velocity but occurred at short, intermediate, and long latencies after the instruction to go. The firing rate began to increase at roughly the same latency from onset of the target (go signal), but the rate of increase was faster for the shorter latency saccades. Notice that the firing rate reaches a common value (horizontal gray bar) just preceding saccade initiation, consistent with the basic accumulator and LATER models in **Figures 2(a)** and **2(d)**. Adapted from Schall JD and Bichot NP (1998) Neural correlates of visual and motor decision processes. *Current Opinion in Neurobiology* 8: 211–217.

the onset of a visual target and movement initiation. It remains to be seen what role neurons in the FEF and other candidate structures play. Responses in the LIP, FEF, and SC can be altered by prior probability, reward expectation, uncertainty, and urgency, but it remains to be seen whether these responses interact with accumulation in the manner prescribed by LATER.

Limitations and Extensions of Accumulator Models

Certain kinds of tasks are less well suited to the simplest form of accumulator models. Some might necessitate modifications to the models in Figure 2, whereas others may simply require a different mechanism altogether. Simply put, accumulating evidence as it arrives in time is not always an optimal strategy for decision making. For example, when attempting to detect a relevant stimulus that occurs at an unpredictable time, accumulating evidence may be a poor strategy. If the brain were to accumulate evidence at the start of the trial, it might accumulate nothing but noise for the lengthy period of time while no stimulus is present. The accumulation of noise would cause a decision variable like the one depicted in Figure 1 to drift away from the starting point (in a random walk) toward one of the bounds, before the relevant information is even present. Not surprisingly, visual detection tasks typically do not appear to be mediated by the kind of accumulation strategies discussed here. When attempting to detect a low-contrast visual stimulus, humans perform only slightly better when the stimulus is presented for a longer durations. Up to ~80 ms, there is very clear improvement, as if stimulus intensity were accumulating in time (a phenomenon known as Bloch's law). But longer durations support only modest improvement in sensitivity. The improvement is explained by assuming that there is no accumulation of signal at all, but that longer viewing durations afford more independent opportunities to detect the stimulus. More opportunities decrease the probability that the stimulus will be missed.

Even without accumulation, it is possible to preserve the architecture of decision mechanism in Figure 2 for detection tasks. A time-varying decision variable is compared to a threshold in a race against other competing interpretations. Suppose the accumulation of momentary evidence is not perfect, but 'leaks' away. This way, even if noise causes the decision variable to drift toward one of the bounds, it will return to a neutral position fairly quickly. In principle, such a leaky accumulator could obey a time constant appropriately matched to the time course of the signals it is trying to detect – in other words, those governed by physiological responses to the visual stimulus. This approach has been championed with great success in psychophysics and cognitive decision making.

There is some evidence for this type of decision mechanism in neurophysiology. EP Cook and JH Maunsell trained monkeys to detect the onset of coherent motion. The monkey stared at a fixation point while random dots appeared in a patch of a video display. At the beginning of each trial, the dot display was completely random, like the 0% coherence condition in the discrimination task described earlier. On half of the trials, the motion became coherent after a random time interval. The monkey released a lever to indicate that he detected the coherent motion. Cook and Maunsell recorded from direction-selective neurons in area MT and the ventral intraparietal (VIP) area while the monkey performed the detection tasks. Neurons in area MT are strongly selective for the direction of stimulus motion when it is presented in a part of the visual field known as a neuron's receptive field. Neurons in area VIP receive a strong input from MT neurons and many exhibit responses that are selective for the direction of motion as well. The patch of random dots was aligned to the neuron's response field and the motion was in the

direction that would cause an increase in firing rate. Indeed, on trials in which the patch changed to coherent motion, the neurons increased their firing rates. The monkey detected the change when the instantaneous firing rate exceeded a criterion level. Importantly, the detection decision does not appear to be based on an accumulation of the MT response but rather on an instantaneous measure of firing rate. This makes sense because the brain cannot know when to begin accumulating evidence. (The actual estimate of instantaneous firing rate, whether performed by the brain or in data analysis, is achieved by smoothing the time series of spikes using a filter. The process can be described as leaky integration, but this should not be confused with accumulation.)

Accumulation of evidence in time may be misguided for other kinds of decisions as well. For example, some decisions involve comparing information across time. It would be detrimental to accumulate information in the time gap between two stimulus presentations. There is a need for some flexible control of integration in neural circuits. Indeed, as evidenced by R Romeo and colleagues in a two-interval vibrotactile comparison, neurons in the prefrontal cortex appear to encode both the vibration of the first stimulus, its memory in the time gap before a second comparison stimulus, and then the accumulation of evidence as the second stimulus is compared to the first. Clearly this requires an elaboration of the accumulation models depicted in Figure 1. On the other hand, storage (i.e., working memory) and accumulation are close cousins. Both rest on integration in the calculus sense, for both involve a stable value at a particular moment based on the history of inputs up until that moment. In this sense, working memory is just an accumulation of an impulse. In principle, a common mechanism might underlie both working memory and accumulation of evidence. Thus investigating not only the circuits involved in decisions, but also the cellular mechanisms of the neurons in those circuits, will be illuminating.

Real-World Decisions

The simple accumulator model will need to be elaborated to handle more complex decisions. There is some evidence that it can explain choice and decision times in decisions that are more complicated than a direction discrimination. However, a critical limitation is that samples of momentary evidence are accumulated in a single number, what we term a decision variable. But some decisions involve combining apples and oranges: perhaps evidence arrives from two different sensory modalities. One possible solution is that the brain does not accumulate raw evidence but rather evidence as it bears on a decision. For example, evidence from different sources may be more or less reliable. Studies of human perception and action suggest that the brain can combine such evidence by giving appropriate weights to the more and less reliable sources. The simple accumulators in Figure 2 need to be elaborated to explain such observations.

Certainly much work is still needed to bridge the gap between simple decision making in the laboratory and complex decision making in the real world. However, it would be a mistake to think that the kinds of mechanisms that have successfully described decision making so far would be ill suited to decisions in a more natural context. Some interesting examples from ecology suggest that animals accumulate evidence for and against particular choices. In prey selection, for example, a predator may observe a number of potential prey before making a decision about which to choose. Wolves are known to do this, and it is a strategy which greatly assists their hunting: a wolf might survey a herd of moose, for example, for quite some time, taking into account each animal's age, size, physical health, and even dental health before launching an attack. Making a choice too quickly could be detrimental to a wolf because a young healthy moose can retaliate quite effectively, injuring or even killing a wolf. This kind of decision making raises the question of how accumulators might work on different timescales. The difference between a LIP neuron responding to dot motion for about 800 ms and a wolf surveying his prey for several hours or even days is considerable. Nevertheless, these ecological observations suggest that animals in the wild might accumulate evidence and fine-tune speed–accuracy trade-offs the same way that monkeys and human subjects do in a laboratory setting.

Decision-Making in Financial Markets

P Bossaerts, California Institute of Technology, Pasadena, CA, USA

Finance

Financial markets are a relatively recent phenomenon. They are markets where agents trade claims to future monetary payoffs, commonly referred to as securities or assets. Almost invariably, the payoffs are uncertain. That is, they entail financial risk. The first modern organized financial market was set up in Antwerp, in the lower countries (present-day Belgium), in 1460. At the time, the securities were claims on future payments by established buyers of goods and services, as well as sovereigns. Only much later (around the middle of the nineteenth century) was the type of asset – namely, equity – that most people would be familiar with in modern-day financial markets introduced. Equity, or common stock, is a claim on the residual earnings of firms, which means that the holder is entitled to the cash flow of the firm after the firm pays all debtors (which includes suppliers, employees, and banks). Much more recently, derivative securities were introduced (although many of them were already occasionally traded by the Dutch in the sixteenth century). These are claims on the payoffs on other securities. Options constitute the classical example of derivatives. Nowadays, a bewildering variety of securities are traded on and off organized exchanges.

Finance studies the behavior of agents when faced with financial risk, as well as the pricing of such risk in markets. Finance is both descriptive (why are prices the way they are?) and normative (how to compute optimal portfolios?). In many respects, finance is a subfield of economics, but there are a couple of features that really set it apart. The differences will be discussed shortly, because they may lead to fresh insights for neuroscience. Far more than economics, finance relies on probability theory. This is not surprising: early developments of probability theory derived from attempts to understand monetary games, as exemplified by Pascal's proposal for computing winning odds. That is, probability theory originated in many respects from efforts to formalize financial risk.

Many Facets of Risk

One dimension in which finance and economics differ substantially is that the former explicitly deals with the many facets of risk. Rather than summarizing the attractiveness of monetary gambles in terms of a single-dimensional index, ever since the work of Harry Markowitz, in the early 1950s, finance scholars have represented risk in terms of expected payoff, payoff variance, skewness, and even kurtosis. These constitute mathematical characterizations of payoff distributions. The expected payoff is just the mean payoff that one anticipates. The variance is the (square of the) typical ('standard') deviation from the mean. The skewness measures whether payoffs below the mean are more likely (negative skewness) or not (positive skewness). Kurtosis measures to what extent extreme payoffs (both above and below the mean) are more likely, compared to a benchmark payoff distribution – namely, the well-known bell-shaped gaussian distribution.

Analyzing Risky Payoffs

Let p_t denote the payoff on a monetary gamble in trial period t. Let x_t denote the anticipated, or expected, payoff. Mathematically:

$$x_t = \mathrm{E}[p_t]$$

where E denotes the expectations operator (whereby all possible outcomes are multiplied by their respective probabilities and summed). The payoff variance is defined as follows:

$$\upsilon_t = \mathrm{E}[(p_t - x_t)^2]$$

So, the payoff variance is the anticipated deviation from the expected payoff.

The skewness is defined as the expectation of the third-order power of the difference from the expected payoff:

$$\phi_t = \mathrm{E}[(p_t - x_t)^3]$$

The kurtosis is proportional to the fourth-order power:

$$\kappa_t \sim \mathrm{E}[(p_t - x_t)^4]$$

(The constant of proportionality is such that the kurtosis of a gaussian random variable equals 3, independent of its expected outcome and its variance.) Like variance, skewness and kurtosis are anticipated deviations from the expected payoff, but negative deviations are counted separately in computing skewness (because the third power of a negative number is negative, unlike the second and fourth powers), and the fourth power with which the kurtosis is computed effectively puts a heavy weight on outliers.

While there may be many other facets of risk, finance in general limits its attention to these four relationships. In the case of common stock, often only the first two (expected payoff and payoff variance) are considered (see Figure 1). It is known, however, that expected payoff and payoff variance provide an incomplete description of the risk of other securities, such as options. Humans are sensitive to skewness and kurtosis as well, and the most convincing way to confirm this is to consider the prices of options, which include huge premia for the skewness and the kurtosis of their payoffs.

Economists take a different approach. Ever since Bernoulli proposed logarithmic expected utility, economists have generally insisted on representing the attractiveness of risky gambles in terms of a single-dimensional index. There are very few exceptions. Even the celebrated Prospect Theory remains a representation of preferences in terms of a single-dimensional expected utility index. In Prospect Theory, the index is basically a multiplication of (subjective) probabilities of each of the possible payoffs with their respective utilities (nonlinear transformations of the payoffs). Of course, one can justify the finance approach in terms of a mathematical operation on expected utility – namely, a Taylor series expansion in terms of expectation, variance, skewness, and kurtosis. As such, an agent with logarithmic expected utility (i.e., Bernoulli's agent) prefers higher expected return, is averse to variance, prefers positive skewness (while averse to negative skewness), and is averse to kurtosis.

But the Taylor series approach is by no means necessary. Moreover, by not insisting that monetary gambles are ranked in terms of a single-dimensional index, one avoids properties that many would find counterintuitive. For instance, in expected utility theory and its variations (such as Prospect Theory), there is a tight relationship between the curvature of the utility function and risk aversion. In particular, the degree to which the utility function becomes less curved as wealth increases and, hence, the degree to which utility of an extra dollar decreases with wealth determine one's risk aversion. The faster the utility of an extra dollar decreases, the more risk averse one is. As such, fear of uncertainty is tied to decreasing utility for (certain!) extra monetary units, a rather counterintuitive property (see Figure 2).

After it was introduced in the 1950s, the finance 'mean-variance' approach proved extremely useful for determining optimal portfolios of securities. Indeed, it is rather complicated mathematically to

Figure 1 Trade-off between expected payoff and payoff standard deviation (square root of variance) from investing in several asset classes, based on historical data from 1926 to 2004. Payoffs are expressed in percentage returns (i.e., in percent per dollar invested). Returns are computed from investing at the end of the year and selling at the end of the subsequent year. Notice the trade-off: higher expected returns (e.g., on US common stock) imply higher risk (higher payoff variance). The degree to which one requires higher expected payoffs in order to be willing to accept higher risk measures one's risk aversion. Based on data from Center for Research in Security Prices of the University of Chicago.

Figure 2 Effect of curvature of the utility function on risk aversion in the context of expected utility preferences. Shown are two utility functions. The black one is less curved than the blue one, in the sense that the degree to which additional utility of a dollar decreases with wealth is smaller for the former. This translates into lower risk aversion: the expected utility of a gamble that pays 0.5 or 2 with equal chance is higher for the black utility curve than for the blue one, implying that a person with the black utility function is willing to pay more for the gamble compared to someone with the blue utility curve. Using a simple geometric trick, the expected utility can readily be located by intersecting the vertical line through the expected payoff (vertical dotted red line) and the chord that connects the utility of the low payoff (0.5) with that of the high payoff (2) (solid red lines).

analyze the attractiveness of simultaneous risky gambles with correlated risks if one insists on, say, logarithmic expected utility, let alone Prospect Theory. In contrast, the properties of optimal portfolios in a simple mean-variance framework are very intuitive, and, after their discovery, led to profound insights in the 1960s about the pricing of risk in financial markets. In particular, it was realized that financial markets would not compensate investors for the entire risk as measured by a security's payoff variance, but only to the extent the payoff covaries (correlates) with the payoff on all other available securities. The covariation risk has become known as the 'beta' risk of a security. Laboratory experiments have demonstrated that the principle is correct. In such experiments, groups of human participants trade securities over anonymous, electronic markets. The securities are short-lived and their payoff patterns are deliberately kept simple and intuitive.

But there are other reasons why the finance approach is convenient. Among other things, it allows one to describe risk differences in very intuitive, statistical terms, and it facilitates learning. Both properties are relevant to neuroscience.

Describing Differences between Environmental and Financial Risks

It is likely that, through evolutionary pressures, the human brain is optimized to deal with environmental risks. This would inspire one to believe that the human brain is well adapted to financial risks as well. Yet financial risks and environmental risks differ substantially.

Two differences stand out. First, many environmental risks are adequately described by the gaussian distribution. This is not so for financial risks, which often display substantial excess kurtosis (extreme events happen far more often than predicted under the gaussian distribution). See Figure 3, for instance, which compares the risks of investing in Microsoft common stock and weather-related risks. Second, environmental risks often emerge in clusters, which means that the chance of their occurrence depends on whether they have just occurred. In contrast, the expected payoffs from investing in securities are rather independent over time, as witnessed by the ubiquitous warning in investment prospectuses that "past performance is no indication of future performance."

Figure 3 Histograms of daily returns (1-day payoffs per dollar invested) on Microsoft common stock (14 March 1986 till 31 December 1997; left panel) and of daily average temperature in Geneva, Switzerland in January (1995–2006). Red lines indicate best gaussian fit. The financial data (left panel) exhibit far more kurtosis than does the gaussian distribution, in the sense that extremely high and low returns are far more frequent. The histogram of the financial data is cut at a distance of about 4 standard deviations from the mean: seven data points are lost as a result; in particular, the maximum (17.97%) and the minimum (−30.12%) are not shown. The histogram of the temperature data (right panel) is not trimmed. The kurtosis of the financial data is estimated to be 15; the kurtosis of the temperature data is about 3, which is equal to the theoretical kurtosis of a gaussian random variable. Source: Center for Research in Security Prices of the University of Chicago (financial data) and the University of Dayton (Ohio) average daily temperature archive (temperature data).

Figure 4 Time series correlation of daily returns on Microsoft common stock and of the average daily temperature in Geneva, Switzerland. Shown are the estimated correlations between the outcome of a series and its outcome *k* days in the past, where *k* is the lag indicated on the horizontal axis. A time series correlation close to zero indicates absence of predictability (past and future are uncorrelated); correlations close to 1 or −1 imply substantial predictability (the past is a very good indication of the future). Time series correlations of lag 0 are equal to 1, by definition (see **Figure 3** caption for data details).

Figure 4 illustrates the difference by comparing the time series correlation of payoffs on Microsoft common stock and that of the average daily temperature in Geneva, Switzerland.

One could claim that the differences between environmental and financial risks may explain why humans' attitudes toward financial risks are often 'irrational.' Before jumping to this conclusion, however, it is important to consider that, as we shall discuss soon, the brain seems to be using the very statistical language in terms of which the disparities between financial and environmental risks are most readily detected.

Learning in a Finance Framework

Learning is easy within the language of finance. This is because monetary gambles are described in terms of statistical moments of their payoffs (expectation, variance, skewness, kurtosis), and these moments can be estimated in an unbiased and efficient way using simple averages of past outcomes. This contrasts with learning in the context of single-dimensional utility indices. With the exception of classical expected utility indices, it is not obvious how updating should be done. Controversy remains even today, for instance, on how individuals with Prospect Theory preferences update their (biased) beliefs.

Predicting Changes in Prediction Risk

Financial payoffs are almost never equal to their predictions; actual and expected payoffs generally differ. That is, there is prediction risk. A second respect in which finance differs significantly from economics, and in fact from almost all other fields, is in its concern for tracking prediction risk. This is because financial prediction risk at times increases suddenly, generally after unusually large or small payoffs, and it decreases only gradually afterwards (see **Figure 5**). A simple statistical model known as generalized autoregressive conditional heteroskedasticity (GARCH) describes this process. As proposed by Robert Engle in the mid-1980s, in the GARCH model, risk increases after a large error in assessing prediction risk. If no further errors occur, prediction risk gradually decreases.

In computational neuroscience, one often distinguishes between estimation risk and (pure) risk. The former is the expectation of the size of the difference between estimates and true values of parameters that describe the distribution of outcomes; it reflects 'ignorance.' The latter is the expectation of the size of the difference between outcomes and the theoretical value of these parameters; 'output noise' is sometimes used as a synonym. When one is only concerned about prediction, this distinction may not be very relevant. All that matters is the prediction risk – that is, the expected size of the difference between outcomes and predictions. For other purposes, the distinction is crucial (e.g., when one is interested in testing whether the theoretical value of underlying parameters is different from zero). From a practical point of view, finance is about prediction, and, hence, the terms risk and prediction risk are used interchangeably. So, the payoff standard deviation plotted in **Figure 1** is really the prediction risk, measured as the historical standard deviation of the prediction error. (Likewise, the expected payoffs plotted in **Figure 1** are really predictions based on historical data.)

Prediction risk is of utmost importance in finance, among other factors, because the value of derivative securities such as options depends crucially on the risk in predicting the payoff of the underlying asset. Therefore, correct valuation of financial securities requires close monitoring of changes in prediction risk. This implies, in particular, tracking of prediction risk errors, to be used to update one's estimate of future prediction risk. The importance of this endeavor is further underscored by the recent introduction in many organized financial markets of securities with payoffs that depend on realized prediction risk (realized volatility).

Figure 5 Historical daily returns on Microsoft common stock (top panel) and estimate of return prediction risk (bottom panel), over 2985 trading days (14 March 1986 till 31 December 1997). Return prediction risk is estimated as a 40-day moving average of the squared return. The sudden increases in prediction risk are visible despite the smoothness that the moving-average filter attempts to impose. Once prediction risk has increased, it decreases only gradually over time. These are the two main features of a generalized autoregressive conditional heteroskedasticity (GARCH) process. The GARCH model not only describes prediction risk in financial markets at the daily level (displayed here), but also at the minute or even subminute level.

Finance is one of the few fields in which prediction risk is considered to be stochastic. In many other fields, prediction risk is assumed to change deterministically. For instance, in the celebrated Kalman filter model, prediction risk changes according to a nonstochastic set of difference equations. The Kalman filter model applies to cases in which the underlying causes behind outcomes change slowly over time. The model is inadequate as a description of financial risk, however, wherein prediction risk often increases suddenly with past prediction risk errors, which means that prediction risk is stochastic. This is exactly what the GARCH model does capture.

Prediction Risk: Comparing The Kalman Filter and GARCH Models

Let p_t denote the payoff on a monetary gamble in trial period t and let x_t denote the predicted (expected) payoff. Let e_t denote the prediction error. That is,

$$e_t = p_t - x_t$$

Let υ_t denote the prediction risk, measured as the expectation of the square of the prediction error. In the Kalman filter model, υ_t changes over time deterministically, as follows:

$$\upsilon_{t+1} = a^2\upsilon_t + q$$

for some scalars a and q. In the simplest GARCH model,

$$\upsilon_{t+1} = a^2\upsilon_t + \kappa(e_t)^2$$

There are more complicated GARCH models, wherein the evolution of the prediction risk depends on lags of the prediction risk and of the squared prediction error beyond one period. But the essential difference with the Kalman filter model is that prediction risk changes stochastically because of the presence of a random term (the square of the prediction error e_t).

It may seem that the GARCH model is rather complicated. Yet, there is a relationship between the GARCH model and the Rescorla–Wagner reinforcement learning (RL) model from neuroscience. Specifically, a simple application to prediction risk of the Rescorla–Wagner rule produces a particular case of the GARCH model. This means that a simple RL model on prediction risk errors generates a GARCH model.

Reinforcement Learning Models for Risk Prediction as Special Cases of GARCH

The prediction risk error is defined as the difference between the realized prediction risk, measured as the squared prediction error $(e_t)^2$, and the anticipated prediction risk (υ_t):

$$\delta_t = (e_t)^2 - \upsilon_t$$

Applying the temporal difference (TD) model to update prediction risk, one obtains:

$$\begin{aligned}\upsilon_{t+1} &= \upsilon_t + \kappa\delta_t \\ &= \upsilon_t + \kappa[(e_t)^2 - \upsilon_t] \\ &= (1-\kappa)\upsilon_t + \kappa(e_t)^2\end{aligned}$$

which is a GARCH model with the restriction that the coefficient a^2 equals $(1-\kappa)$.

Neuroscience: The Finance Perspective

Evidence has accumulated recently that one of the primary roles of the dopaminergic system in the primate brain is to facilitate reward learning. Electrophysiology studies have confirmed that phasic firing of midbrain dopamine neurons correlates with errors in prediction (of cumulative anticipated rewards), and that these prediction errors affect future predictions through a simple but powerful Rescorla–Wagner rule. Functional magnetic resonance imaging (fMRI) scanning studies have found corresponding blood-oxygen-level-dependent (BOLD) signals in key subcortical dopaminoceptive areas such as ventral striatum and putamen. From a finance point of view, however, the Rescorla–Wagner rule is not fully satisfying as a model to predict rewards. This is because it does not take into account prediction risk.

Learning and Prediction Risk

Prediction risk is a key factor in determining how prediction errors should affect one's estimate of future payoffs. If the prediction risk is large, then a large prediction error is to be expected, and, hence, the prediction error should not have a large impact on future predictions. Conversely, if the prediction risk is small, then a large prediction error should cause one to substantially update one's prediction.

In terms of the Rescorla–Wagner rule of learning, this means that prediction errors should be scaled (normalized by) prediction risks in order to obtain a scale-free prediction error with which to update predictions. In general, the scaling is not simply a matter of dividing the prediction error by the (square root of the) prediction risk, but in certain cases it is. This suggests the hypothesis that the dopaminergic system encodes not just the prediction error, but also a scale-free version.

Accommodating Prediction Risk in the Rescorla–Wagner Learning Rule

When prediction risk is high, prediction errors should not change one's future predictions much because the prediction errors were expected to be sizeable anyway. Therefore, one should not update one's prediction with a constant κ, as in the traditional model. Using the notation introduced in previously, the traditional model reads as follows:

$$x_{t+1} = x_t + \kappa e_t$$

Instead, the update should be based on a scale-free prediction error η_t. In prediction of rewards in the model underlying the standard Kalman filter, the scaling takes on a very simple form:

$$\begin{aligned}x_{t+1} &= x_t + (\tilde{\kappa}/\upsilon_t^{1/2})e_t \\ &= x_t + \tilde{\kappa}(e_t/\upsilon_t^{1/2}) \\ &= x_t + \tilde{\kappa}\eta_t\end{aligned}$$

where, as before, υ_t denotes the prediction risk for trial period t ($\upsilon_t = \mathrm{E}[(e_t)^2]$). (Optimal prediction can be shown to imply that $\tilde{\kappa}$ should be proportional to the covariance between the outcomes and the scaled prediction error η_t.) Recent electrophysiological evidence from the nonhuman primate brain obtained in Wolfram Schultz' lab supports this hypothesis: at the time of reward delivery, the encoding of prediction errors in midbrain dopamine neurons appears to be scale-free (see Figure 6).

If dopaminergic neurons are able to attune firing to prediction risk, the brain must not only keep track of predictions, but also prediction risk. It seems that the brain does so, and the relevant signal may even be in the dopaminergic system itself. First, Schultz' lab has discovered that (other) midbrain dopamine neurons fire with delay during the anticipation period and throughout the period of reward delivery and that this delayed firing increases with prediction risk. This may provide the input signal with which raw prediction errors are scaled at the time of reward delivery. Second, fMRI analysis of certain subcortical dopaminoceptive regions of the human brain has also revealed a delayed signal that increases in prediction risk (see Figure 7).

One could go a step further. Because prediction risk generally changes over time, there is a need for the brain to encode prediction risk errors, with which to update prediction risk. To date, it is not known whether and where this is accomplished in the brain.

Figure 6 Spiking of primate midbrain dopamine neurons in three different types of trials involving a stochastic juice reward. In the first type, shown on top, the predicted reward (expected reward) and prediction risk (reward variance) are low. Predicted reward and prediction risk increase in the second trial type (middle) and again in the third trial type (bottom). The increase in predicted reward can be seen in the spiking of the neurons at stimulus onset, which is known to reflect prediction errors relative to baseline. The spiking at the time of reward is known to reflect prediction errors relative to expectation at stimulus onset. Only rewarded trials are shown, which is why the spiking at reward onset is always positive. Notice that the size of the spiking at reward onset does not reflect the differences of the sizes in prediction risk across trial types. In other words, the prediction error encoded in spiking at reward onset is scaled in a way that accommodates prediction risk. Reprinted from Tobler PN, Fiorillo CD, and Schultz W (2005) Adaptive coding of reward value by dopamine neurons. *Science* 307: 1642–1645, with permission from AAAS.

There is some recent suggestive evidence that insula is crucial to encoding uncertainty-related phenomena, including prediction risk, but there is no account of prediction risk errors. Some of the evidence on activation of the midbrain locus coeruleus seems to suggest that norepinephrine may play the role for prediction risk errors that dopamine plays for prediction errors. Peter Dayan's group have recently started to distinguish between predicted and unpredicted uncertainty and have pointed to the role of norepinephrine in capturing the latter. Unpredicted uncertainty has an obvious relationship with prediction risk errors.

Figure 7 Functional magnetic resonance imaging evidence of activation of the subcortical dopamine system in the human brain modulated by prediction risk (measured as reward variance). Shown are time courses of the blood-oxygen-level-dependent signal in the left ventral striatum (L vst) in trials stratified by prediction risk. Left-hand gray area indicates period of stimulus onset (when reward prediction and prediction risk for the trial are conveyed); right-hand gray area indicates period of reward realization. Note that the prediction risk signal emerges with a delay: activation differentiation is maximal only after 7 s, which is approximately 2 s after peak activation in the canonical hemodynamic response. Reproduced from Preuschoff K, Bossaerts P, and Quartz S (2006) Neural differentiation of expected reward and risk in human subcortical structures. *Neuron* 51: 381–390, with permission from Elsevier.

A Dual Role for Encoding Prediction Risk

The encoding of prediction risk not only facilitates learning: it can simultaneously play a crucial role in the determination of preferences. In finance, prediction risk is a crucial determinant of the desirability of a gamble. In Figure 1, the prediction risk of various securities is plotted on the horizontal axis (prediction risk is measured in terms of variance). As such, the encoding of prediction risk not only allows the brain to correctly update predictions, but at the same time, it also provides one of the parameters with which the brain can rank gambles. It is significant in this regard to note that the evidence for a prediction risk signal in the left ventral striatum of the human brain (see Figure 7) emerges even when there is no role for learning, and when individuals' behaviors (choice, reaction time) and brain activation (across trials) indeed do not show any evidence of updating. That is, the prediction risk signal plays a purely perceptual role.

The dual role of the encoding of prediction risk implies economy. The resulting efficiency is a powerful argument why the brain would not want to characterize the desirability of gambles in terms of a single-dimensional index, in contrast to economic theory. Of course, there is still the possibility that

the brain does build a single-dimensional index on the basis of signals of expected payoff and payoff variance, but the point is that the raw inputs with which the index is computed come from a decomposition of the features of a random payoff in terms of statistical moments, as is done in finance. Moreover, the statistical inputs need not always be weighted in the same way, thus potentially explaining why attitudes toward risk appear to be unstable.

Declarative Memory System: Anatomy

W A Suzuki, New York University, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Think for a moment about all the memories you conjure up in a typical day. Perhaps something in today's newspaper reminds you of a recent debate with a friend, a TV program brings to mind a memorable vacation, or a perfume sampled at the department store recalls a favorite aunt. Our ability to retrieve the factual and event-based information from our past is called declarative memory. More formally, declarative memory is defined as the facts and events from our own personal histories that can be consciously brought to mind. We form and retrieve declarative memories every hour of the day. Without a functioning declarative memory system, as is the case in amnesia, we would be unable to hold down a job, keep track of our daily appointments, or find our way around. Declarative memory not only plays a critical part of our daily lives, but the facts and events in our declarative memory help shape our personalities and define who we are.

Surprisingly, the first systematic studies of human memory did not begin until the late 1800s. In 1881, the French psychologist Theodule Ribot published *Les Maladies de la Memoire* (Diseases of Memory). In it, Ribot provided the first systematic description of human amnesic patients, noting that when brain injury causes memory impairment, recent memories are more susceptible to disruption than remote memories. This principle has become known as Ribot's Law. In 1885, Hermann Ebbinghaus published *Uber das Gedachtnis* (On Memory), in which he was the first to apply systematic experimental approaches to the study of normal human memory. For example, he showed that some memories are only short-lived while others are long lasting, and the amount of repetition can influence the duration of the memory. In 1890, the famous American psychologist William James published *Principles of Psychology* in which he described distinctions between what he called primary memory, defined as information that forms the focus of current attention, and secondary memory, defined as memory that persists even after it has dropped out of consciousness.

By the beginning of the twentieth century a major debate in the field concerned whether memory function was localized to a particular brain area or was distributed throughout the brain. The results from early experimental studies were mixed. However, in the 1920s Karl Lashley, a well-known psychologist at Harvard University, performed a series of influential experiments that addressed this debate. He trained rats to run in a simple spatial maze and then examined the effect of lesions to different parts of their cortex. He found that the larger the cortical lesion, the more severe the memory impairment on the rat's maze performance. He referred to these findings as the Law of Mass Action and concluded that memory was distributed over widespread cortical areas. This view dominated the field for more than 25 years, until findings from a single landmark study transformed our understanding of the localization of memory in the brain.

In 1957, Scoville and Milner described the effects of experimental bilateral lesions of the medial temporal lobe in 10 patients. These surgeries were done in an attempt to relieve a variety of psychiatric or neurological conditions, including schizophrenia, manic depressive psychosis, and, in one case, epilepsy. One striking and completely unexpected result of these experimental procedures was a profound memory loss that appeared to be correlated to the amount of bilateral hippocampal damage sustained by the patients. This memory loss was most obvious and easiest to study in patient H.M., who underwent the surgery in an effort to relieve severe and intractable epilepsy. Other patients also exhibited memory loss, but were more difficult to study because of their persistent psychiatric conditions. H.M., who received one of the largest medial temporal lobe resections, was described as being able to recall nothing of recent events of his life, though his childhood memories remained intact. Moreover, while H.M.'s memory impairment was profound, affecting memory for all sensory modalities tested (i.e., visual, auditory, somatosensory, and even olfactory memory), his general cognitive and intellectual abilities were spared.

This landmark study demonstrated several fundamental principles of memory organization in the brain. First, it showed definitively that memory could be localized to a particular brain area, namely the medial temporal lobe. Second, it demonstrated that memory could be studied independently of other general cognitive functions. Third, it led the way to more recent demonstrations that the medial temporal lobe has a critical and selective role in establishing declarative memory for facts and events. Fourth, this report was the catalyst for the ensuing experimental studies focused on defining more precisely the neuroanatomical basis of declarative memory. The following sections describe findings from the

series of experimental lesion studies and neuroanatomical studies in animals that, cumulatively, led to the identification of the subset of medial temporal lobe structures important for declarative memory.

The Amygdala, Hippocampus, and Development of an Animal Model of Human Amnesia

The amygdala and the hippocampus are two prominent structures that sit just deep to the cortex of the medial temporal lobe. The amygdala is a rounded almond-shaped structure that is situated in the anterior portion of the medial temporal lobe behind the cortex of the temporal pole. The hippocampus is an irregular tube-shaped structure that is located just posterior to the amygdala. The noted neurosurgeon Dr. William Scoville, who performed the surgery on patient H.M., described the medial temporal lobe resection as removing 8 cm of the medial temporal lobe tissue, including the temporal pole, amygdala, and approximately two-thirds of the anterior–posterior length of the hippocampus (Figure 1). Scoville and Milner initially hypothesized that bilateral damage to the hippocampus was responsible for the severe memory impairment, but because H.M.'s resection also included bilateral damage to the amygdala, they could not rule out the possibility that combined damage to both the hippocampus and the amygdala was collectively responsible for the deficit.

To address the question of which medial temporal lobe structure or structures underlie declarative memory, experimentalists attempted to develop an animal 'model' of human amnesia. Nonhuman primates have been particularly valuable animal model systems because their general brain organization, intelligence, and dominant visual system mirror our own. The strategy was to determine if bilateral medial temporal lobe lesions in an animal model could reproduce the profound memory impairment seen in patient H.M. If the deficit could indeed be reproduced, this animal model then becomes a very useful tool with which to examine the effect of damage to specific structures or combinations of structures on memory. In 1978, Mishkin was the first to successfully develop an animal model of human amnesia in the monkey. This study focused on recognition memory, defined as the ability to determine that a given stimulus has been seen before. Recognition memory is a form of declarative memory known to be impaired in human amnesic patients. In his seminal study, Mishkin examined the effect on recognition memory of combined damage to the hippocampus and the amygdala, made to resemble the damage sustained by patient H.M. Animals with separate lesions of either

Figure 1 This is a reproduction of the original from the 1957 work of Scoville and Milner, illustrating Scoville's estimate of H.M.'s medial temporal lobe resection. The drawing at the top shows a ventral view of the human brain, indicating the estimated boundaries of the lesion. (a through d) Coronal sections arranged from anterior (a) to posterior (d), showing the estimated extent of the lesion. In these coronal sections, the left side shows the estimated amount of tissue removed while the right side is shown intact in order to label the different target brain structures. Reproduced from Scoville WB and Milner B (1957) Loss of recent memory after bilateral hippocampal lesions. *Journal of Neurology, Neurosurgery & Psychiatry* 20: 11–21, with permission from the BMJ Publishing Group.

the hippocampus or the amygdala were also tested. All of the lesions included some inadvertent damage to the surrounding cortical areas. Recognition memory was tested using a delayed nonmatching to sample task (Figure 2(a)). In this now widely used task, animals are first shown either a single sample stimulus or a series of to-be-remembered sample stimuli. After a variable delay interval, animals are presented with a sample stimulus and a novel stimulus. They must learn to choose the novel, or 'nonmatching,' stimulus to receive a reward. Mishkin's study showed convincingly that combined, but not separate, lesions of the hippocampus and amygdala produced a severe recognition memory deficit (Figure 2(b)). These results suggested that it was combined damage to

Figure 2 (a) This panel shows a schematic diagram of the delayed nonmatching to sample task, a benchmark task used for studying recognition memory in monkeys. Animals are first presented with a rewarded (+) 'sample' stimulus over a central food well. After displacing the sample object and retrieving the reward, there is a variable delay interval (typically between 8 s and 10 min), after which time the sample stimulus and a novel stimulus are presented over two lateral food wells. The animals learn to choose the novel, or 'nonmatching,' test stimulus to receive a reward (+). After the intertrial interval, the sequence is repeated using a novel pair of objects. The objects used in this task are typically 'junk' three-dimensional objects, including small toys, containers, or other similarly sized objects. (b) Illustration of the performance of groups of monkeys with combined damage to the amygdala and hippocampus (AH lesion group), or separate amygdala (A group) or hippocampal (H group) lesions on the delayed nonmatching to sample task. Delay interval indicates the time delay between the sample and the test phase of the task. List length refers to a condition where lists of 3, 5, or 10 sample stimuli were presented before the test phase. This manipulation increases memory demand by increasing interference between the sample stimuli. Note the profound memory deficit of the AH group even on the shortest delay interval used. Adapted from Mishkin M (1978) Memory in monkeys severely impaired by combined but not by separate removal of amygdala and hippocampus. *Nature* 273: 297–298.

the hippocampus and amygdala that was responsible for H.M.'s severe memory deficit.

Other scientists replicated the severe memory impairment observed in monkeys following large medial temporal lobe lesions (Figure 4(a)). This lesion has been referred to by Zola-Morgan and his colleagues as the H+A+ lesion, where H refers to hippocampal damage and A to amygdala damage, with the + symbols indicating inadvertent damage to the surrounding cortex made to access the underlying hippocampus and amygdala (Figure 3). Additional studies showed that the memory impairment exhibited by the H+A+ group paralleled key features of human amnesia. Specifically, it was shown that the impairment extended to both the visual and the somatosensory modalities, that it was long lasting, and that the memory impairment was selective for only certain forms of memory while other forms of memory known to be spared in human amnesia were intact.

Findings from human neuropsychological studies reported at about the same time that the effects of H+A+ lesions being characterized showed that bilateral damage limited to the hippocampus resulted in significant memory impairment. However, the memory impairment was not as severe as that of patient H.M. To confirm these observations in human patients experimentally, Zola-Morgan and his colleagues tested a group of monkeys with bilateral lesions limited to the hippocampus and the adjacent cortex (H+ group) on the delayed nonmatching to sample task. The H+ lesion group exhibited significant memory impairment on this task, but similar to the observations in human patients, the deficit was not as severe as the deficit seen following large H+A+ lesions (Figure 4(a)). Note that this finding differed from Mishkin's report of no memory impairment following hippocampal lesions (H lesion in Figure 2(b), which also included damage to the surrounding cortex), most likely because that study used the relatively less sensitive prelesion training strategy while the H+ group was tested using a more sensitive postlesion training strategy.

These findings suggested that additional damage sustained by the H+A+ group, but not the H+ group, must be underlying this more severe deficit. Based on the original report by Mishkin, the first

Figure 3 Schematic illustration of the extent of damage sustained in Zola-Morgan's H+A+ lesion group. Shown on the top is a ventral view of a macaque monkey brain. Shaded areas indicate the approximate location of the intended lesion. Also shown are the relative locations of the amygdala and hippocampus, which are situated just below the cortex of the ventral medial temporal lobe. Drawings (a)–(e) show coronal sections through the lesion site, illustrating the largest (stippled) and smallest (gray area) extent of damage. Note the similarities between the lesion illustrated here and the illustration of H.M.'s presumed lesion in **Figure 1**. Also note the similarity between the intended lesion of the AH group of Mishkin (**Figure 2(b)**) and the H+A+ group of Zola-Morgan and colleagues. The major difference was simply the nomenclature used by the two groups. Adapted from Zola-Morgan S and Squire LR (1985) Medial temporal lesions in monkeys impair memory on a variety of tasks sensitive to human amnesia. *Behavioral Neuroscience* 99: 22–34.

obvious candidate was the additional damage to the amygdala. To test this idea, Zola-Morgan and colleagues developed techniques that would allow selective damage of the amygdala without involvement of the surrounding cortex. In contrast to the prediction from Mishkin's study, Zola-Morgan showed that animals with bilateral lesions limited to the amygdala performed completely normally on the delayed nonmatching to sample task (**Figure 4(b)**). Even more convincingly, it was shown that the addition of a selective amygdala lesion to a H+ lesion (H+A lesion group) did not exacerbate the memory deficit observed following H+ lesions alone. These findings showed definitively that the additional damage of the amygdala was, in fact, not contributing to the severe memory impairment of the H+A+ group. This left the possibility that the inadvertent damage to the surrounding cortex was underlying the more severe memory deficit of the H+A+ group. This possibility was particularly surprising because ever since the original description of H.M., attention had focused almost exclusively on the likely role of the hippocampus and amygdala in memory. Cortical damage was acknowledged (**Figures 1 and 3**), but generally considered unrelated to the memory impairment. Two additional pieces of evidence emerging at the time further strengthened the idea that the surrounding cortical areas may be important for declarative memory.

The Entorhinal Cortex

The first piece of evidence came from anatomical studies examining the connections of the monkey entorhinal cortex, a brain area strongly associated with the hippocampus. In the early 1900s the famous Spanish neuroanatomist Ramón y Cajal first noted the massive projections from layers II and III of the entorhinal cortex to the dentate gyrus, part of the hippocampal region. Based on this strong anatomical projection, Cajal speculated that the functions of the entorhinal cortex and hippocampus would also be strongly linked. To emphasize this strong anatomical link, the term 'hippocampal formation' is often used to refer to the hippocampal region, including the dentate gyrus, hippocampus proper, and subicular complex, together with the entorhinal cortex.

Boundaries and connections In the monkey, the entorhinal cortex is situated medial to the rhinal sulcus on the ventromedial aspect of the anterior temporal lobe (**Figures 5 and 7**). Important early anatomical studies by Van Hoesen and colleagues described some of the cortical inputs to the monkey entorhinal cortex. However, the full complement of anatomical projections to this area was not known. To address this question, Insausti, Amaral, and colleagues analyzed a series of retrograde tracer injections made throughout the monkey entorhinal cortex. Retrograde tracers are transported from the axons that terminate in the injection site to the cell bodies of origin, where the tracer can be visualized. Plotting the locations of retrogradely labeled cell bodies resulting from a given injection site identifies all the brain areas that project to that site, while the number of labeled cells in each brain area provides an indication of the relative strength of that projection.

Figure 4 (a) This graph illustrates the memory deficit exhibited by the H+ and H+A+ group on the delayed nonmatching to sample task. Note that the H+ group exhibited a significant but less severe memory impairment compared to the H+A+ group. For both groups, the most severe impairment is seen at the longest delay intervals. (b) This graph illustrates the effect of selective amygdala damage on the delayed nonmatching to sample task. This graph makes two key points: first, that bilateral lesions limited to the amygdala that do not involve the surrounding cortex (A group) do not cause memory impairment, and second, that the addition of an A lesion to an H+ group (H+A) does not exacerbate the memory deficit of the original H+ group. This study showed definitively that the amygdala was not contributing to the severe visual recognition memory deficit exhibited by the original H+A+ group. C, control group. Adapted from Zola-Morgan S, Squire LR, and Amaral DG (1989) Lesions of the amygdala that spare adjacent cortical regions do not impair memory or exacerbate the impairment following lesions of the hippocampal formation. *Journal of Neuroscience* 9: 1922–1936; and Zola-Morgan S, Squire LR, Amaral DG, and Suzuki WA (1989) Lesions of perirhinal and parahippocampal cortex that spare the amygdala and hippocampal formation produce severe memory impairment. *Journal of Neuroscience* 9: 4355–4370.

Figure 5 illustrates the cortical connections of the monkey entorhinal cortex. A major finding was that the entorhinal cortex receives almost two-thirds of its direct cortical inputs from the surrounding perirhinal and parahippocampal cortices. Earlier anatomical studies suggested that these areas are higher-order association areas that receive convergent inputs from multiple sensory modalities. Other direct inputs to the entorhinal cortex include olfactory and somatosensory inputs from the piriform cortex and insula, respectively, spatial inputs from the retrosplenial cortex, auditory inputs from the superior temporal gyrus, and multimodal sensory inputs from the orbitofrontal cortex. The discovery that the major cortical inputs to the entorhinal cortex originate in the surrounding perirhinal and parahippocampal cortices suggested that these adjacent cortical areas were more intimately linked to the hippocampal formation than previously appreciated.

The second critical piece of evidence highlighting the possible role of the perirhinal and parahippocampal cortices in memory was a reexamination of the extent of the lesion in Zola-Morgan's original H+A+ group. This reexamination revealed that not only was the entorhinal cortex removed in this group, but also a much larger extent of both the perirhinal and the parahippocampal cortices was damaged than had originally been appreciated. These findings, together with the newly described connections of the entorhinal cortex, strongly suggested that the extra damage to the surrounding perirhinal and parahippocampal cortices was underlying the more severe memory impairment in the H+A+ group relative to the H+ group.

The Perirhinal and Parahippocampal Cortices

Lesion studies To test the hypothesis that the perirhinal and parahippocampal cortices contribute to memory, Zola-Morgan and colleagues examined the effects of bilateral lesions limited to these areas that spared the adjacent and underlying entorhinal cortex, hippocampus, and amygdala (PRPH lesion group) on a battery of memory tasks, including the delayed nonmatching to sample task. Consistent with this hypothesis, PRPH lesions produced a severe recognition memory impairment that was similar in severity to the deficit exhibited by the original H+A+ group (Figure 6). Like human amnesia, the impairment of

Figure 5 Illustration of the relative strength of the cortical inputs to the monkey entorhinal cortex. These data were taken from one representative case of retrograde tracer injection in the entorhinal cortex (Case IM-6 of Insausti and colleagues). The entorhinal cortex receives nearly two-thirds of its direct cortical input from the adjacent perirhinal and parahippocampal cortices. Other inputs include olfactory inputs, somatosensory inputs as well as strong multimodal input from the orbitofrontal cortex, and spatial input from the retrosplenial cortex as well as auditory input from the superior temporal gyrus (STG). Reproduced from Suzuki WA (1996) Neuroanatomy of the monkey entorhinal, perirhinal and parahippocampal cortices: Organization of cortical inputs and interconnections with amygdala and striatum. *Seminars in the Neurosciences* 8: 3–12.

Figure 6 Illustration of the severe deficit exhibited by the perirhinal and parahippocampal (PRPH) group on the delayed nonmatching to sample task. The performance of the H+A+ group is shown for comparison. Adapted from Zola-Morgan S, Squire LR, Amaral DG, and Suzuki WA (1989) Lesions of the perirhinal and parahippocampal cortex that spare the amygdala and hippocampal formation produce severe memory impairment. *Journal of Neuroscience* 9: 4355–4370.

the PRPH lesion group encompassed multiple sensory modalities and was long lasting. Findings from numerous other studies confirmed that damage including the perirhinal and parahippocampal cortices resulted in severe memory impairment. These lesion findings provided definitive evidence that the perirhinal and parahippocampal cortices contributed to memory. Subsequent neuroanatomical studies focused on these areas helped clarify how these areas contribute to memory.

Boundaries and connections A major factor that slowed progress in identifying the memory functions of the perirhinal and parahippocampal cortices was the fact that at the time, very little was known about these cortical medial temporal lobe areas. For example, both the boundaries and the nomenclature applied to these areas had been highly inconsistent, making it difficult to know where one area ended and the next one began. Amaral and colleagues performed a preliminary reevaluation of the boundaries of these areas as part of their description of the cortical inputs to the entorhinal cortex. The current boundaries of the perirhinal and parahippocampal cortex are informed by data from tract tracing studies, cytoarchitectonic analyses of the cell staining and density patterns, as well as chemoarchitectonic analyses of neuropeptide staining patterns. Figure 7 illustrates the boundaries of the perirhinal and parahippocampal cortices on a ventral view of the monkey brain as well as in coronal sections. By comparing the boundaries of the perirhinal and parahippocampal cortices shown in the coronal sections in Figure 7 to the boundaries of the H+A+ lesion shown in the coronal sections of Figure 3, one can gain an appreciation for how much of the perirhinal and parahippocampal cortex was damaged in the original H+A+ group.

What are the connections of the perirhinal and parahippocampal cortices? Early anatomical studies suggested that both the perirhinal and parahippocampal cortices received convergent input from areas involved in processing multiple sensory modalities. But like the entorhinal cortex, it was unclear if all of the inputs to the perirhinal and parahippocampal cortices had been identified. To address this question, a series of neuroanatomical studies were undertaken to define the full complement of cortical inputs to these areas. The results from a series of retrograde tracer injections made throughout the perirhinal and parahippocampal cortices revealed two major findings. First, these areas receive a massive convergence of input from widespread areas, including visual, somatosensory, and auditory association areas, as well as higher order multimodal association areas, including the frontal lobe and the dorsal bank of the

Figure 7 (Top) Photograph of the ventral view of a macaque monkey brain, where the boundaries of the entorhinal (ER), perirhinal (PR), and parahippocampal (PH) cortices are shown on the right hemisphere and the major sulci are labeled on the left hemisphere. The dashed line on the right hemisphere shows the location of the rhinal sulcus, which forms the boundary between the entorhinal cortex medially and the perirhinal cortex more laterally. Drawings (a)–(d) illustrate individual coronal sections through the perirhinal and parahippocampal cortices. The locations of these coronal sections are indicated by vertical lines in the ventral view. Note that by comparing this figure with **Figure 3**, one can gain an appreciation of the extent of the perirhinal and parahippocampal cortices damaged in the H+A+ group. A, amygdala; amts, anterior middle temporal sulcus; H, hippocampus; ots, occiptotemporal sulcus; rs, rhinal sulcus; STS, superior temporal sulcus.

superior temporal sulcus. Second, the perirhinal and parahippocampal cortices receive distinctly different sets of cortical inputs, suggesting potentially different roles in memory.

The major input to the perirhinal cortex (**Figure 8**) arises from the adjacent visual area TE, a major component of the 'ventral visual pathway' important for processing visual object information. The second strongest input to the perirhinal cortex originates in the parahippocampal cortex, suggesting strong cross-talk between the two areas. Other inputs-include multimodal sensory input from the dorsal bank of the superior temporal sulcus and orbitofrontal cortex as well as somatosensory input from the insular cortex. These projections are largely reciprocal. The powerful inputs from visual area TE, taken together with the devastating effects of lesions, including the perirhinal cortex on the delayed nonmatching to sample task, suggest that perirhinal cortex is particularly important for visual object memory.

Like the perirhinal cortex, the parahippocampal cortex also receives strong visual input, but this input comes from more posterior visual areas TEO and V4 (**Figure 9**). In contrast to the perirhinal cortex, with its prominent inputs from the highest order visual area TE, the parahippocampal cortex receives more prominent input from the so-called dorsal visual processing pathway, important for processing visual–spatial information. These spatial inputs arise from the retrosplenial cortex, posterior parietal cortex, dorsal bank of the superior temporal gyrus, and dorsolateral regions of the prefrontal cortex. These findings suggest that the parahippocampal cortex may be particularly important for spatial memory.

Neuroanatomy of Declarative Memory

Figure 10 illustrates the connections of the key medial temporal lobe structures important for declarative memory. These areas include the hippocampus, together with the surrounding and strongly interconnected entorhinal, perirhinal, and parahippocampal cortices. The connections of these areas exhibit a hierarchical organization, with the hippocampus acting as the ultimate site of information convergence. The hippocampus receives its major input and provides it major output to the entorhinal cortex, which receives its major cortical inputs and outputs from the surrounding perirhinal and parahippocampal cortices. The latter two areas act as a gateway of sensory information flow between the hippocampal formation, on the one hand, and widespread areas of neocortex, on the other.

Figure 8 Schematic illustration of the relative strength of the cortical inputs to the perirhinal cortex. These data were taken from one representative case of retrograde tracer injection in the perirhinal cortex (Case M3–90 of Suzuki and Amaral). The strongest input to the perirhinal cortex arises from visual area TE and TEO, important for processing visual object information. The parahippocampal cortex also provides a very strong input to the perirhinal cortex. Other inputs include somatosensory input from the insula as well as multimodal input from the dorsal bank of the superior temporal sulcus (STSd) and orbitofrontal cortex. Thus, while the perirhinal cortex is a site of multimodal sensory convergence, its major input originates in visual areas TE and TEO. Reproduced from Suzuki WA (1996) Neuroanatomy of the monkey entorhinal, perirhinal and parahippocampal cortices: Organization of cortical inputs and interconnections with amygdala and striatum. *Seminars in the Neurosciences* 8: 3–12.

Figure 9 Schematic illustration of the relative strength of the cortical inputs to the parahippocampal cortex. The percentages shown here are taken from one prototypical case of retrograde trace injection in the parahippocampal cortex (Case M2–90 of Suzuki and Amaral). Like the perirhinal cortex, the parahippocampal cortex also receives strong visual input, but this input arises from more posterior visual area V4. Relative to the perirhinal cortex, the parahippocampal cortex receives disproportionately more direct input from the so-called dorsal visual processing stream, important for processing spatial information. These inputs arise from the retrosplenial cortex, the dorsal bank of the superior temporal sulcus, the posterior parietal lobe, and the dorsolateral prefrontal cortex. Reproduced from Suzuki WA (1996) Neuroanatomy of the monkey entorhinal, perirhinal and parahippocampal cortices: Organization of cortical inputs and interconnections with amygdala and striatum. *Seminars in the Neurosciences* 8: 3–12.

Understanding the anatomical connections of these medial temporal lobe areas provides the foundation for elucidating the role of these structures in declarative memory. For example, these anatomical connections suggest that the severe memory impairment exhibited by the PRPH group is not due exclusively to damage of the perirhinal and parahippocampal cortices, but also to the fact that the PRPH lesion cuts off virtually all of the cortical interconnections of both the entorhinal cortex and the hippocampus (Figure 10). Importantly, numerous studies have confirmed that damage limited to the hippocampal formation both in humans and in monkeys also produce significant, though less severe, memory deficits than the deficits seen following damage to the surrounding cortex. The powerful and reciprocal interconnections between these medial temporal lobe structures suggest that functional interactions between these areas may also be important for memory. This idea is supported by findings showing that the extent of medial temporal lobe damage correlates with the severity of impairment on the delayed nonmatching to sample task. However, the differences in the connections of these areas, particularly between the perirhinal and parahippocampal cortex, suggest that these cortical areas may also participate in different forms of memory, with perirhinal cortex important for object memory and the parahippocampal cortex important for spatial memory. This idea is also supported by experimental findings in monkeys.

The lesion and anatomical studies in the monkey model system also make strong prediction with respect to the actual brain damage sustained by patient H.M. Specifically, it is clear that the impairment in patient H.M. is substantially more severe than the memory impairment in patients with damage limited to the hippocampal formation bilaterally. Findings from animal studies predict that that patient H.M.'s lesion involves the hippocampus together with the surrounding cortex. Unfortunately, for many years the precise extent of H.M.'s lesion could not be confirmed with structural magnetic resonance imaging (MRI) scans because it was thought that the surgical clips left in place after his original surgery were not compatible with imaging. However, it was later determined that the clips would not pose a danger to H.M., and in 1997 Corkin and colleagues brought the study of the neuroanatomy of declarative memory full circle when they published a historic MRI analysis of H.M.'s brain lesion. This study confirmed that H.M. sustained bilateral damage to the amygdala as well as approximately the anterior

Figure 10 Schematic illustration of the connections of the hippocampus and the entorhinal, perirhinal, and parahippocampal cortices. The relative strength of the connections estimated from retrograde tracer experiments is illustrated by the color and thickness of the interconnecting lines (see key in upper right). Note the hierarchical organization, with the hippocampus acting as the pinnacle of the hierarchy. The hippocampus receives its major inputs and outputs from the entorhinal cortex, which receives its major inputs from the perirhinal and parahippocampal cortices. These latter two cortical areas act as the major gateway of sensory information flow between widespread areas of the neocortical mantel, on the one hand, and the hippocampal formation, on the other. Note the differences in the patterns of inputs between the perirhinal and parahippocampal cortices. These anatomical connections provide a framework for understanding the mnemonic functions of the medial temporal lobe. HPC, hippocampus; Ia, agranular portion of the insula; Id, dysgranular portion of the insula; Ig, granular portion of the insula; LIP, lateral intraparietal area; STG, superior temporal gyrus; STSd, dorsal bank of the superior temporal sulcus. Reproduced from Suzuki WA and Amaral DG (1994) Perirhinal and parahippocampal cortices of the macaque monkey: Cortical afferents. *Journal of Comparative Neurology* 350: 497–533.

half of the hippocampus. Moreover, consistent with the predictions from the animal studies, the MRI scans confirmed that the resection also involved all of the entorhinal cortex and parts of the perirhinal cortex bilaterally, though the parahippocampal cortex was spared. These findings, taken together with studies of other well-characterized amnesic patients with MRI or histological confirmation of the medial temporal lobe damage, support the idea that results from experimental animal studies are directly applicable to humans. These parallel findings reinforce the value of animal models in elucidating the principles of memory organization in the brain.

The discussion here has emphasized the lesion and anatomy studies in monkeys. However, important studies in the rodent model system have also provided fundamental contributions to our understanding of the medial temporal lobe areas important for declarative memory. Taken together, these experimental studies have not only identified the structures important for declarative memory, but have also laid the groundwork for the next generation of questions concerning how each of these medial temporal lobe areas contribute and/or interact to acquire new declarative memories. These studies also form the foundation for clinical strategies to treat various neurological conditions wherein declarative memory is impaired, including both normal human aging and Alzheimer's disease. Progress in the basic research of the brain basis of declarative memory will be critical in addressing these pressing clinical issues.

Decoding Neuron Transcriptome by SAGE

Y C Kim and S M Wang, Northwestern University, Evanston, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Each somatic cell in the body of an individual contains the same genome with the same genes. However, the genes expressed in different cells can be very different in order to fulfill specific physiological activities. The brain is one of the most complex tissues, having different cell types, and the genes in the brain are expressed most actively in all human tissues. To fully understand brain function, the activity of each gene in brain tissue needs to be studied. One approach to doing this is to identify the direct gene products, the transcripts, expressed in the brain. Serial analysis of gene expression (SAGE) has been applied for this purpose.

Basics of SAGE

SAGE is a technique widely used for transcript identification. SAGE collects a short sequence, named a SAGE tag, from a long transcript to represent the whole transcript. Information from the SAGE tag can be used to detect and quantify the gene activities in the analyzed cells. The SAGE tags derived from transcripts of known genes represent the activity of known genes; the SAGE tags derived from unknown transcripts represent the activity of unknown genes, and such SAGE tags provide clue to discovering novel genes.

A standard procedure for SAGE tag generation is shown in Figure 1. Starting from an mRNA sample isolated from the target cells, cDNAs are synthesized and are digested by restriction enzyme NlaIII (CATG). The 3′-most cDNAs after the last CATG site are recovered, and SAGE tags are released after the last CATG site. SAGE tags are concatemerized, cloned, and sequenced. SAGE tags are extracted from the sequences with a copy number for each SAGE tag representing its quantitative information.

The standard SAGE is the most widely used; it is composed of 14 bp and is extracted as just described. Several variations of SAGE have been evolved for studying specific issues. LongSAGE elongates the standard SAGE tag to a 21 bp tag. The extended length improves the specificity of the transcripts and increases the mapping frequency of the tags to the reference genomic tags. SuperSAGE extends the length further to 26 bp, which allows superSAGE tags to be used directly as microarray probes and makes it useful for studying gene expression in species in which there is no genome or expressed sequence tag (EST) information. Cap analysis of gene expression (CAGE) collects 21 bp tags from the 5′ end of cDNAs to determine the 5′ end of transcripts and the location of the promoter. Gene identification signature (GIS) collects longSAGE tags from both the 5′ and the 3′ ends of the same transcript to determine the 5′ and 3′ ends of the detected transcripts.

The full-length cDNA and ESTs provide high specificity for the transcripts detected, but they have limited sensitivity for detecting low-abundance transcripts. SAGE has a high sensitivity for detecting both known and unknown transcripts present from high- to low-abundance levels. Comparing the full-length cDNA and ESTs, however, SAGE tags have a lower specificity for the detected original transcripts due to its short length. This could be improved by increasing the tag length into 3′ EST using the generation of longer cDNA fragments from SAGE tags for gene identification (GLGI) or rapid amplification of cDNA 3′ ends (3′-RACE) methods.

Three types of SAGE data analysis can be used to extract information from SAGE data.

1. *Quantitative analysis*. By using statistical analysis, the alternative gene activities among different samples represented by SAGE tag copies can be determined. Several standard statistical methods are used for this purpose, such as the Audic and Claverie pairwise test, Fisher's exact test, Greller and Tobin test, the *R* test, and general chi-squared tests. The Audic and Claverie test is efficient when detecting the differential expression of genes in pairwise comparisons. The chi-squared test is more efficient when there are variations with weakly expressed genes. An online program, IDEG6, provides several statistical programs specifically formatted for SAGE data analysis to identify differential gene expression.

2. *Determining the original gene for the detected SAGE tags*. This is achieved by comparing the experimental SAGE tags with a reference tag database based on the known transcript sequences. A reference SAGE database contains virtual SAGE tags extracted from known transcripts, including well-characterized full-length cDNA, mRNA, and ESTs. The widely used databases include the SAGEmap database at the National Center for Biotechnology Information (NCBI; the largest official collection of experimental SAGE tags exists on NCBI GEO for many species; the standard SAGE tag collection from human can be found as a platform data GPL4 and the longSAGE

Figure 1 SAGE procedure. mRNA is isolated from the targeted sample. After being converted into cDNA, SAGE tags are released from the 3′ part after the last restriction site CATG and concatemerized for sequencing. SAGE tags are extracted from the sequences. Their gene origins are identified through matching to known transcript sequences.

tags from human samples are in GPL1485) and the SAGE Genie database at the National Cancer Institute (NCI). The SAGEmap tags are extracted from known transcripts or genes. SAGE Genie has a large collection of deposited tags from human and mouse, and it provides various tools for tag analysis. The experimental SAGE tags are compared with the virtual SAGE tags in the database. When an experimental SAGE tag matches a virtual SAGE tag, this implies that the experimental SAGE tag originated from the same mRNA or gene represented by the virtual SAGE tag. When the experimental SAGE tag does not match any virtual SAGE tag, the experimental SAGE tag is considered an unknown transcript.

3. *Identifying novel transcribed regions in the genome*. By mapping SAGE tags to the genome sequences, the origin of the transcripts detected by the SAGE tag can be identified. Those mapped to the intergenic regions or antisense regions, or intronic regions, represent potential novel transcribed regions in the genome. This is mainly achieved by using the longSAGE tags; the standard 14 bp SAGE tags are too restrictive for this type of study due to their short length.

When analyzing SAGE data, we need to pay attention to several factors that affect the quality of SAGE tag interpretation. These factors include experimental artifacts, sequencing errors, multiple loci in the genome containing the same SAGE tag sequence, incomplete annotated reference databases, transcript isoforms, alternate splicing, and single nucleotide polymorphisms (SNPs). When planning downstream functional studies, it is better to use different methods to confirm the results, for example, to use Northern blotting or real-time polymerase chain reaction (PCR) to confirm that the candidate genes are differentially expressed in different samples and to use reverse transcription (RT)-PCR to confirm the presence of transcripts from the novel gene candidates.

Applying SAGE to Brain Transcriptome Studies

Since SAGE was introduced, it has been increasingly used for transcriptome study. One of the major tissue types analyzed by SAGE is the human brain. This has been largely achieved by Gregory Riggins's laboratory, supported by the NCI's Cancer Genome Anatomy Project.

The Total SAGE Tags Collected from the Human Brain

A total of 95 standard SAGE and 8 longSAGE libraries were constructed from RNA samples of human brain sources. A total of 8 million SAGE tags have been collected from those libraries, which account for 25% of the 30 million SAGE tags collected so far that are of human origin. Table 1 summarizes the brain SAGE data collected from each sample. The accumulation curve (Figure 2) shows that even using this scale of SAGE tag collection, a saturated stage of transcript detection in brain has not been reached. This implies that more unknown transcripts expressed in the brain remain to be identified.

The SAGE Tags from Normal Brains and Brains with Tumors

Of the 103 SAGE libraries, 12 are from normal human tissues and 91 are from different types of brain tumors (Table 2). Most of the standard SAGE samples are from brain cancers, such as astrocytoma, ependymoma, glioblastoma, medulloblastoma, meningioma, and oligodendroglioma. The information from the normal tissue provides the gene expression information in normal conditions, and the information from the tumors is valuable for studying tumorigenesis and for identifying tumor-specific markers for diagnosis and classification.

Comparing Brain SAGE Tags to Known Transcript Sequences

Comparing the SAGE tags with the known human transcript sequences shows that, in the individual SAGE

SAGE data are from the SAGE Genie database. Total unique SAGE tags count the SAGE tags that overlap among different libraries only once.

tag set, between 22% and 74% of SAGE tags match a known transcript sequences and that the overall matching rate is 36% (Table 3). The matched sequences are included in a total 32 968 UniGene clusters that include most of the genes annotated in the human genome, indicating that most of the known human genes are expressed in brain. Significantly, between 24% and 78% of SAGE tags in individual SAGE tag sets do not match known transcript sequences, with an overall unmatched rate of 64%. Although a certain portion of these might be due to experimental artifacts, they contain a substantial number of unknown transcripts or the genes in the genome that remain to be identified. The quantitative distribution of the mapped SAGE tags shows that most of the detected transcripts are present at a low-abundance level (Figure 3).

Mapping SAGE Tags to Human Genome Sequences

The longSAGE tags can be mapped specifically to the genome; therefore, we can use the longSAGE

Figure 2 Accumulation of brain SAGE tags: (a) regular 14 bp SAGE tags; (b) longSAGE tags. Total brain SAGE tags were used for the plotting. SAGE tags were divided into 100 000 per set and the unique tags from each set were compared with the previous ones. Only the new unique tags identified in later SAGE tag set were kept to indicate the detection of new transcripts. The curves show that the saturated stage of transcript detection in the brain has not been reached.

Table 2 Summary of SAGE tags from different brain tissues

Tissue type	*Libraries*	*Total tags*	*Unique tags*
SAGE tags

to identify the genome origin of the detected transcripts. There are 201 448 unique longSAGE tags from brain tissues. Mapping these brain longSAGE tags to human genome sequences shows that, of the longSAGE tags mapped to the genome, 15% map to the loci that have no annotated gene information and that represent potential novel transcribed regions in the genome (Table 4).

In conclusion, brain SAGE data provide one of the richest sources of transcriptome information. The brain SAGE data will be a valuable resource for studying brain biology and pathology and for studying human genome annotation.

Deep Brain Stimulation

Clinical Applications of Deep Brain Stimulation

During the past two decades, deep brain stimulation (DBS) has evolved from an experimental technique to a well-established therapy for a range of medically refractory neurological disorders. To date, the most effective application of DBS technology has been in the treatment of movement disorders. DBS can alleviate symptoms and improve the quality of life for disabling diseases such as Parkinson's disease (PD), essential tremor (ET), and dystonia in appropriately selected patients. Surgical interventions for movement disorders have a long history, beginning with early studies that used lesions to eliminate activity in localized brain regions. In the mid-1980s, Benabid and colleagues found that stimulation of the brain had effects similar to lesioning, specifically that high-frequency stimulation (~100 Hz) of the motor thalamus produced tremor arrest. These early studies led to the advent of DBS as an experimental therapy that eventually overtook lesioning as the functional neurosurgery treatment of choice for movement disorders. Thalamic DBS has virtually replaced ablative lesions of the thalamus for the treatment of ET. DBS of the subthalamic nucleus or globus pallidus internus (GPi) has largely replaced pallidotomy in the treatment of the cardinal motor features of PD (tremor, rigidity, and bradykinesia). GPi DBS has emerged as an effective therapy for dystonia. In addition, multiple pilot studies are examining the utility of DBS for epilepsy, obsessive–compulsive disorder, Tourette's syndrome, and depression.

DBS Components and Implantation

Currently, Medtronic (Minneapolis, MN, USA) produces the only commercially available Food and Drug Administration-approved DBS medical device systems. However, as a result of the growing clinical demand for DBS technology, additional commercial entities are beginning to enter the marketplace. The fundamental components of the Medtronic DBS system consist of a quadripolar stimulation lead and an implanted pulse generator (IPG). The stimulation lead is a cylindrical column 1.27 mm in diameter with four narrowly spaced platinum–iridium electrode contacts near the tip of the lead. Each electrode contact is a cylinder 1.5 mm in length and 1.27 mm in diameter, resulting in a surface area of ~6 mm^2. The IPG is battery powered, uses constant voltage stimulation, and the stimulation parameters can be adjusted via telemetry. Typically, a single electrode contact is used to deliver the stimulation and the clinician has the opportunity to adjust the amplitude (voltage), width, and frequency of the stimulus pulses.

The implantation procedures for a DBS system are different at different centers, but in general the procedure combines noninvasive imaging, stereotactic neurosurgery, and microelectrode neural recording and stimulation. The patient's head is fitted with a stereotactic head frame and then undergoes computed tomography (CT) and/or magnetic resonance imaging (MRI) before entering the operating room (**Figure 1(a)**). The results of the CT/MRI scan are merged with a brain atlas, and the neurosurgeon identifies the x, y, and z location of the target brain structure within the context of the stereotactic frame (**Figure 1(b)**). An electrode trajectory is then identified to avoid major blood vessels and ventricles, a burr hole is drilled in the skull, and a microelectrode drive system is attached to the stereotactic frame. The microelectrode is inserted into the brain along the planned trajectory, and detailed neural recordings are made as the probe is advanced in micrometer increments (**Figure 1(c)**). The microelectrode recordings from the different deep brain structures exhibit characteristic firing patterns that the neurosurgeon and/or neurophysiologist use to further define the brain region where the DBS electrode will be implanted. Integration of the neuroanatomical (imaging and brain atlas) and neurophysiological (microelectrode) data allows definition of a target location in the stereotactic reference frame for placement of the permanent DBS electrode (**Figure 1(d)**). The DBS electrode is implanted, the individual electrode contacts are tested, and their location is verified by intraoperative X-ray. The burr hole is capped with the DBS lead left externalized, traditionally concluding the first surgical day, which lasts approximately 4 h for each lead implanted. In a subsequent surgical procedure, the electrode lead is internalized and connected to the IPG, which is implanted in the chest just below the collarbone.

Extracellular Electrical Stimulation

The fundamental purpose of DBS is to modulate pathological neural activity with extracellular electric fields. When stimulating within the central nervous system, the electrode is placed within a complex electrical environment in which there exist three general

Figure 1 DBS electrode implantation. (a) DBS electrodes are commonly implanted into the thalamus (yellow volume) or subthalamic nucleus (green volume). (b) Following identification of a target in reference to the stereotactic frame and MRI, microelectrode recording of neural activity is acquired along a trajectory that goes through the target (blue line). Single-unit extracellular recordings of neurons representative of thalamus (yellow dots), subthalamic nucleus (green dots), and substantial nigra (blue dots) are recorded to define the electrophysiological borders of the deep brain structures. (c) Multiple trajectories may be evaluated to map the area around the target. (d) The DBS electrode (pink electrode contacts) is placed within the anatomical and electrophysiological environment of the subthalamic nucleus.

classes of neurons that can be affected: local cells, afferent inputs, and fibers of passage. Local cells represent neurons that have their cell body in close proximity to the electrode. Afferent inputs represent neurons that project to the region near the electrode and whose axon terminals make synaptic connections with local cells. Fibers of passage represent neurons where both the cell body and axon terminals are far from the electrode, but the axonal process of the neuron traces a path that comes in close proximity to the electrode. The electric field generated by DBS is nondiscriminately applied to each class of neurons, thereby affecting action potential signaling across a wide range of neurons.

The electric field generated by DBS is a three-dimensionally complex phenomenon that is distributed throughout the brain. This field is applied to the three-dimensional geometry of the surrounding neural processes (i.e., axons and dendrites). The applied field generates an extracellular voltage distribution along each neural process, which generates transmembrane current flow. Because of the laws of conservation of current, if the applied field generates depolarization in one part of a neuron, hyperpolarization will be generated in another part to compensate. The distribution of depolarization/hyperpolarization for a given neuron can be qualitatively predicted by the second spatial derivative of the potential distribution along each neural process. The generation of an action potential in response to the applied stimulation will depend on the response of the voltage-gated sodium channels to the membrane polarization. As a result, a neuron can either be activated or suppressed in response to extracellular

stimulation. This activation or suppression can happen in many different ways and in different sections of the neuron depending on its positioning with respect to the electrode and the stimulation parameters used.

Activation or inhibition of the different classes of neurons surrounding the electrode can result in dramatically different physiologic and/or behavioral outputs. Given the stimulation parameters and electrode geometries currently used, it is likely that DBS directly affects every class of neurons surrounding the electrode: local cells, afferent inputs, and fibers of passage. This complicates our ability to specifically address the role of activation or inhibition of each class of neurons in the physiological effects and therapeutic mechanisms of DBS. However, a number of generalized concepts can be used to bias stimulation to a specific class of neurons. For example, fibers of passage are preferentially activated by cathodic (negatively pulsed) stimulation with short ($<100\,\mu s$) pulse widths, and local cells are preferentially activated by anodic (positively pulsed) stimulation with long ($>100\,\mu s$) pulse widths.

DBS Parameter Selection

DBS is an attractive alternative to surgical ablation of brain tissue for a variety of reasons. DBS allows for bilateral procedures without the high incidence of side effects associated with ablative procedures. In addition, side effects associated with the stimulation are reversible, and DBS allows for customization of the therapy to the individual patient's needs over time via alteration of the stimulation parameters. Furthermore, DBS does not destroy tissue, allowing the opportunity for patients to benefit from emerging restorative therapies. However, programming DBS devices for maximal clinical benefit can be a difficult and time-consuming process that typically requires a highly trained and experienced individual to achieve optimal results. Although guidelines exist on stimulation parameter settings that are typically effective for movement disorders, it is not feasible to clinically evaluate each of the thousands of stimulation parameter combinations that are possible. In addition, application of DBS technology to epilepsy, dystonia, and neuropsychiatric disorders is especially problematic because the beneficial effects of stimulation can take weeks to months to manifest and it is currently unclear what stimulation paradigms are optimal for these different disorders.

The physician has the opportunity to adjust a range of stimulation parameters to customize the DBS to each patient. In addition to selecting an electrode contact to deliver the stimulation, the clinician must set electrical parameters of polarity, amplitude, pulse width, and frequency. Typical therapeutic stimulation parameter settings for PD use a square-wave cathodic stimulus pulse $\sim$3 V in amplitude and $\sim$90 μs in duration, delivered at a frequency of $\sim$130 Hz. The specific parameters for a given patient are determined by testing various stimulation parameter combinations and addressing the clinical outcome. This process is guided by clinical intuition and requires periodic adjustments over a period of months to address various therapeutic and side effects of the stimulation.

Mechanisms of Action

Substantial clinical evidence supports the use of DBS technology to treat a wide range of neurological disorders. However, debate continues in the scientific community on the therapeutic mechanisms of DBS. Currently, there exist four general hypotheses to explain the therapeutic mechanism(s) of DBS: (1) stimulation-induced alterations in the activation of voltage-gated currents that block neural output near the stimulating electrode (depolarization blockade), (2) indirect inhibition of neuronal output via activation of axon terminals that make synaptic connections with neurons near the stimulating electrode (synaptic inhibition), (3) synaptic transmission failure of the efferent output of stimulated neurons as a result of transmitter depletion (synaptic depression), and (4) stimulation-induced disruption of pathological network activity (jamming).

Depolarization blockade and synaptic inhibition represent two of the earliest hypotheses to explain the similarity between the therapeutic benefit of ablation and high-frequency stimulation. Single-unit recordings of local cells in the stimulated nucleus support both of these hypotheses. However, the limitation of these hypotheses is that they do not take into account the possible independent activation of the efferent axon of projection neurons. Theoretical and experimental results show that the axon plays the most important role in the activation of neurons surrounding the electrode during extracellular stimulation. Additionally, the response of the cell body does not necessarily represent the output of the axon during DBS. Therefore, although synaptic inhibition and/or depolarization blockade may occur in the cell body, the functional effect of these phenomena may have limited significance in the therapeutic mechanism(s) of DBS.

If DBS does generate efferent outputs in neurons surrounding the electrode, why do ablation and DBS generate similar therapeutic effects? One possibility is that neurons activated by the stimulus train are unable to sustain high-frequency synaptic action on

efferent targets due to depletion of neurotransmitter. In turn, synaptic depression represents an attractive connection between the functional effects of DBS and ablation. However, several *in vivo* experimental studies have shown increases in transmitter release and changes in firing of efferent nuclei consistent with activation of neurons around the electrode and subsequent synaptic action on their targets during high-frequency stimulation. Therefore, although some level of synaptic depression is undoubtedly occurring throughout the stimulated network of neurons, this phenomenon does not appear to be sufficient to block signal transmission between nuclei.

The abnormal motor activity effectively controlled by DBS is most likely generated by altered patterns, increased neuronal synchronization, and/or low-frequency rhythmic oscillation of neurons within the basal ganglia and thalamus. It is possible that DBS overrides these altered patterns and low-frequency oscillatory activity and replaces it with tonic high-frequency output. Analysis of theoretical and neurophysiological data suggests that this more regularized pattern of activity may be more easily compensated for by the remaining elements of the basal ganglia–thalamocortical network. However, limitations in understanding of the dynamics of the basal ganglia network hinder scientific definition of a mechanistic connection between network activity induced by DBS and therapeutic behavioral outcomes.

In summary, a number of questions remain to be answered before the true mechanisms of DBS are explained. Advances in knowledge on the electrophysiological effects of DBS are necessary for a more detailed understanding of this medical technology. Continued scientific advancement in this area will lead to novel stimulation paradigms, surgical techniques, and medical device designs that will improve the clinical outcomes for patients receiving DBS therapies in the future.

Deep Brain Stimulation and Movement Disorder Treatment

A W Laxton, C Hamani, E Moro, and A M Lozano, University of Toronto, Toronto, ON, Canada

© 2009 Elsevier Ltd. All rights reserved.

History and Development

The first attempts at therapeutic deep brain stimulation (DBS) in humans began in the 1950s and 1960s. At this time, reliable surgical stereotactic frames were being developed to enable the precise localization of subcortical targets for lesioning procedures used to treat movement disorders. Electrical stimulation was used in these early procedures to identify desirable target locations for lesion placement. Over time, electrical stimulation itself was used to treat movement disorders, psychiatric disorders, epilepsy, cerebral palsy, and pain. Long-term application of these therapies was limited by the unavailability of suitable implantable electrodes and batteries, however. Furthermore, the success of levodopa to treat Parkinson's disease (PD) in the early 1970s led to a general decline in functional neurosurgery until the late 1980s. In the 1990s, DBS became an accepted therapeutic option for a variety of movement disorders, including PD, levodopa-induced dyskinesias, essential tremor (ET), and dystonia. More than 30 000 DBS operations for movement disorders have been performed worldwide.

Description

The goal of DBS is to improve neurological function through the targeted application of electrical current to specific brain regions or structures. It involves the placement of electrode leads into desired brain regions (see Figure 1). These electrode leads are then connected to a programmable internal pulse generator (IPG). The IPG is placed subcutaneously in the subclavicular region. Each currently available DBS lead has four electrode contacts at its tip, typically 1.5 mm wide and 0.5 or 1.5 mm apart. The DBS leads are made out of polyurethane tubing, and the electrodes are made out of platinum and iridium. The IPG consists of a silver vanadium oxide or lithium ion cell and integrated circuits encased in titanium with an insulating coating.

The typical wave shape of the delivered current of stimulation is square. Stimulation parameters are commonly set to a frequency in the range of 130–185 Hz, a pulse width in the range of 60–120 μs, and an amplitude in the range of 2–4 V, according to the type of movement disorder treated and the type of IPG implanted. Although stimulation can be delivered continuously or in cycles, the continuous mode is used most commonly. The longevity of the IPG battery depends on the stimulation parameters set for each patient. With typical stimulation parameters, the IPG needs to be replaced every 3–5 years.

Indications and Targets

DBS is appropriate for PD patients who have shown a positive response to dopamine agonist medications, such as levodopa, in the past, whose response to dopaminergic agents is of limited or decreasing duration, and who experience significant motor fluctuations or dyskinesias in response to levodopa. The primary goals of DBS are to reestablish the maximal benefit patients have previously achieved with levodopa or to allow a levodopa dose reduction which will diminish drug-induced dyskinesias while maintaining the patient in a good 'on' state throughout the day. DBS may also be used for patients with severe, disabling tremor such as ET or primary and to a lesser extent secondary dystonia that is unresponsive to medical treatments.

The subthalamic nucleus (STN) is the most commonly used target in patients with PD. For patients with ET or tremor secondary to multiple sclerosis, head injury, cerebellar disease or stroke, the most commonly used DBS target is the ventral intermediate nucleus of the thalamus (Vim). For segmental or generalized dystonia, the internal segment of the globus pallidus (GPi) is currently used most commonly although the pallidal-receiving thalamus and the STN may also be useful (see Figure 2).

More recently, pedunculopontine nucleus DBS has been investigated in PD patients, with promising preliminary results. There have been a few reports of the efficacious application of GPi DBS in patients with Huntington's disease and other types of chorea. Patients with Tourette's syndrome have also recently been treated with thalamic and GPi DBS, with variable results.

Anatomy and Pathophysiology

Structural lesions, neural degeneration, problems in connectivity, neurotransmitter deficiencies, and intrinsic disruptions in neural activity are likely contributors to the disturbances in normal motor physiology that underlie movement disorders. These disturbances are funneled to the output structures of the basal ganglia and cerebellum and conveyed to the thalamus and then to the corresponding cortical terminal fields to cause

Figure 1 X-ray images of a patient who had subthalamic nucleus deep brain stimulation electrodes implanted. Anteroposterior (a) and lateral (b) skull X-rays showing the bilaterally implanted electrodes with four contacts each (small arrows are pointing at the most dorsal contacts). The large arrow in (b) is pointing to one of the extension cables that connect the electrodes to the internal pulse generator (IPG). (c) Chest X-ray showing the extension cables (arrowhead) that connect the IPG (small arrow) to the electrodes.

the widespread disturbance in neural activity and function that is characteristic of movement disorders. Several theories have been proposed for how the activity within this circuit is regulated. There is evidence for alterations in neuronal firing rates, changes in patterns of discharges and neuronal bursting behavior, the emergence of oscillatory behavior among specific groups of neurons, enhanced correlated activity across neurons, and the expansion of sensorimotor receptive fields as potential contributors to the pathophysiology of movement disorders.

Movement disorders arise when the normal activity within the motor circuit is disturbed. In PD, the activity is disrupted to a large extent because dopaminergic output from the degenerating substantia nigra pars compacta (SNc) is decreased. In primary generalized dystonia, the pattern of GPi neuronal discharge is altered for unknown reasons, leading, it is thought, to dysregulated thalamocortical activity. In ET, groups of thalamic neurons fire synchronously with the peripheral limb tremor. It is believed that DBS interferes with this dysfunctional activity, leading to more-normal motor function.

Mechanism of Action

Electrical brain stimulation affects a broad range of neural elements, including neuronal cell bodies, afferent and efferent axons, and glia. The electrophysiological properties associated with each of these elements vary depending on anatomical location. The effects of electrical stimulation on these elements are incompletely understood but are thought to vary with the intrinsic properties of the stimulated elements and with the stimulation parameters used (i.e., frequency, amplitude, and pulse width).

Because high-frequency stimulation (HFS) of certain targets mimics the effects of lesions to those targets,

it had been believed that stimulation was inhibitory. However, this simple view ignores the possibility of stimulation's activating inhibitory circuits, the potential complex polysynaptic downstream effects of local activation, the possible differential effect of stimulation on cell bodies versus axons, and the possibility that HFS may lead to neurotransmitter depletion or synaptic failure. To better account for the mechanisms of DBS, several explanations have been proposed.

It has been observed that single pulses in the vicinity of GPi neurons produce a cessation of spontaneous activity for 15–25 ms. Because of the latency and duration of this effect, it has been suggested that γ-aminobutyric acidergic (GABAergic) synaptic transmission may be involved. That is, stimulation within GPi causes GABA release from either pallidal (pars externa) or striatal axons projecting onto GPi neurons, or local dendritic release of GABA, resulting in GPi neuronal inhibition. Although the GPi also receives glutamatergic afferents from the STN, the larger GABAergic input is believed to trump these excitatory signals. Further supporting the synaptic transmission proposal, studies have demonstrated increased firing rates in the GPi following STN HFS, and decreased firing rates in the thalamus following GPi HFS. Similarly, glutamate release in the downstream GPi has also been found to be increased following STN HFS. Computer modeling studies have suggested that DBS may inhibit neuronal cell bodies and excite axons. Functional imaging also corroborates the role of HFS in activating axonal elements as increased upstream (antidromic) and downstream (orthodromic) activity has been demonstrated. A variation on the synaptic transmission proposal states that although HFS is excitatory, the stores of neurotransmitter are soon depleted, resulting in functional inhibition.

The ability of HFS to alter intrinsic membrane properties has also been posited as a potential mechanism of the DBS effect. Some *in vitro* studies suggest that HFS transiently depresses voltage-gated Ca^{2+} channels, producing a 'depolarization block.' Alternatively, HFS may also directly activate Na^{+} channels, leading to depolarization. The relevance of these *in vitro* findings awaits further investigation.

The seemingly contradictory explanations for DBS effects may actually be complementary. That is, the effect of DBS may depend on several mechanisms, and the effects may vary depending on what structures are being stimulated and how far a structure is from the stimulating electrode. In addition, since the pathophysiology of most of the movement disorders is still not entirely known, the stimulation of the same target in different diseases may require different parameters of stimulation (e.g., low-frequency GPi stimulation in Huntington's disease and high-frequency in PD). The net effect of DBS, however, appears to be to disrupt the dysfunctional neuronal activity associated with movement disorders.

Operative Procedure

DBS surgery involves brain imaging, target identification, and the insertion of DBS electrodes and an IPG. The STN and GPi can be visualized with magnetic resonance imaging. The Vim target is estimated indirectly, relative to the position of the anterior and posterior commissures. Intraoperative electrophysiological mapping is used to characterize the location of the recording electrode in relation to the desired target, to assess the therapeutic effect of an electrode in a particular location, and to identify the potential unwanted side effects associated with stimulation in a given location. Approaches may involve one or more microelectrodes (single unit recording; local field potentials; microstimulation) or macroelectrodes (usually, the DBS electrode itself; local field potentials; macrostimulation). The majority of DBS centers use a combination of these techniques.

Standard mapping of the STN begins with microelectrode recordings starting in the range of 10–15 mm above the chosen target. The single unit activity recorded depends on the specific trajectory chosen but may include the following structures, in order (see Figure 3): the thalamus (with its characteristic bursting cells), the zona incerta (exhibiting a low firing rate), the STN (with its characteristic dense cellular activity in the range of 30–50 Hz, and occasional 4–6 Hz bursting activity synchronized to the patient's tremor), and then the substantia nigra pars reticulata (characterized by a more regular firing rate in the range of 50–70 Hz, without bursting or tremor cells). When the STN has been reached, testing begins to determine whether the cellular activity changes in response to the patient's active or passive limb movements. The presence of movement-related activity suggests that the electrode may be in a therapeutically desirable location. At this point, microstimulation may also be performed within the STN to check for tremor arrest or benefit to the other clinical signs or to detect the presence of paresthesias, muscle contractions, double vision, or other unwanted side effects (related to current diffusion into the areas surrounding the STN, which aids in the identification of the correct electrode locations). The microelectrodes may be repositioned to sample other STN areas and to identify the portion of the STN populated by movement-responsive neurons – the 'motor territory.' The microelectrodes are then removed and replaced by the DBS electrode. This insertion is done using X-ray guidance to ensure that the electrode is placed in the desired location. Once in place, each contact of the DBS electrode

Figure 3 Schematic representation of sagittal sections of the brain that are 12 mm (a) and 20 mm (b) from the midline. The oblique line in the center of the figures represents a typical microelectrode trajectory during the physiological exploration of the subthalamic nucleus (STN) (a) and globus pallidus (b) in patients with Parkinson's disease. (a) During the exploration of the subthalamic region, neuronal activity may be recorded from the thalamus, STN, and substantia nigra pars reticulata (SNr). Examples of a thalamic bursting cell and an irregularly firing STN cell are shown on the left side of the trajectory line. (b) Neuronal activity recorded from the globus pallidus externus (GPe) and globus pallidus internus (GPi). Stimulation of the optic tract often induces phosphenes and maps the bottom of the trajectory. For details on the neuronal firing characteristics in each of these regions, reader is referred to the text.

is stimulated with incrementally increasing voltage to check the threshold for stimulation-induced clinical benefit and unwanted side effects. The DBS electrode position can be adjusted to minimize adverse effects.

The general procedure and rationale for intraoperative electrophysiological mapping of the GPi and Vim are similar to those described for the STN, except for differences in regional anatomy and associated cellular characteristics. The microelectrode trajectory to the GPi traverses the striatum, external segment of the globus pallidus (firing activity around 50 Hz), the GPi (high-frequency activity around 80 Hz with occasional 4–6 Hz tremor-associated bursts), and then either the optic tract (inferiorly) or the internal capsule (medially and posteriorly). As with the STN, movement-related cells are sought within the GPi, and microstimulation is used to identify side effects such as muscle contractions (posterior limb of the internal capsule) or visual phosphenes (optic tract). To reach the Vim, the microelectrode may traverse the following thalamic nuclei, depending on trajectory: ventral oralis anterior/posterior (Voa/Vop; tonic firing rate around 20 Hz; active movement-responsive activity), Vim (around 25 Hz; passive movement-responsive activity), ventral caudalis (Vc; cellular activity similar to Vim but displays tactile/sensory-responsive activity), and finally beyond the thalamus into the medial lemniscus. Stimulation of the Voa/Vop and Vim should produce tremor suppression; stimulation of the Vc and medial lemniscus elicits paresthesias.

Advantages, Disadvantages, and Alternatives

Prior to the development of DBS, lesioning procedures were the standard surgical approach to treat movement disorders. Lesions are made with high-radiofrequency stimulation to the same targets used in DBS therapy. While lesion surgery is still practiced, bilateral lesions can be associated with a high incidence of adverse effects (e.g., cognitive impairment, dysarthria, and dysphagia) and is only rarely used. The adjustability and reversibility of DBS are two of its main advantages over lesioning procedures. With DBS therapy, stimulation parameters can be adjusted to enhance or maximize a positive effect or to decrease unwanted side effects (e.g., paresthesias, muscle contractions, and dysarthria). Postoperative programming of the DBS system involves adjustments to the following parameters: choice of contact, type of stimulation (monopolar or bipolar), mode of stimulation (continuous or cycled), amplitude (voltage), frequency, and pulse width. Another interesting advantage of DBS over lesioning is the possibility of performing a bilateral procedure with a lower incidence of the severe complications that have been found with bilateral ablative surgery.

The major disadvantages of DBS include its expense; the need to replace IPGs (batteries) every 3–5 years, which involves minor surgery; and because it entails implanted foreign bodies, an increased infection risk relative to lesions. In addition, DBS surgery requires the

involvement and coordination of a large multidisciplinary team (neurologist, psychiatrist, neuropsychologist, neurophysiologist, and neurosurgeon) in order to select the appropriate candidates before surgery and to manage medication reductions, DBS programming, and possible DBS complications after surgery.

Outcomes

For patients with PD, STN DBS has been shown to produce improvements in the range of 60–70% in overall motor functioning (based on the motor component of the Unified Parkinson's Disease Rating Scale). Stimulation-associated improvements in the off-medication state vary across the various motor domains of PD and are approximately as follows: tremor, 90%; rigidity, 75%; gait, 60%; bradykinesia, 50%; postural instability, 40%; and dystonia, 30–50%. Some of these improvements, particularly in tremor and rigidity, can persist for 5 or more years. The benefits in gait and postural disability, however, wane by 2 years. STN DBS improves dyskinesias by allowing dopaminergic medication dosages to be reduced (on average by approximately 50%) and through a direct antidyskinetic effect. STN DBS has also been found to improve patients' activities of daily living and quality of life. The benefits of GPi DBS in PD may approach those seen with STN DBS, but the outcomes are less well characterized.

Vim stimulation is associated with up to 80–90% tremor reduction in PD and ET patients. In comparison with STN and GPI stimulation, however, Vim DBS does not improve the bradykinesia and rigidity associated with PD. For patients with ET, Vim stimulation may be more effective at treating hand tremor than voice and head tremor.

For primary generalized dystonia, GPi DBS is associated with an approximately 50% improvement in motor functioning and reduction in disability, on the basis of the Burke–Fahn–Marsden Dystonia Scale, and an improved quality of life related to general health and physical functioning. These beneficial effects can be expected to last for 1 or more years. GPi DBS may be more effective in improving motor function in the neck, trunk, and limbs than in improving facial movements and speech. The emergence of DBS over the last decade is a major advance in the surgical treatment of movement disorders.

Introduction

Deep brain stimulation (DBS) of the ventral intermediate nucleus of the thalamus (Vim) in Parkinson's disease (PD) has been performed since the late 1980s, mimicking the effect of the lesion against tremor. Bilateral approaches with DBS and bilateral thalamotomy were similarly effective, but the incidence of adverse events was much lower with DBS. Thus, DBS of the Vim replaced thalamotomy in patients with tremor. The realization that DBS delivered similar benefits with fewer adverse events than did lesions, the need for bilateral surgery in the majority of severe PD patients, the reversibility of this approach in contrast to the lesion, and a study in 1-methyl, 4-phenyl-1,2,3,6 tetrahydropyridine monkeys showing high antiparkinsonian efficacy using high-frequency stimulation of the subthalamic nucleus (STN) led to the introduction of DBS of the STN in the therapeutic armamentarium for advanced PD patients. Concomitantly, this technique was also applied to the globus pallidus pars interna (GPi) in an attempt to achieve the benefit of a bilateral approach without the undesirable adverse effects induced by the lesions. Initial results were positive, leading to a multicenter trial begun in 1996 to assess the safety, viability, and short-term efficacy of DBS of both STN and GPi. The positive findings of this trial allowed a prompt spreading of this therapy, which continues to the present, with stimulation of the STN predominating. This article reviews the most important aspects of bilateral DBS of the STN and GPi.

Methodological Aspects

The success of surgical treatment with DBS in PD depends on several factors. The selection of the appropriate candidate for DBS is the first critical point. Thus, the clinician has to evaluate in every patient the known negative and positive predictive factors for the outcome of this therapy. The second key factor is the accuracy in targeting the STN or GPi during the surgical procedure and prior to the implant of the therapeutic electrode. The precise location of the electrode in the nucleus determines a better antiparkinsonian benefit without stimulation-induced adverse events. Last, the careful exploration of the benefit obtained with the different programming of the electrodes, the adequate selection of the parameters for continuous stimulation, and the concomitant adjustment of medication guarantee an optimization of the therapy.

Selection of PD Patients for Surgical Therapy with DBS

The experience gained in the last decade with PD patients submitted to DBS has allowed us to define a profile of patients with a higher probability of obtaining better results with this therapy. Numerous factors need to be taken into account in the evaluation of whether a patient with PD is a good candidate to be treated with DBS.

Advanced age, concomitant severe medical illness, and neuropsychological and psychiatric disturbances can be a drawback in the outcome of this therapy. Although age-related comorbidities seem to be more important than age *per se*, and so no specific age cutoff has been defined, in practice, the vast majority of centers exclude patients older than 75. Serious systemic or neurologic disease other than PD should be regarded as a contraindication for DBS, as they would significantly compromise DBS benefits or amplify surgical risks. Previous functional surgery should not exclude additional DBS procedures. Neurobehavioral contraindications may include primary psychotic disorders, primary and compensated bipolar disorders, severe treatment refractory depression, severe substance abuse, and severe personality disorders.

It is important to note that factors related to the PD itself and levodopa-induced side effects have to be carefully analyzed. Dementia, frequently seen in advanced PD patients, should be considered a contraindication for surgery despite the lack of outcome studies. Levodopa-resistant symptoms (i.e., freezing of gate, instability, speech disturbances) are not significantly improved by DBS and, although not a formal contraindication, should be considered in every particular case. As a rule, DBS improves PD signs that are alleviated with levodopa therapy. Preoperative levodopa response is a predictive factor for the positive response to surgery, with the possible exception of drug-refractory but otherwise classical rest tremor. Currently, all studies that have evaluated predictors of benefit from DBS have found that levodopa response is the best one. Thus, a test evaluating the motor improvement in response to a high dose of levodopa is crucial to estimate the achievable antiparkinsonian benefit with DBS. A minimum 25–50% reduction in the Unified Parkinson's Disease Rating Scale (UPDRS) motor part (III) score following the

administration of an effective dose of levodopa in the practically defined off-medication state (a minimum of 12 h without antiparkinsonian medication) is considered a significant response. There is some controversy about the dose of the levodopa challenge used for the test: the first dose of levodopa in the morning or a suprathreshold dose (50% more of this dose) is the most frequently employed.

Another important issue is the outcome of DBS surgery in patients with dopaminergic-induced psychiatric disturbances. Although some publications indicate patients with gambling and dopamine dysregulation syndrome can improve both the parkinsonism and the dopaminergic side effects with DBS of the STN, there is not enough data in the literature at present to draw conclusions. Thus, no recommendation can be made on this particular and relevant aspect of PD until more experience is accumulated.

In addition to the previous criteria, it is recommended to operate on patients with a score higher than 30 in the motor UPDRS scale in the off medication state and with a disease duration of at least 5 years (to allow for atypical forms of parkinsonism to become evident).

A question recently raised is the benefit of this therapy in patients with genetic forms of PD. The available data indicate these patients can be successfully operated on with bilateral DBS of the STN. The inclusion and exclusion criteria are the same as for idiopathic PD.

Surgical Issues

Accuracy in targeting the STN or GPi is critical for the outcome of DBS in PD, as previously explained. Stereotactic functional surgery is the procedure universally employed. Thus, the first step of the intervention is the stereotactic targeting of the nucleus by using computed tomography, magnetic resonance imaging, venticulography, or neuronavigational systems. They are all safe and reliable techniques that have been used effectively by experienced groups. Image fusion may improve the accuracy but is not mandatory. Imaging techniques should be coupled with physiological and/or clinical intraoperative testing for target refinement. The physiological definition of the nuclei is usually undertaken with microelectrode or semimicro electrode recording of the neuronal activity of the nucleus (STN or GPi) (Figure 1). Macroelectrodes can also be used for recording but provide very poor spatial resolution. When physiological methods are employed, once the target is precisely identified, microstimulation with the electrode used for micro or semimicrorecording and/or macrostimulation must beused for refining the final target location. In those centers that do not use physiological

Figure 3 Axial magnetic resonance image of a patient which leads for DBS bilaterally implanted in the Gpi.

parameters to better define the intended target, clinical intraoperative testing with a macroelectrode or with the DBS electrode can also be performed directly. In any case, and independent of the method used, once the therapeutic electrode has been positioned (Figures 2 and 3), intraoperative DBS stimulation is conducted to assess the benefit of the therapy against parkinsonian signs and to test the possible induction of stimulation-related adverse events that could thereafter preclude the utilization of this treatment. It has to be known that in some instances, there is an 'impact' or 'lesionlike' effect that consists of an amelioration of the parkinsonian signs after the mechanical introduction of the therapeutic electrode into the nucleus. In these cases, the intraoperative stimulation with the DBS electrode does not provide any relevant information.

Patients remain awake during the whole intervention in off-medical condition. Local anesthesia is used in the area of the burn hole. In some particular cases (i.e., severe tremor or dystonia), antiparkinsonian medication, sedation, or general anesthesia is administered. This situation is far from ideal because it interferes with the neuronal activity of the nucleus and its recognition by the physician while recording and because it does not allow testing of the antiparkinsonian efficacy and side effects of the stimulation.

Once the therapeutic electrode has been placed in the nucleus and the effect of the stimulation has been evaluated, the next step is to confirm its location by intraoperative fluoroscopy before securing it to the burn hole with a specific device.

Apart from the therapeutic electrode(s), the rest of the hardware (external cable and battery) has to be placed under the subcutaneous cellular tissue and connected to the lead already implanted (Figure 4). The battery or internal pulse generator (IPG) is placed in a tissue pocket located in the upper chest or abdomen and connected to the therapeutic electrode through the external cable. This procedure is undertaken with general anesthesia and can be done in the same surgery or later.

Another important decision when bilateral procedures are planned is whether they should be done in the same surgery. Available data show no significant differences between surgical time and patient clinical outcome, and every case should be individually evaluated.

Postoperative Management

Postoperative antiparkinsonian treatment should be restarted as soon as possible to relieve discomfort and limit the risk of acute dopaminergic withdrawal and malignant hyperthermia. The postoperative levodopa equivalent dose (LED) should be the same as the presurgical dose and composed primarily of levodopa to facilitate simple titration during the process of programming the stimulation. A confusional state may be present in some patients, but it generally lasts a few days and can be managed easily with atypical antipsychotics such as clozapine or quetiapine.

Figure 4 Schematic representation of the implanted device for DBS.

Neuroimaging to confirm the electrode location and to rule out intracranial adverse events is recommended.

Programming can be initiated at any time after the whole device has been implanted depending on the center and the situation of the patient. When a lesion-like effect is present, the programming can be delayed until the parkinsonian symptoms reappear. Programming should be started in the off-medication state to select and set up the parameters with the highest antiparkinsonian efficacy. Parameters inducing permanent adverse events should be ruled out. Stimulation with the greatest efficacy and fewest side effects is selected for therapy. Once programming has been selected, gradual reduction of drug doses has to be initiated to adjust the medication to the new motor state. Levodopa and STN stimulation have similar and additive effects in the antiparkinsonian and dyskinetic states. Thus, in PD patients treated with DBS of the STN, medication titration is needed for fine adjustment of the motor situation in the majority of patients. In cases with DBS of the GPi, this additive effect of stimulation and medication is not as strong, and LED cannot be reduced.

Treatment should be maintained with levodopa to allow the programming to be adjusted adequately to both off- and on-medication motor conditions. Once programming is stable, dopaminergic agonists can help to achieve a more stable motor benefit than levodopa.

After this first adjustment of stimulation and medication, the frequency of visits to the neurologist depends on the patient's needs and on the available resources of each center. In any case, follow-up visits are recommended.

Results of Bilateral DBS in PD

The multicenter study conducted in 1996 to assess the safety, viability, and efficacy of DBS of the STN and GPi was not randomized, and no specific guidelines were issued for allocating patients to STN or GPi surgery. Both groups showed significant improvement induced by stimulation. Over the years, many groups all over the world have applied DBS of the STN and GPi to treat PD, but studies properly comparing the therapeutic efficacy of the two targets are limited.

Nevertheless, STN DBS has become the preferred approach in most centers. There appear to be three main reasons. First, the impression that the clinical relief of the cardinal features of PD obtained by STN DBS was greater than that obtained by GPi DBS spread quickly after the initial trial despite absence of validated data. Second, from a surgical point of view, it may be easier to physiologically define the sensorimotor region and surrounding structures of the STN than those of the GPi. Finally, and as an established fact, STN DBS allows a significant reduction in the daily dose of dopaminergic drugs that is not achieved with GPi DBS. This is a very attractive clinical possibility considering the profusion of motor problems (i.e., dyskinesia) and nonmotor problems (e.g., psychiatric complications, sleep disturbance) associated with chronic levodopa treatment. Overall, the issue of advantages and disadvantages of either target remains unresolved.

Bilateral DBS of the STN

Bilateral DBS of the STN has become the most frequent surgical therapy for PD patients.

Since the first patients operated on by the Grenoble group early in the 1990s, a huge number of publications have described the effect of this therapy in PD patients at different points in the postoperative follow-up. Some of them, because of the number of patients included or long-term follow-up, are more indicative of the benefit–risk ratio of this treatment. A meta-analysis of the outcome of DBS of the STN based on a review of the literature from 1993 until June 2004, while acknowledging between-study heterogeneity, reached the conclusion that the treatment is highly effective in PD patients. It improves UPDRS-II or activities of daily living (ADL) scores by 50%, UPDRS-III scores by 52%, dyskinesia scores by 69.1%, daily off-medication time by 68.2%, and quality of life by 34.5%. LED was reduced in 55.9%. After June 2004, and therefore not included in this meta-analysis, many more articles about DBS of the STN in PD have been published with similar findings. Because of the profusion of data, only those studies with long-term follow-up (4–5 years) published after the meta-analysis are reviewed in this article (Table 1).

Table 1 Summary of the most relevant long-term follow-up studies of DBS of the STN

Rodriguez-Oroz et al. reported the results of a multicenter study that is the follow-up of the first multicenter trial aimed at assessing the safety, viability, and efficacy of DBS of either the STN or the GPi. Overall, 49 patients treated with DBS of the STN were available for study after 4 years. Stimulation of the STN in off-medication condition induced a reduction of 50% in the motor UPDRS score and of 43% in the ADL score compared with the preoperative medication off state. All cardinal features were also improved except speech. In the on-medication situation and in comparison with the preoperative on-medication state, stimulation did not improve either the motor or the ADL-UPDRS scores. Motor fluctuations were reduced with an increment of the time spent in the on-medication condition without dyskinesias. Dyskinesia severity was reduced by 59% with respect to baseline and LED in 35%. Comparison of the improvement induced by STN stimulation at 1 year and at 4 years showed a worsening in axial signs (speech, postural stability, and gait) in both off- and on-medication conditions. This result is similar to the one obtained in a cohort of 49 patients after 5 years of follow-up by Krack et al. that was included in the meta-analysis. Adverse events were frequent (53% of patients) and will be detailed below.

In addition to the multicenter study, there are other studies with very similar results (Table 1). Visser-Vandewalle reported that the benefit of stimulation of the STN in the off-medication condition was maintained after 4 years in the UPDRS motor score and in all cardinal signs of PD (tremor, rigidity, bradykinesia and gait) when compared with the off-medication state at baseline. Antiparkinsonian benefit was lower at 4 years than at 3 months (i.e., total motor UPDRS score reduction of 54% at 3 months and 43% at 4 years). In the on-medication state, stimulation-linked improvement in total UPDRS motor score, rigidity, and akinesia at 3 months vanished at 4 years, and gait worsened significantly. Dyskinesias, motor fluctuations, and ADL were similarly improved by 79%, 78%, and 59%, during the 4 years of follow-up, and LED was reduced by 42.8%.

Another cohort of 18 patients has shown similar results after 4 years of follow-up. Stimulation induced significant benefit in the off-medication situation compared with the off-medication preoperative state in ADL and motor UPDRS scores except for the axial signs (postural stability, gait, speech), which also were significantly worsened compared with the 1-year and basal condition. Stimulation in the on-medication state did not improve the total motor score, and there was even a worsening of speech and postural stability compared with the on-medication condition at baseline. The reduction in LED was 29%. It is interesting that the benefit of levodopa in axial signs and total motor UPDRS was significantly lower at 4 years.

Shüpbach et al. showed a 49.5% UPDRS motor score benefit of stimulation in the off-medication state, a less-striking improvement in the axial signs, and a 40% benefit in the ADL. Motor complications and dyskinesias were reduced by 67% and 79%, respectively, although motor complications were significantly higher at the 5-year evaluation than at the 6-month follow-up. The reduction in LED was 54%.

Recently the effect of DBS of the STN has been compared with the best medical management in two trials. Deuschl et al. studied 156 patients in a multicenter, randomized-pairs trial with 6 months of follow-up. Stimulation produced greater improvement in the quality of life and the various motor evaluations (UPDRS, motor fluctuations, etc.) than the best medical treatment. In the other trial, only young patients (younger than age 55) with no severe PD were included in a study aimed at assessing the benefit of this surgery in comparison with the best medical treatment at an early stage of the disease. Similar to the previous trial, the patients who underwent surgery early after the onset of PD had an outcome superior to that of patients treated with the best medical therapy.

In summary, bilateral stimulation of the STN produces a significant benefit on the off-medication motor and ADL UPDRS scores and in cardinal features of PD patients after long-term follow-up, a benefit that is less striking in axial signs. In the on-medication condition, stimulation tends to lose efficacy in the motor and ADL scores. Remarkably, a significant decline in the effect of stimulation in the off-medication states between the short- and long-term evaluations was observed in all the studies, mainly in the axial signs. However, this worsening in axial features was also seen in the on-medication condition, indicating that it may reflect the progression of the disease and extension of the pathological process beyond the nigrostriatal dopaminergic system. Moreover, in terms of quality of life, parkinsonian signs, and motor complications, this therapy seems to be more beneficial than the best medical therapy.

Bilateral DBS of the GPi

Bilateral stimulation of the STN became the preferred approach for DBS in PD. Thus, the data about the efficacy of DBS of the GPi are less abundant. With the exception of the multicenter study initially undertaken in 1996 and the follow-up of this trial at 4 years after surgery, the majority of studies conducted to assess the outcome of this intervention are open trials, the numbers of patients are small, and the follow-up

after surgery is variable. The most important studies of DBS of the GPi are summarized in Table 2.

In the first multicenter study, the final evaluations were undertaken after 6 months of surgery in 36 patients bilaterally treated with DBS of the GPi. Stimulation in the off-medication condition compared with the same state at baseline induced a significant improvement of 33% and 35% in motor UPDRS and ADL scores, respectively. All cardinal features were also improved. In the on-medication state compared with baseline on-medication, stimulation provided 26.6% and 30% reduction in the motor UPDRS and the ADL scores, respectively. Not all cardinal features were improved in this medication condition. Dyskinesias were reduced by 66.6%, and the time spent in the on-medication condition without dyskinesias was increased by 56%. The total dose of antiparkinsonian medication was unchanged.

An extended follow-up of this multicenter study that evaluated the effect of this treatment in 20 patients after 4 years showed the benefit of stimulation was maintained during this period of time in the off-medication state. There was a reduction of 39% and 28% in motor UPDRS and ADL scores, respectively, with respect to the preoperative off-medication state. The improvement on postural stability and speech initially observed was lost at 4 years in the off-medication state. Furthermore, the on-medication assessment at 4 years showed a progressive decline in motor UPDRS, gait, and ADL scores with respect to the 1-year situation in the on-medication state, with no significant changes in the off-medication scores. Dyskinesias were reduced by 76% with respect to the baseline situation. These data indicate DBS of the GPi maintains its efficacy in the long-term follow-up in the off-medication state but not in the on-medication situation, with a worsening in the motor state, predominantly in the axial features. The antidiskinetic effect was maintained, and the dose of medication was unchanged with respect to baseline (a slight increment was not significant).

In contrast to this study, Volkmann et al. reported that in 11 patients treated with bilateral DBS of the GPi, there was a significant improvement in the parkinsonian condition in the off-medication situation in the first year after the surgery, but that it started to decline after 3 years and was not maintained at 5 years. Cardinal features were not equally improved, and the axial signs (speech, swallowing, gait, and posture) were the least improved. Actually, there were four patients with lack of efficacy mainly due to gait deterioration after 1 year who required a new-intervention with bilateral stimulation of the STN, with significant improvement. In on-medication condition, stimulation induced a significant benefit in the motor and ADL UPDRS scores but no benefit in individual cardinal features with respect to the preoperative on-medication status in the short term. After 5 years, the benefit had vanished. On the other hand, the reduction in on-condition dyskinesias was maintained during the 5 years. The dose of antiparkinsonian medication was unchanged.

Some other studies with a smaller number of patients and variable follow-up report similar results. Ghika et al. reported six patients in whom bilateral stimulation of the GPi improved ADL and motor UPDRS scores in the off-medication state, the time spent in off condition during the day, and the on dyskinesias after 2 years. During this follow-up period, four patients developed motor fluctuations and needed additional medication, and three patients developed gait initiation failure resistant to stimulation of the GPi. Stimulation did not improve the on-medication state at any interval after surgery. The improvement in the severity of on-condition dyskinesias was significant during the whole period. Another study, also conducted with a small number of patients, found similar results in the off-medication state in the short term but found that after 3 years, the motor scores showed a progressive decline. There was no improvement in the on-medication condition at any point. Benefit was maintained in the on-medication dyskinesias during the entire period.

Recently another study of 11 patients treated with bilateral DBS of the GPi for 2 years reported similar results. There was a benefit in the off-medication state in the motor UPDRS score, with all cardinal signs improved. There was a slight benefit of 18% in the on-medication status in comparison with the on-medication state preoperatively. Dyskinesias were improved by 76%, and no change in the medication dosage was found.

In summary, all studies with short-term follow-up have shown that bilateral GPi stimulation induces a dramatic decrease of on-medication dyskinesia, with or without change in the on-medication motor and ADL UPDRS scores, and a significant improvement in the off-medication motor and ADL UPDRS scores, with different degrees of benefit in the cardinal features. It is important to note that in spite of the antiparkinsonian benefit, the dopaminergic treatment cannot be reduced. In the long-term follow-up, the antidyskinetic effect is maintained, but there is a tendency to lose the antiparkinsonian benefit in the on-medication state and, in many reports, also in the off-medication state, mainly in the axial signs. Actually, for a significant number of patients, the antiparkinsonian benefit is no longer

sustained. It is interesting that some of them have had successful surgery on the STN. Although nowadays the STN is the preferred target for most of the surgical teams, until the results of a randomized-to-either-target, prospective, double-blind, multicenter study are available, the GPi could be considered in some patients in whom dyskinesias are the most relevant problem.

Adverse Events

Complications or adverse events (AEs) associated with DBS can be categorized as related to the surgery itself, to the implanted device, or to the stimulation and/or disease progression.

Surgical and Device-Related AEs

The most severe complication associated with the surgical procedure is the intraoperative bleeding which occurs in 1–5% of operated patients. Hemorrhages should be handled according to accepted neurosurgical practice. Misplacement of leads is an infrequent complication of the surgery. It is associated with lack of efficacy and significant stimulation-induced side effects. Another intervention for re-placement of the electrode may be needed.

Superficial infections of the surgical wounds can occur immediately after surgery. Erosions or infections in the skin covering the device (extension cable, IPG, cap of the burn hole) are not infrequent (from 1% to 15%), even months or years following surgery. They must be treated with intravenous or oral antibiotics with good tissue penetration. Deep infections involving purulent collections around hardware must be surgically treated, often requiring device removal. They may be related to systemic infections (sepsis), cellulitis, or skin erosion exposing the implant.

Device-related or hardware complications such as lead or extension wire fracture and consumption or malfunction of the IPG are frequent long-term complications. In these circumstances, loss of effect, intermittent stimulation, or tolerance can be the signs indicating the abnormal functioning of the device. Once the broken or malfunctioning component is identified, it must be replaced.

Stimulation and/or Disease-Related AEs

Stimulation AEs are problems that clearly arise because of the stimulation of the structures surrounding the nucleus or the nucleus itself such as dyskinesias in the case of STN and sometimes GPi. It has been reported that GPi DBS may induce dyskinetic movements when stimulating with more dorsal contacts. On the contrary, stimulation-induced akinesia was observed in the same patients when activating the most ventral contacts of the electrode. Persistent AEs, such as muscle contraction due to stimulation of the corticospinal fibers, can also be seen in both STN and GPi DBS. This effect is unbearable, requiring this particular programming to be ruled out.

The majority of stimulation-induced AEs has been observed in STN DBS. Among the most frequent ones are paresthesias, speech dysfunction (dysarthria and hypophonia), eyelid apraxia, and ocular and visual disturbances. In these cases, modulation of the parameters of stimulation can ameliorate the AEs, but if the result is not satisfactory, the parameters should be changed.

Weight gain is a common AE in STN-treated patients. Candidates for a surgical procedure may be given preoperative nutritional counseling to prevent excessive weight gain. Uncontrolled long-term observations suggest that the weight of most patients normalizes after 1–2 years.

Some other AEs are present with and without stimulation and are also frequent in PD patients not treated with DBS. Thus, the relation to stimulation or to the disease is not clear at this moment. Psychiatric, cognitive, and behavioral disturbances have been associated with STN DBS. Depression, apathy, abulia, desinhibition, mania and hypomania, hallucination, and other disturbances have been described. One important point to consider is the possibility that a large number of patients might already have psychiatric complications or cognitive deficits which could be worsened after surgery. Some studies indicate that patients with depression after STN DBS had depressive episodes before surgery. Nevertheless, cognitive and mood changes have been reported more frequently in STN DBS than in GPi DBS and may be related to the spreading of the current to limbic or associative portions of the nucleus or areas surrounding the STN.

Memory decline, psychiatric disturbances, and axial problems (gait and speech difficulties, disequilibrium, and falls) are also frequently described as AEs in patients treated with DBS but seem to be more frequent among those patients treated with DBS STN, as reported in the multicenter study at 4-year follow-up. It is interesting that all these complications are also frequently seen in advanced PD patients treated chronically only with pharmacological means, so they may be related to the disease. In this context, the multicenter study shows that for the STN DBS-treated patients, depression, thought disorders, rising from a chair, and gait were more affected at baseline in those patients who were to exhibit AEs at 4 years' follow-up. These data support the idea that the AEs exhibited

by STN-treated patients could be mainly due to the disease progression rather than to stimulation. At present no conclusion can be reached, and well-designed studies will be needed to clarify these crucial aspects in relation to the disease and to DBS therapy.

In summary, DBS for PD is a successful therapy with a good long-term evolution result. Adverse events associated with this therapy are frequent, but in the majority of cases, they do not preclude the continuation of the therapy. The greatest motor benefits associated with DBS of the STN have to be prospectively evaluated in studies with patients randomly operated in the STN or in the GPi. The recent impression that DBS of the STN produces more AEs than DBS of the GPi also needs to be confirmed. It is necessary to rule out the possibility that the disease evolution is the major contributor to AE.

Delayed Reinforcement: Economics

C Harris, University of Cambridge, Cambridge, UK

© 2009 Published by Elsevier Ltd.

Introduction

In general, an economic subject faces many dimensions of choice. How much should she consume, and when should she consume it? What sort of career should she choose, and what sort of education and training should she undertake in order to prepare best for that career? What sort of spouse should she choose? Should she have children, and if so how many and when? How much should she work, and when should she retire? In which, among the bewildering array of assets on offer, should she place her savings?

This article focuses on just one of these dimensions: when should a subject consume? In other words, the focus is on the essence of intertemporal choice: time. The author does not consider the question of how much she should consume. The author does, however, allow for uncertainty. This is essential, for three reasons. First, in practice, most problems of intertemporal choice involve uncertainty. Second, even in the laboratory, there may be some uncertainty in a subject's mind as to whether she will actually receive the rewards being promised to her. Third, it is not possible to make sense of even the most basic concepts of the theory of intertemporal choice such as discount factors and discount rates unless the subject makes choices involving uncertainty.

Both economists and psychologists frequently analyze problems of intertemporal choice in terms of a subject's discount function. It is therefore important to begin by understanding what the use of a discount function does and does not entail. One thing that it does not entail is an assumption that the subject actually has a discount function. The point is that she behaves as if she had a discount function. The discount function itself is simply a convenient device that quantifies her choices. What the use of a discount function does entail is three assumptions about the nature of her choices: they must be complete, transitive, and substitutable. This is because a discount function is simply a particular kind of utility function: it assigns a utility to each date at which the subject could consume.

The three requirements of completeness, transitivity, and substitutability are controversial from both a theoretical and an empirical point of view. It is therefore somewhat surprising that psychologists are willing to work with discount functions. Nonetheless, there is one respect in which they are rather permissive: they are satisfied by essentially any discount function. Narrowing the range of possible shapes for the discount function therefore seems to be a higher priority than widening the enquiry to include behavior that is not consistent with having a discount function. Psychologists have taken an experimental approach to this problem, and they are inclined to interpret the data as suggesting that discount functions are hyperbolic. Following Samuelson, economists were inclined to assume for conceptual and mathematical convenience that discount functions were exponential. However, with the arrival of more powerful computers and more powerful analytical techniques, they have been increasingly willing to respond to the challenge to this paradigm contained in Strotz.

Much of the attraction of exponential discounting derives from the fact that it satisfies both dynamic consistency and stationarity. These requirements can be expressed as follows. Suppose that we are given two dates, $t > s > 0$. Then dynamic consistency means that, if the subject decides at date 0 that she would like to consume at date t, then she would not want to revise her decision at date s if given the opportunity to do so. Stationarity means that, if the subject decides at date 0 that she would like to consume at date t, then she would decide a date s to consume at date $s + t$.

Consider the following example. At 2 p.m., a subject is asked when she would like to eat supper. She chooses 7 p.m. Two hours later (i.e., at 4 p.m.) she is unexpectedly given the option of revising her choice. If she still chooses 7 p.m., then she is acting in a dynamically consistent manner. If, however, she chooses a different time (say 6 p.m.), then she is acting in a dynamically inconsistent manner. This change could be explained by the arrival of new information. For example, she may have learned at 3 p.m. that her 5 p.m. appointment had been cancelled. In this case, the dynamic inconsistency arises because she was asked to make an unconditional choice. Had she instead chosen a pair of times for supper, one to apply in the event that the appointment was on and the other to apply in the event that it was off, then she would have chosen the pair {7 p.m. if appointment, 6 p.m. if no appointment} and no revision in her choice would have been necessary. The dynamic consistency requirement embodied in an exponential discount function does not rule out changes that arise from the arrival of new information. It simply rules out changes that occur in the complete absence of any new information. As such, it is more reasonable than it might appear at first sight.

Now consider the same example, but from the point of view of stationarity. Stationarity requires that, when the subject is given the option of revising

her choice at 4 p.m., she chooses 9 p.m.! The point is that, at 2 p.m., she wanted to have supper 5 h later. So, at 4 p.m., she should again want to have supper 5 h later. Stated in this way, the requirement of stationarity appears ridiculous: if the subject wanted to delay supper by 5 h at 2 p.m., then, at 4 p.m. when she is presumably hungrier, she should want (at the very minimum) to delay supper by less than 5 h. The problem does not lie with stationarity, however. It lies with an incompletely specified model. If hunger is an important factor in the subject's decision making, then it should be included in the model. Once it is included, the subject's choices become stationary again: for any given level of hunger, she will choose the same delay until supper. So stationarity too is more reasonable than it may appear at first sight.

Unfortunately, the exponential discounting model appears to be rejected by the experimental data. Dynamic consistency, stationarity, or both must therefore be wrong. From an experimental point of view, it would be hard to abandon stationarity: experiments are ultimately based on the idea that subjects will keep on doing the same thing if they are placed repeatedly in the same situation. It is therefore more sensible to abandon dynamic consistency, at least in its present form.

The experimental data also suggest that subjects are more patient with respect to any given delay, the further in the future that delay occurs. The present article proposes a method for deriving discount functions with this property and uses the method to derive a unified discount function that incorporates all three of the most popular discount functions (namely, exponential, hyperbolic, and generalized hyperbolic) as special cases.

Finally, if dynamic consistency is abandoned, then a subject's decision problem becomes an intrapersonal game. In this game, the interests of the future self are not necessarily aligned with those of the current self, and the current self has to try to anticipate the behavior of the future self. Anticipation is made easier by stationarity, which ensures that the outlook of the future self will be identical to that of the current self, but made harder by the fact that the future self may face circumstances different from those faced by the current self. Two extremes can be identified: a naive subject fails completely to anticipate the behavior of her future self (and fails to notice that she is failing to anticipate), and a sophisticated subject anticipates the behavior of her future self perfectly.

An Idealized Example

Consider the following idealized example of choice over delayed outcomes. Suppose that there is an infinite sequence of possible dates at which the subject can eat an apple: $t = 0$ (today), $t = 1$ (tomorrow), $t = 2$ (the day after tomorrow), and so on. Denote the set of all possible dates by $\mathbb{T} = \{0, 1, 2, \ldots\}$; define a probability distribution p over $\mathbb{T}$ to be simple if the number of dates t for which $p(t) > 0$ is finite; and denote by $\mathbb{P}$ the set of simple probability distributions (SPDs) over $\mathbb{T}$. The idea is then that:

1. The experimenter will offer the subject a choice of two SPDs.
2. The subject will choose between them.
3. The experimenter will use a suitable randomizing device to generate a date t according to the SPD chosen.
4. The subject will then wait until that date, at which point the experimenter will give her the apple and she will eat it straight away.

Faced with this problem, it can be argued that the perfect subject should proceed as follows. First, before she is actually asked to make any choice, she should formulate her preferences as between any pair of SPDs she could conceivably be offered. In other words, for any pair of SPDs p_1 and p_2, she must decide that (i) p_1 is at least as good as p_2; or (ii) p_2 is at least as good as p_1; or (iii) p_1 and p_2 are equally good. Second, her preferences should be consistent in the sense that, if she thinks that p_1 is at least as good as p_2 and that p_2 is at least as good as p_3, then she must also think that p_1 is at least as good as p_3. Third, if we start with three SPDs p_1, p_2 and p_3, and if we create two compound probability distributions $\tilde{p}_1$ (in which p_1 is chosen with probability γ and p_3 is chosen with probability $1-\gamma$) and $\tilde{p}_2$ (in which p_2 is chosen with probability γ and p_3 is chosen with probability $1-\gamma$), then the subject should again be consistent, this time in the sense that if she thinks that p_1 is at least as good as p_2 then she should also think that $\tilde{p}_1$ is at least as good as $\tilde{p}_2$. The logic behind this requirement is that, in moving from $\tilde{p}_2$ to $\tilde{p}_1$, we simply replace the intermediate outcome p_2 with the better intermediate outcome p_1. Substitutability, as defined later, incorporates a second requirement: provided that the probability distribution over final dates is the same, the subject should not care whether the probabilistic procedure used to arrive at this probability distribution takes place in two stages (as in a compound probability distribution) or in one (as in a simple probability distribution). This requirement is often called the reduction of compound lotteries.

More precisely, if we express the statement that the subject thinks that p_1 is at least as good as p_2 by writing $p_1 \text{ B } p_2$, then it can be argued that the subject's preferences should satisfy the following three requirements:

Completeness: For all $p_1, p_2 \in \mathbb{P}$, we have either p_1 B p_2 or p_2 B p_1 or both.
Transitivity: For all p_1, p_2, $p_3 \in \mathbb{P}$, if p_1 B p_2 and p_2 B p_3, then p_1 B p_3.
Substitutability: For all p_1, p_2, $p_3 \in \mathbb{P}$ and all $0 < \gamma \leq 1$, if we put $\tilde{p}_1 = \gamma p_1 + (1-\gamma)p_3$ and $\tilde{p}_2 = \gamma p_2 + (1-\gamma)\, p_3$, then p_1 B p_2 if and only if $\tilde{p}_1$ B $\tilde{p}_2$.

These requirements can be challenged on both theoretical and empirical grounds. For example, why would the subject want to evaluate the vast number of hypothetical alternatives envisaged by the requirement of completeness? Why not simply wait until she is actually asked to make a choice, and only then evaluate the pair of dates that she is actually offered? Moreover, if she evaluates only a single pair of dates, then the consistency issue addressed by the requirement of transitivity – which in general involves three pairs of dates – never arises. Finally, the requirement of substitutability (for all its theoretical appeal) has not fared well when subjected to experimental testing. A full discussion of these challenges would, however, take us too far away from our main theme.

If the requirements of completeness, transitivity, substitutability, and a fourth technical requirement are all satisfied, then the following result holds:

Expected-Utility Theorem: There exists a utility function $u : \mathbb{T} \to \mathbb{P}$ that represents the subject's preferences in the sense that p_1 B p_2 if and only if

$$\sum_{t \in \mathbb{T}} p_1(t)\, u(t) \geq \sum_{t \in \mathbb{T}} p_2(t)\, u(t)$$

The fourth requirement says roughly that, if the subject strictly prefers p_1 to p_2, and if p_3 is a third simple probability distribution, then there is a small positive probability γ such that: (1) the subject strictly prefers the compound probability distribution $\widehat{p}_1$ (in which p_1 is chosen with probability $1-\gamma$ and p_3 is chosen with probability γ) to p_2; and (2) the subject strictly prefers p_1 to the compound probability distribution $\widehat{p}_2$ (in which p_2 is chosen with probability $1-\gamma$ and p_3 is chosen with probability γ). More precisely:

Archimedean axiom for all p_1, p_2, $p_3 \in \mathbb{P}$ such that p_1 B p_2 but not p_2 B p_1 (i.e., p_1 is strictly preferred to p_2), there exists $\gamma \in (0, 1)$ such that, if we put $\widehat{p}_1 = (1-\gamma)\, p_1 + \gamma\, p_3$ and $\widehat{p}_2 = (1-\gamma)\, p_2 + \gamma\, p_3$, then: (1) $\widehat{p}_1$ B p_2. but not p_2 B $\widehat{p}_1$ (i.e., $\widehat{p}_1$ is strictly preferred to p_2); and (2) p_1 B $\widehat{p}_2$ but not $\widehat{p}_2$ B p_1 (i.e., p_1 is strictly preferred to $\widehat{p}_2$).

We shall not discuss this requirement further.

In other words, there exists a utility function that characterizes the subject's choices in the sense that she chooses p_1 over p_2 if and only if the expected utility associated with p_1 exceeds the expected utility associated with p_2. (The expected utility of an SPD p is calculated by multiplying the probability $p(t)$ with which the date t is generated by the utility $u(t)$ associated with that date, and then adding up over all dates that occur with positive probability.) This result does not say that the subject has a utility function, only that she behaves as if she had one.

The utility function provided by the Expected-Utility Theorem is not unique: for all scalars $\alpha \in \mathbb{R}$ and $\beta > 0$, the utility function $\upsilon : \mathbb{T} \to \mathbb{R}$ defined by the formula $\upsilon(t) = \alpha + \beta\, u(t)$ does just as well. However, this is also the only sense in which u is not unique. More precisely, the following result holds:

Cardinal-Information Theorem: If there is a second utility function $\upsilon : \mathbb{T} \to \mathbb{R}$ that also represents the subject's preferences, then there exist scalars $\alpha \in \mathbb{R}$ and $\beta > 0$ such that $\upsilon(t) = \alpha + \beta\, u(t)$ for all $t \in \mathbb{T}$.

This result is essential for what follows. Indeed, important concepts in the analysis of intertemporal choice such as the discount factor and the discount rate are defined directly in terms of the utility function. Yet many different utility functions can be used to represent the subject's choices. We therefore need to make sure that any such concept is independent of which utility function is used to represent the subject's choices. In this way we can guarantee that it has a meaning directly in terms of what we observe, namely, the subject's behavior.

Consider the following analogy. We can measure temperature on the Celsius scale (corresponding to u) or on the Fahrenheit scale (corresponding to υ). Water freezes at 0° and boils at 100° on the Celsius scale, and it freezes at 32° and boils at 212° on the Fahrenheit scale. So statements like "the temperature is 0°" or "the temperature increased by 100°" do not make sense until one specifies whether the temperature scale is Celsius or Fahrenheit. However, statements like "when he heated the pan with a Bunsen burner the temperature rose by twice as much as when he heated it with a candle" make sense even if we do not know which temperature scale is being used. It is to statements like these that we must therefore confine ourselves. (The definitions of discount factor and discount rate given below both conform to this pattern.) Finally, in order to move between the Celsius scale and the Fahrenheit scale, we need to set $\alpha = 32$ and $\beta = \frac{9}{5}$.

Dynamic Consistency and Stationarity

Up to this point, we have assumed that, at date 0, the subject chooses a date at which to consume. She is then committed to that date. This is rather artificial: in an experimental setting, the experimenter can provide the external discipline that ensures that the subject really is committed to wait until the chosen

date, but in everyday settings, a subject is likely to have opportunities to reconsider her choices.

Suppose by way of an example that $u(1) > u(2) > u(0) > u(3) > u(4) > \ldots$. In other words, while the subject knows that apples are good for her, given the choice of eating the apple today ($t = 0$) or tomorrow ($t = 1$), she would rather eat it tomorrow. Similarly, given the choice of eating the apple today ($t = 0$) or the day after tomorrow ($t = 2$), she would rather eat it the day after tomorrow. However, given the choice of eating the apple today ($t = 0$) or 3 days from now ($t = 3$), she would rather eat it today: even though she does not particularly like apples, she recognizes that she really must eat an apple from time to time.

Suppose further that the experimenter offers the subject a choice of eating the apple today ($t = 0$) or tomorrow ($t = 1$). Then the subject will certainly choose tomorrow. Suppose, however, that, when tomorrow actually arrives, the experimenter offers the subject a new choice: she can either have the apple right away (i.e., at $t = 1$, as originally planned), or she can have it on the following day (i.e., at $t = 2$). On the face of it, the subject is better off than she was before: she still has the option that she originally chose, but in addition she has the option of waiting another day. What will she do?

If we accept the logic of the preceding two sections, then the answer is that she should formulate a new utility function $\tilde{u}$ over the set $\tilde{\mathbb{T}} = \{1, 2, 3, \ldots\}$ of remaining dates. The question, then, is what relationship should this new utility function bear to the old utility function u? There does not seem to be a compelling answer to this question, but there are three possibilities.

Dynamic Consistency

One possible answer is that the subject will rank the dates $1, 2, 3, \ldots \in \tilde{\mathbb{T}}$ in exactly the same way that she ranked the dates $1, 2, 3, \ldots \in \tilde{\mathbb{T}}$. More explicitly, for all $t_1, t_2 \in \tilde{\mathbb{T}}$, $\tilde{u}(t_1) \geq \tilde{u}(t_2)$ if and only if $u(t_1) \geq u(t_2)$. In other words, the subject has preferences over absolute (or calendar) dates, and these preferences do not change with the passage of time. In the context of the example given above, that means that if (at date 0) the subject preferred to eat the apple at date 1, then (at date 1) the subject will still prefer to eat the apple at date 1.

Stationarity

Another possible answer is that the subject's preferences are really a kind of perspective on the future. The subject will therefore rank the dates $1, 2, 3, \ldots \in \tilde{\mathbb{T}}$ in exactly the same way that she ranked the dates $0, 1, 2, \ldots \in \mathbb{T}$. More explicitly, for all $t_1, t_2 \in \tilde{\mathbb{T}}$, $\tilde{u}(t_1) \geq \tilde{u}(t_2)$ if and only if $u(t_1 - 1) \geq u(t_2 - 1)$. In other words, the subject has preferences over relative dates, and these preferences do not change with the passage of time. In the context of the example given previously, that means that if (at date 0) the subject preferred to eat the apple 1 day later (i.e., at date 1), then (at date 1) the subject still prefers to eat the apple 1 day later (i.e., at date 2).

Exponential Discounting

Dynamic consistency ensures that a subject never wants to revise plans formulated at date 0, even if she is given the opportunity to do so. Stationarity means that a subject will approach a new planning problem in exactly the same way that she approached earlier planning problems. Can both of these advantages be incorporated within a single model? The answer is that they can, but only if the discount function takes a very particular form: it must be exponential.

In order to explain why, note that dynamic consistency implies that u and $\tilde{u}$ are simply two different representations for the same preferences over the dates in $\tilde{\mathbb{T}} = \{1, 2, 3, \ldots\}$. The Cardinal-Information Theorem therefore implies that we can find scalars $\alpha_{DC} \in \mathbb{R}$ and $\beta_{DC} > 0$ such that

$$\tilde{u}(t) = \alpha_{DC} + \beta_{DC}\, u(t) \qquad [1]$$

for all $t \in \tilde{\mathbb{T}}$. Similarly, stationarity implies that there are scalars $\alpha_S \in \mathbb{R}$ and $\beta_S > 0$ such that

$$\tilde{u}(t) = \alpha_S + \beta_S\, u(t-1) \qquad [2]$$

for all $t \in \tilde{\mathbb{T}}$. Inverting eqn [1] to express $u(t)$ in terms of $\tilde{u}(t)$, and then using eqn [2] to substitute for $\tilde{u}(t)$, we obtain

$$u(t) = \alpha_E + \beta_E\, u(t-1) \qquad [3]$$

for suitable scalars $\alpha_E \in \mathbb{R}$ and $\beta_E > 0$. (The scalars in question are $\alpha_E = \beta_{DC}^{-1}(\alpha_S - \alpha_{DC})$ and $\beta_E = \beta_{DC}^{-1}\beta_S$.)

Now, eqn [3] is a simple difference equation. If $\beta_E \neq 1$, then it has the unique solution

$$u(t) = \frac{\alpha_E}{1-\beta_E} + \beta_E^t\left(u(0) - \frac{\alpha_E}{1-\beta_E}\right) \qquad [4]$$

and, if $\beta_E = 1$, then it has the unique solution

$$u(t) = u(0) + t\,\alpha_E \qquad [5]$$

At first sight, these equations may appear to be rather complicated. Nothing could be further from the truth: they can be simplified dramatically by choosing a more convenient utility scale. More precisely, we can replace u with an equivalent utility function $\upsilon = \alpha + \beta\, u$ for suitably chosen α and β. If $\beta_E \neq 1$ and $u(0) = \frac{\alpha_E}{(1-\beta_E)} \neq 0$ then one uses $\alpha = -\frac{\alpha_E}{(1-\beta_E)}$ and $\beta = \left|u(0) - \frac{\alpha_E}{(1-\beta_E)}\right|^{-1}$; if

$\beta_E \neq 1$ and $u(0) - \frac{\alpha_E}{(1-\beta_E)} = 0$ then one uses $\alpha = -\frac{\alpha_E}{(1-\beta_E)}$ and $\beta = 1$; if $\beta_E = 1$ and $\alpha_E \neq 0$ then one uses $\alpha = -u(0)$ and $\beta = |\alpha_E|^{-1}$; and if $\beta_E = 1$ and $\alpha_E = 0$ then one uses $\alpha = -u(0)$ and $\beta = 1$. In this way, we find that there are essentially only five possible choices for the subject's utility function:

1. $\upsilon(t) = \beta_E^t$ for some $\beta_E \neq 1$;
2. $\upsilon(t) = -\beta_E^t$ for some $\beta_E \neq 1$;
3. $\upsilon(t) = 0$;
4. $\upsilon(t) = t$; and
5. $\upsilon(t) = -t$.

These cases occur, respectively, if (1) $\beta_E \neq 1$ and $u(0) - \frac{\alpha_E}{(1-\beta_E)} > 0$; (2) $\beta_E \neq 1$ and $u(0) - \frac{\alpha_E}{(1-\beta_E)} < 0$; (3) either $\beta_E \neq 1$ and $u(0) - \frac{\alpha_E}{(1-\beta_E)} = 0$, or $\beta_E = 1$ and $\alpha_E = 0$; (4) $\beta_E = 1$ and $\alpha_E > 0$; and (5) $\beta_E = 1$ and $\alpha_E < 0$. Cases 1, 2, and 3 could be summarized by saying that, viewed from the perspective of date 0, the utility of eating the apple at date t is the product of two factors: (1) an instantaneous utility (i.e., a utility that is obtained at the actual moment of consumption) that takes one of the three values 1, −1, and 0; and (2) a discount factor $\beta_E \neq 1$ raised to the power of t. There is nothing in the theory that we have sketched that requires that $\beta_E < 1$, so β_E can take any value in $(0,1) \cup (1, \infty)$. Cases 4 and 5 are limiting cases of cases 1 and 2, obtained when β_E tends to 1. This is easier to see when preferences are represented by the utility function u. Indeed, rewriting eqn [4] in the form $u(t) = \frac{(1-\beta_E^t)}{(1-\beta_E)}\ \alpha_E + \beta_E^t\ u(0)$, we find that $u(t) \to t\ \ \alpha_E + u(0)$ as $\beta_E \to 1$. In other words, we obtain eqn [5]. There are other ways of taking limits. For example, if we let $\beta_E \to 1$ in case 1, then $\widehat{u}(t) \to 1$. This is, of course, case 3, the case in which the subject is indifferent among all dates. Similarly, if we let $\beta_E \to 1$ in case 2, then $\widehat{u}(t) \to -1$. This is again case 3.

The Discount Factor

Intuitively speaking, the discount factor at date t tells us what fraction of the utility gain from an increase in consumption at date t the subject would still obtain if that increase in consumption were deferred until date $t+1$. This is a measure of the subject's patience at date t: the bigger the fraction of the utility gain that she still gets, the more patient she can be said to be.

Now, in our model, there are only two possible levels of consumption at date t: either the subject eats one apple or she eats no apples. However, to say that she eats no apples is ambiguous: it leaves open the question of when she does eat the apple. The best way to resolve this ambiguity is to introduce a new possibility into our model, namely, that the subject never eats the apple. This possibility can be captured by adding the new date ∞ (i.e., infinity) to the existing list of dates $\mathbb{T} = \{0, 1, 2, \ldots\}$. Choosing $t \in \mathbb{T}$ then means choosing to eat the apple at date t, and choosing $t = \infty$ means choosing never to eat the apple. It is also helpful to impose the requirement that $u(t)$ converges to $u(\infty)$ as t gets large. This ensures that deferring the consumption of the apple indefinitely and never consuming it yield essentially the same utility. Having to introduce the date ∞ into the model is the one small price that we have to pay for eliminating the level of consumption from the model.

We can now make precise the definition of the discount factor outlined previously. Indeed, the utility gain from eating the apple at date $t+1$ instead of never eating it is $u(t+1) - u(\infty)$, the utility gain from eating the apple at date t instead of never eating it is $u(t) - u(\infty)$, and the discount factor at date t is

$$\delta(t, 1) = \frac{u(t+1) - u(\infty)}{u(t) - u(\infty)}$$

For example, if $u(t) = \beta_E^t$ for some $\beta_E < 1$, then $u(\infty) = 0$ and $\delta(t, 1) = \beta_E$ for all t. Notice that $\delta(t, 1)$ is unchanged if we replace u by the equivalent utility function $\upsilon = \alpha + \beta u$. The discount factor is therefore a genuine behavioral measure.

The Discount Rate

In order to derive some alternatives to the exponential-discounting model, it will be helpful to treat t as a continuous variable. In the theory that we have sketched, a single indivisible good is consumed once. It is therefore relatively easy to adapt the theory to the continuous-time case. We can then ask what fraction of the utility gain from an increase in consumption at date t the subject would still obtain if that increase in consumption were deferred until date $t + \tau$. More precisely, we can introduce a generalization of the discount factor, namely,

$$\delta(t, \tau) = \frac{u(t+\tau) - u(\infty)}{u(t) - u(\infty)}$$

This is again a measure of the subject's patience at date t. Like $\delta(t, 1)$, $\delta(t, \tau)$ is unchanged if we replace u by the equivalent utility function $\upsilon = \alpha + \beta u$. It too is therefore a genuine behavioral measure.

Now, we would ideally like to make τ as small as possible, to ensure that we measure the subject's patience at date t as precisely as possible. However, $\delta(t, \tau) \to 1$ as $\tau \to 0$. We therefore look instead at the discount rate

$$\rho(t) = \lim_{\tau \to 0} \frac{1 - \delta(t, \tau)}{\tau}$$

This tells us how quickly $\delta(t, \tau)$ falls below 1 as the delay τ grows from 0. It is therefore a measure of the subject's impatience at date t. Elementary calculus shows that

$$\rho(t) = \frac{-u'(t)}{u(t) - u(\infty)} \qquad [6]$$

For example, if $u(t) = \beta_E^t$ for some $\beta_E < 1$, then $\rho(t) = -\ln(\beta_E) > 0$.

In some respects, the terminology of discount factor and discount rate is unfortunate: it might have been better to use the terms patience factor and impatience rate instead.

Beyond Exponential Discounting

According to the exponential-discounting model, the subject's discount rate ρ is constant. However, if there is one thing on which the experimentalists all agree, it is that ρ decreases with time: a given delay is regarded as less serious, the further in the future it occurs.

One way of modeling this stylized fact is to make $\rho(t)$ a weighted average of a short-run discount rate λ and a long-run discount rate μ in which the weight placed on μ increases with time. For example, we could put

$$\rho(t) = \frac{1}{1+\nu t}\lambda + \frac{\nu t}{1+\nu t}\mu \qquad [7]$$

Here ν is a strictly positive parameter which measures the speed with which the discount rate moves from its short-run value λ to its long-run value μ, and the weight placed on μ increases from 0 when $t = 0$ to 1 when $t = \infty$.

If we substitute this formula for $\rho(t)$ in eqn [6], then we obtain a simple differential equation for the utility function u, $(1+\nu t)\,u'(t) + (\lambda + \mu\nu t)\ (u(t) - u(\infty)) = 0$. It is easy to verify that this equation has the general solution

$$u(t) = C\ \exp(-\mu t)(t+\nu t)^{-\frac{(\lambda-\mu)}{\nu}} + u(\infty) \qquad [8]$$

where C is an arbitrary constant. This solution is consistent with our requirement that $u(t) \to u(\infty)$ provided that either $\mu > 0$ and $\lambda \in \mathbb{R}$, or $\mu = 0$ and $\lambda > 0$. Assuming this to be the case, we can choose the utility scale in such a way that $u(\infty) = 0$. There are then three basic possibilities: $C = 1$, $C = -1$, and $C = 0$. Focusing on the case $C = 1$, we obtain

$$u(t) = \exp(-\mu t)\ (t+\nu t)^{-\frac{(\lambda-\mu)}{\nu}} \qquad [9]$$

This is an attractively simple functional form with both exponential and hyperbolic features: $u(t)$ is the product of the exponential discount factor $\exp(-\mu t)$ and the hyperbolic discount factor $(1+\nu t)^{-\frac{\lambda-\mu}{\nu}}$. Moreover, the parameters λ, μ, and ν are all readily interpretable.

Equation [9] is sufficiently general to encompass both exponential and hyperbolic discounting. Indeed, if we set $\mu = 0$, then we obtain

$$u(t) = (1+\nu t)^{-\frac{\lambda}{\mu}} \qquad [10]$$

This is the generalized hyperbola of Harvey and Loewenstein and Prelec. And, if we specialize further by putting $\lambda = \nu$, then we obtain

$$u(t) = (1+\nu t)^{-1} \qquad [11]$$

This is the original hyperbola of Herrnstein. Third, if we put $\lambda = \mu$, then we obtain

$$u(t) = \exp(-\mu t) \qquad [12]$$

This is the exponential used by Samuelson.

Equation [9] also offers a flexible functional form for statistical testing. For example, while it is widely thought that the discount rate $\rho(t)$ is decreasing in t, it would be desirable to be able to know the statistical significance of this finding. Because eqn [9] is valid for both $\lambda - \mu > 0$ and $\lambda - \mu < 0$, it can be used as the basis of a one-tailed test of whether $\lambda - \mu > 0$ (as expected) or not. Similarly, while it is widely thought that discount functions are not exponential, it would be desirable to know the statistical significance of this finding. Equation [9] can be used as the basis of a two-tailed test of whether $\lambda - \mu = 0$ or not (as expected). Third, it is sometimes claimed that discount rates are close to 0 for large t. Because eqn [9] is valid for all $\mu \geq 0$ (provided at least that $\lambda > 0$), it can be used as the basis of a test of whether the restriction $\mu = 0$ is rejected by the data or not.

Equation [9] does, however, have one fault. Except in the special case where $\lambda = \mu$ (i.e., the case of exponential discounting), it is difficult to incorporate into theoretical models in a mathematically tractable way. This difficulty can be overcome. Notice that there are essentially four elements in the construction of eqn [9]: (1) the short-run discount rate λ, (2) the long-run discount rate μ, (3) the pattern of adjustment $t \to \frac{t}{1+t}$, and (iv) the speed of adjustment ν. The trick is to change the (seemingly simple) pattern of adjustment

$$t \to \frac{t}{1+t}$$

into the (seemingly complex) pattern of adjustment

$$t \to \frac{\theta(1-\exp(-t))}{\exp(-t) + \theta(1-\exp(-t))}$$

where θ is a nonnegative parameter. (Notice that θ is not the rate of adjustment.) Making this change leads to the (thankfully simple!) discount function

$$u(t) = \exp(-\mu t)\ (\exp(-\nu t) + (1-\exp(-\nu t))\theta) \qquad [13]$$

introduced by Harris and Laibson. This discount function is the product of two factors: the exponential discount function $\exp(-\mu t)$ and the supplementary discount function $\exp(-\nu t) + (1 - \exp(-\nu t))\,\theta$. The supplementary discount function attaches weight 1 to date 0 and weight θ to date ∞, and the difference between these two weights decays exponentially at rate ν. If $\theta < 1$, there is therefore a transparent sense in which the present is overweighted relative to the future.

The idea behind eqn [13] is to divide time into two phases. During both of these phases, discounting takes place at rate μ. However, at the point of transition between them, an additional discount factor θ is applied. Finally, the transition between them takes place at rate ν. The perceptive reader may wonder why we do not assume that discounting takes place at different rates in the two phases. For example, why not assume that discounting takes place at rate $\widehat{\lambda}$ during the first phase, that discounting takes place at rate $\widehat{\mu}$ during the second phase, that an additional discount factor $\widehat{\theta}$ is applied at the transition between the two phases, and that the transition between the two phases takes place at rate $\widehat{\nu}$? The answer is that this leads to no increase in generality: under these assumptions the discount function still takes the form given in eqn [13] with $\theta = \frac{\widehat{\beta}\widehat{\nu}}{(\widehat{\nu}+\widehat{\lambda}-\widehat{\mu})}$, $\mu = \widehat{\mu}$, and $\nu = \widehat{\nu} + \widehat{\lambda} - \widehat{\mu}$. In other words, one of the parameters $\widehat{\theta}$, $\widehat{\lambda}$, $\widehat{\mu}$ and $\widehat{\nu}$ is redundant. This construction is a compromise between the homogeneity of exponential discounting (which involves only a single phase) and the complete inhomogeneity of discount functions like that given in eqn [9] (which involve a continuum of phases).

Intrapersonal Games

If exponential discounting is rejected by the data, then dynamic consistency, stationarity, or both must be wrong. The author concludes this article by exploring the theoretical implications of abandoning dynamic consistency, but retaining stationarity, doing this in the context of an example.

Suppose that $u(1) > u(2) > u(0) > u(3) > u(4) > \cdots > u(\infty)$. This is the same as the example in the section titled 'Dynamic consistency and stationarity,' except that the new date ∞ has been added. Suppose, however, that the subject is now free to choose any date she wishes.

One possible approach to this problem is to assume that the subject is naive. At date 0, the subject's preferences are represented by the utility function $u_0 = u$. More explicitly, we have $u_0(1) > u_0(2) > u_0(0) > u_0(3) > u_0(4) > \cdots > u_0(\infty)$. She will therefore plan to consume at her most preferred date, namely, $t = 1$. However, at date 1, stationarity implies that her preferences over future dates can be represented by the utility function u_1 given by the formula $u_1(t) = u_0(t-1)$. More explicitly, we have $u_1(2) > u_1(3) > u_1(1) > u_1(4) > u_1(5) > \ldots > u_1(\infty)$. She will therefore plan to consume at her most preferred date, which is now $t = 2$. And so on, indefinitely.

This reads like a textbook example of procrastination: every day the subject plans to eat the apple the following day, with the result that she never eats it. The weakness of the analysis is that the subject never learns from her repeated failure to eat the apple that her plan to eat the apple the following day is unrealistic.

A second possible approach is to assume that the subject is sophisticated. From the very outset, she recognizes that she cannot bind her future self to take the actions that she deems desirable today. So, instead, she tries to anticipate the choice c_t that she will make at date t in case she has not already consumed the apple. In this case, there are three stable patterns of behavior. They are summarized in Table 1. Each column of this table contains the choices made at a particular date. The first three rows contain the choices made in the three possible behaviors of the sophisticated subject. The fourth row contains the choices made by a naive subject, for the purposes of comparison. A value of 1 denotes that the subject decides to eat the apple, and a value of 0 denotes that she decides not to eat it.

If the behavior of the sophisticated subject follows the first pattern, then she ends up consuming the apple straight away. This is in marked contrast to the naive subject, who never consumes it. This pattern of behavior is supported by the following logic.

At date 0, the subject recognizes that if she does not eat the apple immediately, then (because she will not

Table 1

Date	*0*	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*	...
Behavior 1 of sophisticated subject	1	0	0	1	0	0	1	0	0	1	0	...
Behavior 2 of sophisticated subject	0	1	0	0	1	0	0	1	0	0	1	...
Behavior 3 of sophisticated subject	0	0	1	0	0	1	0	0	1	0	0	...
Behavior of naive subject	0	0	0	0	0	0	0	0	0	0	0	

eat it at dates 1 or 2) she will end up eating it at date 3. Since $u(0) > u(3)$ (and therefore $u_0(0) > u_0(3)$), she decides to eat the apple straight away. Similarly, at date 1, she recognizes that if she does not eat the apple immediately, then (because she will not eat it at date 2) she will end up eating it at date 3. Since $u(2) > u(0)$ (and therefore $u_1(3) > u_1(1)$, by stationarity), she decides not to eat the apple. Similarly, at date 2, she recognizes that if she does not eat the apple immediately, then she will eat it at date 3. Since $u(1) > u(0)$ (and therefore $u_2(3) > u_2(2)$, by stationarity), she decides not to eat the apple. And so on.

Notice that the naive subject ends up with the lowest possible utility, namely, $u(\infty)$, and that (under behavior 1) the sophisticated subject ends up with the better utility $u(0)$. Sophistication, therefore, does pay in this example. However, the sophisticated subject does better still under behavior 3 (which results in a utility of $u(2)$) and best of all under behavior 2 (which results in a utility of $u(1)$).

Five other points are worth noting. First, we do not obtain a unique prediction for the behavior of a sophisticated subject. This is typical of all but the simplest games. But we do still get clear predictions. For example, a naive subject will never eat the apple, whereas a sophisticated subject will eat it within the first three periods. Second, although the model is stationary, none of the three predictions for the behavior of the sophisticated subject is stationary. While it may not be reasonable to rule out behaviors that are nonstationary, it is reasonable to look for behaviors that are. One way of obtaining stationary behavior is to allow the subject to randomize. Third, randomization can be given an attractive interpretation in this model. It need not mean that the subject deliberately randomizes between eating and not eating the apple (e.g., by tossing a coin). It could mean instead that she is unsure whether she will eat the apple tomorrow or not: all she knows is that she will eat it with some probability. Fourth, the game-theoretic approach we have adopted in the analysis of the sophisticated subject effectively reinstates dynamic consistency in a more subtle form. Previously, a subject was deemed to be dynamically consistent if the future self would always find it to be in her own interests to go along with any plan formulated by the current self. Now the current self recognizes that the interests of the future self may not coincide with her own and chooses the best plan that the future self will be willing to go along with. Finally, the behavior of a naive subject is absurdly naive: even pigeons can do better than that. Similarly, the behavior of the sophisticated subject is absurdly sophisticated: even the most intelligent human being would struggle to foresee as much as she does. The truth probably lies somewhere in between.

Theoretical Bases

A basic principle of human and animal behavior is that organisms tend to carry out voluntary actions which lead to rewarding outcomes. Couched in such simple terms, this principle conveys little information, because the terms 'voluntary action' and 'rewarding outcome' are defined with reference to one another, leading to a proposition that is essentially circular. The problem is not resolved merely by replacing the everyday notions of voluntary action and reward by technical terms such as 'operant behavior' and 'reinforcement.' What is needed is first a formal statement of the reinforcing relation which allows the key terms to be defined rigorously, and second a means of anchoring the statement to some underlying biological mechanism. The burden of fulfilling the first requirement has been shouldered variously by psychologists, behavioral ecologists, and economists, while the task of addressing the second requirement has been taken on by behavioral neuroscientists. While considerable advances have been made with each of these endeavors, a complete understanding of reward-motivated behavior awaits a successful integration of the two approaches. This article argues that one area where such an integration is nearly within reach is the analysis of the effects of delayed reinforcement.

It is generally agreed that the efficacy or 'value' of a reinforcer is an inverse function of its delay. Specifying the mathematical form of this function is an important step in the direction of defining the reinforcement process. Choice schedules have played a crucial part in establishing the nature of this function. Faced with a choice between two reinforcers of different sizes, animals will, other things being equal, prefer the larger one. Similarly, faced with a choice between two reinforcers associated with different delays, animals will, other things being equal, prefer the one that can be obtained sooner. In real life, of course, other things are seldom equal, and choice between rewarding outcomes inevitably involves consideration of the relative merits of the two rewards along more than one dimension. For example, in the situation that has been most extensively studied in the operant behavior laboratory, the study participant must choose between a smaller reinforcer that may be obtained after a brief delay and a larger reinforcer whose delivery is considerably postponed; in such an 'intertemporal choice' situation, the participant's choice behavior necessarily reflects the influences of both size and delay of reinforcement.

In a pioneering experiment by George Ainslie, pigeons repeatedly chose between a smaller reward, A, delivered after a delay d_A, and a larger reward, B, delivered after a longer delay, d_B. With d_A set at zero, the birds showed a strong preference for A. However, when both delays were progressively increased by the same amount, D, preference for A weakened, and eventually reversed, so that at high values of D the birds actually preferred B to A. Ainslie's demonstration of preference reversal delivered, in the eyes of many psychologists, the coup de grâce to models of choice based on classical microeconomic theory, in which the value of a commodity is presumed to decline exponentially as a function of delay. Exponential delay discounting is epitomized by eqn [1]

$$V = q\mathrm{e}^{-kd} \qquad [1]$$

where V is the hypothetical value of a reward, q is its size or quantity, d is delay, and k is an exponential decay parameter. In keeping with economic notions of 'rational choice,' exponential delay discounting functions decline in parallel (provided that k is held constant), with the result that if A is preferred to B when their respective delays are d_A and d_B, A will still be preferred to B when their delays are $d_A + D$ and $d_B + D$. However, as pointed out by Ainslie, preference reversal is entirely compatible with hyperbolic delay discounting, as shown in **Figure 1**.

An elegantly simple statement of hyperbolic delay discounting, championed by James Mazur, is given in eqn [2]

$$V = \frac{q}{1 + Kd} \qquad [2]$$

where K is a parameter expressing the rate of (hyperbolic) delay discounting.

In fact, exponential discounting (eqn [1]) can be made to accommodate preference reversal, provided that k is allowed to vary inversely with q, in other words, if the rate of discounting is allowed to be higher for small reinforcers than for large ones. Such may indeed be the case when humans make choices between hypothetical monetary reinforcers. However, there is good evidence that this so-called 'magnitude effect' does not apply when animals make choices between food reinforcers, suggesting that eqn [2] is to be preferred to eqn [1].

Figure 1 Ainslie's theoretical account of preference reversal, based on the principle of hyperbolic delay discounting. The vertical lines represent the instantaneous values of a large (continuous line) and a small (broken line) reinforcer. The curves show the decline in value that results from imposition of a delay between the response and the delivery of the reinforcer. At the indifference point ('preference reversal'), the values of the two reinforcers are equal. If the organism makes its choice when the delay to the small reinforcer is relatively short (i.e., at a delay value to the right of the indifference point), the smaller reinforcer is preferred. If the delays to both reinforcers are increased, so that the organism is required to make its choice at some time point to the left of the indifference point, the larger reinforcer will be preferred. Note that the intersecting value curves are a consequence of hyperbolic discounting (exponential discounting gives rise to curves that decline in a parallel fashion: see text).

Recent work in our laboratory suggests that eqn [2] somewhat oversimplifies the discounting function. The problem arises from the fact that eqn [2] implies that, if d is held constant, V is directly proportional to q, the physical size of the reinforcer. There are, however, good reasons to doubt this supposition. For instance, when rats make choices between reinforcers consisting of different numbers of food pellets, preference for the larger reinforcer is stronger when the two reinforcers consist of one and two pellets than when they consist of three and six pellets. This suggests a nonlinear relation between V and q. According to one model, the 'multiplicative hyperbolic model' (MHM), the relation is hyperbolic, as defined by eqn [3]

$$V = \frac{q}{q+Q}\,\frac{1}{1+Kd} \qquad [3]$$

where Q is a parameter which modulates the effect of reinforcer size upon value. It should be emphasized at this point that the role of Q is not merely to explain away embarrassing departures from the straightforward predictions of eqn [2]. As will be seen later in this article, neurobiological interventions can alter animals' choices between reinforcers by altering their sensitivity to delay and/or their sensitivity to size. Q provides a vehicle for formalizing and quantifying the effects of interventions on sensitivity to reinforcer size.

According to MHM, eqn [3] may be expanded in order to accommodate the effects of other variables on reinforcer value. For example, probability of reinforcement, p, can be accommodated thus:

$$V = \frac{q}{q+Q}\,\frac{1}{1+Kd}\,\frac{1}{1+H\theta} \qquad [4]$$

where θ is the odds against the occurrence of the reinforcer ($[1/p] - 1$) and H is a an odds-discounting parameter. Equation [4] allows risky choice, a matter of great interest to students of foraging behavior, to be considered within the framework of MHM.

It will not have escaped the reader's notice that V is not a directly measurable quantity. As an intervening variable, it is useful only to the extent that it can be linked to some explicit feature of behavior. Two ways of dealing with V can be found in the literature. The first approach is to link it to notions of 'response strength' and to infer changes in V from changes in the rate or vigor of responding. The second approach is to write equations which allow V to be canceled out; this is the indifference or null equation approach. The fundamental assumption underlying the derivation of indifference equations is that when the animal displays indifference between two reinforcers, A and B, their values are equal: $V_A = V_B$. This equality may be expanded using the definition of V specified by eqn [4], and then reduced to simple relations among the quantitative features of the two reinforcers. For example, in an experiment in which an animal makes choices between a small reinforcer, A, delivered after a short delay and a larger reinforcer, B, delivered after a longer delay, the delay to B that results in indifference between A and B ($d_{B(50)}$) is a linear function of the delay to A (d_A):

$$d_{B(50)} = \frac{1}{K}\left[\frac{q_B(Q+q_B) - q_A/(Q+q_A)}{q_A/(Q+q_A)}\right] + d_A\left[\frac{1+Q/q_A}{1+Q/q_B}\right] \qquad [5]$$

Equation [5] is one member of a family of null equations that may be derived to describe indifference between two reinforcers; it is particularly suited to experiments in which the sizes of the two reinforcers are held constant and delays are systematically varied (see **Figure 2** for an example). Other equations can be derived to describe situations in which size, rather than

Figure 2 Derivation of a linear indifference function: example of data obtained from one rat. (a) Preference functions: percent responding on lever B (%B) is plotted against the delay to the larger of two reinforcers (d_B). Each plot shows the data obtained from one phase of the experiment, in which the delay to the smaller reinforcer (d_A) was fixed at the value shown in inset panel. The horizontal line signifies indifference (%B = 50), and the vertical lines indicate the indifference delays ($d_{B(50)}$) obtained in each phase (values shown under the abscissa). (b) Linear indifference function ($d_{B(50)}$ vs d_A) derived using the indifference delays shown in (a). The fitted line is the linear function specified by eqn [5]. Unpublished data from Kheramin S, Body S, Bradshaw CM, Szabadi E, Deakin JFW, and Anderson IM.

delay, is systematically manipulated, or in which reinforcer probability is the variable of interest.

As well as specifying the form of the indifference relation (in the case of eqn [5], a linear relation), null equations also offer a means of characterizing the effects of interventions on the discounting parameters. A more ambitious goal, which, unfortunately, is often thwarted by the intrinsic variability of the behavioral data, is to derive quantitative estimates of the discounting parameters pertaining to individual animals. For example, the slope of the linear function specified by eqn [5] is determined entirely by the sizes of the two reinforcers and the size-discounting parameter Q. The delay-discounting parameter K may be obtained using the formula $K = (\text{slope} - 1)/\text{intercept}$.

Indifference equations highlight a feature of choice behavior which has important implications for neurobiological analyses of reinforcement processes: choice usually entails a compromise. In the situation characterized by eqn [5], the compromise is one between size and delay. Indifference implies that a balance has been struck between the competing attractions of the larger size of reinforcer B and the shorter delay associated with reinforcer A. This balance can be upset, and hence the indifference point displaced, by altering the animal's sensitivity to either size or delay of reinforcement, or both. This is illustrated in **Figure 3**, which shows the effects of hypothetical interventions on the linear indifference function defined by eqn [5]. The left-hand graph shows the effect of an intervention that alters sensitivity to delay (via an increase in K), the middle graph shows the effect of an intervention that alters sensitivity to size (via a reduction of Q), and the right-hand graph shows the effect of an intervention that alters sensitivity to both of these features of reinforcers (via increases in both K and Q).

If the foregoing analysis is correct, it follows that the reluctance of an individual animal to select the larger and more delayed of two reinforcers does not necessarily indicate that it is especially sensitive to delay of reinforcement; it is equally possible that it differs from its peers only in its sensitivity to the relative sizes of the two reinforcers. Therefore, interpretation of induced shifts of preference favoring smaller, less delayed reinforcers in terms of 'accelerated delay discounting' or 'delay aversion' should be made with due caution. Moreover, the time-honored anthropomorphisms 'impulsive' and 'self-controlled' choice have little to recommend them. While they have served a useful purpose in highlighting the distinction between different uses of the term 'impulsiveness' in clinical and lay discourse, in particular the distinction between impulsive choice (selection of smaller earlier reinforcers) and impulsive action (acting rapidly in situations where delay is advantageous), they can be seriously misleading if they are identified with hypothetical behavioral processes. As we have seen, models such as MHM imply that altered sensitivity to delay of reinforcement is neither a necessary nor a sufficient condition for a shift in preference in favor of smaller earlier reinforcers.

Figure 3 Effects of three hypothetical interventions on the linear indifference function defined by MHM (eqn [5]). Ordinates: indifference delay to the larger of two reinforcers, $d_{B(50)}$; abscissas: delay to the smaller reinforcer, d_A. In each graph, the broken line represents the 'baseline' function and the continuous line represents the function derived in the presence of an intervention that alters the delay-discounting parameter, K (left-hand graph), the size-discounting parameter, Q (middle graph), or both parameters (right-hand graph). Note that preference for the smaller, earlier reinforcer (A) can be promoted by either an increase in K or a reduction of Q, but the slope of the function is altered only in the latter case. If K and Q are both increased, the baseline and altered functions may intersect, resulting in stronger preference for A at low values of d_A, and weaker preference for A at high values of d_A, in the presence of the hypothetical intervention.

Methodology

Numerous methods have been devised to investigate intertemporal choice behavior. A full description of these methods is beyond the scope of this article, and the interested reader is referred to the articles listed in the 'Further reading' section. Some of the most commonly used approaches are outlined in this section.

Free-Operant Concurrent Schedules

In these schedules, the study participant has continuous access to two operanda that are associated with different outcomes. One type of concurrent schedule that lends itself well to studies of delayed or probabilistic reinforcement is the concurrent-chains schedule, in which equal initial-link schedules (e.g., a pair of concurrent variable-interval schedules) provide access to mutually exclusive terminal-link schedules (e.g., response-independent reinforcer delivery following different delays). Relative response rate in the initial links provides the measure of preference, and equality of response rates is taken to indicate equality of the reinforcing values of the terminal links. Of course, precise indifference may not be obtained in any one pair of schedules; however, the indifference point may be estimated from a series of concurrent schedules by application of the 'generalized matching law.'

The 'time-left' procedure is a concurrent chain schedule which yields continuous, graded measure of preference. Equal initial-link schedules provide access, at unpredictable times after the start of a trial, to two mutually exclusive terminal links which deliver reinforcement either after a fixed delay or, after a variable delay, at the end of the trial. Early in the trial, the fixed delay is shorter than the variable delay, whereas toward the end of the trial, the variable delay is shorter. Preference for the variable delay accordingly increases from approximately zero at the start of the trial, to near 100% at the end of the trial. The locus of the indifference point (50% choice of the variable delay) depends on the length of the fixed delay and the sizes of the reinforcers offered in the two terminal links. It has been shown that the indifference delay is a linear function of the length of the fixed delay, in accord with eqn [5].

Discrete-Trials Concurrent Schedules

These schedules comprise a series of trials in each of which the participant chooses between two mutually exclusive alternatives. Preference is measured as proportional choice of one alternative across a number of trials. Discrete-trials concurrent schedules tend to engender exclusive preference; this is the expected outcome of repeated exposure to choice between mutually exclusive alternatives, A and B, since alternative A will always be chosen whenever $V_A > V_B$, and vice versa (see earlier). However, indifference points may be determined by systematic manipulation of a relevant independent variable (e.g., delay to one reinforcer), and estimation of the value of that variable corresponding to 50% choice of each alternative.

Conventional T-maze tasks are a type of discrete-trials concurrent schedule; they can be adapted to the study of intertemporal choice by delaying reinforcer delivery in one of the goal boxes by some specified time. Most studies employing T-maze tasks have used proportional choice of the delayed reinforcer as a simple measure of preference, a measure which can

only yield an indifference point if preference is tested using a range of delays.

J. L. Evenden and C. N. Ryan introduced a protocol for examining the effect of delay in a discrete-trials lever-pressing task. In each free-choice trial, lever A delivers a small reinforcer immediately, whereas lever B delivers a larger reinforcer after a delay, d_B; d_B is progressively increased in successive blocks of trials. The value of d_B at which preference switches from B to A may be taken as the indifference delay, $d_{B(50)}$. In our laboratory, the method has been extended, using a range of delays to the smaller reinforcer (d_A), to enable linear indifference functions to be obtained between $d_{B(50)}$ and d_A, as prescribed by MHM.

An important technical development in the estimation of indifference points was Mazur's introduction of the adjusting delay schedule. In this schedule, the participant undergoes a series of trials in which the sizes of the two reinforcers and the delay to the smaller reinforcer are fixed, while the delay to the larger reinforcer is allowed to vary in accordance with the participant's choices. When the participant shows a preference for the larger reinforcer, the delay to that reinforcer is increased; when preference shifts to the smaller reinforcer, the delay to the larger reinforcer is reduced. Extended training on this schedule results in the establishment of a quasi-stable delay to the larger reinforcer, which is taken as the indifference delay.

J. B. Richards and colleagues have devised a variant of Mazur's method, the adjusting-amount schedule, in which rats make repeated choices between a delayed liquid reinforcer of fixed volume and an immediate reinforcer, the volume of which is adjusted in accordance with the animals' choices. The volume of the variable reinforcer at which indifference is achieved is often taken as an index of the 'value' of the fixed-volume delayed reinforcer. However, it should be noted that the logic of this method is based on the assumption that value is linearly related to reinforcer size, in accordance with eqn [2], an assumption that is contradicted by models such as MHM, which assume that value is constrained by an asymptotic function such as that defined by eqn [3]. An important practical advantage of the adjusting-amount schedule is the rapid (within-session) attainment of stable indifference that has been reported in many studies.

Effects of Neurobiological Interventions on Choice of Delayed Reinforcers

The 5-Hydroxytryptaminergic Pathways

Twenty years ago, Phillipe Soubrié proposed that the ascending 5-hydroxytryptaminergic (5-HTergic, or serotonergic) pathways may play an important role in enabling organisms to tolerate delay of reinforcement, and that dysfunction of these pathways might therefore promote selection of small immediate reinforcers in preference to larger delayed reinforcers. Several studies have since investigated the effects of lesions of the 5-HT pathways, and acute treatment with drugs whose mode of action is believed to involve these pathways, on choice between small immediate and large delayed rewards. Unfortunately, these experiments have produced varied, and sometimes conflicting, results. The results of experiments investigating the effects of central 5-HT depletion are summarized in Table 1.

Several early experiments employed intraraphe injections of the selective neurotoxin 5,7-dihydroxytryptamine (5,7-DHT) to destroy the ascending 5-HTergic pathways. These studies generally indicated that loss of central 5-HT was associated with a shift of preference toward smaller, less delayed reinforcers.

Table 1 Effects of central 5-HT depletion on intertemporal choice behavior

5,7-DHT, 5,7-dihydroxytryptamine; i.c.v., Intracerebroventricular injection; *p*cpa, *p*-chlorophenylalanine.

More recent experiments, generally employing intracerebroventricular injections of the same neurotoxin, have not replicated this result. The reason for this discrepancy is unclear; obvious candidates are different techniques for inducing 5-HT depletion and different behavioral paradigms used to measure choice behavior. A weakness of most of these studies is the use of a single preference function or indifference point, which, as discussed previously, can cloud the interpretation of any changes observed. However, this is unlikely to be the sole reason for the discrepant results, because the only study to have used a multiple-indifference-point approach found that 5-HT-depleted rats showed a parallel displacement of the linear indifference function defined by eqn [5], consistent with a selective increase of the delay-discounting parameter K (see **Figure 3**, left-hand graph). This pattern of effect implies that the shift of preference favoring smaller earlier reinforcers should occur at all values of delay, and therefore the outcome of the experiments should not have been affected by the use of different delays in different experiments. The possible role of the 5-HTergic pathways in risky choice is a largely unexplored area. Two recent studies found no evidence that 5-HT depletion promotes selection of large low-probability rewards (a putative model of gambling); however, this is clearly a topic that requires further research.

There have been some attempts to explore the effects of drugs that interact with 5-HTergic mechanisms on intertemporal choice. Earlier studies, which mainly used T-maze-based choice paradigms, reported that 5-HT uptake-inhibiting drugs generally promoted choice of the larger, more delayed of two reinforcers, in keeping with Soubrié's proposal that endogenous 5-HT contributes a restraining influence on the selection of small immediate gains. More recent experiments, using discrete-trials operant procedures, have indicated that 5-HT_{1A} receptor stimulation tends to promote the selection of smaller earlier reinforcers, possibly via an interaction between 5-HTergic and dopaminergic mechanisms in the ventral striatum. Unfortunately, all these studies have examined the effects of drugs on a single preference function. Confirmation that the reported effects reflect changes in the rate of delay discounting must await the results of parametric studies that allow clear separation of delay discounting from sensitivity to reinforcer size.

The Dopaminergic Pathways

The possibility that the central dopaminergic pathways may contribute to the control of behavior by delayed reinforcement has attracted considerable interest because of the putative involvement of dopaminergic dysfunction in attention-deficit/hyperactivity disorder (ADHD), a condition in which 'impulsiveness' is a prominent feature. Unfortunately, a clear picture of dopamine's role in intertemporal choice has yet to emerge.

Selective dopamine depletion from the nucleus accumbens and local injection of dopamine receptor antagonists into this region have generally been found to have little effect on preference for the smaller and earlier of two reinforcers. This is in contrast to the effect of excitotoxic lesions of this structure, which have been found to promote the selection of small immediate reinforcers (see later). In one study, injection of the selective catecholamine-depleting neurotoxin 6-hydroxydopamine into the orbital prefrontal cortex (OPFC) had a complex effect on intertemporal choice, promoting the selection of the larger, more delayed reinforcer to an increasing degree as the delay to the smaller reinforcer was progressively increased (see **Figure 3**, right-hand graph). This finding can be interpreted on the basis of MHM (eqn [5]) in terms of a dual effect on delay discounting (K was increased) and sensitivity to relative reinforcer size (Q was increased).

A number of studies have investigated the effects of systemic treatment with psychostimulant drugs, which facilitate dopaminergic function. Earlier studies yielded disconcertingly disparate results; however, it now seems that these apparently inconsistent findings may be reconcilable. As shown in **Table 2**, there are reports that the catecholamine-releasing agent amphetamine can promote the selection of either the smaller immediate reinforcer or the larger delayed reinforcer in intertemporal choice schedules. A methodological factor whose importance has come to light in more recent experiments is the presence or absence of a cue during the delay interval. There are theoretical and empirical reasons for believing that an intradelay cue functions as a conditioned reinforcer whose reinforcing efficacy is inversely related to the duration for which it is presented. Consistent with this notion, it has been found that rats generally tolerate much longer delays to reinforcement when a cue is presented during the delay than when no cue is provided. Since amphetamine and related drugs are believed to enhance the effect of conditioned reinforcers, it might be expected that these compounds would promote the selection of the more delayed of two reinforcers when the delay is signaled by an explicit cue, and this indeed turns out to be the case. In the absence of such a cue, the predominant effect of amphetamine is to promote selection of the smaller earlier reinforcer. Unfortunately there are no published studies that have

Table 2 Effects of amphetamine and related drugs on intertemporal choice behavior

[b]Dose-dependent effect: lower doses promoted choice of the larger reinforcer, higher dose promoted choice of the smaller reinforcer.

incorporated a range of indifference points, and therefore it remains unknown whether the effects of amphetamine on intertemporal choice reflect a selective influence on delay discounting.

The Nucleus Accumbens Core

Excitotoxic bilateral destruction of the nucleus accumbens core (NAC) has been found to displace preference functions in favor of smaller immediate reinforcers. However, it has yet to be established, on the basis of parametric studies, whether this is due to facilitation of delay discounting.

The Prefrontal Cortex

Excitotoxic lesions of the ventral–medial and dorsal–medial (anterior cingulate) prefrontal cortex have been found to have no effect on intertemporal choice behavior. However, destruction of the OPFC produced a complex pattern of effect (Figure 4); preference was minimally affected when short delays to the smaller reinforcer (d_A) were employed, whereas the lesion promoted preference for the larger reinforcer to an increasing degree as d_A was progressively increased. Analysis of the linear indifference functions using MHM (eqn [5]) indicated that the OPFC-lesioned subjects had a higher rate of delay discounting (K was increased) and a greater sensitivity to relative reinforcer size (Q was increased) compared to sham-lesioned control subjects.

Future Directions

There is, as yet, no unanimous agreement on the most appropriate model of delay discounting; however, there is a good level of agreement about the range of phenomena that a successful model should accommodate – preference reversal and indifference functions are prominent among these phenomena. More controversial is the issue of how the influences of different features of reinforcers, for example, delay and magnitude, may be disentangled. The model advocated in this article (MHM) is an attempt to address this problem; while we make no claim that MHM is unique in this respect, we are convinced that formal models, of which MHM is one example, can provide a framework for quantifying the effects of various features of reinforcers, which may be of considerable help in the quest to identify the neurobiological substrate of choice behavior.

Emerging evidence for the involvement of the NAC and OPFC in intertemporal choice, discussed earlier, is of particular interest in the light of recent neurophysiological evidence that these structures are active during prereinforcer delays. It has been suggested that neural activity in these areas may help the organism to bridge the gap between an operant response and a rewarding outcome, and may therefore play an important role in 'anticipation' of rewarding events. An important question that should be addressed in future research is whether the putative involvement of these structures in intertemporal choice reflects their

Figure 4 The effect of excitotoxin-induced lesions of the OPFC on intertemporal choice. (Left-hand graphs) Preference functions: percent responding on lever B (%B) is plotted against the delay to the larger of two reinforcers (d_B). Each plot shows the data obtained from one phase of the experiment, in which the delay to the smaller reinforcer (d_A) was fixed at the value shown in the inset panel. The horizontal line signifies indifference (%B = 50). Introduction

Dementia is derived from the Latin words for 'away/from' (*de*) and 'mind' (*mens*), and is defined as an abnormal decline in cognitive function, with relative sparing of alertness and attention, that results in a significant change from the normal premorbid functioning of an individual.

Dementia generally is defined by decline in two or more domains of cognitive function, usually including memory. Neuropsychological testing can be used to test different cognitive domains, and can also be used to compare an individual to normal controls of the same age and education level. Mild cognitive impairment (MCI) has emerged as a term that describes an intermediate stage between 'normal' aging-related cognitive decline, also called benign forgetfulness of aging, and dementia. MCI indicates that cognition has declined from previous levels, or is abnormal compared to age- and education-matched controls, but that deficits are not severe enough to impair social or occupational functioning. It is when deficits impair daily functioning that the severity criterion for dementia is reached. It should be noted that this definition can be remarkably imprecise; given the same performance on neuropsychological testing, an individual in an intellectually demanding profession could meet the criterion for dementia, whereas another individual with few daily intellectual demands might not. Thus, the clinical distinction between MCI and dementia may not be sharp. The pathological distinctions between MCI and dementia also appear imprecise, as studies suggest that the pathology underlying MCI is often that of early Alzheimer's disease (AD), the most common cause of dementia.

An important point in educating patients is that dementia is not a specific diagnosis, but rather a symptom that can result from many different disorders. The most common causes of dementia include AD and other neurodegenerative diseases, vascular dementia, and the (pseudo) dementia of depression (Table 1).

Decline from previous functioning distinguishes dementia from mental retardation. However, individuals with mental retardation can also develop a superimposed dementia, as generally occurs in individuals with Down syndrome, who develop AD-like neuropathology and dementia as they age. Another key distinction is the difference between dementia and delirium; the latter state is also referred to as encephalopathy or acute confusional state. In delirium, the predominant abnormality is a disturbance of alertness or attention. It is important to note that delirium is not a specific diagnosis, but, like dementia, is a symptom that can result from many different causes. However, whereas the usual causes of dementia are neurodegenerative diseases, the typical causes of delirium are toxic–metabolic derangements. Thus, delirium is often characterized as acute and reversible, and dementia as chronically progressive and irreversible, though these are really characteristics of the typical diseases causing delirium and dementia, and not inherently of delirium and dementia. It is also important to note that dementia and delirium frequently co-occur. Some diseases, such as dementia with Lewy bodies, may cause both delirium and dementia. In addition, patients with dementing illnesses are more prone to develop delirium in response to urinary tract infections, medication adjustments, anesthesia, or even simple changes in environment. 'Sundowning' refers to the disorientation and agitation that can develop as night falls in cognitively impaired elderly persons removed from the familiar and comforting surroundings of their own homes. In fact, delirium often provides the first indication of an incipient dementia that had previously not been recognized.

Dementia and delirium should be viewed as symptoms, each term designed to trigger a search for specific causative diseases. As with the rest of neurology, the key features in the diagnosis of dementing diseases are the time course and pattern of anatomical involvement. A subacute, rapidly progressive course suggests Creutzfeldt–Jakob disease (CJD) or paraneoplastic limbic encephalitis, whereas insidious onset and slow progression suggest chronic neurodegenerative diseases. Within the neurodegenerative diseases, the key differentiating feature is the pattern of anatomical involvement, particularly early in the course of the illness. Prominent early involvement of memory (hippocampus) and naming or visuospatial function (temporoparietal polymodal association cortices) is strongly suggestive of AD. In contrast, when nonfluent aphasia or bizarre inappropriate behavior is prominent early in the course, the diagnosis is likely to be frontotemporal degeneration (FTD). In addition to the history of the present illness and the neurobehavioral examination, use of techniques such as brain imaging, including magnetic resonance imaging (MRI), single-photon emission tomography (SPECT), and positron emission tomography (PET) may assist in defining the pattern of anatomical involvement. A detailed workup also includes obtaining a family history, social history

Table 1 Major categories of dementia

Neurodegenerative diseases
Alzheimer's disease
Parkinson's disease and diffuse Lewy body disease
Frontotemporal dementia (Pick's disease; corticobasal degeneration; progressive supranuclear palsy)
Trinucleotide repeat neurodegenerative diseases
(Huntington's disease; spinocerebellar ataxias, multiple system atrophies)
Creutzfeldt–Jakob disease (prion diseases)
Storage diseases (i.e., leukodystrophies)
Dementia pugilistica
Vascular dementias
Psychiatric diseases (dementia of depression, schizophrenia, among others)
Toxic–metabolic encephalopathies (toxins, infectious, endocrine, vitamin deficiency, nutritional, systemic illness, inborn errors of metabolism)
Structural brain lesions and other neurological diseases
Brain trauma
Chronic subdural hematoma
Brain tumors (i.e., frontal meningioma)
Paraneoplastic limbic encephalitis
Normal pressure hydrocephalus
Obstructive hydrocephalus
Granulomatous diseases (i.e., sarcoid)
Multiple sclerosis
Epilepsy

(including alcohol intake, history of smoking, and possible exposures to toxins), list of medications, and prior and current medical conditions.

The pathophysiology of specific diseases is discussed within each of the following sections. The key observation, in overview, is that aging is by far the most important risk factor for the neurodegenerative diseases causing dementia, although the underlying biological mechanisms are only incompletely understood. Genetic predispositions and cumulative damage from oxidative stress are among the leading hypothesized mechanisms of age-related cognitive decline. Reduced function of normal cellular degradative systems, such as the endosomal–lysosomal and ubiquitin–proteasome systems, also appears to be important. Indeed, neurodegenerative diseases of aging are increasingly linked with the aberrant accumulation of cellular deposits. Altered age-related cardiovascular function also appears to contribute significantly to the age-related decline in cerebral function.

Dementia typically implies a progressive decline in function over months to years, although dementia can be precipitated acutely, such as from a stroke or head trauma. Dementia can present as a more focal alteration of cognitive function other than memory, as occurs with subcategories of FTD, such as progressive aphasia. AD generally presents with more localized symptoms attributable to short-term memory loss (amnesia), which in its earliest stages can be defined as amnestic MCI. Word-finding difficulties and orientation difficulties in relation to previously familiar surroundings are other common early features of AD. AD is often described as a temporal–parietal dysfunction, since the medial temporal lobes (memory consolidation, language) and parietal lobes (visuospatial function) are involved relatively early in the disease process, compared to FTD, in which frontal (executive function) and lateral temporal (language) lobes are preferentially involved early on. Evidence for selective, compared to more general, cerebral dysfunction can be obtained from the medical history of a patient and from neurobehavioral testing and brain imaging.

The care of demented patients scales in accord with functional ability, often categorized as mild, moderate, or severe. In mild dementia, self-care activities of daily living, such as eating, dressing, and personal hygiene, are not impaired. In moderate dementia, these activities are impaired, though they can still be accomplished with verbal cuing or other simple assistance. In severe dementia, the caregiver provides almost complete support. In such cases, meticulous nursing care is an important determinant of survival. The cause of death in severe dementia is typically from infections, due especially to aspiration, urosepsis, or decubitus ulcers.

The broad differential diagnosis that needs to be considered in the clinical workup of dementia stems from the multiple potential causes for reduced cognitive function in an individual. Normal cognition depends on the maintained connectivity and functioning of multiple interconnected neural circuits. Structural and chemical alterations can impair normal cognitive function. Alterations in the chemical milieu of neurons, from altered levels of electrolytes, oxygen, pH, or toxins, among others, can affect normal neuronal physiology and synaptic functioning. Side effects of medications often can affect cognition, and when they occur for months can be a cause of dementia, especially in the elderly.

Alzheimer's Disease

AD is the leading cause of dementia, estimated to occur in 50–75% of those afflicted by dementia. AD is characterized by an incipient and gradually progressive decline in cognitive function, with deficits especially in memory retrieval, semantic fluency, and visuospatial function. Loss of insight into cognitive deficits is a characteristic of AD. Although deficits in attention are uncommon and deficits in short-term memory are characteristic, impairment in other domains of cognition can be quite heterogeneous in AD. The diagnosis of AD is definitively confirmed only at

autopsy, when the typical dementia is found to be accompanied by sufficient numbers of cerebral amyloid plaques and neurofibrillary tangles. Loss of synapses is considered the best pathological correlate of cognitive decline in AD. Progressive cerebral atrophy and loss of neurons also characterize the disease. It is estimated that clinical diagnosis is accurate up to 95% of the time at specialized memory disorder clinics. Remarkably, age-related deposition of plaques and tangles is seen also in cognitively normal, aged individuals, and considerable neuropathology can be seen at the time of amnestic MCI. Functional imaging in genetically at-risk individuals indicates premorbid reductions in cortical activity that can precede a diagnosis of dementia by years to decades, suggesting that the prodrome of AD begins prior to overt symptoms.

Accumulation of β-amyloid peptides (Aβ), the principal component of plaques, is increasingly viewed as playing an important role in the pathogenesis of the disease (Figure 1). Several lines of evidence support that Aβ accumulation precedes and can induce tangle pathology. Genetic mutations in familial forms of early-onset AD (*PSEN1*, *PSEN2*, and *APP*, encoding presenilin 1, presenilin 2, and β-amyloid precursor protein; see Table 2) and genetic risk factors for late-onset AD (*apolipoprotein E* ε4 allele) have been shown to increase levels of Aβ in the brain. Aβ is a short, hydrophobic peptide that is cleaved from the larger type I transmembrane precursor protein, β-amyloid precursor protein (APP). Aβ peptides aggregate easily, especially the disease-linked Aβ42 form. The molecular mechanism whereby Aβ is involved in AD pathogenesis remains unclear, although increasing evidence links Aβ to alterations at synapses. More recently, accumulation of Aβ42 has been shown to occur within neurons (i.e., intracellularly) prior to the characteristic extracellular Aβ plaques. For example, there is early intracellular Aβ accumulation within disease-prone neurons in individuals with Down syndrome (trisomy 21), who invariably develop β-amyloidosis and dementia in their 30s and 40s, due to triplication of the *APP* gene located on chromosome 21. One can speculate that effects of intraneuronal Aβ accumulation may play a role in the observations of premorbid reductions in cerebral activity noted in individuals at risk for AD. Emerging experimental treatment strategies for AD are increasingly targeting reduction in Aβ.

Environmental risk factors for the development of AD include a history of head trauma associated with loss of consciousness, reduced educational attainment, and diet-related cardiovascular risk factors. Epidemiological studies suggest that increased physical and cognitive activities reduce the risk of developing AD.

Current treatment in AD has centered on findings from the 1970s and 1980s demonstrating that acetylcholine levels are especially reduced in AD brains. Cholinesterase inhibitors are the main class of currently employed US Food and Drug Administration (FDA)-approved medications for the symptomatic treatment of AD, although benefits, when present, tend to be modest, at best. The most recently approved medication for AD is an atypical *N*-methyl-D-aspartate (NMDA) antagonist; although the mechanism whereby it can

Apolipoprotein E (*APOE*, ε4 allele; chromosome 19)

provide benefit in the disease currently is poorly understood.

Vascular Dementias

Vascular-related damage to the brain can occur from different etiologies and probably is the second most common cause of dementia. A large embolic stroke can result in an acute onset of dementia. In contrast, multiple small 'lacunar' strokes can cause a more gradual, although usually stepwise, vascular dementia. Transiently reduced perfusion to the brain, such as occurs during cardiac arrest, can cause ischemic damage to vulnerable areas of the brain, including the hippocampus, thereby resulting in an amnestic dementia. Strategic infarct dementia is caused by a relatively small stroke in a part of the brain that is especially critical for cognition.

Vascular damage is also commonly observed in AD, and epidemiological studies are increasingly linking established cardiovascular risk factors, such as elevated cholesterol and diabetes, to an increased risk of AD. Progressive microvascular ischemic disease, especially of the periventricular white matter, formerly called Binswanger's disease, is another form of vascular dementia. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) due to mutations in Notch3 manifests with psychiatric disturbances, migraine, and strokes, and can result in dementia. Hereditary cerebral amyloid angiopathies (CAA) cause amyloidosis within the cerebral blood vessels and can cause dementia, especially from lobar hemorrhages. CAA is a common co-occurrence in AD, although specific mutations in *APP* or *BRI* genes can cause more localized amyloidosis of the cerebral vasculature in the relative absence of parenchymal amyloidosis.

Frontotemporal Dementia

FTD includes a group of previously separately classified diseases that have clinical, pathological, and genetic overlap. Formerly known as Pick's disease and frontotemporal lobar degeneration, FTD also includes semantic dementia and progressive nonfluent aphasia. Other studies are incorporating corticobasal (cortical–basal ganglionic) degeneration and even progressive supranuclear palsy (PSP) in an extended classification of FTD. FTDs are often misdiagnosed as AD. Early symptoms in FTD that can help differentiate it from AD are behavioral in nature; these include especially changes in personality, such as the development of inappropriate behavior or apathy. FTD is generally separated into types that affect behavior or language early on. Subtypes of FTD can be associated with concomitant parkinsonism or motor neuron disease. Common neuropathology features include the presence in many cases of neurofibrillary tangles and/or Pick bodies in the absence of Aβ plaques. Familial mutations in the principal component of tangles, the microtubule-associated protein tau, have been linked with some forms of FTD.

In contrast to AD, consolidation and retrieval of new memories are relatively spared in the early stages of FTD. At the same time, the early involvement of frontal lobes, with resultant behavioral alterations and/or impairment in executive functions (planning, reasoning, fluency, set shifting) can lead to apparent reduction in memory function, though recall is often assisted by cueing. Individuals with FTD can show signs of early dysfunction in complex attention and concentration, which are important for remembering. Structural imaging can show focal lobar atrophy of frontal and lateral temporal lobes, or with corticobasal degeneration, of superomedial frontal and parietal lobes.

Parkinson's Disease

Dementia is a frequent component of Parkinson's disease (PD). PD neuropathology is characterized by eosinophilic cytoplasmic inclusions within neurons containing α-synuclein and ubiquitin, called Lewy bodies. Lewy body diseases encompass PD and Lewy body dementia (or diffuse Lewy body disease), which can be viewed as a clinical–pathological spectrum differentiated by initial clinical symptoms and site of pathology. Initial Parkinsonism, characterized by psychomotor slowing, resting tremor, rigidity, and hunched posture/gait disturbance, in the setting of Lewy body pathology predominantly in the substantia nigra, pars compacta, is characteristic of PD. Initial cognitive decline, followed later by Parkinsonism (usually without tremor) and Lewy bodies predominantly in the cerebral cortex, is characteristic of Lewy body dementia. Lewy body dementia is characterized by visual hallucinations early in the course of the disease (within the first 2 years). The course of Lewy

body dementia may also include episodes of delirium not explained by infection or other toxic–metabolic derangement. Treatment with cholinesterase inhibitors can provide modest benefit. The neuropathology of AD is a frequent co-occurrence when prominent cortical Lewy bodies are present, prompting use of the term 'Lewy body variant of Alzheimer's disease.'

Psychiatric Diseases

Dementia of depression is a leading diagnosis among patients presenting with complaints of cognitive decline. Depression can cause subtle to profound cognitive deficits in multiple areas of cognition. The cognitive findings are typically characterized by prominent impairment in attention and concentration. Amnesia and other focal cognitive deficits, such as aphasia, are not characteristic of depression. Continued social stigma associated with psychiatric diseases can make diagnosis difficult. In contrast to AD, in which individuals often deny significant cognitive dysfunction, cognitive complaints are often pronounced in depression. At times, individuals may not be aware that they are depressed. Neurovegetative symptoms, particularly involving sleep and appetite, weight changes, loss of interest in previously enjoyable activities, and increased crying, can provide clues to the presence of depression. Cognitive dysfunction can markedly improve and normalize upon treatment of depression. Depression and AD are not mutually exclusive, but in fact co-occur frequently. New-onset depression in the elderly has been associated with an increased incidence in developing subsequent AD. Interpretation of the mechanism whereby depression might relate to AD is complicated by AD neuropathology also selectively affecting neurotransmitter systems involved in depression, such as the serotonergic system. Other psychiatric conditions, such as schizophrenia, formerly referred to as dementia praecox, can also cause dementia.

Toxic–Metabolic Encephalopathies

Although more typically a cause of delirium, various insults that can transiently alter cognitive function can also be a cause of dementia, when the insult persists (i.e., medication side effect) or damage is irreversible (i.e., toxins). Toxic–metabolic encephalopathies are generally characterized by a more global cognitive dysfunction, although toxins and nutritional deficiency can also cause more focal damage. Toxins that can cause dementia are numerous and most prominently include alcohol abuse. Chronic alcoholism can result in Wernicke–Korsakoff's syndrome, which is characterized by amnesia and confabulation. Acute (i.e., herpes encephalitis) and chronic (i.e., HIV/AIDS, syphilis, Lyme disease, chronic meningitis) infections can cause dementia. Prion diseases can be categorized either among the toxic–metabolic encephalopathies due to prion infectivity or as neurodegenerative diseases, with which they share many features. Prion protein, similar to β-amyloid in AD, aberrantly accumulates in the brain in genetic (i.e., Gerstmann–Sträussler–Scheinker disease) or sporadic prion diseases. Hormonal alterations, especially from thyroid disease, need to be considered in the workup of dementia. Nutritional and vitamin deficiencies (i.e., B_{12}, folate, and thiamine) can be causes of dementia. Various systemic illnesses, including collagen vascular diseases; pulmonary and hepatic disease, uremia, and anemia, need to be considered in the differential diagnosis of dementia. In contrast to most other causes of dementia, treatment of the underlying cause in toxic–metabolic dementias can halt or even reverse cognitive decline.

Effects of Dementia on Language

Language production begins with the formulation of a message and includes steps of discourse planning, lexical selection, and syntactic encoding. Language comprehension involves the analysis of discourse, syntactic, and lexical representations. Because of the many levels of analysis and the necessity of integrating information from all levels, both aspects of language use are compromised to some extent in all types of dementia beyond the small but significant effects of normal aging. Errors can arise at any stage of production or comprehension as a result of attentional lapses, processing limitations, or execution problems. For example, normative aging processes may exacerbate production or comprehension problems due to general slowing of cognitive processes, reductions of working memory capacity, or a breakdown of inhibitory processes. In dementia, these deficits are exacerbated by the breakdown of cortical connectivity within and between language processing regions, depending on the locus and severity of damage. This article examines what is currently known about the way dementia affects language use and attempts to distinguish pathological changes from normative age-related changes to language.

One issue has tended to dominate theoretical discussions of the effects of dementia on language: the modularity of phonological, syntactic, semantic, and/or discourse processes. Modularity, or autonomy, theory holds that language production or comprehension involves a sequence of processing stages or levels. Typically, four properties are ascribed to this sequence of processing stages: (1) each stage corresponds to a distinct linguistic rule system; (2) each stage involves a discrete representational system; (3) processing flows unidirectionally through the sequence of stages; and (4) each stage may be characterized by independent constraints on the rules, representations, or processing operations at that stage. Most models assume that there are a number of autonomous levels of processing, including a phonological level, which specifies the sequence of sounds composing each word; a morphological level, at which part-of-speech information is determined; a syntactic level, in which individual words are formed into phrases and clauses; a semantic level, at which meaning relations within and between words and phrases are determined; and a discourse, or pragmatic level of message structure and function. The degree of interactivity among these levels of representation and the possibility of bidirectional flow of information between levels are at the center of this controversy. Specific forms of dementia can attack any or all these levels, perhaps reflecting the mapping of linguistic functions onto cortical or subcortical structures.

A variety of specific tests for the effects of dementia on language are commonly included as part of the assessment of dementia, including tests of verbal fluency, picture naming, and immediate and delayed recall of word lists and short passages. For example, the Mini-Mental State Examination includes tests of sentence production, object naming, immediate and delayed verbal memory, and the ability to follow verbal commands, in addition to tests of orientation, attention, and constructional praxis. Psycholinguists and neuropsychologists have assessed the effects of dementia on various language-related tasks, such as picture naming, word-picture and sentence-picture verification, metalinguistic judgments, and reading and listening comprehension.

Many linguistic tests are relatively complex, involving a variety of component processes that may be affected by normal aging or other age-related conditions; some of these tests are often used to assess other cognitive processes, such as executive function. One example is verbal fluency. Tests of verbal fluency, such as the Controlled Oral Word Association Test, allow individuals a set amount of time, often 1 min, to generate words in response to a cue, such as words beginning with a target letter or phoneme (e.g., words beginning with an 'f') or members of a semantic category (e.g., the names of animals). Because the task draws on both semantic memory and executive function, deficits are found in nearly all dementias. For example, it is well established that individuals with Parkinsonian dementia and Alzheimer's dementia have verbal fluency deficits, particularly on tests involving retrieval of members of semantic categories. These deficits in individuals with Parkinsonian dementia have typically been attributed to nonsemantic problems associated with executive function, such as problems of inhibitory control, whereas similar deficits in individuals with Alzheimer's dementia have been attributable to a breakdown of semantic memory or semantic retrieval processes. Some attempts have been made to develop separate semantic and executive-function

components of verbal fluency performance by tracking the time course of responses, requiring responses to alternate or switch between two categories, and varying other task parameters.

Differential Effects

Dementias differentially affect language processes, primarily because of the location and scope of damage from the particular disease. Thus, some symptoms may be similar to those resulting from stroke affecting the same cortical region. However, dementias are degenerative, so the initial effects often are much milder than those resulting from stroke, more difficult to detect in early stages, and progressive. Alzheimer's dementia has been studied in some depth, whereas research into other dementias has been more limited.

Alzheimer's Dementia

Early in the disease, Alzheimer's dementia primarily affects posterior association cortex and only rarely extends to the perisylvian region. Consequently, phonology and phonetics, the sounds of words and the ability to articulate them, are typically affected only late in the disease, if at all. Similarly, morphological processing (e.g., appropriate use of verb tenses and sentence structure) is also considered a primarily perisylvian function that is usually preserved during early stages of the disease, although grammatical errors increase in frequency as the disease progresses.

In contrast, Alzheimer's dementia has a more significant effect on other aspects of language that rely on semantic knowledge (i.e., word meanings) and conceptual knowledge (i.e., knowledge about items and their attributes) and on the ability to integrate the meanings of several words. Often an early sign of Alzheimer's dementia is a marked increase in word-finding problems during conversation, as individuals experience frequent 'tip of the tongue' events, substitute generic references (e.g., "that thing"), and rely on metalinguistic references (e.g., "oh, you know who I mean"). At diagnosis, most Alzheimer's dementia patients score below normal on picture-naming tests, and this impairment increases over time. Errors are typically substitutions of words from the same semantic category, (e.g., saying 'horse' for 'giraffe') or category names (e.g., 'animal' or 'tool'), although other types of errors, such as visual errors and failures to respond, also occur. However, the structure of semantic knowledge remains intact until quite late in the disease; thus, patients have little difficulty sorting pictures by semantic category or verifying the category membership of an item. Performance on word–picture matching tasks in which the individual must identify a spoken or written target within an array of pictures is also more preserved than picture naming, particularly if there is little visual similarity among distracter pictures. Visual-perceptual difficulties may also contribute to the difficulties of Alzheimer's dementia patients in such tasks.

Extensive research has suggested that word-finding problems in conversation and picture-naming tasks are due to both a degradation of the meanings of words and difficulty accessing word meanings. Preserved partial meanings are evident in 'circumlocutions'; for example, someone unable to recall 'horse' may say, "Oh, you ride it. You put a leather thing on its back and you ride it. They race them too." The disease appears to impair the ability to focus word searches, resulting in activation of conceptually similar words (e.g., horse, deer, cow, donkey). These alternatives may compete for production, contributing to a breakdown in word retrieval. As the disease progresses, word meanings themselves appear to deteriorate. Even so, individual words, particularly high-frequency, highly familiar words, may be preserved, and comprehension is somewhat spared relative to production throughout the disease process.

Oral reading is preserved in mild Alzheimer's dementia, although comprehension of written sentences and texts is impaired. Thus, they may be able to read connected text that they cannot understand. In contrast, writing is impaired relatively early in Alzheimer's dementia and is characterized by simplified grammatical structures, loss of content, and regularized spelling.

Although the speech of individuals with mild or moderate Alzheimer's dementia is often described as 'empty speech,' it is quite distinct from the empty speech produced by individuals with fluent aphasia following stroke. Individuals with Alzheimer's dementia do not produce strings of words with little relevance to context, perseverate, or use ungrammatical phrases or 'word salad' jargon until extremely late in the disease, if at all. Instead, the conversational speech of individuals with Alzheimer's dementia is characterized by the overuse of general nouns (e.g., 'thing,' 'stuff') and verbs (e.g., 'get,' 'do') and by an overreliance on pronouns. These phenomena decrease the amount of information conveyed and can make following their conversations difficult. Even so, in Alzheimer's dementia, the fundamental building blocks of sentences are relatively intact; sentences contain noun and verb phrases and may also include complex grammatical constructions. Thus, conversational speech is often relatively coherent until moderate and late stages of the disease.

Understanding conversational speech requires listeners to combine the meanings of many words, often

across sentence boundaries; keep these in memory; and integrate the new information with past knowledge. Thus, it is an extremely demanding task. Patients with Alzheimer's dementia often miss a good deal of the information in a conversation; however, they may understand the gist of a conversation by relying on contextual cues. As the disease progresses, the appropriateness of language declines as behavior becomes increasingly disinhibited. Even mild-mannered Alzheimer's dementia patients may become verbally abusive. Typically, speech output also declines as the need to communicate dwindles. Gradually, conversational speech disappears, eventually ending in mutism.

Parkinsonian Dementia

Parkinson's disease primarily affects the ability to smoothly coordinate and perform speech, resulting in slow, dysarthric articulation in combination with a soft, breathy voice. The ability to produce consonants that require tongue movements, such as /t/, /d/, /l/, /n/, /k/, and /g/, is most impaired. Individuals with Parkinsonian disease may evidence 'articulatory undershoot,' in which the tongue does not quite reach the appropriate spot in the mouth or does not achieve full closure to block the flow of air when necessary. Further, if they do achieve adequate closure, they may either release it too fast or maintain it too long, decreasing intelligibility. Speech rate varies among patients; some may speak faster than normal, others at a normal rate. Often, there is a lack of awareness of these deficits; individuals with Parkinson's disease may feel that they are shouting when they are barely audible to others.

Recent research has revealed that other aspects of language use are also impaired in Parkinsonian dementia, suggesting either that subcortical structures play a role in language use or that the reduced dopamine production in Parkinson's disease impairs frontal lobe function, secondarily affecting language use. Converging evidence for the latter argument comes from findings that individuals with Parkinsonian dementia often score poorly on tests of immediate memory, executive function, and processing speed, all of which have been found to be associated with performance on language tasks in healthy older adults. Consequently, performance on all language tasks that rely on memory or executive function, such as reading comprehension and the production of complex sentences, is likely to be impaired. Micrographia, extremely small writing, is characteristic of Parkinson's disease. However, there are no studies on the content of writing in Parkinsonian dementia and very few on reading connected text or producing connected speech.

Frontotemporal Dementias

Frontotemporal dementia (FTD) is usually described as having three variants that differ in their behavioral manifestation depending on the locus of damage. These include primary nonfluent aphasia, semantic dementia, and frontal-variant FTD. In contrast to Alzheimer's disease, damage in FTD is relatively focal; consequently, episodic memory, spatial cognition, and orientation are usually preserved until late in the disease. Frontal-variant FTD manifests primarily as social and behavioral impairments. Language is relatively unimpaired in this group, although there are mild deficits affecting category and letter fluency and a very mild impairment of picture naming. Most language impairments in this subgroup seem to be related primarily to deficits in executive function.

Primary nonfluent aphasia Primary nonfluent aphasia, also known as primary progressive aphasia, is characterized by increasing difficulty programming speech movements, which leads to severely impaired spoken output, or dysarthria, from early in the disease. Speech becomes slower and more effortful over time and is marked by long word-finding pauses, phonemic paraphasias, and distortions. Intonation patterns also deteriorate, possibly because of the increasing effort needed to produce speech or the decreasing length of utterances.

Word-finding difficulties are often among the initial complaints of individuals with primary nonfluent aphasia; these difficulties are evident in both picture naming and spontaneous speech and become increasingly severe over time. As mentioned above, the difficulty seems to be in determining and producing the sounds of the words. In contrast, comprehension of single words as measured by word–picture matching tests is largely intact until late in the disease. Thus, in individuals with primary nonfluent aphasia (about 30% at the mild stage of the disease), there is a large discrepancy between the ability to comprehend words and the ability to name pictures, and this discrepancy increases as the disease progresses. Based on these findings, several researchers consider that the primary impairment in primary nonfluent aphasia affects the phonological output representations.

Primary nonfluent aphasia may affect different parts of speech in different ways; phonemic paraphasias may occur primarily with nouns, and semantic paraphasias primarily with verbs. There is mounting evidence that in some patients, primary nonfluent aphasia degrades the semantic or conceptual representations of verbs and that this degradation, in turn, disrupts sentence production. As in acquired aphasias, verb impairments are often accompanied by

impaired use of verb endings and difficulties comprehending complex or reversible sentences. Some individuals with primary nonfluent aphasia have been described as producing agrammatic speech. Very little is currently known about how primary nonfluent aphasia affects written production or the comprehension of sentences or discourse in either spoken or written modalities.

Semantic dementia Semantic dementia, also called progressive fluent aphasia, results when FTD primarily affects the anterior inferior temporal lobe. The defining feature in semantic dementia is a progressive loss of semantic and conceptual knowledge. Thus, semantic dementia affects performance on all tasks that require the access to or manipulation of word meanings, leading to extremely poor picture naming and severely impaired verbal fluency. In contrast, sentence grammar and discourse are relatively preserved although disrupted by the prevalence of word-finding difficulties.

Because the disorder impairs conceptual knowledge as well as semantic knowledge, individuals with semantic dementia may not be able to demonstrate how to use common items, such as a hammer or comb. Visual-perceptual aspects of meaning (e.g., shape and relative size) can be especially impaired, particularly knowledge of biological categories, such as fruits, vegetables, or animals. Comprehension of sentences is also impaired, although the patients may be able to abstract a 'gist' meaning based on whatever partial semantic information is available to them. Due to the deterioration of conceptual knowledge, reading comprehension and written communication are also impaired. Reading aloud may resemble surface alexia, in which irregularly spelled words are pronounced as they are written. Similarly, writing may also be impaired, with regularized spelling and low information content.

Other dementias: vascular dementia and Lewy body disease The effects of other dementias on language have not been well studied. Two of the more common types of dementia on which there is some language research are vascular dementia and Lewy body disease. Vascular dementia is difficult to differentiate from Alzheimer's dementia without reliance on neuroimaging. Both syndromes show impairments in word finding, picture naming, and letter and category fluency. However, individuals with vascular dementia are particularly poor at letter fluency relative to category fluency, and the reverse is true for individuals with Alzheimer's dementia. Individuals with vascular dementia also outperform those with Alzheimer's dementia on verbal memory tasks, such as free verbal recall, delayed verbal recall, and recognition memory of verbal material. Both vascular dementia and Alzheimer's dementia patients show a range of attention, executive function, and working memory impairments. Thus, the cognitive and linguistic characteristics of vascular dementia and Alzheimer's dementia are very similar, and to date, there are no 'cut-off' scores available to distinguish between these groups.

Lewy body disease primarily affects visual-spatial skills and the extrapyramidal systems rather than language, although it frequently accompanies both Parkinson's disease and Alzheimer's dementia. While those with Lewy body disease and Alzheimer's dementia are similar with respect to performance on picture-naming and word fluency tasks, attention and executive function are usually more impaired in Lewy body disease. On the other hand, individuals with Lewy body disease typically have better verbal memory, especially with respect to delayed recall and recognition memory, than do individuals with Alzheimer's dementia. Individuals with Lewy body disease also exhibit profound visuospatial and visuoconstructional impairments very early in the disease; for example, they are often unable to copy the overlapping pentagons in the Mini-Mental State Examination, even at an early stage of the disease. The spontaneous speech of the two groups differs qualitatively. Conversational speech in Alzheimer's dementia is characterized by a lack of content and relatively intact grammar; conversational speech in Lewy body disease is marked by confabulation.

Unfortunately, few studies have examined sentence and discourse level language production or comprehension in either spoken or written modalities in individuals with vascular dementia or Lewy body disease.

Interactions and Interventions

Family members and other caregivers of individuals with dementia typically cite communication problems as a major source of caregiver stress. Breakdowns in communication, whether from word-finding problems, dysarthria, or repetitive questions, may lead to other problem behaviors, such as agitation and aggression, and may impair quality of care. Little systematic research has assessed intervention and training programs targeted at alleviating communication problems with dementing individuals – largely as a result of the perception that, because these are

degenerative conditions, language treatment would be a waste of resources. Two studies of semantic training in semantic dementia have shown immediate gains in naming ability but no maintenance of these gains at follow-up. At least one study has shown maintenance of treatment gains in picture naming in Alzheimer's disease 2 months after treatment. However, most intervention programs target caregivers, emphasizing the use of functional communication strategies, such as making eye contact, repeating key words, using yes–no questions and lexical prompts, and providing memory books and other conversational stimuli. Other programs have targeted the development of techniques for minimizing repetitive questions and other disruptive behaviors.

A special speech register, sometimes termed 'elderspeak,' is often recommended as a way to enhance or facilitate communicating with older adults, especially those with dementia. Elderspeak has been characterized as involving a simplified speech register with exaggerated pitch and intonation, simplified grammar, limited vocabulary, and slow rate of delivery. Many of the characteristics of elderspeak, such as its slow rate and simplified syntax and vocabulary, may be helpful for ensuring comprehension in impaired populations, although there has been little research assessing its effectiveness. On the other hand, certain characteristics of elderspeak, such as the use of exaggerated prosody, collective pronouns (e.g., saying 'we' instead of 'you'), diminutives (e.g., 'Chrissy' instead of Chris or Mrs. Smith), and terms of endearment (e.g., 'honey' and 'darling'), resemble another register of speech, 'baby talk.' These characteristics are often perceived as demeaning or controlling. Alternative strategies for enhancing communication with adults with dementia must be developed by combining clinical observation with empirical research.

Implications and Conclusions

There has been considerable interest in using linguistic measures to predict risk, aid in diagnosis, and track the progression of dementia, particularly Alzheimer's dementia. Performance on tests of verbal memory, such as immediate and delayed word list recall, as well as tests of verbal fluency, appear to be particularly sensitive indicators of risk for dementia and its onset and seem to covary with other known risk factors, such as apolipoprotein E genotype. However, deficits in verbal fluency are not specific to Alzheimer's disease, as discussed above. The relationship between linguistic ability and the risk for Alzheimer's disease and longevity has been the focus of the Nun Study, an ongoing longitudinal, epidemiological study of aging. Low linguistic ability in young adulthood, determined from an analysis of language samples written by the nuns at age 18 to 32 years, was associated with increased risk for poor performance on cognitive and memory tests in late adulthood, increased neuropathology characteristic of Alzheimer's disease, and increased all-cause mortality among participants. These findings suggest that linguistic ability may offer a general measure of cognitive and neurological development. Low linguistic ability in young adulthood may reflect suboptimal neurocognitive development, which in turn may increase or reflect susceptibility to Alzheimer's and other dementing diseases.

Demyelinating Diseases

A Javed and B G W Arnason, University of Chicago, Chicago, IL, USA

© 2009 Published by Elsevier Ltd.

Introduction

The demyelinating diseases are important because of their frequency and the disability that they cause. Common to all is a patchy destruction of myelin sheaths, usually secondary to an inflammatory response. Myelin loss occurs in other conditions: examples include (1) genetically determined defects in myelin metabolism, (2) toxin exposures, and (3) infections of oligodendrocytes, the myelin producing cells of the central nervous system (CNS). These entities are usually not classified as demyelinating diseases.

The demyelinating diseases can be divided into those affecting CNS myelin and those affecting peripheral nervous system myelin. CNS diseases include multiple sclerosis (MS), acute disseminated encephalomyelitis (ADEM), neuromyelitis optíca ((NMO) Devic's disease), and acute necrotizing hemorrhagic encephalomyelitis (ANHE). Peripheral nervous system diseases include acute inflammatory demyelinating polyradiculoneuropathy, chronic inflammatory demyelinating polyradiculoneuropathy, anti-myelin-associated glycoprotein (MAG) neuropathy, and POEMS syndrome (so named due to polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes). The major demyelinating diseases are considered here, with emphasis directed toward mechanisms of disease causation and to treatments directed against them.

CNS Demyelinating Diseases

Multiple Sclerosis

MS presents with recurrent attacks of focal neurological disorder involving brain, spinal cord, and optic nerves. Disease usually begins in young adults. In the United States, one person in 500 has this disease by age 50. During episodes of relapsing–remitting MS, neurologic deficits worsen over a period of several days to 3–4 weeks, after which they remit. Remission may be complete after early attacks but more often is incomplete, and as relapses accumulate, stepwise progression leads to increasing deficit. In 15% of cases the illness manifests as a slowly progressive disease, so-called primary progressive MS. This is particularly likely when onset begins after age 40. In cases with earlier onset, and after multiple relapses over many years, the disease usually transitions into a slowly but continuously progressive worsening of motor deficit called secondary progressive MS. The cause of MS is unknown, but there is agreement that abnormal immune system function characterizes the disease. Evidence for this is summarized in the following discussion.

Certain histocompatibility antigen alleles are overrepresented in MS. Notable is the DR2 allele of the HLA histcombatibility complex. Possession of DR2 increases risk for MS fourfold. Many diseases are associated with histocompatibility abnormalities. Such diseases usually have (1) a chronic or recrudescent course, (2) a moderate tendency to be inherited that does not obey classical Mendelian rules, (3) an inflammatory component, and (4) an infectious or autoimmune basis in almost all instances in which cause is known. The first three features apply to MS. By analogy, the fourth likely applies as well.

Twenty percent of MS patients have a first- or second-degree blood relative with the disease. This could reflect genetic endowment, a shared environmental factor, or some combination of the two. Concordance for MS in identical twins approximates 25% and for siblings, 1–3%. Thus, there must be a strong genetically determined propensity to develop the disease, but there must also be some environmental initiator. The genetic component includes histocompatibility, but almost surely additional genetically determined characteristics, at present unknown, are involved. All attempts to identify the environmental factor that sets MS in motion have failed. Most researchers believe it will prove to be an infectious agent. One candidate is the Epstein–Barr virus that causes infectious mononucleosis. All MS patients have serologic evidence of prior infection with this virus at time of diagnosis.

MS is most common in north Europeans and in those whose forebears were north Europeans. MS is almost unknown among blacks in Africa. Among African Americans who develop MS, there is an increased representation of the HLA-DR2 allele, an uncommon allele among blacks in Africa. Thus, the propensity of African Americans to develop MS, and its rarity among blacks in Africa, may reflect both genetic and environmental differences. MS is uncommon in China and India. MS remains uncommon among descendents of Chinese immigrants to America, but not among descendents of immigrants from India, again indicating both regional environmental factors and genetic endowment as determinants for development of MS.

MS lesions consist of foci of demyelination, known as plaques, in CNS white matter. The earliest lesions

consist of minute pervenular foci within white matter. Over time these accumulate, enlarge, and coalesce to form plaques of considerable size, many of which abut the lateral ventricles. Axons coursing through regions where myelin has been lost are relatively but not completely spared, at least initially, although they are denuded of their insulation. Naked axons may continue to conduct nerve impulses, albeit imperfectly. Stripped axons can cease functioning when sustained effort is attempted, or if body temperature is elevated. Fatigue on effort, and worsening of deficits with fever, are characteristics of MS.

Active MS plaques contain T lymphocytes. These can be subdivided into two major categories known as CD4 and CD8 cells. CD4 and CD8 are surface proteins that facilitate interactions between T cell receptors and antigenic peptides and antigen-presenting cells such as macrophages. Antigenic peptides recognized by T cells are contained within clefts of major histocompatibility complex proteins expressed on the surfaces of antigen-presenting cells. CD4 cells recognize peptide fragments presented by class II histocompatibility alleles. CD8 cells recognize fragments presented by class I alleles. DR2, overrepresented in MS, is a class II allele, indicating a major role for CD4 cells in lesion formation in the early stages of the disease. CD4 cells can be further subdivided into T helper Th1 and Th2 subtypes. Th1 cells are responsible for delayed-type hypersensitivity responses. They secrete numerous cytokines (signaling proteins of the immune system), notably interleukin-2 (a stimulator of T cell proliferation), interferon-γ (an activator of macrophages), and lymphotoxin. The latter two proteins can damage oligodendrocytes. Elevated numbers of interferon-γ-secreting cells are detected in the blood during MS attacks and in MS plaques when disease is active. Interferon-γ, together with interleukin-2, activates macrophages that then secrete tumor necrosis factor, a protein which shares with interferon-γ and lymphotoxin the ability to damage oligodendrocytes. There is a yin-yang between Th1- and Th2-type T cells. Preferential activation of Th2-type T cells inhibits Th1 cells, and in this way may be protective in MS. Activation of Th2-type T cells is one goal of MS therapy.

MS plaques also contain macrophages. Macrophages often predominate within plaques even early on, and invariably predominate once disease has become progressive . Macrophages lack immunological specificity but can be armed to attack tissues under the influence of cytokines released by T cells, or by antibodies (immunoglobulins) released by B cells. Cytokines clearly activate macrophages during MS attacks. Antibodies may further facilitate macrophage activation during MS attacks and are, in all probability, the main activator of macrophages in progressive forms of MS. Thus, macrophages are the final vectors of myelin destruction throughout the course of MS. They also scavenge debris.

CD8 cells can be subdivided into cytotoxic cells and immunoregulatory (suppressor) cells. CD8 cells are found within MS plaques, but whether they are cytotoxic, have suppressor function, or both, has not been established. Interferon-β activates cytotoxic T cells yet protects MS patients (see later), making a role for cytotoxic T cells in MS problematic. In contrast, the function of circulating CD8 suppressor T cells, as measured by several tissue culture assays, is grossly deficient when MS is active, and treatment with interferon-β (a drug approved for treatment of MS) restores circulating suppressor T cell function to near normal levels in relapsing–remitting MS patients. Interferon-β also inhibits production of interferon-γ, lymphotoxin, and tumor necrosis factor, at least *in vitro*.

While the details of the immune response during MS relapses are imperfectly worked out, one possible scenario is as follows: failed regulatory T cell function (Th2 cells, CD8 cells, or both) permits reactivation of Th1 cells with specificity for an unknown brain antigen or antigens; the Th1 cells then stimulate macrophages, which attack and destroy myelin and oligodendrocytes. Restoration of regulatory cell function ends the relapse.

The disease produced by MS has prompted development of therapies directed toward correcting the immune system abnormalities. Interferon-β, an agent approved for the treatment of relapsing–remitting MS, reduces MS attack frequency by 35–55%. In addition to activating CD8 suppressor cell function, and hence inhibition of proinflammatory cytokine production, Interferon-β also inhibits T cell entry into the CNS. Glatiramer acetate, another approved drug for treatment of MS, reduces MS attack frequency by 30%. It has been proposed that it activates regulatory CD8-type T cells, and promotes Th2 cell development. Natalizumab, a third class of drug, is recommended for treatment of relapsing–remitting MS patients who fail to respond to other therapies. Natalizumab drastically curtails T cell trafficking into the CNS. Trials with other agents are ongoing.

A set of diseases that share numerous clinical and pathologic features with MS can be induced in laboratory animals. These diseases are known collectively as experimental autoimmune encephalomyelitis (EAE). They are induced by immunization with any of several CNS myelin proteins. The most commonly employed are myelin basic protein (MBP), proteolipid protein (PLP), and myelin oligodendrocyte protein

(MOG). The pathogenesis of most forms of EAE is a T-cell-mediated delayed hypersensitivity response directed against the individual proteins used to immunize the animals. The T cells responsible for the activation of macrophages that eventuates in myelin destruction during EAE are analogous to human Th1-type T cells, suggesting that T cells of this lineage are the prime movers in acute attacks of MS as well. Antibodies directed against proteins expressed on the myelin surface contribute to the demyelination seen in subacute and progressive forms of EAE, suggesting, by analogy, an ancillary role for antibodies in early MS and a substantial role, possibly a dominant one, in progressive MS. That antibodies are likely to have a major role in the axonal damage of progressive MS is supported by the observation that T cell ablation has minimal effect on progressive motor disability once MS has evolved into its progressive form.

T cells from animals with EAE proliferate when exposed to MBP, PLP, or MOG, depending on the protein used to induce disease. T cells from MS patients seldom proliferate when exposed to these same proteins, or at least to no greater extent than do T cells from controls, so that an immune response directed against them is unlikely to be implicated in MS. Nonetheless, given the similarities between EAE and MS, it is possible that there may be some unique antigen against which an immune response is directed in MS. None has been found with certainty to date despite assiduous search. This could mean that the EAE models provide a false lead. Alternatively, and more likely, the antigen (or antigens) for MS simply awaits discovery.

Mature oligodendrocytes are depleted in MS plaques. For this reason some have proposed that the immune attack in MS may be directed against oligodendrocytes rather than against their product, myelin, inasmuch as compromised oligodendrocytes might be expected to divest themselves of their myelin. Remyelination can follow myelin loss. This occurs to a more limited extent in MS than in other demyelinating processes. Preoligodendrocytes, the precursors of oligodendrocytes, are responsible for remyelination in the human brain. A substantial pool of them is present in the adult brain. During the events that eventuate in remyelination, preoligodendrocytes mature to become oligodendrocytes. Curiously, preoligodendrocytes are present in substantial numbers in MS plaques that are depleted of mature oligodendrocytes, yet remyelination fails. What prevents preoligodendrocytes from repairing myelin in MS is unknown.

Spinal fluid of MS patients contains immunoglobulin G (IgG) in increased amount, a finding that provides useful corroborating evidence when a diagnosis of MS is suspected. Spinal fluid IgG from MS patients, subjected to isoelectric focusing, exhibits oligoclonal banding. Oligoclonal bands bespeak expansion of specific B cell clones that produce monoclonal (i.e., single antigen-specific) antibodies within the brain, the basis for which is not understood. Much of the monoclonal antibody made in the brain in MS is irrelevant to disease pathogenesis. This does not negate the possibility that some may be directed against MS-relevant antigens, yet undiscovered.

Spinal fluid in MS contains T cells. Many are activated even when disease seems quiescent (i.e., during clinical remissions). The activated cells belong to the delayed hypersensitivity response–effector cell lineage. The data point to more persistent disease activity than is apparent clinically. Similarly, when magnetic resonance imaging (MRI) scans are obtained monthly, gadolinium-positive lesions are detected in five scans obtained between overt MS attacks for every gadolinium-positive scan obtained during a relapse. Gadolinium transport into the CNS is a marker for disease activity. The finding again indicates that the illness is far more active than it appears to be clinically, and supports the strategy of continuous long-term immunomodulatory treatment for the illness.

To sum up, immune mechanisms are implicated in MS, but no disease-specific antigen against which an immune-mediated attack is directed has been proved to be the cause. Similarly, attempts to implicate a virus in disease pathogenesis have failed. Yet, immunomodulatory therapies favorably affect the long-term course of MS.

Acute Disseminated Encephalomyelitis

ADEM, a rare disease, is an acute multifocal demyelinating process that follows an infectious illness. Formerly, ADEM occurred particularly often in children with measles. Nowadays the illness most often follows a nondescript viral infectious illness. Although encountered in adults, most cases occur in children. Children seldom get MS, indicating that ADEM constitutes a distinct entity. ADEM occurs throughout the world, and may even be more common in less developed countries where MS is rare, than in developed ones where MS is common. In ADEM, the white matter of the brain and spinal cord is peppered with multiple foci of acute demyelination of varying size. The foci contain T cells and macrophages and most, sometimes all, are simultaneously gadolinium positive on MRI scanning. The illness is usually monophasic; recurrences after a delay are uncommon, although recrudescences may be encountered when glucocorticoid treatment (see later) is abbreviated.

In animals, an acute monophasic form of EAE, with T cell sensitivity to MBP, mimics the human

disease. Sensitivity of lymphocytes to MBP, and antibodies to MBP, have been demonstrated in ADEM, and the disease is a reasonably faithful human counterpart of acute monophasic MBP-induced EAE. Animals, recovered from acute monophasic EAE, are refractory to attempts to induce recurrences. Refractoriness is believed to reflect expansion, in recovered animals, of MBP-specific suppressor cells that damp down any future response to MBP. In MS, unlike the situation in ADEM, recurrences are the rule. Perhaps failed suppressor cell function favors these recurrences – that is, if a means to persistently augment suppressor function were at hand, MS relapses might be prevented.

ADEM begins abruptly and evolves rapidly. Headache and delirium at onset that give way to lethargy and coma are common in childhood cases, less so in adults. Seizures are not infrequent, particularly in children. Later, multiple focal signs emerge, flaccid paralysis of the limbs and brain stem signs being particularly common. The symptoms observed at the onset of ADEM are associated with inflammation alone. The multiple focal findings that follow coincide with onset of demyelination. In former times, mortality was 20%, with 50% of survivors having residual deficits. The prognosis has subsequently become much more favorable.

Treatment of choice is high-dose glucocorticoid administered systemically for several days, followed by an extended oral glucocorticord taper over 6–8 weeks. Controlled trials are lacking, but recrudescences are fewer when this regimen is employed than when it is not, strongly suggesting a benefit from glucocorticoid treatment, as might be expected for a T-cell-mediated process. Remyelination during recovery from ADEM is more extensive than that seen in MS, and the majority of patients recover completely. MRI scanning during the acute phase reveals subcortical white-matter lesions with fuzzy margins, some quite large, with, unlike the situation in MS, periventricular sparing. Follow-up MRIs often reveal complete resolution of prior lesions and, again unlike MS, no new ones. The spinal fluid often shows a florid lymphocytosis at disease onset.

Neuromyelitis Optica (Devic's Disease)

NMO is an uncommon inflammatory disease in which inflammation, restricted to the optic nerves and spinal cord, occurs either sequentially or simultaneously. There has been debate regarding the etiology of this entity given its topographical specificity. Until recently NMO was usually viewed as an MS variant.

NMO has features that permit it to be set apart from MS or ADEM (Table 1).The clinical course is monophasic in one of five of instances. Four-fifths of patients have recurrent bouts of inflammation involving the spinal cord and/or the optic nerves. These relapses are reminiscent of relapsing–remitting MS. In patients with monophasic NMO, visual and motor involvement is severe initially, but recovery, although delayed, is usually substantial. In contrast, patients with relapsing disease have less severe involvement initially, but as attacks accumulate progressive disability follows. Disability can become devastating, with total blindness and complete motor paralysis sometimes being the end result. There is a 30% incidence of respiratory failure, usually fatal, in recurrent NMO due to upper cervical cord and medullary function compromise. Respiratory failure is rare in MS or in ADEM.

NMO lesions have unique features. Spinal cord lesions exhibit prominent vascular fibrosis and hyalinization. Spinal cord NMO lesions involve gray as well as white matter and there may be prominent necrosis, cavitation, and axonal loss. Extensive demyelination is seen, as is extensive oligodendrocyte loss. Lesions in the spinal cord tend to be centrally located in NMO rather than peripheral (i.e., restricted to white matter), as is the case in MS. NMO lesions, seen on MRI scans of the spinal cord, span a greater longitudinal extent than do the spinal cord lesions of MS. Macrophages predominate; T cells are rare. Distinct to NMO is prominent infiltration of neutrophils, eosinophils, and ringlike perivascular deposits of immunoglobulin M (IgM) and IgG. Complement products are also seen in NMO lesions.

The incidence of other autoimmune diseases in NMO is 15-fold increased over that in the general population. Frequent associations are with Sjögren's disease, systemic lupus erythematosus, rheumatoid arthritis, mixed connective tissue disease, and myasthenia gravis. Evidence pointing to other autoimmune processes may be subtle. Rare associations of NMO with tuberculosis, cancer (especially small-cell lung carcinoma), and lymphoma have been described.

An IgG antibody specific for NMO has been discovered. The antibody has a sensitivity of 73%, a specificity of 91%, and permits a clear distinction to be made between NMO and MS. The antibody is directed against aquaporin 4, a water channel protein expressed in astrocyte foot processes.

NMO patients fail to respond to standard MS therapies. Acute attacks are typically treated with high-dose systemic glucocorticoids plus courses of plasmapheresis or of intravenous immunoglobulin. Pulse treatments with plasmapheresis or with intravenous immunoglobulin given every 4–6 weeks, and/or long-term maintenance on an immunosuppressive drug such as azathioprine, methotrexate, or mycophenolate

Table 1 Features of the major CNS demyelinating diseases

Feature	*NMO*	*Multiple sclerosis*	*ADEM*
Median age of onset (years)	40	30	15
Sex ratio (F:M)	8:1 (relapsing)	2:1 (relapsing)	1:1
Ethnicity	↑ Incidence in non-Caucasians	Primarily Caucasian	All populations at risk
Clinical course			
Monophasic	20%	NA	>95%
Relapsing	80%	85% initially	<5%
Primary progressive	NA	15%	NA
MRI features			
Brain white-matter lesions	Absent at onset	Oval, usually perpendicular to ventricles	Large, disseminated, seldom periventricular
Spinal cord lesions	Longitudinally extensive	Punctate	Variable
Optic nerve lesions	Unilateral or bilateral with poor recovery	Usually unilateral with good recovery	Unilateral or bilateral with good recovery
Cerebrospinal fluid findings			
White blood cell count	↑↑↑ Lymphocytes, neutrophils	↑ Lymphocytes	↑↑ Lymphocytes, occcasionally neutrophils
Total protein	Elevated	Typically normal	elevated
Oligoclonal bands	Usually absent	>90% present	Usually absent
Pathology			
Gray matter	Necrosis	Limited demyelination	Limited demyelination
White matter	Necrosis, demyelination	Demyelination	Demyelination, edema
Lesion immunopathology			
Macrophages	+++	+++	+++
T cells	+/−	+++	+++
Eosinophils	++	None	None
Neutrophils	+++	None	Rare
Antibodies	+++	Variable	Variable
Complement	++	Variable	Variable
Coexisting autoimmune diseases	30–50%	Infrequent	Not seen
Disability progression	Relapse related	Independent of relapses	Relapse related

NMO, Neuromyelitis optica; ADEM, acute disseminated encephalomyelitis.

mofetil, have been given in attempts to lessen the likelihood of future relapses. Rituximab has been used recently in recurrent NMO prophylaxis. Rituximab, a monoclonal antibody directed against the CD20 protein expressed on the surface of B cells, potently depletes B cell number and lessens antibody production.

Acute Necrotizing Hemorrhagic Encephalomyelitis

ANHE is a rare disease that resembles ADEM save for its apoplectiform onset and unique pathologic features. There is massive destruction of white matter to the point of liquefaction, and the lesions are flecked with multiple small hemorrhages. As in ADEM, regions of tissue damage contain lymphocytes and macrophages, but, additionally, necrotic vessels. Polymorphonuclear cells infiltrate regions of necrosis and are found in spinal fluid, as are red blood cells. A model for ANHE can be induced by giving endotoxin to animals about to develop acute EAE. This 'double hit' superimposes a Shwartzman reaction onto the animal model for ADEM. A few cases of ANHE complicating MS have been reported.

Peripheral Nervous System Demyelinating Diseases

Demyelination in the peripheral nervous system may be caused by immune mechanisms that involve T cell- and macrophage-mediated mechanisms, by antimyelin antibodies, or by cytokines released at a distance from nerves. Mixed mechanisms are also seen. Examples are presented in the following sections.

Guillain–Barré Syndromes

Demyelinating and axonal forms of Guillain–Barré syndromes are recognized. The demyelinating form, often designated as acute inflammatory demyelinating neuropathy (AIDP), predominates in North America, Europe, and Australia. Axonal forms predominate in other countries, most notably in China. Annual frequency of AIDP is 1.5 persons per 100 000 across all

age groups, so that one person in 1000 will contract this illness at some point over their lifetime. AIDP follows an acute infectious illness in two-thirds of patients. Some 10% of cases follow infection with cytomegalovirus, another 5% follow Epstein–Barr virus infection (both are herpes viruses). Some 20–30% of cases follow infection with *Campylobacter jejeuni*, a bacterium that causes diarrhea. An additional 5% of cases follow infection with *Mycoplasma pneumoniae*. This agent can also incite a concurrent ADEM to give a mixed CNS and peripheral nervous system presentation. Weakness, leading to frank paralysis, that requires respiratory support in 20% of AIDP cases evolves subacutely over several days for up to 4 weeks; 5% of patients succumb and the rest recover, usually completely, although 15% have residual disability. AIDP is usually monophasic. Relapses occur months or years later in fewer than 5% of cases.

Pathologic examination reveals peripheral nerve infiltration with lymphocytes and monocytes/macrophages. The latter strip myelin to leave denuded axons. Segmental demyelination occurs throughout the peripheral nervous system but more so in nerve roots and distal nerve terminals. Remyelination, which can be extensive, correlates with relatively rapid restoration of function. In severe cases axons may be interrupted, followed by either slow regrowth once the inflammatory process has ceased, and hence delayed restoration of function, or no regrowth and permanent deficit.

Complement deposition on the surface of Schwann cells is seen early on, suggesting a potential role for antibody directed against a myelin antigen that remains unknown. It is also likely that nerve-invading CD4-type T cells instruct macrophages to attack myelin. In cases with a protracted course, a late-stage role for CD8-type cytotoxic T cells has also been proposed. Courses of either plasmapheresis or of intravenous gamma globulin have been shown, in controlled clinical trials, to provide substantial benefit in AIDP.

Animal models that mimic AIDP with varying degrees of fidelity exist. Experimental autoimmune neuritis (EAN) is an acute inflammatory neuritis induced by immunization with proteins of peripheral nerve myelin. T cells from such animals proliferate when challenged with myelin proteins and the disease can be transferred to naive recipients with T cells from EAN donors, indicating that EAN is mediated largely by T cells. EAN mimics the histological and clinical features of AIDP, yet sensitivity of T cells from AIDP patients to myelin proteins can be shown in only a minority of cases.

The axonal forms of the Guillain–Barré syndrome are characterized by purely motor involvement (acute motor axonal neuropathy, or AMAN), a mixed motor and sensory neuropathy (acute sensorimotor axonal neuropathy, or ASMAN), and the Miller Fisher syndrome, in which oculomotor paralysis, ataxia, and areflexia are cardinal features. These illnesses are mediated by antibodies to gangliosides situated on axonal membranes. Most cases follow infections with *C. jejeuni*. The antibodies are directed against oligosaccharides of the *Campylobacter* bacterium, but cross-react, because of molecular mimicry, with peripheral nerve gangliosides.

In AMAN, antibodies to anti-GM1/anti-GD1a gangliosides are the rule, whereas in the Miller Fisher syndrome antibodies to GQ1b ganglioside are usually detected. GM1 is enriched at nodes of Ranvier and at motor nerve terminals. Deposition of antibodies and of complement at these sites explains motor nerve functional compromise. GQ1b is enriched in extraocular nerves so that anti-GQ1b antibodies preferentially localize to extraocular nerves in the Miller Fisher syndrome. The axonal forms of the Guillain–Barré syndrome involve nerve impulse conduction block when mild, and irreversible axonal transection when severe. They are not demyelinating. Nonetheless, the finding that antiganglioside antibodies cause paralysis has led to speculation that AIDP may likewise be mediated by antibodies directed against some substance expressed on the surface of peripheral nerve myelin. The issue remains open.

Chronic Inflammatory Demyelinating Neuropathy

Chronic inflammatory demyelinating neuropathy (CIDP) may be an AIDP variant. The illness is characterized by progressive loss of motor and sensory function that evolves over many years. The process is roughly symmetrical, weakness of proximal and distal muscles predominating. Sensory dominant forms are uncommon. The onset is usually insidious without, unlike AIDP, any evident precipitating event. Some patients have a series of relapses prior to developing a progressive course. CIDP can occur at any age but is more common with advancing years. CIDP predominantly affects spinal roots, major plexuses, and proximal nerve trunks. The process is demyelinating, as readily documented by electrophysiologic testing. This reveals dispersed slowing of nerve conduction velocity. The spinal fluid protein is elevated, in keeping with leakage from damaged spinal roots. Tendon reflexes are usually lost.

Histologic examination of active lesions reveals lymphocytic infiltrates, usually modest, and macrophage-mediated demyelination. Macrophages insert processes between myelin lamellae, phagocytose myelin, and denude axons. The process is morphologically

identical to that seen in AIDP, albeit more indolent. Repair occurs to some extent as witnessed by thinned myelin and shortened internodal distances, cardinal features of successful remyelination. As the illness evolves, interruption of naked axons becomes engrafted onto the demyelinating process. Failed attempts at remyelination are evidenced by layers of Schwann cell cytoplasm separated by collagen fibers forming concentric rings, or so-called onion bulbs.

The process is held to be primarily T cell mediated, but T cell reactivity to characterized myelin proteins is seldom found, and the putative antigen, or antigens, against which the T cell response is directed remains unknown. A role for antibody in CIDP has also been proposed since a small proportion of patients have antibody to the Po protein of peripheral nerve myelin.

Most patients respond modestly to oral glucocorticoids when these are first given. This treatment is not helpful in AIDP. There is also evidence that intravenous IgG and plasma exchange may offer modest benefit for a time. Treatment for this condition remains unsatisfactory over the longer term.

Anti-Myelin-Associated Glycoprotein Neuropathy

MAG neuropathy is a demyelinating neuropathy mediated by monoclonal IgM antibody that binds to an oligosaccharide shared by MAG, a minor myelin protein, and two glycolipids of peripheral nerve, sulfated 3-glucuronyl lactosaminyl paragloboside and sulfated 3-glucuronyl paragloboside. The clinical picture is one of a primarily sensory distal and symmetric neuropathy. IgM antibodies have low affinities, but this is compensated for by high avidities due to their pentameric structure. MAG is primarily expressed in uncompacted myelin of the periaxonal and paranodal regions and in Schmidt–Lantermann clefts. Anti-MAG antibody and complement are deposited at these sites and MAG is selectively lost. MAG is implicated in the maintenance of axonal function and its loss compromises axonal function. Anti-MAG antibodies injected into the sciatic nerves of cats cause demyelination, proving that anti-MAG antibody causes the neuropathy. A blood test for anti-MAG antibody is reliable and confirms the diagnosis.

Electrophysiologic studies reveal a demyelinating process with distal accentuation of reduced conduction velocity. Treatment with antimetabolic drugs such as the purine analog fludarabine has been reported as helpful, as has rituximab, a humanized murine monoclonal antibody directed against the CD20 antigen expressed on B cells. Rituximab exerts a cytotoxic effect on B cells with, as a consequence, reduced anti-MAG antibody titers.

POEMS Syndrome

The POEMS syndrome, a demyelinating neuropathy, was originally described as a complication of sclerosing myeloma, an immunoglobulin-secreting plasma cell tumor. Most myelomas are osteolytic and multifocal, but 3% of them are solitary tumors that cause bone to sclerose. Fifty percent of patients with a sclerosing myeloma develop the POEMS syndrome. Radiation therapy of a sclerosing myeloma can be followed by remission of the neuropathy, indicating that some product released by the tumor causes the POEMS syndrome. Those sclerosing myelomas that cause the POEMS syndrome invariably secrete monoclonal IgG or IgA immunoglobulin into the blood. Documentation of this secretion is required for diagnosis, although the monoclonal immunoglobulin may be secreted in such miniscule amounts as to prove difficult to detect. The light chain of the IgG or IgA released by the tumor is of the λ type in almost all instances.

Other B cell dyscrasias can be complicated by the POEMS syndrome, including multicentric angiofollicular lymph node hyperplasia (Castelman's disease), an entity characterized by gross lymph node hyperplasia, and polyclonal plasma cell proliferation. In cases complicated by the POEMS syndrome, focal accumulations of monoclonal plasma cells secreting IgG λ are detectable, pointing to a communality with sclerosing myeloma-associated POEMS syndrome.

The POEMS acronym emphasizes several of its cardinal features: polyneuropathy, the dominant clinical feature; organomegaly; endocrinopathy, most often gonadal dysfunction; M (i.e., myeloma) protein; and skin changes, including hyperpigmentation and hypertrichosis. There are additional features not described by the acronym. These are elevated intracranial pressure with or without papilledema, edema of the extremities, effusions in body cavities, and, ultimately, renal failure and/or failure of multiple other organs. The process that begins as a neuropathy ultimately becomes widespread.

The neuropathy is symmetrical and begins with distal sensory abnormalities, numbness, and dysesthesias predominating. The process then ascends and weakness supervenes. Nerve conduction studies reveal evidence for both demyelination and axonal loss, as do nerve biopsies. Importantly, there is no inflammatory cell infiltrate nor is immunoglobulin deposition within nerves seen. The latter finding indicates that monoclonal IgG or IgA does not cause the neuropathy. Endoneurial blood vessels show endothelial cell hypertrophy. Endothelial cell processes extend into the lumen, reduce luminal diameter, and hence promote hypoxia. Disruption of the tight

junctions that ordinarily join nerve endothelial cells to one another is also seen with, as a consequence, leaky vessels. Vascular endothelial growth factor (VEGF) is an angiogenic hormone. Elevated levels of VEGF are observed in the blood in POEMS syndrome and levels correlate with the tempo of worsening. VEGF levels return to normal with successful treatment of solitary myelomas by radiation, or with alkylating agents and glucocorticoids when the process is more widespread. These findings have led to the postulate that excessive VEGF production by plasma cells causes endothelial cell proliferation and leaky vessels. VEGF, acting far from its site of origin to compromise blood flow throughout the body, fits well with the multiorgan involvement seen in the later stages of the POEMS syndrome.

Demyelination and Demyelinating Antibodies

F J Seil, Oregon Health and Science University, Portland, OR, USA

Demyelinating antibodies are generally defined by their destructive effects on myelin *in vitro*. Such antibodies are of interest because of a possible role in demyelinating diseases *in vivo*, including multiple sclerosis (MS), and because of their potential use as probes for the study of myelination.

Experimental allergic encephalomyelitis (EAE) is a demyelinating disease that can be induced in animals by intradermal injection of Freund's complete adjuvant (FCA) in combination with whole central nervous system (CNS) tissue, white matter, or purified CNS myelin. It was discovered that sera from animals with EAE induced by these antigens produced demyelination upon application to myelinated CNS tissue cultures while sparing axons. The demyelinating activity was complement dependent and associated with the immunoglobulin G (IgG) fraction of serum, and additional evidence was presented to support the antibody nature of these serum factors. The demyelinating reaction was reversible, and removal of the antisera, even after several days, was followed by the reappearance of myelin *in vitro*. If similar antisera were applied to CNS cultures before myelin formation, myelination and oligodendrocyte differentiation were inhibited, even at much lower concentrations of serum than required to produce demyelination. Antisera directed against whole CNS tissue, white matter, or purified CNS myelin were specific for centrally myelinated fibers and did not demyelinate peripheral nervous system (PNS) myelin *in vitro*.

The primary encephalitogenic agent in CNS tissue is myelin basic protein (MBP), and EAE can be induced with MBP or with MBP fragments plus FCA. In early attempts to identify the specific myelin antigens that induced antimyelin antibodies, attention was directed to encephalitic proteins and peptides. Sera from animals with EAE induced with encephalitogenic peptides or MBP did not demyelinate CNS cultures, and anti-MBP sera did not inhibit myelin formation. The major CNS myelin protein, proteolipid protein (PLP), which can induce a chronic form of EAE, also did not provoke the production of demyelinating or myelination-inhibiting antibodies. Galactocerebroside (GC), a glycolipid component of myelin, did not induce EAE, but tissue culture demeyelinating and myelination-inhibiting activity were found in sera from rabbits inoculated with GC and FCA. However, the antimyelin activity was not confined to CNS myelin, because PNS cultures were also demyelinated and myelination-inhibited.

Other myelin components were investigated. Myelin-associated glycoprotein (MAG), a minor component of CNS myelin localized at the myelin membrane surface, and thus a good candidate for antibody induction, induced neither EAE nor antimyelin antibodies. Immunization of rabbits with gangliosides, glycolipid components of neuronal and myelin membranes, had been reported to induce a form of demyelinating disease. No demyelinating or myelination-inhibiting activity was evident in CNS–PNS cultures exposed to rabbit antisera to GMI, a major ganglioside. By immunoabsorption and fractionation experiments and complement fixation studies, tissue culture demyelinating factors in sera from whole CNS- or CNS myelin-sensitized guinea pigs were characterized as antibodies to an antigen designated M2. M2, which was absent in PNS myelin and was different from MBP and GC, was identified as a glycoprotein component of oligodendrocyte membrane.

Extraction of CNS myelin with chloroform-methanol removes PLP, almost all of the MBP, and most of the lipids. The remaining chloroform-methanol insoluble protein (CMIP) fraction contains a large number of low- and high-molecular-weight proteins, including the glycoproteins, among which are MAG, M2, and the myelin oligodendrocyte glycoprotein (MOG), the last a minor protein localized at the external surfaces of myelin sheaths and oligodendrocyte membranes. Rabbits inoculated with the CMIP fraction and FCA did not develop clinical EAE but did have occasional focal perivascular mononuclear inflammatory infiltrates, sometimes with spread into the surrounding CNS parenchyma, and their sera demyelinated and inhibited myelination of centrally myelinated fibers while sparing peripheral myelin. Immunization of rodents with MOG induced EAE and application of a monoclonal anti-MOG antibody to myelinated reaggregating brain cell cultures resulted in reversible, complement-dependent demyelination. Other characteristics of anti-MOG antibody remain to be defined. However, because MOG is present in the CMIP fraction of myelin, it is probable that such features as specificity for CNS myelin and myelination-inhibiting capability will be the same as for anti-CMIP antibodies. It is also probable that MOG and M2 are the same glycoproteins.

A PNS equivalent of EAE is experimental allergic neuritis (EAN), which can be induced with FCA plus

whole PNS tissue or the P2 protein fraction of PNS myelin. The P2 protein is also a basic protein but is structurally different from MBP and is found only in PNS myelin. Antisera directed against whole PNS tissue consistently demyelinated and inhibited PNS myelin formation in tissue cultures, while having variable results against CNS myelin. Antisera to the neuritogenic P2 protein, as with the encephalitogenic counterpart, MBP, demonstrated no antimyelin activity *in vitro*.

A summary of the various antigens evaluated for their ability to induce antimyelin antibodies is presented in Table 1. Also indicated in the table is whether or not the antigens induced experimental demyelinating disease. It is apparent from this table that induction of EAE and EAN can be completely dissociated from induction of antimyelin antibodies, raising the question of the relevance of these antibodies to the pathogenesis of disease. Although such antibodies may not be necessary for disease induction, it has been suggested and some supporting evidence has been presented that antimyelin antibodies have an augmenting role in demyelination, their presence being correlated with more severe demyelination in experimental animals. The notion that combined action of cellular and humoral mechanisms to produce inflammatory demyelinating lesions in EAE was reinforced by the finding that MOG, which induces EAE with both inflammatory and demyelinating components, evoked a T-cell-mediated immune reaction and a B-cell-secreted demyelinating antibody response. On the other hand, extensive demyelination has been described in the absence of antibodies that bind to myelin, indicating that antibody augmentation is not always necessary for demyelination. Antimyelin antibodies have also been reported to opsonize myelin for phagocytosis by macrophages.

Sera from some subjects with MS, a human CNS demyelinating disease, and from human subjects with idiopathic polyneuritis (Guillain–Barré syndrome), in which peripheral nerves and nerve roots are segmentally demyelinated, also demonstrated demyelinating activity in CNS and PNS tissue cultures. The MS serum factors paradoxically did not inhibit myelination. Sera from subjects with MS specifically demyelinated centrally myelinated fibers, and sera from patients with idiopathic polyneuritis were active against both CNS and PNS myelin. Demyelinating factors from the latter group of human subjects have not been systematically studied, but attempts have been made to further characterize MS sera.

There was a degree of correlation between the presence of serum demyelinating factors and disease activity in MS. Demyelinating activity of MS sera was removed by absorption with brain tissue and a nonmyelin CNS tissue pellet that included oligodendrocytes but not with purified myelin. No immunostained myelin was evident when demyelinating MS sera were applied to CNS cultures and fixed and treated with peroxidase-conjugated antihuman globulin, suggesting that the demyelinating activity of MS sera was not associated with a myelin-binding

immunoglobulin. Depletion of γ-globulin from MS sera did not decrease their tissue culture-demyelinating capability, and isolated immunoglobulin fractions from most MS sera did not demyelinate CNS cultures, further supporting the concept that demyelinating activity in most MS sera is associated with a serum factor other than γ-globulin.

More recently, anti-MOG antibodies bound to disintegrating myelin sheaths were detected in acute lesions from three human subjects with MS, suggesting that MOG could be a target for antibody-mediated demyelination in some cases of MS. However, given that 60–70% of subjects with active MS have serum demyelinating activity and that only 12.5% of demyelinative MS sera are associated with immunoglobulins, 8–9% of MS cases at most would appear to have serum demyelinating activity related to immunoglobulins, such as anti-MOG antibody, which could be consistent with the currently espoused concept that MS is a disease of heterogeneous pathogenesis. Also, serum demyelinating factors are not specific for MS, as demyelinating activity has been reported in sera from a significant proportion of human subjects with other neurological diseases, further complicating interpretation of the significance of serum demyelinating factors in human diseases.

There are other reasons for studying antibodies to specific myelin antigens, however, including their use as cell markers (e.g., anti-GC antibody as a marker for oligodendrocytes) and as probes for dissecting some of the steps involved with myelination. It has been shown, for example, that antisera to whole CNS tissue can, in the presence of complement, inhibit oligodendrocyte differentiation *in vitro*, whereas decomplemented anti-CNS sera allow oligodendrocyte differentiation but prevent oligodendrocytes from successfully wrapping axons and forming compact myelin. Similar probes may define still other aspects of the complex interactions between neurons and supporting cells that result in myelination.

Dendrite Development, Synapse Formation and Elimination

H Cline, Cold Spring Harbor Laboratory, Cold Spring Harbor, NY, USA

Introduction

In the central nervous system of adult animals, many neurons have functionally polarized architecture in which dendrites, which receive information from other neurons, are physically separate from axons, which send information to other neurons. In general, axons and dendrites both have complex treelike structures, called arbors. The area covered by the axons and dendrites and the density of branches within the dendritic and axonal arbors govern the type and number of neurons which are connected within a circuit. Consequently, the mechanisms that control the development and maintenance of neuronal structure critically affect the ability of the neuron to function within the brain circuit. For instance, the importance of neuronal structure in brain function is clear from studies of brains of children with mental retardation, in which neurons are dwarfed in size compared to those in healthy children.

The acquisition of mature neuronal structure is classically described as being governed by both 'intrinsic' and 'extrinsic' factors, although in fact extrinsic factors, such as growth factors and synaptic inputs, affect intrinsic events such as gene transcription and trafficking of guidance molecules to the cell surface. Several recent studies using modern molecular genetic, imaging, and electrophysiological methods now provide strong evidence that excitatory synaptic inputs control the development of neuronal structure in the intact brain.

Synaptogenesis and Synapse Maturation

The formation and maturation of synapses can be distinguished into several steps:

1. *Establishment of an adhesive contact*. Dynamic filopodial processes from growing presynaptic axons and postsynaptic dendrites come into contact and form an initial adhesive contact, possibly mediated by integrins, cadherins, or Wnt/Frizzled cell surface adhesive molecules.
2. *Conversion of the adhesive contact to a nascent synapse*. In the case of glutamatergic synapses in the vertebrate central nervous system, nascent synapses are characterized by the predominance of *N*-methyl-D-aspartate (NMDA)-type glutamate receptors. NMDA receptors (NMDARs) require postsynaptic depolarization at the same time as ligand (i.e., glutamate) binding in order to permit conductance through the channel. As such, the NMDAR acts as a coincidence receptor. In the context of synapse formation, this ensures that transmission at nascent synapses occurs when other inputs to the postsynaptic neuron surpass a threshold synaptic strength. NMDARs are permeable to calcium. Intracellular calcium signaling may be required for maturation of the developing synapse.
3. *Synapse maturation*. Glutamatergic synapse maturation is characterized by the recruitment of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type ionotropic glutamate receptors into synapses. This renders the synapses functional at resting potentials. The assembly of the complex postsynaptic density, including scaffolding proteins and signaling proteins, occurs as glutamate receptors are trafficked into developing synapses.

Features of Nascent and Mature Synapses

Studies in many experimental systems indicate that synaptic transmission at newly formed synapses is mediated by the NMDA type of glutamate receptors and that AMPA receptors (AMPARs) are added to synapses as they mature. Synapses with only NMDARs are 'silent' at resting potential due to the voltage-dependent block of the NMDAR channel, and the addition of AMPARs to synapses renders them functional at resting potentials. Similarly, the fraction of silent synapses, in which transmission is mediated solely by NMDARs, is high in early stages of synapse formation and decreases as synapses and neurons mature, due to the insertion of AMPARs at synaptic sites. Consequently, the fraction of silent synapses and the ratio of AMPA to NMDA receptor-mediated transmission can be used as indicators of synaptic maturity (see Figure 1). Although some glutamatergic synapses reportedly develop without NMDARs, a sequence in which transmission at new synapses is mediated principally by NMDARs followed by the addition of functional AMPARs to synaptic sites appears to occur at the majority of glutamatergic synapses. Indeed, trafficking of AMPARs into developing synapses is required for their maturation and is required for synaptic plasticity in adult animals under a variety of conditions, including experience-dependent sensory plasticity and fear-conditioned learning. Although these data suggest

Figure 1 Synaptogenesis and dendrite development are concurrent. *In vivo* images of a neuron from the optic tectum of *Xenopus laevis* tadpoles were collected once a day over 3 days. The dendritic arbor increases in complexity over this time period through the net addition of arbor branches. Images collected over shorter intervals (not shown) demonstrate that net arbor growth occurs as a result of rapid branch addition and retraction. Synapses are located throughout the arbor. New excitatory synapses are mediated principally by *N*-methyl-D-aspartate (NMDA)-type glutamate receptors, shown as red dots. α-Amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type receptors, shown as green dots, are added to these synapses as they mature. Even after 3 days of growth, the dendritic arbor continues to show structural changes and to add new (NMDA receptor (NMDAR) only) synapses.

that AMPAR trafficking is the key element required for synapse maturation and synaptic plasticity, AMPAR trafficking into synapses may escort other proteins into the postsynaptic density, and it is possible that these other proteins in combination with AMPARs are required for synaptic plasticity.

Developing glutamatergic synapses can be distinguished from mature synapse by several other features. Synapse maturation includes changes in the presynaptic element, including recruitment of presynaptic machinery and proteins into the axon terminal and recruitment of synaptic vesicles. Ultrastructural studies indicate that developing synapses have few, sparsely packed synaptic vesicles, and that the most reliable ultrastructural indicator of synaptic maturation is the density of synaptic vesicles.

In vertebrate neurons the subunit composition of synaptic NMDARs switches during development, from receptors containing mostly NR2B subunits to those including NR2A subunits. This change in subunit composition can be detected pharmacologically and by a faster decay of the synaptic responses. Furthermore, immature synapses may show greater spillover of transmitter from the synaptic cleft to activate extrasynaptic receptors, due to relatively poor envelopment of nascent synapses by glia.

Synapse maturation and developmental plasticity of the strength of synaptic communication are thought to be regulated by changing the efficacy of transmitter release from the presynaptic terminal and by changing the response of the postsynaptic neuron to the input signal. The mechanisms underlying these changes are similar to those which occur during learning and memory in the adult animal. For instance, calcium influx through NMDARs, Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) activation, and AMPAR trafficking underlie both synapse maturation and changes in synaptic strength associated with learning.

Process of Dendritic Arbor Development

In vivo time-lapse imaging experiments have shown that dendrites of central nervous system neurons grow by the highly dynamic addition and retraction of fine branches. Although most newly added branches retract within about 10 min of being added to the arbor, a small fraction of branches is maintained and these extend to become more stable components of the arbor. The newly added branches may sample the local environment for appropriate presynaptic contact sites. Establishment and maintenance of synapses may then confer a longer lifetime on the branches that form stable synapses and permit the dendritic arbor to enlarge over time (see Figure 1).

Classical studies using fixed anatomical preparations have led to the idea that axonal and dendritic arbors go through a period of exuberant overgrowth followed by pruning of branches based on competitive mechanisms (see Figure 2). This model of neuronal growth and pruning suggests that neurons in the adult brain have limited capacity to recover following injury, and this in turn has discouraged scientists and clinicians from exploring the potential of the brain to regain function after trauma.

Modern *in vivo* imaging methods demonstrate that neurons in the brain grow very differently than thought from classical studies. Specifically, branch additions and retractions are concurrent, so that the neuron has an ongoing capacity to add new branches and to refine its connections within the

Figure 2 Models of dendritic and axon arbor elaboration. Dendritic and axon arbor elaboration and pruning are concurrent, not sequential. Top: Diagrams of the patterns of growth of axons and dendrites according to the traditional model, in which neurons undergo an exuberant growth phase followed by a temporally distinct phase of net branch retraction. Bottom: Diagrams of the patterns of growth of axons and dendrites in which branch additions and retractions are concurrent. Adapted from Hua JY and Smith SJ (2004) Neural activity and the dynamics of central nervous system development. *Nature Neuroscience* 7: 327–332.

circuit (Figure 2). The refinement of the arbor structure occurs in response to signals from the environment and from other neurons in the circuit. These observations provide critical insight into the cellular mechanisms governing dendritic and axonal arbor development and clearly indicate that learning and recovery from trauma can occur even in the adult brain by tapping into the cellular mechanisms that shape the neuronal structure during development of the brain.

Synaptic Inputs Increase Dendrite Arbor Growth

Several time-lapse imaging experiments now provide convincing support for the hypothesis that the formation and maturation of synaptic contacts stabilize dendritic arbor structure (Figure 3). Direct *in vivo* time-lapse imaging reveals that visual stimulation increases the growth of optic tectal dendritic arbors *in vivo* by promoting the stabilization of newly added branches. Pharmacological blockade of either AMPA- or NMDA-type glutamate receptors decreases dendritic arbor growth *in vivo* and blocks visual stimulation-induced dendritic arbor growth. Similarly, deafferentation or blocking inputs within the auditory system, as well as other sensory systems, has severe effects on dendritic arbor development of neurons that receive and process sensory information. *In vivo* imaging experiments in which the maturation of glutamatergic synapses was blocked show that AMPAR trafficking into developing synapses is required for the stabilization of newly added dendritic arbor branches and the cumulative elaboration of the complex dendritic arbor. Together, these data indicate that the iterative process of dendritic arbor development requires the coordinate formation and stabilization of glutamatergic synaptic inputs (Figures 1–3).

Conclusion

Synapse formation is characterized by the assembly of a complex protein machine that spans a specialized junction, the synapse, which forms between two neurons. Recent multidisciplinary experiments combining time-lapse *in vivo* imaging, molecular manipulations, and electrophysiological recordings demonstrate that synapse formation and maturation are required for the normal development of neuronal structure, including the axon and dendrite. These experiments have also shown that the development of axons and dendrites occur as a result of simultaneous addition and retraction of branches within the neuron. These observations

Figure 3 Synaptic input drives dendrite development. The normal rate of dendritic arbor development is increased by enhanced synaptic input and is decreased when glutamate receptor activity or synapse maturation is blocked. The extent of dendritic arbor growth under 'normal' levels of circuit activity in the brain is depicted at the top. The effect of increasing activity on dendritic arbor development is shown in the second row; the effects of blocking *N*-methyl-D-aspartate receptor activity or blocking synapse maturation are shown in the third and fourth rows. Based on data from Sin WC, Haas K, Ruthazer ES, et al. (2002) Dendrite growth increased by visual activity requires NMDA receptor and Rho GTPases. *Nature* 419: 475–480; Rajan I and Cline HT (1998) Glutamate receptor activity is required for normal development of tectal cell dendrites *in vivo*. *Journal of Neuroscience* 18: 7836–7846; and Haas K, Li J, and Cline HT (2006) AMPA receptors regulate experience-dependent dendritic arbor growth *in vivo*. *Proceedings of the National Academy of Sciences of the United States of America* 103: 12127–12131.

overturn two previous ideas about brain development, that neuronal growth can occur in the absence of synapse formation and synaptic activity, and that neurons undergo a phase of exuberant growth followed by a separate period of pruning. This modern view of neuron development suggests that brain activity will increase synapse formation as well as the establishment and maintenance of optimal neuronal circuits. This view also lends hope to the idea that brain exercises will aid recovery from trauma even in adults.

Dendrites: Localized Translation

Introduction

In eukaryotic cells, translational control of gene expression is an important means in the long-term regulation of cellular structure and function. For complex and highly elongated cells such as neurons, translational control may be at least as significant as transcriptional control in the nucleus. In such cells, reliance on translational control is a consequence of their complex geometry which demands that gene expression be regulated at sites far away from the DNA in the nucleus and in a manner that is specific to the dynamic requirements of numerous and mosaic local sites. On-site translational control mechanisms at the synapse are thus well suited for the long-term, input-specific management of local protein repertoires in response to physiological stimuli. They are now thought to constitute one of the fundamental pathways that underlie neuronal plasticity and, consequently, various higher brain functions. We present a synopsis of the current state of the field, highlighting past achievements as well as key areas of current investigation.

Translational Components in Dendrites

Since the discovery of dendritically localized polyribosomes more than 20 years ago, evidence supporting the concept of localized translation in dendrites has been steadily increasing. Such evidence includes the identification in dendrites of components of translational machinery, posttranslational organelles, and diverse types of RNAs.

Translational Machinery

Polyribosomes are located beneath postsynaptic sites at the base of dendritic spines. Polyribosomes are redistributed from dendritic shafts to spines after induction of long-term potentiation (LTP), and spines with polyribosomes have larger synapses, indicating that local protein synthesis may serve to stabilize stimulation-induced postsynaptic growth. In addition to polyribosomes, other components of the translational machinery have been identified in dendrites. Such components include eukaryotic initiation factor (eIF) 2α, eIF4E, eIF4G, eIF4A, eukaryotic elongatiofactor (eEF) 2, and poly(A) binding protein (PABP). Transfer RNA (tRNA) and aminoacyl-tRNA synthetase are also localized to dendrites.

Posttranslational Organelles

Organelles that participate in cotranslational and posttranslational processing – that is, the rough endoplasmic reticulum and Golgi apparatus – are located in dendrites. The entire endoplasmic reticulum-to-Golgi secretory pathway has been delineated in dendrites. Newly synthesized membrane or secretory proteins are sorted locally to associate with dendritic Golgi outposts.

RNAs

In 1988, microtubule-associated protein 2 (MAP2) mRNA became the first transcript to be detected in dendrites. Others soon followed. Proteins encoded by dendritic mRNAs belong to a variety of functional groups. One important group includes receptors such as the inositol 1,4,5-trisphosphate (InsP3) receptor type 1, several glutamate receptor subtypes, glycine receptors, and TrkB as well as its ligand, brain-derived neurotrophic factor (BDNF). Another group of proteins encoded by dendritic mRNAs includes cytoskeleton-associated proteins such as MAP2 and activity-regulated cytoskeleton-associated protein (ARC/ARG 3.1). Kinase mRNAs have also been reported in dendrites, including those for the α subunit of Ca^{2+}/calmodulin-dependent protein kinase II (CaMKIIα) and for protein kinase Mζ. It is estimated that the number of dendritically localized mRNA species may be several hundred.

In addition to mRNAs, untranslated RNAs are also localized to dendrites. Such RNAs include ribosomal RNAs (rRNAs), tRNAs, microRNAs (miRNAs), and small brain-specific cytoplasmic RNAs (BC RNAs) such as BC1 and BC200. As discussed later, some of these small RNAs have been implicated in translational control mechanisms at the synapse.

RNA Transport in Dendrites

The targeted delivery of select RNAs to synaptodendritic domains is a functional prerequisite for local protein synthesis at the synapse. A general picture has been emerging, from work with neurons as well as with other eukaryotic cell types, that targeting *trans*-acting factors (TAFs) recognize *cis*-acting dendritic targeting elements (DTEs) in dendritic RNAs. DTEs contain spatial codes that are recognized by TAFs:

Such decoding results in the assembly of RNP complexes which in turn are propelled along cytoskeletal elements by molecular motors.

Local Protein Synthesis in Dendrites

The dendritic location of translational machinery and the active transport of specific RNAs to dendritic destination sites are indicative that proteins are locally synthesized in dendrites. This concept is well supported by experimental evidence, and mechanisms of local translational control are being investigated.

Activity-Dependent Local Translation

Dendritic proteins may be locally synthesized in response to various synaptic activations. Activation of glutamate receptors appears to regulate dendritic translation. For example, application of the metabotropic glutamate receptor (mGluR) agonist (RS)-3, 5-dihydroxyphenylglycine (DHPG) increases local levels of fragile X mental retardation protein (FMRP) by twofold within 5 min. Blockade of *N*-methyl-D-aspartate receptor (NMDAR) activation with antagonist 3-(2 carboxypiperazin-4yl) propyl-1-phosphonic acid prevents the increase in CaMKIIα protein levels in synaptic fractions from dark-reared, light-exposed animals. Tetanic stimulation of the Schaffer collateral pathway, which induces NMDAR-dependent LTP, increases autophosphorylation of CaMKIIα both in cell bodies and in apical dendrites, whereas total CaMKIIα levels increase only in apical dendrites.

Synaptic stimulation by neurotrophins such as BDNF and NT-3 has been suggested to upregulate dendritic synthesis of specific proteins. Local protein synthesis is required for neurotrophin-induced synaptic plasticity in CA1 dendritic regions. BDNF was also shown to induce translation of Arc mRNA in synaptosome preparations as well as dendritic translation of a GFP reporter mRNA that contained both 5′ and 3′ untranslated regions (UTRs) of CaMKIIα mRNA.

Mechanisms of Translational Control at the Synapse

Translational control mechanisms that have been implicated in local synaptic regulation can broadly be categorized into three groups: mechanisms that target the initiation step, those that target the elongation step, and those that operate at the RNA level. We discuss each category in turn (Figure 1).

Translation initiation Translation is mechanistically subdivided into the three steps of initiation, elongation, and termination. Initiation is often rate limiting and the target of regulation. Among translation initiation factors, eIF4F plays a strategic role in the recruitment of 43S preinitiation complexes to mRNAs. eIF4F is a heterotrimeric complex that consists of three subunits: eIF4E, a cap binding protein; eIF4G, a scaffolding protein providing the binding sites for eIF4A, eIF3, and PABP; and eIF4A, an ATP-dependent RNA helicase. eIF4E serves as a target for translational control in several neuronal signaling pathways. BDNF and the mammalian target of rapamycin (mTOR) pathway have been implicated in regulating eIF4E. mTOR is a serine/threonine kinase that phosphorylates eIF4E binding proteins (eIF4E-BPs), inducing the subsequent dissociation of eIF4E-BPs from eIF4E and thereby activating translation initiation. BDNF-induced synaptic potentiation in hippocampal slices is inhibited by application of mTOR inhibitor rapamycin. In addition, in cortical neurons and other systems, application of BDNF induces phosphorylation of eIF4E, eIF4E-BP, and mTOR. Work with gene arrays has identified a subset of mRNAs the translation of which increases upon exposure to BDNF. Among these mRNAs, postsynaptic density scaffolding protein Homer 2 has been linked to the BDNF-activated mTOR pathway. The previous data suggest that the mTOR pathway is essential for BDNF to activate translation in dendrites. Independently, the mitogen-activated protein kinase (MAPK) signaling pathway has also been linked to eIF4E. Phosphorylation of MAPK/extracellular signal-regulated kinase kinase activates its downstream signaling targets, resulting in the phosphorylation of eIF4E and in the activation of local translation. The combined data suggest coordination between these two pathways and raise the possibility of multilevel translational regulation in dendrites.

Work with *Drosophila* has shown that eIF4E mRNA may be a target of translational control in postsynaptic microdomains. Pumilio, an important factor for the anterior–posterior patterning during early *Drosophila* embryogenesis, has been suggested to inhibit synthesis of eIF4E at the *Drosophila* neuromuscular junction through interactions with the 3′ UTR of eIF4E mRNA.

Translation initiation factor PABP interacts with eIF4F and enhances initiation of both cap-dependent and encephalomyocarditis virus (EMCV)-type internal ribosome entry site (IRES)-mediated translation. Dendritic BC1 RNA regulates translation initiation by interacting with eIF4A and PABP, repressing formation of the 48S translation initiation complex. BC1 RNA represses cap-dependent and EMCV–IRES-mediated initiation. Because BC1 RNA targets unwinding factor eIF4A, mRNAs with highly structured 5′ UTRs would be particularly sensitive to BC1-mediated translational control.

Figure 1 Schematic illustration of translational control pathways in dendrites. Adapted from Kindler S, Wang H, Richter D, and Tiedge H (2005) RNA transport and local control of translation. *Annual Review of Cell and Developmental Biology* 21: 223–245, with permission.

Cytoplasmic polyadenylation is another translational control mechanism that may operate at the synapse. As was first reported with *Xenopus* oocytes, some mRNAs have short poly(A) tails and remain translationally dormant; translation is activated only subsequent to their cytoplasmic polyadenylation. Polyadenylation is initiated through phosphorylation of CPEB by the kinase aurora. Phosphorylated CPEB binds to CPEs that are contained in 3′ UTRs, and it recruits poly(A) polymerase to extend mRNA poly(A) tails. The result is a dissociation of maskin from eIF4E, allowing eIF4E to interact with PABP through eIF4G and thus to initiate translation. Translation of dendritic CaMKIIα mRNA has been suggested to

involve the cytoplasmic polyadenylation mechanism. Two CPE-like sequences have been localized to the 3′ UTR of CaMKIIα mRNA. In addition, factors involved in the polyadenylation mechanism, such as aurora, CPEB, poly(A) polymerase, but not maskin, have been identified at neuronal synapses. NMDAR activation is required for the induction of aurora phosphorylation and thus for the initiation of dendritic CaMKIIα mRNA translation. Similarly, the translation of dendritic plasminogen activator (tPA) mRNA has also been reported to depend on the polyadenylation mechanism: After mGluR simulation, tPA mRNA is rapidly polyadenylated and translated into its cognate protein.

Translation elongation Elongation may also be the target of local translational control in neurons. Phosphorylation of eEF2 can be induced by visual stimulation and is dependent on the activation of NMDARs in the amphibian tectum. Overall protein synthesis is reduced upon phosphorylation of eEF2, although individual neuronal mRNAs may be differentially receptive to such elongation control. FMRP has also been suggested to regulate translation at the level of elongation. Unphosphorylated FMRP is associated with actively translating polyribosomes, whereas a fraction of phosphorylated FMRP is associated with translationally inactive polyribosomes.

Elongation factors can be targets of regulation as well. Upon induction of hippocampal LTP, the protein levels of eEF1A increase within 5 min. Application of rapamycin blocks this effect, indicating that the previously discussed mTOR pathway is involved in this regulation. The expression of eEF1A has also been shown to be increased after DHPG-induced LTD or after induction of LTP by high-frequency stimulation of the perforant path; however, only the former appears to be sensitive to protein synthesis inhibitors.

RNA level Several translational control mechanisms operate at the RNA level. For example, in addition to the aforementioned mechanism, FMRP has been suggested to repress protein synthesis by binding to mRNAs, and activation of both mGluRs and NMDARs is important for the FMRP pathway at the synapse. One of these targets is eEF1A mRNA because FMRP represses its translation by direct binding. Independently, hippocampal mGluR-dependent long-term depression (LTD) triggers rapid translation of FMRP-interacting mRNAs. In addition, mGluR-dependent LTD also induces a transient, translation-dependent increase in FMRP; increased FMRP is in turn rapidly degraded through the ubiquitin–proteasome pathway. These data implicate yet another mechanism in the management of local protein repertoires: protein degradation.

miRNAs have also been associated with dendritic translational control. miRNAs are small RNAs (21–24 nt) that repress translation through partial base pairing with their target mRNAs. miRNAs have been found enriched in polyribosome fractions in mammalian brain preparations. Work with *Drosophila* neurons suggests that CaMKIIα contains two putative miRNA binding sites, indicating the possibility of translation repression through miRNA interaction. Components of the RNA-induced silencing complex have been found at the synapse, where one of them, SDE3 helicase Armitage, degrades during learning. Brain-specific miRNA-134 inhibits the translation of Limk1, a protein kinase that controls dendritic spine development, thus negatively regulating spine size. This effect can be alleviated by exposure to extracellular stimuli such as BDNF. In addition, FMRP has been proposed to interact with miRNAs as well as components of the miRNA pathway, including Dicer and the mammalian ortholog of Argonaute 1 (AGO1).

Translational Repression during Transport

Although the coordination of mRNA transport with translational repression has been well characterized in other systems such as *Drosophila* oocytes and early embryos, only recently have the mechanisms of transport-coupled translational repression been described in more detail in neuronal systems. ZBP1, the aforementioned β-actin mRNA TAF, has been shown to play an additional role as a translational repressor during transport. In a neuroblastoma cell line and in cultured hippocampal neurons, ZBP1 associates with β-actin mRNA and prevents its translation at the initiation step; when ZBP1–RNA complexes reach their destination, translation of β-actin mRNA is activated through phosphorylation of a key tyrosine residue in ZBP1 by protein kinase Src. These data provide clear evidence of a direct link between translational repression and RNA transport in neurons.

A similar coordination between RNA transport and translational repression has been discussed for transport RNPs. CPEB, shown to facilitate dendritic transport of CPE-containing mRNAs, is co-localized with the translational repressor maskin during transport. Neuronal RNP particles have also been found to contain translational repressors FMRP and RNA granule protein 105. These data suggest the possibility of additional functional links between RNA transport and translational repression.

Perspective

Local translational control of gene expression in synaptodendritic microdomains has been firmly established as a key mechanism in the long-term regulation of synaptic form and function. By transferring decision-making authority to the synapse, this mechanism in essence decentralizes control of gene expression, thus fulfilling a *conditio sine qua non* for experience-dependent, input-specific long-term modulation of synaptic strength.

Future efforts will certainly continue to address the two most fundamental open questions in local translational control. First, we urgently need to understand the spatial codes that RNAs use to specify their synaptodendritic destination sites. Such codes are most likely expressed as three-dimensional architectural RNA motifs. In contrast to linear information coding in DNA, RNA information coding is, except for open reading frames, often three-dimensional. It will be important to be able to read such codes and to understand how they are being decoded by targeting TAFs. Second, despite much progress in recent years, translational control mechanisms at the synapse remain poorly understood. Thus, although it has become clear that most, if not all, local translational modulators are in fact repressors, little is known about how local translation is de-repressed in response to appropriate input stimuli.

It will also be important to learn which proteins are locally synthesized upon stimulation – that is, how mRNAs are selected for local translation in a given synaptodendritic microdomain. Are such decisions implemented through selective translational activation (i.e., de-repression) of only a few mRNAs out of a larger locally available subset, or is this selection made at an earlier stage (i.e., through the selective recruitment of only a few specific mRNAs to that microdomain)? These two options are not mutually exclusive, and specificity may thus be achieved at the level of selective mRNA availability at local sites, at the level of selective local translational activation/de-repression, or both. Given Nature's resourcefulness, it would indeed be surprising if examples of either mode of regulation would not be identified in due course.

Introduction

Dendrites are master integrators of information flow in the brain and the sites of postsynaptic structural modifications that regulate the plasticity of synapse strength in response to neurotransmission. Recent data suggest that dendrites are also an important site for the dynamic regulation of localized gene expression in the nervous system, with subsets of synapses possessing the ability to independently alter synapse strength through the local synthesis of proteins. An important component to this regulation is the active transport of a select group of messenger RNAs (mRNAs) from the cell body into dendrites and targeting of these mRNAs to specific translation sites. Since several long-lasting forms of plasticity require protein synthesis, synaptic stimulation appears to be an important mechanism for the regulation of mRNA trafficking within dendrites.

Discovery of Dendritic mRNA Transport

Early speculations about the nature of synaptic connections led to the idea that cytoskeletal proteins played an important structural role in neuronal function, and the identification of translational machinery in dendrites but not axons by ultrastructural methods and actin protein localized to dendritic spines spawned an era of investigation into the nature of localized gene expression that is still ongoing. As it was found that microtubule-associated protein 2 (MAP2) was expressed selectively in the dendritic compartment, markers for neuronal polarity became the subject of great curiosity. Subsequent work tracked total mRNA movements in cultured neurons by pulse labeling with radioactive nucleotides to visualize time-dependent migration of mRNA into dendrites and showed the asymmetric localization of cytoskeletal mRNAs to dendrites, such as MAP2. More recently, eloquent molecular approaches have demonstrated the presence of numerous diverse mRNAs by directly aspirating cytoplasm from transected dendrites and identification by polymerase chain reaction. These studies served as the foundation for the idea that many regulatory and cytoskeletal mRNAs may be selectively transported into neuronal dendrites on microtubules and subsequently activated for translation at synapses in response to neuronal stimulation, an idea that currently has enormous support and has led to breakthroughs in visualizing specific transcript motility in living cells.

Structure and Composition of Dendritic Transport mRNPs

mRNAs are transported into dendrites in the form of large, electron-dense RNA- and protein-containing granules. Since these transport granules are distinct from stress granules, they will be referred to as transport messenger ribonucleoproteins (mRNPs). Neuronal cytoplasmic transport mRNPs appear quite heterogeneous in size and have been estimated by ultrastructural methods to be between 200 and 600 μm in diameter and greater in mass than polyribosome complexes (>500 S). They are formed initially when nucleocytoplasmic shuttling RNA-binding proteins (RBPs) associate with nascent transcripts in the nucleus to prevent premature ribosomal loading and translation and to aid in nuclear export of mRNAs. While the composition of proteins in transport mRNPs may change on exit to the cytoplasm, exchanging factors specific to export, for example, several RBPs appear to remain associated with transcripts until they are delivered to distal dendritic sites for translation. Numerous biochemical and proteomic experiments suggests that these cytoplasmic neuronal transport mRNPs are not homogeneous in composition, containing many different RBPs, such as Staufen, zipcode-binding protein 1 (ZBP1), heteronuclear RNP-A2 (hnRNP-A2), Pur-alpha and the fragile X mental retardation protein (FMRP), as well as many mRNA species, such as calcium/calmodulin-dependent protein kinase II (CaMKII)-alpha, activity-regulated cytoskeletal-associated (Arc), beta-actin, and the noncoding BC1. Included in the hundreds of diverse mRNAs that have been isolated from dendrites biochemically are several subunits of glutamate receptor subtypes and translational machinery components, such as ribosome subunits and elongation factor 1a. In addition, transport mRNPs contain multiple cytoskeletal motors such as conventional kinesin (Kif5) and dynein, which contribute to plus end- and minus end-directed transport along microtubules within dendrites. While the protein content may be diverse, the RBPs in transport mRNPs all appear to be important for repression of translation of mRNAs until reaching their distal site, where they are derepressed by regulatory signals. Both biochemical work and ultrastructural work have shown that they contain many densely packed ribosomes but are not translationally

competent as they lack proteins essential for initiation (e.g., eIF4). It is interesting to note that these mRNPs are dramatically remodeled on neuronal depolarization, presumably releasing ribosomes and mRNAs into local active translational complexes. The composition of transport mRNPs suggests that they represent motile pretranslation units that undergo dynamic remodeling in response to signals that induce their dendritic transport and subsequent translation.

Sequence and Structural Characteristics of Localization Signals in Neuronal Transport mRNPs

A unifying theme in the analysis of many localized mRNAs is the requirement for a *cis*-acting sequence for targeting the transcript to specific sites, or 'zipcodes.' These zipcodes are mostly localized to the 3′ untranslated regions (UTRs) of transcripts, where they are bound by *trans*-acting RBPs involved in the localization process (see Table 1). The zipcodes may contain several units that function in a multistep pathway to mRNA localization. One example is the localization of myelin basic protein (MBP) mRNA to the myelin-rich oligodendrocyte compartment. This is a two-step process involving an 11 nt element (the RNA transport signal, RTS) sufficient to direct a reporter mRNA into processes and a distinct 342 nt element (the RNA localization region) required for MBP mRNA targeting to or retention at the myelin-specific subcompartment in oligodendrocytes. The 11 nt RTS has been shown to mediate granule formation and dendritic trafficking with hnRNP-A2 in primary hippocampal cultures as well; however, a requirement for this 11 nt sequence in the transport of the native MBP mRNA has not been established. It is interesting to note that a conserved version of the RTS has also been found in several other dendritic mRNAs, such as MAP2, CaMKII-alpha, Arc, and γ-aminobutyric acid-A-receptor subunit and therefore may play an important role in mRNA targeting using similar machinery in neurons. However, the fact that a 640 nt element of MAP2 mRNA 3′UTR was found to be necessary for dendritic targeting suggests that there may be additional required elements present in the 3′UTR that control localization or stability. Another example of a bipartite element is the beta-actin mRNA, which contains both a 54 nt and a 43 nt zipcode, required for efficient localization to neuronal processes and growth cones. While some zipcodes in localized mRNAs such as beta-actin are necessary for localization of the native mRNAs, most zipcodes have been tested using reporter mRNAs, and therefore their requirement in the localization of native mRNAs is not known. Future work using genetic deletions or antisense technology can more directly address these shortcomings.

Some mRNAs, such as *bicoid* in *Drosophila*, may contain zipcode elements that are repeated several times in the 3′UTR to effect a more efficient localization as the deletion of one or more redundant elements is not sufficient to completely abolish targeting but rather diminishes the amount of mRNA localized over time. This is a feature shared by the beta-actin mRNA 3′UTR zipcode, which has a consensus sequence of ACACCC repeated twice within one zipcode element (the 54 nt chicken zipcode). Although some zipcodes may be conserved between mRNAs, there is no clear indication yet that the same proteins are involved in their localization. Rather diverse collections of RBPs have been found to associate with transcripts that have conserved zipcodes. This has inspired a thorough analysis of secondary structural features in zipcodes that may be more important than primary sequence conservation

Table 1 RNA-binding proteins and their corresponding *cis*-acting sequences in brain

RNA-binding protein	*mRNA*	*Sequence and location*	*Required for localization*[a]
ZBP1	beta-actin	ACACCC, within 54 nt zipcode in 3′UTR	+
hnRNPA2	MBP	GCCAAGGAGCC, 3′UTR	
	MAP2	GCCAAGGAGUC, coding	
CPEB	CaMKII-alpha	UUUUUUAUU X 2 (separated by 82 nt), 3′UTR	
HuD	tau	240 nt, 3′UTR	+
MARTA1/2	MAP2	640 nt, 3′UTR	
Unknown	CaMKII-alpha	3.0 kb, 3′UTR	+/−
		94 nt, 3′UTR	

[a]Plus sign (+) indicates *cis*-acting sequences shown to be required for full-length (either endogenous or exogenous) mRNA localization in dendrites either by deletion of element or using antisense to the endogenous element; no entry symbolizes that the *cis*-acting elements were tested only for localization of a heterologous reporter mRNA; +/− indicates conflicting reports for this mRNA (one study indicated that this 94 nt sequence can localize a heterologous reporter to dendrites (−), and another showed significantly diminished dendritic localization of this endogenous mRNA with a 3.0 kb deletion in the 3′UTR that left the 94 nt sequence intact (+)). CaMKII-alpha, calcium/calmodulin-dependent protein kinase II; CPEB, cytoplasmic polyadenylation element binding protein; hnRNPA2, heteronuclear ribonucleoprotein-A2; HuD, one of the embryonic lethal abnormal vision family of RNA-binding proteins; MAP2, microtubule-associated protein 2; MARTA, MAP2-RNA *trans*-acting protein; MBP, myelin basic protein; UTR, untranslated region; ZBP1, zipcode-binding protein 1.

since RNA can assume diverse three-dimensional structures and the 3′UTRs can possess structure without interfering with translation. Indeed many zipcodes appear to contain stem–loop structures where the essential sequences present binding sites for RBPs, as has been shown for ZBP1 binding to the 54 nt zipcode in beta-actin mRNA and for Staufen binding to the 3′UTR of *bicoid* mRNA. It is important to note that individual nucleotide changes that conserve the stem hydrogen bonding structure do not alter binding to the *trans*-acting RBPs or localization of the mRNAs whereas nucleotides that do disrupt the structure diminish binding and localization. A more thorough analysis of structural motifs common to localized mRNAs, may reveal a class of conserved structures present within mRNAs that share *trans*-acting RBP recognition sites. Indeed more-detailed structural information may explain how the dendritic targeting element (DTE) of MAP2 mRNA is recognized by the diverse RBPs Staufen, hnRNP-A2, MAP2-RNA *trans*-acting protein (MARTA)1, and MARTA2, or how MARTA1 recognizes both the DTE and the zipcode of beta-actin mRNA, which show little primary sequence homology.

Trans-Acting Factors Involved in Dendritic mRNA Transport

The persistent association of RBPs with mRNAs from birth at the transcription site until death after mRNA translation and degradation suggests that RBPs are critical to the spatiotemporal regulation of mRNA expression. At least 300 RBPs are expressed in vertebrate brain during early developmental stages, defined by the presence of conserved RNA-binding motifs, such as the K-homology domain of hnRNP-K family of RBPs. Other common RNA-binding motifs include the RGG-box, the RNA-recognition motif, and the double-stranded RNA-binding domain. These RBPs usually have nuclear shuttling domains (nuclear export and import) to facilitate entry and exit from the nucleus, where they first associate with transcripts in their journey to distal sites for regulated translation. An important theme is that the mRNA must be translationally repressed by these RBPs to facilitate temporally and spatially localized gene expression and that this repression must be linked to the process of mRNA transport. Therefore RBPs may function to repress translation and initiate assembly of the transport-competent higher-ordered mRNP granules before being recognized by the transport machinery. This idea is supported by the observation that exogenous MBP mRNA injected into oligodendrocytes induces the formation of larger RNP particles before their transport into processes. Several RBPs involved in the regulation of mRNA transport and translation in neurons, such as cytoplasmic polyadenylation element binding protein 1 (CPEB1), ZBP1, and Staufen, have been implicated in this dual functional role already.

While a causal role for RBPs in the transport and translational regulation of dendritic mRNAs appears concrete, there is surprisingly little direct evidence for an essential role of these proteins in RNA localization (see Table 1), most likely because many of these proteins may play an essential role in early development and therefore knockout animals may not be viable. However, a viable knockout mouse has been generated for CPEB1, and neurons from these mutant mice have shown reduced dendritic localization of a reporter mRNA containing cytoplasmic polyadenylation elements (CPEs) within the 3′UTR. The absence of data demonstrating a reduction in the dendritic localization of endogenous mRNAs containing CPEs suggests that several RBPs, such as the other recently added members to the CPEB family of RBPs, may play a role in targeting different mRNAs containing CPEs to dendrites along with CPEB1. Alternatively, distinct RBPs may solely regulate specific stimulus-induced pathways for mRNA localization, as has been shown for the neurotrophin-induced localization of beta-actin mRNA to neurites and growth cones. This localization requires the beta-actin mRNA zipcode recognition by ZBP1 because uncoupling of the mRNA from ZBP1 using antisense oligonucleotides that are complementary to the zipcode has caused a reduced localization of beta-actin mRNA by this stimulation paradigm. Other proposed functions for RBPs in dendritic transport include a role for connection of the mRNA to molecular motors, such as that proposed for CPEB. The trafficking of MBP mRNA by hnRNP-A2 in oligodendrocytes and CaMKII-alpha mRNA in hippocampal neurons was reduced by antisense oligonucleotide knockdown of conventional kinesin (Kif5). Recent proteomic approaches have identified numerous RBPs in complex with this form of kinesin from brain extracts, including proteins already implicated in RNA localization: Staufen, Pur-alpha, and hnRNP-U. However, the molecular evidence for a connection to kinesin is still lacking, and further work is needed to understand the mechanism behind this connection, as well as connections to the minus end-directed microtubule motor dynein that contributes to the oscillatory and retrograde trajectories of transport mRNPs.

Dynamic Regulation of Transport mRNP Motility

Early studies in the transport of mRNAs to dendrites showed that on synaptic stimulation, immediate early genes such as Arc are turned on, and the mRNAs are rapidly transported into dendrites. This transport

Figure 1 Analysis of rapid dendritic transport of calcium/calmodulin-dependent protein kinase II (CaMKII)-alpha messenger RNA (mRNA) in living hippocampal neurons. Cultured mouse hippocampal neurons (10 days *in vitro*) were transfected with the indicated constructs and imaged 18 h later using epi-fluorescence microscopy with filter sets for green fluorescent protein (GFP; a 100×, 1.35 numerical aperture lens was used here) and a closed-chamber heated coverslip apparatus (Bioptechs, USA). (a) Schematic of constructs used to visualize CaMKII-alpha mRNA in living cells. One construct is a fusion of GFP to the viral protein MS2 (GFP fusion protein) and contains a nuclear localization sequence. The second construct is the reporter mRNA, which consists of a fusion of the lac Z coding region (lac Z) to 8 repeats of the MS2-binding hairpin loops (MS2 hl) and the zipcode sequence, which here is the 3′UTR of murine CaMKII-alpha (both the MS2 loops and the zipcode are in the 3′UTR of this construct). Since the MS2 hairpin loops each contain two binding sites for MS2 protein, each mRNA can theoretically be linked to 16 GFP molecules. (b) Analysis of CaMKII-alpha reporter mRNA movements in neurons using Image J. A time-lapse movie stack was converted to a maximum projection image (max), which displays the maximum pixel for each frame with stationary particles as dots and moving particles as lines, highlighting their trajectories over the sequence. A dendritic region of interest (ROI) was highlighted (white box) for further analysis (see **Figure 1(c)**, kymograph), and the line used to analyze a particle trajectory was drawn over that ROI (yellow; see inset). Still frame images of the highlighted particle movements are shown in sequence with the corresponding time stamps (every 1.5 s; upper right corners). An mRNA particle emerges from a stationary particle (red arrow) and traverses another stationary particle (green arrow), which then moves rapidly in the anterograde (right; cell body is at left) direction together with the previously moving particle. The particles move in parallel toward two stationary particles positioned anterograde in the dendrite (yellow arrows), then traverse the first stationary particle (left yellow arrow) and come to a stop at the second, more distal particle (right arrow), where they remain throughout the duration of the imaging series. (c) A kymograph of the rapid CaMKII-alpha

requires *N*-methyl-D-aspartate (NMDA) stimulation but not protein synthesis, and activation of dendritic domains in the medial dentate gyrus by specific stimulation of the medial entorhinal cortex caused a selective increase in Arc mRNA to those sites, implying input-specific localized synaptic activation and subsequent delivery of mRNA to those synapses. This increase in trafficking to dendrites is thought to require the cytoskeleton and interaction of the transport mRNPs with anterograde molecular motors. How the mRNAs recognize the sites at which they are anchored remains unknown, although there is work from other systems such as *Drosophila* that shows a role for microtubule-based motors in anchoring mRNAs. However, given the abundant actin-rich regions surrounding the synapse, one may speculate that myosin motors may also be involved in the anchoring process. In fact, recent data supports a role for MyoVa in RBP movement into dendritic spines.

Neuronal stimulation can cause the localization of mRNAs for neurotrophic factors themselves, such as brain-derived neurotrophic factor (BDNF) and its receptor kinase mediator trkB in cultured neuronal dendrites. In addition, stimulation can enhance the extent of localization, with BDNF and trkB mRNAs enriched only in the proximal dendrites under basal conditions, and upon depolarization, a significant fraction of mRNAs move into the distal dendrite. NMDA and neurotrophin stimulation results in an increase of ZBP1 and beta-actin mRNA localization to dendrites of cultured neurons. With an emerging technology of *in vivo* labeling of mRNAs using green fluorescent protein (GFP)-tagged MS2 reporter construct fusions (see Figure 1), rapid analysis of specific transport mRNP dynamics in living neurons became possible. Particles moved with both oscillatory and persistent trajectories, both in the anterograde and retrograde directions, and neuronal activity modified these dynamics. Neuron-wide depolarization (using KCl) induced the net anterograde transport of CaMKII-alpha mRNA in dendrites and caused a repositioning of the population of mRNAs with respect to synapses for those mRNAs already localized to dendrites. In addition, high-frequency stimulation leads to the rapid increase in CaMKII-alpha mRNA in synapse fractions isolated from dentate gyrus, a process independent of NMDA activation. The results suggest that a fine-tuning mechanism may exist to regulate the local population of mRNAs in shafts and spines, modifying the content of proteins present within those synapses on stimulation in order to effect long-term changes in synapse plasticity. Consistent with this idea, the localization of RBPs involved in plasticity, such as FMRP, is altered in dendrites on stimulation. Both the protein and the mRNA encoding FMRP are trafficked into dendrites of mature hippocampal cultures in response to stimulation of group I metabotropic glutamate receptors (mGluRs). Similarly, alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor subunit mRNAs are increased in their dendritic localization by mGluR, but stimulation of NMDA causes a selective decrease in the abundance of dendritic AMPA subunit mRNAs. This suggests that activity can bidirectionally control the relative abundance of excitatory ionotropic receptor mRNAs within the vicinity of synapses, possibly contributing to changes in synaptic efficacy during developmental plasticity.

Function of Dendritic mRNAs in Synapse Plasticity and Neuronal Polarity

The first evidence of a specific requirement for dendritic mRNA targeting in mediating synaptic plasticity came from studies on CaMKII-alpha mRNA. This mRNA harbors a zipcode within the 3′UTR that is sufficient for dendritic localization of reporter constructs bearing this zipcode. In a mouse that contained a deletion of most of the 3′UTR in the endogenous CaMKII-alpha allele, physiological experiments showed defects in long-term potentiation at synapses, and behavioral experiments showed alterations in several tests for spatial and contextual conditioning that are hallmarks for learning and memory. The neurons from these mice showed significantly diminished CaMKII-alpha protein levels at synapses, suggesting that targeting of the mRNA to dendrites is essential for local protein expression to support long-term plasticity. What remains unclear is at which stage during brain development the requirement for this local synthesis occurs. Also, other studies have indicated that the 5′-most 94 nt of the 3′UTR sequence that was left intact in the above-mentioned deletion mutant was sufficient to mediate dendritic localization of reporter constructs into

mRNA particle trajectory outlined in (b) (max inset, yellow line), where distance moved (in pixels, *x*-axis) is plotted against time (seconds, 1.5 s interval per line). This analysis shows stationary particles as vertical lines and moving particles as nonvertical with velocities equal to the slopes of the lines. An example of the calculation of trajectory velocities is shown (black box) for two particles moving in parallel within the dendrite. These particles appear to merge and then move rapidly (black arrows) toward several other stationary particles, traversing the first stationary particle and then stopping at the second stationary particle. The increased intensity of the right-most vertical line (second stationary particle) after the moving particle stops there confirms this event.

dendrites, suggesting that reporter studies may give misleading results. However, it is interesting that associates with translational regulator CPEB, an RBP that associates with CaMKII-alpha mRNA, plays a role in the modification of synaptic plasticity and is itself phosphorylated by the CaMKII-alpha enzyme. This feedback loop regulation may be an important paradigm for mechanisms that underlie activity-induced changes in synapse strength.

Fragile X syndrome (FXS) is a neuronal disease characterized by mental retardation and spine dysgenesis due to loss of function of FMRP, a key RBP thought to regulate translation of mRNAs in dendrites. Physiological experiments suggest that one form of long-term depression, which depends on mGluR and rapid protein synthesis, is altered in mouse hippocampus bearing a null-mutation for FMRP. Therefore the control of dendritic mRNA processing (transport, translation, or stability) by FMRP may be important for this form of plasticity and may link changes in plasticity to dendritic morphological transformations that are fine-tuned during development. Indeed one of the mRNAs regulated by FMRP is MAP1b, an important cytoskeletal protein that may contribute to the phenotypic alteration of dendritic protrusions that are hallmarks of mental retardation in general and FXS specifically. Another RBP in brain, Staufen2, appears to be involved in regulation of dendritic mRNA transport and causes reduced dendritic spine numbers with concomitant increases in immature-like protrusions when its expression is reduced in neurons. It is interesting to note that one of the target mRNAs that is reduced in dendrites of Staufen2-depleted neurons is beta-actin. The delivery of beta-actin mRNA into dendrites is linked to the growth of dendritic filopodia and formation of filopodial synapses in response to BDNF, a process that requires ZBP1 and its interaction with the zipcode of beta-actin mRNA. These studies implicate a role for transport mRNPs and the delivery of cytoskeletal-encoding mRNAs to dendrites in the regulation of morphological plasticity during neuronal development.

A role for mRNA delivery in establishment of neuronal polarity is under investigation. Two major candidate mRNAs, MAP2 in dendrites and tau in axons, are found in these specific subcellular compartments exclusively, and their local translation there may be important for establishment and maintenance of neuronal polarity. These mRNAs are bound by distinct RBPs that are transported with these mRNAs in dendrites and axons: MAP2 by the MARTA1/2 proteins and tau by one member of the embryonic lethal abnormal vision family of RBPs, HuD. While the molecular mechanism of their differential transport is not well characterized, the details are beginning to emerge. MAP2 mRNA contains a 640 nt zipcode, the DTE mentioned earlier, which is sufficient to confer localization of a reporter mRNA to the dendritic compartment of neurons. An 11 nt sequence within the coding region of MAP2 mRNA has been suggested as a targeting element for localization of a GFP reporter mRNA to oligodendrocyte processes and hippocampal dendrites; however, a reporter mRNA containing the entire coding region of MAP2 is not able to localize efficiently in neurons, suggesting that this element may not be sufficient for dendritic targeting of endogenous transcripts and that inhibitory elements within other regions may serve to regulate transport.

Tau mRNA contains a 240 nt zipcode that is required for targeting to the axonal compartment of differentiated P19 cells that segregate dendritic and axonal markers similarly to primary neurons. This zipcode is also sufficient to redirect the dendritic MAP2 mRNA to axons when substituted for the MAP2 3′UTR. Conversely, the dendritic 640 nt zipcode located in the 3′UTR of MAP2 mRNA is sufficient to redirect tau mRNA to dendrites when substituted for the tau 3′UTR, suggesting that these zipcodes are primary determinants of localized gene expression in the establishment of neuronal polarity. Other factors that may contribute to the distinct localization of MAP2 and tau mRNAs include the association of these transport RNPs with two distinct plus end-directed microtubule motors, Kif5 and Kif3, respectively. Future work may reveal how the localized expression of these genes maintains segregation of downstream determinants of neuronal polarity.

Dendritic mRNP Transport and Neuronal Disease

Several diseases of the nervous system have been attributed to defects in the function of RBPs and in the processing of RNA. FMRP is an RBP highly expressed in brain that is silenced in FXS, the leading cause of inherited mental retardation in humans and a known cause of autism. FMRP binds to numerous mRNAs in brain to repress translation, and loss of FMRP results in elevated mRNA translation and excessive mGluR-dependent long-term depression of synaptic strength in the hippocampus and cerebellum of a mouse model of FXS. In addition, neurons lacking FMRP show an increase in the number and length of dendritic protrusions. Although several identified mRNA targets of FMRP are localized to dendrites and have important functions in neuronal homeostasis, the mechanisms that give rise to altered dendritic morphology and plasticity are not well understood. Similarly, translin is an RBP that is expressed in brain

and regulates mRNA transport and translation in dendrites. Mice lacking translin show altered expression of several mRNAs in brain and have impaired learning and memory function in behavioral tests. One target mRNA of translin is CaMKII-alpha, and since its dendritic transport has been shown to be critical for normal developmental plasticity, this aspect may be altered in neurons lacking translin.

Another RBP is the spinal motor neuron (SMN) protein that is not expressed in the progressive neurodegenerative disease spinal muscular atrophy. SMN functions in the assembly of small nuclear RNP complexes that participate in RNA splicing, and recent work suggests that SMN may play a role in the localization of mRNP complexes to neuronal processes as well. Nova proteins also function in the splicing of neuronal mRNAs, and the autoimmune disorder paraneoplastic opsoclonus myoclonus ataxia (POMA) results in the antagonism of Nova RBP function. One important target of Nova is the inhibitory glycine receptor, and the misregulated splicing of this mRNA may contribute to the excessive motor function in POMA patients. It is interesting to note that Nova-null mice are deficient in a novel form of synaptic plasticity that may result from defective splicing, long-term potentiation of the slow inhibitory postsynaptic current. The localization of Nova target mRNAs in neurons lacking this RBP remains to be determined. Together these alterations in mRNA processing and expression underlie the important function of localized gene expression in the nervous system for the maintenance of synaptic plasticity and normal signal transmission.

Analysis of mRNA Dynamics in Living Neuronal Dendrites

Recent advances in molecular techniques that aid in the visualization of mRNA movements in living neurons have led to the ability to tag mRNAs with fluorescent fusion proteins such as GFP. By insertion of a viral hairpin repeat sequence in the 3′UTR of a given mRNA, one can co-express a GFP fusion containing a small protein, MS2, that binds to these hairpin repeats with nanomolar affinity. With this system, one can follow the movements of a CaMKII-alpha reporter mRNA containing the complete 3.2 kb 3′UTR shown to be sufficient for dendritic targeting in neurons, when fused to eight MS2 hairpin loops. The same system has been used to analyze the transport of CaMKII-alpha reporter mRNAs in living hippocampal neurons with improved camera sensitivity, enabling faster sampling rates (Figure 1).

The analysis of one movie shows several transport mRNP particles (herein termed ‘particles’) moving rapidly in the anterograde and retrograde directions, as well as stationary and oscillatory particles, with an obvious heterogeneity in the intensity of both moving particles and stationary ones, suggesting that the number of mRNAs in these particles varies over a considerable range. To analyze the velocities and trajectories of these particles, the program ImageJ, which is a software that runs on most computer platforms and is available at no cost from the National Institutes of Health, may be employed. Using this program, one can readily identify moving particles by first generating a maximum projection of a time-lapse stack of images (Figure 1(b)). This analysis shows stationary particles as dots and motile particles as lines. The trace of one trajectory with reslicing generates a kymograph that displays time (sequential frames in the stack) on the y-axis and distance (pixels) on the x-axis (Figure 1(c)).

One can notice from the kymograph that the trace line reveals two particles moving in parallel (within the black box) at the same velocity that join together with a stationary particle to form a larger particle (Figure 1(b), red arrow). Then one of these particles rapidly moves out of the stationary particle, almost unnoticeable on the still frame analysis panel (Figure 1(b), green arrow) but very distinct on the kymograph, where it shows a long, almost horizontal line (Figure 1(c), black arrows) that traverses another stationary particle (Figure 1(b), left yellow arrow) and comes to a stop at a second stationary particle (Figure 1(b), right yellow arrow). Overall, this analysis showed that persistent particles containing the CaMKII-alpha reporter mRNA moved at $0.8\,\mu m\,s^{-1}$ on average with a maximal rate of $2.1\,\mu m\,s^{-1}$. In comparison with previous work, this faster sampling rate reveals that transport mRNPs move at rates at least tenfold faster (previous average velocities were estimated at $0.05–0.10\,\mu m\,s^{-1}$ and maximal velocities at $0.1–0.2\,\mu m\,s^{-1}$). It also reveals that many trajectories involve pauses or oscillatory movements that contribute to lower average velocities when sampling is done at lower frequencies. Future work may determine whether classes of transport mRNPs move at homogeneous rates and how neuronal activity may differentially modulate these velocities within dendrites.

Dendritic Signal Integration

N Spruston, Northwestern University, Evanston, IL, USA

Overview: Questions

Most neurons have elaborately branching dendritic trees that receive thousands of synaptic inputs (Figure 1). A majority of dendritic synapses are excitatory, but inhibitory synapses also contact dendrites. A number of simple questions can be asked about dendritic integration:

- How many excitatory synapses need to be activated before an action potential will occur in the axon?
- To what degree does this number depend on the location of the synapses on the dendritic tree?
- How does the spatial relationship between excitatory synapses affect dendritic integration?
- How does inhibition affect the integration of excitatory synaptic inputs?
- How does dendritic inhibition differ from somatic or axonal inhibition?
- How does the spatial relationship between excitatory and inhibitory synapses affect dendritic integration?
- How does the presence of voltage-gated channels in dendrites affect dendritic integration?
- Can spikes be initiated in dendrites and/or propagate along them?
- How do dendritic spines affect synaptic integration?

The answers to these questions depend on several important factors, such as dendritic structure and excitability, as well as the pattern of synaptic activation and the modulatory state of the neural network. Dendritic integration clearly depends on dendritic structure and ion channel expression, so the dramatic variations between cell types (Figure 1) will certainly lead to cell-specific differences in dendritic integration. One goal of dendritic physiologists is to determine common principles that apply to all cell types, while another goal is to determine cell-specific specializations of dendritic integration. Similarly, dendritic integration of fast excitatory and inhibitory synapses is influenced by the modulatory state of the network, which is determined by slower, neuromodulatory transmitters acting on G-protein-coupled receptors, in turn affecting both synaptic function and voltage-gated channels. Another goal of dendritic physiologists is to determine how dendritic integration is affected by these modulatory neurotransmitters.

Approaches

The study of dendritic integration draws on several approaches. Basic anatomical methods define the architecture of dendritic trees, while electron microscopic analysis provides detailed information about the fine structure of dendrites, spines, and synapses, as well as organelles that influence the function of dendrites. Antibodies against ion channels, receptors, and other proteins can provide important information about the molecular composition and organization of dendrites. Immunolocalization of these molecules can be visualized at the light level, but electron microscopy provides the best way of determining which molecules are expressed in dendrites, as opposed to the presynaptic and glial structures that are closely associated with dendrites.

Dendritic physiology has primarily been studied *in vitro* using sharp-microelectrode or patch-clamp recording from neurons in brain slices. The ability to use several variants of the patch-clamp method to record from dendrites in slices has been particularly helpful for investigating dendritic function. Imaging neurons with calcium or voltage-sensitive fluorescent probes has also provided valuable information about dendritic integration, especially in regions of the dendrites that are currently inaccessible to patch-clamp recording. The development of multiphoton imaging and uncaging has improved the resolution and expanded the scope of optical approaches to studying dendritic integration. Although slice physiology has dominated the study of dendritic function because of technical advantages, *in vivo* studies have also been important, because they allow dendrites to be studied in a more natural state. Dendritic recordings have been obtained *in vivo*, and have been complemented by studies using multiphoton imaging. Finally, computational methods have been used extensively in the study of dendritic integration. Computer models of realistic or abstracted dendritic trees allow data from the variety of experimental approaches to be brought together in a quantitative way. Such models are powerful tools for developing theories of dendritic function and for making experimentally testable predictions that lead to new insights.

Synaptic Integration in a Simple Neuron: Cerebellar Granule Cells

A good starting point for understanding synaptic integration is the cerebellar granule cell (Figure 1(e)). These cells are the most numerous types of neurons in

Figure 1 Neurons exhibit dendritic structure. (a) A hippocampal CA1 pyramidal neuron. (b) An interneuron from stratum radiatum of CA1. (c) A stellate cell from layer II of the rat entorhinal cortex. (d) A cerebellar Purkinje cell. (e) A cerebellar granule cell. Neurons in all panels are from the rat; axons have been truncated or removed. The scale bar applies to all panels. (1999) Dendritic calcium spike initiation and repolarization are controlled by distinct potassium channel subtypes in CA1 pyramidal neurons. *Journal of Neuroscience* 19: 8789–8798; (b) from http://www.northwestern.edu/neurobiology/faculty/spruston/sk_models; (c) adapted from Klink R and Alonso A (1997) Morphological characteristics of layer II projection neurons in the rat medial entorhinal cortex. *Hippocampus* 7: 571–583; (d) adapted from Roth A and Häusser M (2001) Compartmental models of rat cerebellar Purkinje cells based on simultaneous somatic and dendritic patch-clamp recordings. *Journal of Physiology* 535: 445–472; (e) adapted from Cathala L, Brickley S, Cull-Candy S, et al. (2003) Maturation of EPSCs and intrinsic membrane properties enhances precision at a cerebellar synapse. *Journal of Neuroscience* 23: 6074–6085.

the brain, and they are also arguably the simplest. Each granule cell receives on average only four excitatory inputs, each made onto a very short dendrite. Because the dendrites are so short, their influence on synaptic integration is minimal. This also offers technical advantages for studying synaptic physiology with patch-clamp recordings from the cell body.

Studies of these and other glutamatergic synapses have revealed that each activated synapse results in an excitatory postsynaptic current (EPSC), which reaches a peak in a fraction of a millisecond and decays in about 1 ms. This unitary EPSC (i.e., one synapse) results in an excitatory postsynaptic potential (EPSP) of a few millivolts. The EPSP, however, decays more slowly than does the EPSC. When current flows though glutamate-gated channels, the charge is stored on the membrane due to its capacitance, thus producing an EPSP. The EPSP continues to grow as long as the synaptic current exceeds the leak current, so the peak of the EPSP corresponds roughly with the end of the EPSC (**Figure 2(a)**). The amplitude of the EPSP depends on both the amplitude and duration of the synaptic current. When the synaptic current has decayed, the charge leaves the cell through leak channels, resulting in approximately exponential decay of the EPSP. The time constant of this decay is governed by the membrane time constant (τ_m) of the cell, which is determined by the product of the membrane capacitance C and membrane resistance R ($\tau_m = RC$). The leakier the cell (lower R) and the less its ability to store charge (lower C), the lower the time constant, and hence the faster the decay of the EPSP. Thus, resting membrane properties affect synaptic integration as much as do the properties of the synapses. In cerebellar granule cells, the EPSC decays with a time constant of about 1 ms (a property of the synapse), while the EPSP decays with a time constant of about 5 ms (a property of the cell membrane).

The difference between the resting potential and action potential threshold in granule cells is about 15 mV, so more than one excitatory synapse needs to be activated simultaneously in order for an action potential to occur in the axon. This is referred to as 'spatial summation' of EPSPs (**Figure 2(b)**), because the synapses are spatially distinct (even though granule cells are very small). Alternatively, one or more synapses may be activated repeatedly, leading to 'temporal summation' of EPSPs (**Figure 2(c)**). In order for

Figure 2 Integration of EPSPs. (a) Activation of a single synaptic input (as shown schematically for a synapse on a cerebellar granule cell) results in a fast inward current (excitatory postsynaptic current; EPSC) that produces an excitatory postsynaptic potential (EPSP). The magnitude of the EPSP depends on the amplitude and duration of the EPSC; the EPSP peaks approximately when the EPSC decays to zero. The magnitude of the EPSP also depends on the postsynaptic capacitance and input resistance, as does the final decay rate of the EPSP. See text for details. (b) Simultaneous activation of two synapses results in spatial summation, which is slightly less than the linear sum of the two inputs alone (dashed line). (c) Repeated activation of a synapse results in temporal summation (also sublinear), provided that the activation interval is shorter than the EPSP decay time. All traces are schematic (additional details are provided in the text).

this to occur, the frequency of this repeated activation must be high enough for each EPSP to occur before the preceding EPSP decays.

A complication of spatial or temporal summation in these neurons is that the EPSP generated by one synapse reduces the current flow at other synapses; thus, EPSP summation is slightly sublinear. This sublinear summation is caused by the effect of membrane potential on current flow at the synapse, which is governed by the driving force for synaptic current. Driving force is the difference between the membrane potential (e.g., at rest, $V_m = -70\,\text{mV}$) and the synaptic reversal potential, which is determined by the ionic permeability of the channels activated at the synapse. For glutamate-gated channels, which are roughly equally permeable to Na^+ and K^+, the synaptic reversal potential (E_{rev}) is 0 mV, so the driving force ($V_m - E_{rev}$) is 70 mV. When one EPSP has depolarized the membrane, the driving force is accordingly reduced, thus reducing the charge that enters at the synapse. For example, a 7 mV EPSP would reduce the driving force by 10%.

This is the basis for sublinear EPSP summation in a passive system. Most neurons, however, also contain voltage-activated channels that are activated in the voltage range between rest and the action potential threshold. The effects of these channels depend on their ionic permeability. For example, subthreshold activation of K^+ channels tends to increase the sublinearity of EPSP summation, while subthreshold Na^+ or Ca^{2+} channel activation can reduce sublinearity or even lead to supralinear EPSP summation. As these channels are voltage sensitive, their effects are dependent on the size of the EPSP. Similarly, the *N*-methyl-D-aspartate (NMDA) type of glutamate receptor has voltage-dependent properties that can amplify EPSPs.

Basic Effects of Dendrites on Synaptic Integration

Because granule cell dendrites are so short, they have a minimal effect on synaptic integration. Most neurons, however, have considerably longer and elaborately branching dendritic trees, which introduces further complexities to the process of dendritic integration. The simplest of these effects is that EPSPs are attenuated as current flows from the dendrites (where most excitatory synapses are located) toward the soma. This attenuation is a significant consideration, because the action potential is initiated in the axon, which typically emanates from the soma. Thus, the soma and axon are often considered to be the final site of synaptic integration.

When charge enters a dendrite through synaptically activated ion channels, much of the charge is deposited onto the membrane locally, due to its capacitance, thus producing a local depolarization. All of the charge eventually flows away from the vicinity of the synapse, however, causing the local membrane potential to decay. Some of this charge leaves the cell via the leak channels that are open at rest in the membrane. Most of the charge, however, flows along the dendrites, with only some of it flowing toward the soma. Furthermore, as charge flows toward the soma, some of it continues to leak out of the cell through the resting leak channels. As a result, the charge that reaches the soma is just a fraction of the original synaptic charge that entered the dendrite. Accordingly, the synaptic potential is smaller in the soma than it is in the dendrite (Figure 3).

Figure 3 Dendritic attenuation and filtering of an excitatory postsynaptic potential (EPSP). A schematic diagram of a pyramidal neuron is shown, containing a pyramidal soma, apical dendrites (from soma apex), basal dendrites (corners of soma base), and an axon (from center of soma base). Activation of a synapse on an apical dendrite produces a local EPSP (top) that is larger and faster than the EPSP recorded at more proximal locations (as indicated by recording electrodes). EPSP attenuation is caused by loss of charge between the synapse and other locations, as well as changes in local input impedance. See text for details.

The attenuation of EPSPs between the synapse and the soma raises the important question of whether synapses that are far from the soma compensate in some way for this distance-dependent disadvantage. Although there is evidence that some synapses, in some neurons, may have larger conductances at more distal locations, different results have been obtained in other types of neurons, so the issue remains unresolved and somewhat controversial.

Another factor increases the difference between the local synaptic EPSP and the somatic EPSP. Because dendrites are small, they have a high input impedance (high resistance); thus, the current flowing at the synapse produces a large voltage change. By contrast, the soma is much larger and therefore has a much lower impedance; the voltage change resulting from an equivalent current is therefore smaller than in the dendrite. Thus, two factors result in EPSP attenuation between the dendritic synapse and the soma: charge attenuation and impedance differences. Both of these factors become more pronounced for synapses located at greater distances from the soma, but the magnitude of the effects depends on many factors, including dendritic structure (diameter, length, and branching) and membrane properties, as well as the kinetics of the EPSP (faster EPSPs attenuate more).

A mathematical theory for analyzing current flow in dendrites and the resultant effects on EPSP attenuation was provided by Wilfrid Rall in the 1950s and 1960s. This theory was called 'cable theory,' because it treated dendrites as conductive cables with leaky membranes immersed in a conductive medium (the extracellular space). The theory drew extensively on insights provided by the analysis of current flow in transatlantic telephone cables. Rall's cable theory now serves as the foundation for modern computer modeling of neurons with dendritic trees. Such models are now being used to provide insight into how charge spreads in elaborately branching dendritic trees containing many different types of ion channels.

Another way that dendrites influence EPSPs is via their effect on spatial summation. If two synapses on the same dendrite are activated together, they will sum sublinearly for the same reasons as described for the simple case of a cerebellar granule cell. If the two synapses are on different dendrites, however, the sublinearity of spatial summation will be reduced, because each synapse has a reduced influence on the other, due to the attenuation from one location to the other. For synapses located on different dendrites this effect can be quite large.

Dendrites also influence EPSPs by affecting temporal summation. Because of the resistance and capacitance of dendrites, EPSP time course is filtered between the dendrites and the soma. At the site of the synapse, the decay of the EPSP is governed primarily by the flow of current along the dendrites, away from the synapse. Because this pathway has a resistance lower than the resistance of the membrane to current flow, most of the local, dendritic EPSP decays more rapidly than does the membrane time constant. By the time the EPSP reaches the soma, however, the EPSP decay is governed mostly by the membrane time constant, which is slower. In addition, the intervening dendrites filter the rise time of the somatic EPSP. As a result of this difference in time course, temporal summation is greater in the soma than it would be in the dendrites. Furthermore, synapses located more distally are filtered more, so in a passive system their temporal summation in the soma is greater.

Effects of Inhibition on Dendritic Integration

Some subtypes of inhibitory interneurons specifically target dendrites. Although relatively little is known

about the differences between these dendritic inhibitory synapses and their counterparts on the soma and axon, an understanding of cable theory informs speculation about the possibly specialized role of dendritic inhibition.

Just as EPSPs are attenuated and filtered between the dendrites and the soma, inhibitory postsynaptic potentials (IPSPs) generated in the dendrites will be smaller and slower in the soma. However, the mechanism of action of most inhibitory synapses is activation of Cl^- channels (e.g., $GABA_A$ receptors). In most cells, the reversal potential of synapses using Cl^- channels is very close to the resting potential, so the driving force at rest is very small. Therefore, activation of these synapses may not produce significant IPSPs; instead, a major effect of Cl^- channel activation is 'shunting inhibition.' If the conductance is large, shunting inhibition can be very effective. When positive charge from an activated excitatory synapse arrives at the inhibitory synapse, it attracts Cl^- ions through the activated Cl^- channels, thus reducing the EPSP. Thus, inhibitory synapses can 'shunt' current from excitatory synapses.

The effectiveness of shunting inhibition is particularly dependent on the relative location of the excitatory and inhibitory synapses activated. Inhibitory synapses located on the soma can shunt excitatory current originating anywhere in the dendritic tree. By contrast, dendritic inhibition will shunt excitatory synapses on the same (or nearby) dendrites more effectively than it will those on other (or more distal) dendrites. Shunting inhibition also has a greater effect on somatic membrane potential (and therefore on action potential initiation in the axon) if it is located on the path between the excitatory synapses and the soma (Figure 4). Inhibitory synapses located off this path are less effective at shunting current as it flows from the synapse to the soma.

Effects of Voltage-Gated Channels on Dendritic Integration

Most of the foregoing analysis of dendritic integration has been based on passive dendrites (i.e., lacking voltage-gated channels). However, it is well known that dendrites contain voltage-gated conductances, which dramatically influence dendritic function. Dendritic patch-clamp recordings have provided direct evidence for the presence of Na^+, Ca^{2+}, K^+, and other voltage-gated channels in the dendrites of many cells. There is also compelling evidence for differences between the density and properties of these channels in dendrites as compared to the soma of the same cell type. For instance, in hippocampal pyramidal neurons, A-type K^+ channels have a higher density and lower activation threshold at increasingly distal dendritic locations. In the same cells, HCN channels (hyperpolarization-activated Na^+/K^+ channels) have the highest density in the most distal apical dendrites. Although some explanations for the functions of these nonuniform channel distributions have been reported, they remain under investigation. In

Figure 4 Dendritic inhibition. A single excitatory synapse (circle) on an apical dendrite is shunted by an inhibitory synapse (triangle) on the path between the synapse and the soma. In response to activation of both synapses (right), the somatic excitatory postsynaptic potential (EPSP) is much smaller than the sum of the EPSP on its own (left) and the inhibitory postsynaptic potential on its own (middle). See text for details.

addition to these region-specific differences in channel densities and properties, there are also cell-specific differences. For example, while expression of dendritic voltage-gated Na^+ channels has been observed in most cell types, these channels are virtually absent from the dendrites of cerebellar Purkinje cells.

Voltage-gated channels expressed in the dendrites may support some of the same functions as do channels expressed in the soma or the axon. For example, there is some evidence that subthreshold activation of dendritic Na^+, Ca^{2+}, or K^+ channels can affect EPSP summation. More compelling evidence exists for two functions of dendritic Na^+, Ca^{2+}, and K^+ channels: dendritically initiated spikes and backpropagating action potentials.

Spikes mediated by voltage-gated Na^+ and Ca^{2+} channels can be initiated in dendrites, usually in response to relatively strong excitatory synaptic activation (Figure 5(a)). NMDA receptors can also contribute to the initiation of spikes in dendrites because of their highly nonlinear voltage dependence. Dendritically initiated spikes may serve several functions, including the induction of plasticity and the release of neurotransmitters or growth factors from dendrites. In addition, dendritic spikes are likely to be important for dendritic integration. Synapses located very far from the soma may not be able to exert a significant influence over action potential initiation in the axon unless they trigger dendritic spikes locally. The ability of dendritic spikes to influence axonal action potential initiation, however, depends on their ability to propagate toward the soma. In pyramidal neurons, where dendritic spikes have been studied most extensively, the forward propagation of dendritic spikes is unreliable, often leading to propagation failure (Figure 5(a)).

Given that forward propagation of dendritic spikes is unreliable, there are two possible scenarios for the function of dendritically initiated spikes. One is that they serve a primarily local function, regulating the induction of synaptic plasticity or release of neurotransmitters from dendrites. Another possibility, however, is that forward propagation of spikes can be regulated by other factors, such as synaptic activity or the modulatory state of the neuron. Indeed, these possible functions are not mutually exclusive and there is some evidence for both of these functions.

The end result of synaptic integration is an action potential in the axon, but these signals can also propagate back into the dendrites. Backpropagating action potentials have been studied in several cell types and in all cases the amplitude of the backpropagating action potential gets smaller as it travels further from the soma (Figure 5(b)). This distance-dependent attenuation of the backpropagating action potential is caused by a relatively low Na^+ channel density, compared to the axon, where action potential propagation is reliable over long distances. Some dendrites also have high K^+ channel density, especially in distal regions. The attenuation of backpropagating

Figure 5 Dendritic excitability. (a) Strong synaptic stimulation can lead to spike initiation in the dendrites. Whether or not the dendritic spike fails (as shown) or propagates successfully to the soma (not shown) depends on several factors (see text for details). (b) An action potential that begins in the axon and soma propagates actively back into the apical dendrites, but with some amplitude attenuation. Backpropagation into basal dendrites may also occur, but is not shown.

action potentials also depends on dendritic structure, with dendritic branching tending to reduce backpropagation. Because both channel density and dendritic architecture vary across cell types, the attenuation of the backpropagating action potential is also cell-type specific. At one extreme are cerebellar Purkinje cells, which lack a significant backpropagating action potential because of the absence of Na^+ channels, as well as extensive dendritic branching. At the other extreme are the dopamine cells of substantia nigra, which show almost no attenuation of the backpropagating action potential, because of high Na^+ channel density and very limited dendritic branching. Even within one cell type, however, backpropagating action potentials are influenced by a variety of factors, including modulatory state and synaptic activity.

The functions of backpropagating action potentials are currently being explored, but there is evidence that they may be involved in the induction of synaptic plasticity and the dendritic release of neurotransmitters or growth factors. Voltage-gated Ca^{2+} channels in dendrites are activated by backpropagating action potentials. Although these channels are not essential for backpropagation, their activation is likely to be important for triggering biochemical events crucial for the functions mentioned above.

Backpropagating action potentials, though attenuated, are always detectable in dendritic recordings. The reverse is not true, however, for dendritically initiated spikes, which sometimes fail to propagate, thus resulting in diminishingly small potentials in the soma. This intriguing difference between backward and forward propagation is actually expected from the branching structure of pyramidal neuron dendrites. When axonal and somatic Na^+ current produces an action potential, a large current is required to support the action potential in the soma, because of its large surface area (and hence low impedance). As this current flows into the dendrites, which are smaller (and have higher impedance), it is relatively easy to depolarize the dendrite to activate the voltage-gated channels required for action potential backpropagation. However, when a spike begins in a dendrite, only a small current is required because of the small size (and high impedance) of the dendrite. As the spike propagates from small dendrites to larger dendrites and eventually into the very large soma, the small current initially generated by the dendritic spike will produce less depolarization of the larger structures (lower impedance). Thus, progressively fewer Na^+ channels may be activated as the spike propagates forward, eventually causing propagation failure.

Although dendritically initiated spikes and backpropagating action potentials are distinct dendritic events, they are not mutually exclusive; a few interesting interactions have been reported. In regions of the dendrites where dendritic spikes are large, Na^+ channels will be inactivated for a period of time following the spike, thus reducing the amplitude of the backpropagating action potential in the same region. The converse situation can also occur, where backpropagating action potentials result in Na^+ channel inactivation and hence a higher threshold for dendritic spike initiation. Another intriguing interaction has been observed in cortical neurons, where backpropagating action potentials – either alone or in combination with synaptic input – can lead to the generation of large dendritic spikes involving sustained activation of voltage-gated Ca^{2+} channels.

Contributions of Dendritic Spines to Dendritic Integration

One of the big mysteries of dendrites is the function of dendritic spines. Aside from relatively simple functions such as increasing dendritic surface area and space for synapses, two functions have been proposed for spines: biochemical and electrical compartmentalization. Biochemical compartmentalization may limit the spread of second messengers and other regulatory factors, thus increasing the specificity of synaptic plasticity. Compartmentalization of Ca^{2+} by the spine has been demonstrated by numerous studies. Electrical compartmentalization is more complicated and has also been more difficult to demonstrate. Membrane potential changes in the dendrite are not likely to attenuate significantly as they spread into spines. This is because the small size (high impedance) of spines makes them very easy to depolarize. On the other hand, EPSPs in spines may attenuate significantly as they spread into the larger (lower impedance) parent dendrite. Such attenuation, if significant, could mean that EPSPs in spines are very large, possibly resulting in activation of voltage-gated channels in spines, such as Ca^{2+} channels known to be present in the spine head. Quantitatively, the magnitude of the electrical compartmentalization imposed by spines depends on the resistance of the spine neck. This parameter is not well known, but imaging studies are beginning to yield important data that will address these and other issues, leading to an improved understanding of the function of dendritic spines.

Concluding Remarks

The basic principles of synaptic integration are well understood, and cable theory provides a solid foundation for using computational models to predict

how dendrites affect synaptic integration in a passive system. However, many questions remain about how excitation and inhibition interact in the dendritic tree and how dendritic integration is influenced by voltage-gated channels. Different types of neurons have different dendritic structure and appear to be equally diverse in the types of voltage-gated channels they contain. In addition, synaptic activity and modulatory neurotransmitters strongly affect how dendritic integration proceeds in any given neuron. Thus, dendritic integration needs to be studied in many different types of neurons and under different conditions. One of the most important issues will be to determine how dendritic integration works in behaving animals. This will require an understanding not only of the structural and functional properties of dendrites, but also knowledge of the patterns of synaptic activation and neuromodulatory background that occurs during various behaviors. Ultimately, this will require refinements, improvements, and extensions of the methods used to study dendrites *in vitro* and *in vivo*.

Dendritic Spine History

A Matus, Friedrich Miescher Institute, Basel, Switzerland

Discovery

Dendritic spines were first seen by microscopists of the late nineteenth century in brain sections stained using the Golgi method (Figure 1), named after the Italian neuroanatomist Camillo Golgi who introduced it in 1873. The beauty of this technique is that it impregnates only a small proportion of neurons, typically less than 1%, but those that are stained are revealed in their entirety, including the fine structure of the smallest branches of both axons and dendrites. Initially some authors, including Golgi himself, dismissed the minute protrusions we now know as dendritic spines as artifacts produced by nonspecific precipitation of silver, a reasonable conclusion considering the frequent presence of silver precipitates in Golgi-stained material. It was not until the Spanish doyen of early microscopic neuroanatomy, Santiago Ramon y Cajal, took up the Golgi method some 14 years after its discovery that the consistent features of spine morphology and their relationship to dendrites were recognized.

Cajal is generally considered to be the first to suggest dendritic spines as structures specialized for forging functional contacts between independent nerve cells in the central nervous system, an idea that remained controversial for many decades and about which he and Golgi famously disagreed, even though they shared the Nobel prize in 1912 for their discoveries in neuronal morphology. An article by Javier DeFelipe on the International Brain Research Organization (IBRO) Website with micrographs and drawings from Cajal himself gives an excellent account of this early period. Cajal's initial description of spines in the avian cerebellum, describing dendrites as "bristling with thorns (punta) and spines (espinas)," was published in Spanish in his own privately funded journal, but several useful descriptions and discussions of his work are available in more recent literature, especially in articles by contemporary Spanish neuroscientists. Cajal is also credited with originating, in his Croonian Lecture to the British Royal Society in 1894, the idea that dendritic spines may be sites of anatomical plasticity in the neuronal circuits of the cerebral cortex.

Fine Structure and Proof of Synaptic Status

Despite the constant improvement of light microscopes and histological techniques, proof that dendritic spines are component parts of synapses only became possible with the invention of the electron microscope, with which cellular structure can be resolved down to nanometers and, crucially, cell surface membranes can be visualized. Although synaptic ultrastructure is so familiar today, limitations inherent in early techniques for preparing nervous tissue for electron microscopy meant that some years elapsed before the essential morphological elements of chemical synapses were established. The limited penetrating power of osmium tetroxide, then used as a primary fixative, was a major problem, so that visualizing critical features such as the existence of a gap between the surface membranes of the pre- and postsynaptic cells – the synaptic cleft – and the presence of synaptic vesicles in the presynaptic compartment remained in doubt. Because of these difficulties in fixation and staining, these structures were first described in tissue preparations chosen for their thinness, such as the frog sympathetic ganglion and earthworm nerve cord. In a particularly influential study, the American neuroanatomist Sanford Palay achieved good preservation of mammalian brain synapses by injecting 2 or 3% osmium tetroxide directly into the fourth ventricle of anesthetized rats. By showing that the cell surface membranes of the pre- and postsynaptic cells were separate at the synaptic junction, Palay's micrographs finally resolved the historic question of whether neuronal processes are fused or separate in favor of Cajal's interpretation. However, with the revelation that the width of the synaptic cleft is only 20 nm, it became clear just how close the old controversy about state of contact between the fine branches of axons and dendrites in the brain neuropil had been. At that time, when the status of glutamate and γ-aminobutyric acid (GABA) as major neurotransmitters was not yet established and electrotonic transmission still seemed a viable mechanism for neurotransmission at brain synapses, the existence of an intracellular cleft at the synaptic junction was an important discovery in establishing that neurotransmission in the central nervous system was essentially chemical.

Palay's article contained neither evidence nor mention of the putative synaptic nature of dendritic spines.

Figure 1 Dendritic spines as revealed by the Golgi method. (a) A drawing by Santiago Ramon y Cajal of pyramidal cell neurons in the cerebral cortex prepared from material stained using the Golgi method. For identification, one spine near the bottom right of the picture is labeled 'b'. This illustration is remarkable for the acute observation and accurate rendering of dendritic spines. Figure 2 The fine structure of dendritic spines. This is an electron micrograph showing dendritic spines in the central nervous system of the rat. The labeling emphasizes the spine apparatus (SA) in the large postsynaptic spine near the top of the picture. Below and slightly to the right, a particularly fortunate plane of section includes an entire spine synapse and shows the presynaptic terminal, packed with synaptic vesicles, attached to a round-headed spine emerging from a narrower neck. Courtesy of George Gray.

That step was taken by the British electron microscopist George Gray, who in 1959 published detailed descriptions of spine synapses in two now-classic papers, one reporting data from slices of rat visual cortex fixed with osmium tetroxide and the other presening a detailed description and interpretation of the ultrastructural features of spine synapses. Included in these papers are the first clear descriptions of the band of dense-staining material applied to the cytoplasmic face of the postsynaptic membrane, now familiar as the postsynaptic density (PSD), and the stacks of membranous sacs, thought to be involved in regulating postsynaptic calcium levels in the spine cytoplasm, which Gray named the spine apparatus (Figure 2). Gray also called attention to the significant configuration of the pre- and postsynaptic elements, with the presynaptic bouton being applied to the tip of dendritic spine, and to the presence of a uniform gap of 20 to 30 nm between the pre- and postsynaptic cell surface membranes. Together, these features left no doubt that the contact between pre- and postsynaptic cells at dendritic spines forms a synaptic junction whose structure is highly specialized for the business of chemically mediated signal transmission.

These papers initiated an outpouring of further detailed studies of synaptic ultrastructure in different brain areas during the 1960s and 1970s demonstrating that dendritic spines are the postsynaptic contact sites for the majority of synapses on categories of neurons ranging from pyramidal calls of the cortex and hippocampus to the eponymous spiny stellate cells in the basal ganglia.

Association with Excitatory Transmission

The physiological relationship between dendritic spines and excitatory synaptic transmission emerged gradually, beginning with studies by Gray and others demonstrating differences in ultrastructure between synapses known to be associated with either excitatory or inhibitory transmission. These distinctions were aided by improvements in tissue preparation for the electron microscope, particularly fixing the brain by transcardiac perfusion with a mixture of formaldehyde and glutaradehyde. In brief, following aldehyde fixation, excitatory synapses were found to have round presynaptic vesicles, whereas those of inhibitory terminals were often flattened. In addition, excitatory synapses were distinguished by a prominent postsynaptic thickening, the PSD, which was

much reduced or absent at inhibitory synapses. Arguing from relationships between morphology and physiology in synaptic connections between Mauthner cells and motor neurons in the fish spinal cord, Diamond, Gray, and Yarsagil introduced two important ideas. First, based on their location and physiology, they pointed out the likely excitatory nature of spine synapses. Second, they hypothesized that "the dendritic spine provides a postsynaptic region which is effectively isolated from other synapses in the neuron" and pointed out the potential role of spines in dendritic integration. This provided the foundation for much later work on spines as physiological compartments involved in synaptic integration.

Ideas about Dendritic Spine Function

An early suggestion, based on the enormous abundance of dendritic spines, was that they serve to increase the area of dendrites so that a greater density of synaptic connections can be accommodated along their length. However, electron microscopy also shows that few synaptic contacts are made onto the smooth surfaces of dendrites between spines, indicating that their numbers are not limited by lack of surface area. Indeed, in mouse cerebral cortex the density of synaptic contacts is greater on nonspiny than on spiny dendrites. More convincing is the notion, debated in the recent literature, that the advantage of spines lies in their ability to make synaptic contacts at a distance from the dendrite surface. Mathematical modeling supports this hypothesis, showing that, by expanding the reach of dendrites without increasing their length, spines significantly reduce the network size required to achieve a given degree of neuronal connectivity. Perhaps even more important, the extended reach of spines also provides a mechanism for individual dendrites to sample a wider array of inputs than would be possible without these protrusions, thus potentially increasing the richness of local signal processing.

Another proposed function of spines concerns their putative electrical properties. In its simplest form, this envisages spine heads acting passively to provide a restricted environment where electrical signals can trigger local changes in synaptic transmission. More recently it has been proposed that spines have active electrical properties and are capable of synaptic amplification, although the extent to which this occurs remains controversial. A more established idea is that dendritic spines act as miniature cellular compartments that partition postsynaptic signals from the bulk of the dendrite. This has been shown clearly in the case of calcium ions, in which increases in calcium ion levels in dendrites following synaptic stimulation can be visualized using calcium-sensitive fluorescent dyes. Such studies have established that, depending on the strength of synaptic signaling, increases in calcium ion levels may be limited to individual spines, may extend to include neighboring spines, or, with more intense stimuli, may spread to encompass entire branches of dendrites. This property enables spines to operate as integrators of synaptic signals impinging on the dendrites of large neurons, such as cortical pyramidal cells, from diverse sources.

Morphological Plasticity and Cytoskeletal Structure

Morphologically dendritic spines are a curious mixture of uniformity and variety. While the 'typical' spine of the textbook diagram consists of a globular head attached to the dendrite shaft by a narrow neck, in the brain itself spines occur in a wide variety of shapes. In the past these were often loosely grouped as 'stubby' (no neck), 'mushroom' (large head with thin neck), and 'thin' (small heads with a long neck), but in fact each of the parameters underlying spine shape diversity varies along a continuum.

The reason for this diversity became apparent when it was discovered that dendritic spines contain high concentrations of cytoplasmic actin which are generally associated with changes in cell shape such as the ruffling movements of crawling fibroblasts and neuronal growth cones. The suspicion that changes in the actin cytoskeleton were responsible for the morphological variety of spines was confirmed when time-lapse recordings were made from cultured neurons expressing actin tagged with green fluorescent protein (GFP) (**Figure 3**). This direct observation of cytoskeletal dynamics showed not only that spines making synaptic contact are capable of changing shape but also that, as a result of the constant dynamics of actin filaments, dendritic spines are in a continuous state of rapid motility. More recently, imaging studies using GFP to visualize dendrites in living mice have shown that in the intact brain spines change not only shape but also turn over, appearing and disappearing over days and weeks in manner that, in sensory areas of the cerebral cortex, is dependent on sensory input.

In vitro studies suggest that changes in spine morphology are regulated by synaptic transmission and depend particularly on receptors for glutamate, the neurotransmitter substance at spine synapses. Activation of postsynaptic glutamate receptors blocks the actin-based motility of spines and, depending on the pattern of activity applied, may lead to an increase or decrease in size of the spine head which is in turn associated with changes in the number of glutamate

Figure 3 Dendritic spines are morphologically plastic. The left panel shows a confocal microscope image of a dendrite segment in a brain slice from a transgenic mouse in which the surface membranes of neurons are labeled with green fluorescent protein (GFP). The entire surface of the dendrite, including the spines, is evenly labeled. This image is part of a time-lapse series made to study changes in spine morphology over a period of 30 min. The image on the right is a motility plot made from the time-lapse series using a computer routine, in which the degree of motility is color coded such that regions of low motility appear blue and regions of high motility are colored red. This reveals dendritic spines as the most morphologically plastic structures on these dendrites. Reproduced from Roelandse M, Welman A, Wagner U, Hagmann J, and Matus A (2003) Focus motility determines the geometry of dendritic spines. *Neuroscience* 121: 39–49, with permission from Elsevier.

receptors present at the synapse. The stimulation patterns that induce these actin-dependent changes on dendritic spine morphology are the same ones that induce long duration changes in synaptic signal strength – long-term potentiation (LTP) or depression (LTD) – that are associated with learning and memory. Indeed, it has been shown that drugs which suppress actin dynamics interfere with the establishment of LTP. Very recently it has been shown that a specific actin-binding protein, profilin, which *in vitro* studies implicate in regulating spine motility, accumulates in dendritic spines in the appropriate area of the brain, the amygdala, during fear-conditioned learning. Together, these discoveries of the past few years support a link between actin dynamics in dendritic spines and learning and memory.

Dendritic Spines and Cognition

The conjuction of *in vivo* studies of morphological plasticity and *in vitro* exploration of molecular mechanisms is currently revolutionizing our knowledge of how brain circuits adapt to changing behavioral demands. However, it is also possible that dendritic spines may contribute to the most enigmatic of brain functions, namely, cognition. Detailed anatomical analysis shows that dendritic spines are not evenly distributed in the brain but vary in abundance between different cell types and different brain areas. As mentioned previously, spine density is especially high on dendrites of large neurons, such as pyramidal cells, that integrate inputs from many sources. In addition, these cells are especially rich in spines in areas of the brain that are associated with advanced cognitive function such as the frontal lobes of the cerebral cortex. A link between dendritic spines and cognitive function is also suggested by evidence that defects in spine morphology are a common feature in diverse forms of mental retardation.

Dendritic spines are also implicated in the processes of hibernation. It has been shown that the entry and reawakening of ground squirrels from the hiberation state is accompanied by significant loss and subsequent recovery of spine numbers. Interestingly, spine loss also occurs in brain slices of rodents when they are cooled to temperatures equivalent to those of

hibernating animals and subsequently recovers when the slices are rewarmed to physiological temperature. Finally, it has been shown that a variety of volatile anesthetics blocks spine motility *in vitro* at concentrations equivalent to those at which they are used to induce loss of consciousness in clinical anesthesia. Although there is no direct mechanism that might explain how the morphological plasticity of dendritic spines may influence animal cognition, the variety of evidence implying that such a link may exist suggests that the history of dendritic spines is far from over.

Depression and the Brain

W C Drevets and M L Furey, National Institute of Mental Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

A major depressive episode (MDE) is a pathological mood state characterized by persistently depressed mood and/or loss of interest and incentive, which results in clinically significant distress and social/occupational impairment. Persons suffering from an MDE also experience anxiety, impaired attention, fatigue, reduced ability to experience pleasure, self-deprecating thoughts, and disturbances of sleep and appetite. When an MDE arises as primary, idiopathic disorder unrelated to any clear medical or psychiatric antecedents, the condition is called 'major depressive disorder' (MDD). When an MDE occurs alternately with manic or hypomanic episodes, the condition is called 'bipolar disorder' (BD). MDEs may also arise secondarily to other neurological, medical, or psychiatric disorders, or in response to specific pharmacological substances. Of the depressive disorders, MDD is the most common. The World Health Organization ranks MDD as the leading cause of years lived with disability.

Patients suffering from MDEs experience prominent physical manifestations, psychological symptoms, and emotional changes. In addition to sadness or depressed mood, the latter may include anxiety, phobic fears, panic attacks, irritability, apathy, anhedonia (inability to experience pleasure or reward), or 'flatness' (lacking in emotional reactivity). The physical manifestations, including fatigue, anorexia, weight change, insomnia, headache, or psychomotor slowing (decrease in the rate and/or amount of motor or mental activity), often eclipse emotional features as the presenting complaint. The psychological manifestations of MDEs confer the greater clinical risk, however, because they include preoccupation with death, hopelessness, guilt, self-deprecation, and suicide. About 15% of patients hospitalized for MDEs ultimately die by suicide, and about one-half of completed suicides occur within the context of an MDE.

Epidemiologists estimate that between 6% and 18% of individuals will develop MDD during their life span. The variability in these prevalence rates partly reflects the lack of objective diagnostic tests and the uncertainties involved in establishing diagnosis in mild cases. This lack of precise and biologically verifiable definition of illness also presumably contributes to inconsistencies in the literature pertaining to neurobiological abnormalities associated with MDD. So long as psychiatric nosology depends on syndrome-based classifications, diagnoses for MDD will likely encompass patients with a wide range of conditions. Illness onset can occur throughout the life span, but cases are grouped, by age at onset, into early-onset depression, when the first MDE occurs before age 40 years, and late-onset depression. The heritability of early-onset MDD is much higher than for late-onset MDD. Moreover, late-onset mood disorders frequently are associated with neuroimaging and clinical evidence of cerebrovascular disease or other neurological disorders.

The course of mood disorders is highly variable. In some cases episodes of depression alternate with periods when function returns to premorbid levels. For such cases the average frequency of episodes is about five to six per 20 years. Many patients, however, experience multiple recurrences per year or develop chronic or intermittent illness without clear returns to the premorbid baseline. Antidepressant pharmacotherapy is thought to shorten the duration of MDEs, and, if continued, to decrease the risk of recurrence.

Finally, MDEs commonly occur comorbidly with anxiety disorders (such as panic disorder, social phobia, and obsessive–compulsive disorder), eating disorders such as bulimia nervosa, and substance abuse/dependence disorders. These comorbid conditions generally worsen or improve in tandem with the severity of depressive symptoms, but in some cases (e.g., social phobia and obsessive–compulsive disorder) they persist despite remission of depressive symptoms. The presence of comorbid anxiety syndromes confers a less favorable prognosis on the course of MDD.

Neurobiological Correlates of Mood Disorders

Despite many psychological and biological theories regarding the pathogenesis of mood disorders, the etiologies of MDD and BD remain unknown. The intrusive, spontaneous, and perseverative nature of MDE symptoms and their responsiveness to antidepressant drugs suggest that abnormal brain processes underlie and maintain these symptoms. Moreover, neurophysiological, neuropathological, and neurochemical abnormalities have been discovered within neural systems that modulate emotional behavior in MDD and BD, although none of these has shown sufficient sensitivity and specificity to prove useful as a diagnostic test.

Twin and other family studies indicate that genetic factors contribute substantially to the liability for developing MDD and BD, particularly in cases characterized by recurrent illness and early age-at-onset status. These data suggest that the transmission of mood disorders involves complex interactions between multiple genes, each exerting relatively small effects on vulnerability. A variety of single-nucleotide polymorphisms are reportedly associated with MDD or BD, although few findings have been replicated. The genetic data also support a role for acquired factors. For example, a gene–environment interaction has been described in which a functional polymorphism of the serotonin transporter promoter region increases the risk for MDE within the context of stress.

Although stressful events may constitute 'acquired factors' that interact with genetic susceptibility in the development of mood disorders, once the illness has been instantiated, the potential links between stressors and subsequent MDE become progressively less evident. Patients generally report that their pattern of depressive symptoms is unrelated to stressful events. The life event most clearly associated with higher risk is the cessation of pregnancy, as the postpartum period constitutes the epoch of greatest risk for developing MDD or BD in females.

A variety of neurological disorders, medical conditions, and pharmacological substances also increase the risk for developing MDE, providing clues about the neurobiological systems in which dysfunction may induce depressive symptoms. For example, Parkinson's disease (PD) is associated with a two- to fourfold increase in the risk for MDEs relative to other similarly disabling conditions. In about one-half of cases, the MDE onset precedes the onset of motor manifestations in PD. These findings have led to hypotheses that degeneration of dopaminergic projections and/or ascending serotonergic projections associated with PD impairs neural processes underlying reward processing and mood modulation, yielding depressive, anhedonic, and anxiety symptoms.

Other medical diseases that increase the risk for MDE or mania include endocrine disturbances (e.g., hypothyroidism, Cushing's syndrome), degenerative basal ganglia disorders (e.g., Huntington's or Wilson's diseases), temporal lobe epilepsy, and structural lesions (tumors, infarcts, injury) involving the striatum, frontal lobe, or mesiotemporal cortex. Pharmacologic agents that may precipitate MDEs include agents that induce neuroendocrine or biochemical changes similar to those found in primary MDD. For example, administration of corticosteroids (e.g., prednisone) or monoamine-depleting agents (e.g., reserpine) can induce an MDE, and also result in neurochemical changes that resemble, respectively, the hypercortisolemia and reduced monoamineregic neurotransmitter function evident in MDD.

Neural Circuits Affected by Mood Disorders

Neuroimaging, neuropathological, and lesion analysis data implicate brain networks that normally regulate the evaluative, expressive, and experiential aspects of emotional behavior in the pathophysiology of mood disorders. These networks include limbic–cortical–striatal–pallidal–thalamic (LCSPT) circuits, formed by the orbital and medial prefrontal cortex (OMPFC), amygdala, hippocampal subiculum, ventromedial striatum, mediodorsal thalamic nucleus, and ventral pallidum. The LCSPT circuits initially were related to emotional behavior on the basis of their anatomical connectivity with limbic structures that mediate emotional expression, such as the hypothalamus and periaqueductal gray (PAG). They initially were implicated in the pathophysiology of depression by the observations that degenerative basal ganglia diseases and lesions of the striatum and orbitofrontal cortex (OFC) increased the risk for MDEs. Because these conditions affect synaptic transmission through the LCSPT circuitry in diverse ways, it appears that dysfunction that alters transmission through these circuits in various ways can produce depressive symptoms.

The structural and functional brain abnormalities associated with mood disorders also implicate the LCSPT circuits and the extended anatomical network formed by neural projections linking the LCSPT components to the mid- and posterior cingulate cortex, superior and medial temporal gyrus, parahippocampal cortex, and midline thalamic nuclei. This extended 'visceromotor' network functions to regulate endocrine, autonomic, neurotransmitter, and behavioral responses to aversive and rewarding stimuli and contexts, by modulating neuronal activity within limbic and brain stem structures that mediate and organize emotional expression (e.g., amygdala, bed nucleus of the stria terminalis, hypothalamus, PAG). Impaired function within this network thus could disinhibit or alter emotional behavior, conceivably giving rise to the signs and symptoms of depression or mania. Compatible with this hypothesis, pharmacological, neurosurgical, and electrical stimulation treatments for MDEs appear to inhibit pathological activity within visceromotor network structures such as the amygdala and subgenual anterior cingulate cortex.

The visceromotor network also is implicated by neuroimaging studies of pathological anxiety syndromes that occur comorbidly with MDD and BD. Notably, antidepressant drugs are the first-line treatments for both depressive and anxiety disorders, suggesting that

inhibition of pathological limbic function may underlie treatment mechanisms for both syndrome types.

Brain Structural Abnormalities

Patients with mood disorders show abnormalities of brain structure in many visceromotor network regions. The extent or prevalence of these abnormalities depends on clinical characteristics, including age at illness onset, capacity for developing mania or psychosis, and evidence for familial aggregation of illness. For example, MDD patients with late-onset depression show an increased prevalence of neuroimaging and neuropathological correlates of cerebrovascular disease, relative both to age-matched, healthy controls and to elderly depressives with early-onset depression. Similarly, in MDD and BD cases in which there is psychosis (delusions and/or hallucinations) or late-life illness onset, there are nonspecific signs of atrophy, such as lateral ventricle enlargement, that are absent in early-onset, nonpsychotic cases.

Nevertheless, early-onset, nonpsychotic MDD and BD cases show volumetric abnormalities in some PFC, cingulate, temporal lobe, and striatal regions (Table 1). The most prominent abnormality reported to date is a 20–50% reduction in gray matter in the left anterior cingulate cortex ventral to the corpus callosum genu (i.e., 'subgenual; sgACC), which is evident in MDD and BD samples with familial clustering of illness or psychotic features. This reduction exists early in illness and in young adults at high familial risk for MDD. Gray-matter volume also is reduced in the OFC (BA11, BA47) and ventrolateral PFC (VLPFC; BA45, BA47) in MDD and BD, frontal polar/dorsal anterolateral PFC (BA9, BA10) in MDD, and posterior cingulate cortex and superior temporal gyrus in BD. Additionally, white matter is decreased in the corpus callosum genu in adults with MDD or BD and their high-risk child or adolescent female offspring, and also is decreased in the corpus callosum splenium in adults with MDD or BD.

Some studies also report reduced hippocampal volume in MDD, ranging in magnitude from 8% to 19%, although other studies have not replicated these differences. The discrepant results across studies may reflect clinical heterogeneity, as one study reported that this reduction was limited to depressed women who suffered early-life trauma, and others reported that hippocampal volume correlated inversely with time spent depressed. In addition, volumetric reductions in the anterior subiculum/ventral CA1 region appear specific to BD.

Conventional antidepressant drug treatment and symptom remission do not alter the reductions in gray-matter volume in sgACC, but may arrest further gray-matter decrements in hippocampus. In contrast, chronic lithium treatment, which exerts robust neurotrophic effects in animal models, has been associated with increasing sgACC gray-matter volume in treatment responders.

Table 1 Neuroimaging and histopathological abnormalities evident in the visceromotor network in early-onset, recurrent major depressive disorder and/or bipolar disorder

Brain region	*Gray-matter volume*	*Cell counts, cell markers*	*Glucose metabolism, CBF*	
	Dep vs. con	*Dep vs. con*	*Dep vs. con*	*Dep vs. rem*
Dorsal medial/anterolateral PFC (BA9)	↓	↓	↓	↑
Frontal polar C (BA10)		↓	↑	↑
Subgenual anterior cingulate C	↓	↓	↓/↑[a]	↑
Pregenual anterior cingulate C	↓	↓	↑	↑
Orbital C/ventrolateral PFC	↓	↓	↑	↑
Posterior cingulate	↓		↑	↑
Parahippocampal C	↓	↓BD	↑	↑
Amygdala	↓/↑[b]	↓MDD	↑	↑
Ventromedial striatum	↓		↑	↑
Hippocampus	↓	↓BD	n.s.	n.s.
Superior temporal G/temporopolar C	↓			↑
Medial thalamus			↑	↑

[a]In the subgenual anterior cingulate cortex, the apparent reduction in CBF and metabolism, seen in positron emission tomographic images of depressed patients, is thought to be accounted for by the reduction in tissue volume in the corresponding cortex, because after partial volume correction for the reduction in gray matter the metabolism appears increased relative to controls.

[b]The literature is in disagreement with respect to the amygdala volume in mood disorders. In major depressive disorders, the volume appears reduced in cases in which major depressive episodes show a chronic or intermit course.

C, cortex; CBF, cerebral blood flow; Dep vs. con, unmedicated depressives versus healthy controls; Dep vs. rem, unmedicated depressives versus themselves in either the medicated or unmedicated remitted phases; G, gyrus; n.s., differences generally not significant; PFC, prefrontal cortex. Empty cells indicate insufficient data.

Neurophysiological Imaging Abnormalities

Many regions where structural abnormalities are evident in mood disorders also contain abnormalities of cerebral glucose metabolism and cerebral blood flow (CBF) (Table 1 and Figure 1). In some visceromotor network structures the physiological activity appears increased in the depressed phase relative to the remitted phase of MDD, based upon longitudinal studies of depressed patients imaged before versus after treatment, and in remission versus during depressive relapse.

Nevertheless, the gray-matter volumetric reduction in some structures is sufficiently prominent to produce partial volume effects in positron emission tomographic (PET) images because of their low spatial resolution, yielding complex relationships between measured physiology and depression severity. For example, relative to controls, depressed MDD and BD patients show metabolic activity that appears reduced in sgACC. When the reduction in gray-matter volume in MDD and BD is taken into account by correcting the metabolic data for partial volume averaging effects, however, metabolism during depression instead appears increased in sgACC. The volumetric reductions in the OFC and VLPFC also may account for the complex relationships observed between PET measures of metabolism and illness severity, as metabolism appears elevated in depressed samples of mild-to-moderate severity, but reduced in more severe, treatment-refractory cases.

Figure 1 Areas of abnormally increased physiological activity in familial major depressive disorder, shown as images of unpaired *t*-values, which were computed using a statistical parametric mapping approach to compare activity between depressives and controls. Upper left: The positive *t*-values in this sagittal section at 17 mm left of midline ($x = -17$) show areas where cerebral blood flow is increased in the depressives in the amygdala and medial (MED) orbital cortex. Anterior is to the left. Upper right: Positive *t*-values in a sagittal section 41 mm left of midline ($x = -41$) show areas where cerebral blood flow is increased in the depressives in the left ventrolateral prefrontal cortex (VLPFC), lateral orbitofrontal cortex, and anterior insula. Lower right: Positive *t*-values in a coronal section 19 mm posterior to the anterior commissure ($y = -19$) show an area where cerebral blood flow is increased in the depressives in the left medial thalamus. Lower left: Coronal (31 mm anterior to the anterior commissure; $y = 31$) and sagittal (3 mm left of midline; $x = -3$) sections showing negative voxel *t*-values where glucose metabolism is decreased in depressives relative to controls. The reduction in activity in this prefrontal cortex (PFC) region located in the anterior cingulate gyrus ventral to the genu of the corpus callosum (i.e., subgenual) appeared to be accounted for by a corresponding reduction in cortex volume (Table 1). Anterior or left is to the left. Upper left: Reproduced from Price JL, Carmichael ST, and Drevets WC (1996) Networks related to the orbital and medial prefrontal cortex; a substrate for emotional behavior? *Progress in Brain Research* 107: 523–536. Upper right: Reproduced from Drevets WC, Gadde K, and Krishnan KRR (2004) Neuroimaging studies of depression. In: Charney DS and Bunney BJ (eds.) *The Neurobiological Foundation of Mental Illness*, 2nd edn., pp. 461–490. New York: Oxford University Press. Lower left: Reproduced from Drevets WC, Price JL, Simpson JR, et al. (1997) Subgenual prefrontal cortex abnormalities in mood disorders. *Nature* 386(6627): 824–827.

Regions where metabolism and depression severity correlate positively include the amygdala, sgACC, and ventromedial frontal polar cortex. Physiological activity decreases in these regions during effective antidepressant drug treatment or deep brain stimulation of the sgACC. Conversely, under experimental conditions involving serotonin or catecholamine depletion, metabolism increases in these regions in recovered MDD patients who experience depressive relapse.

In some regions, abnormalities of physiological activity appear specific to depressive subtypes. In the amygdala, for example, abnormal elevations of resting metabolism are evident in depressed samples categorized as having BD, familial pure depressive disease, or MDD-melancholic type. In such cases amygdala metabolism decreases during effective antidepressant treatment. In contrast, a broader range of depressed individuals show abnormal hemodynamic responses in the amygdala to emotional stimuli. For example, hemodynamic responses of the left amygdala were reduced in depressed children and adults while viewing fearful faces, and prolonged in duration in depressed adults while viewing sad words.

In the accumbens, medial thalamus, and posterior cingulate cortex, metabolism is abnormally elevated in the depressed phase of MDD and BD. In functional magnetic resonance imaging (fMRI) studies, regional hemodynamic responses are attenuated in the ventral striatum in reward-processing tasks, and in both the ventral striatum and posterior cingulate in tasks involving negative feedback.

Neuropathological Correlations

Postmortem studies have characterized the histopathological correlates of gray-matter volumetric abnormalities found in mood disorders. The reductions in sgACC and OFC volumes are associated with reductions in glia, synaptic markers, and neuron size, and elevations in neuron density. Reductions in glial cell counts, density, and markers (especially of oligodendroglia and their product, myelin basic protein), and in glia-to-neuron ratios, also were found in MDD in the pregenual anterior cingulate cortex (pgACC), frontal polar cortex (BA10), dorsal anterolateral PFC (BA9), and amygdala. The density of nonpyramidal neurons was decreased in the ACC and hippocampus in BD, and in the dorsal anterolateral PFC (BA9) in MDD. Reductions in synapses and synaptic proteins were evident in BD patients in the hippocampal subiculum/ventral CA1 region.

Correlations with Rodent Models of Chronic and Repeated Stress

In regions that appear homologous to areas where gray-matter reductions exist in depressed humans (i.e., medial PFC, hippocampus), repeated stress causes dendritic atrophy and reductions in glial cell counts or proliferation in rats. In the basolateral amygdala, chronic, unpredictable stress also produces dendritic atrophy, but chronic immobilization stress instead increases dendritic branching. This dendritic remodeling depends on interactions between the *N*-methyl-D-aspartate (NMDA) receptor stimulation and glucocorticoid secretion associated with repeated stress.

Dendritic atrophy would decrease the volume of the neuropil, which occupies most of the gray-matter volume. The similarities between the histopathogical changes accompanying stress-induced dendritic atrophy in rats and those found in depressed humans suggest that such a process may underlie gray-matter volume reductions in hippocampal and PFC structures in MDD and BD. In rats the stress-induced dendritic atrophy in the medial PFC is associated with impaired extinction of behavioral responses to fear-conditioned stimuli. Notably, the volumetric reductions in depressed humans are associated with greater severity and illness chronicity.

Neurochemical Systems Implicated in Depression

Mood disorders have been associated with abnormalities in serotonergic, dopaminergic, noradrenergic, cholinergic, glutamatergic, γ-aminobutyric acid (GABA)ergic, and glucocorticoid and peptidergic (e.g., corticotropin-releasing factor) function. The monoamineregic systems have received particular attention in research because most antidepressant drugs exert their primary pharmacological actions through these systems. Nevertheless, the delayed onset of antidepressant effects (about 3 weeks) after initiating monoamine reuptake-inhibiting agents suggests that secondary changes in gene expression underlie the therapeutic mechanisms of these drugs. Mechanisms hypothesized to serve as final common pathways for antidepressant responses include (1) increased expression of brain-derived neurotrophic factor and other neurotrophic/neuroprotective factors, (2) enhanced postsynaptic serotonin type 1A receptor (5-HT_{1A}R) function, and (3) reduced sensitivity or transmission of NMDA–glutamatergic receptors.

Serotonergic System

Selective serotonin reuptake inhibitors (SSRIs) exert antidepressant effects, and most other antidepressant drugs also increase 5-HT neurotransmission. This effect was thought to compensate for deficient serotonergic function in MDD, since the density and sensitivity of some 5-HT receptor types were reduced in

MDD. Compatible with this hypothesis, many remitted MDD patients who are unmedicated or are taking SSRI agents experience depressive relapse under tryptophan depletion (which putatively decreases central serotonergic function).

The most promising evidence for a serotonin system deficiency that is compensated by antidepressant pharmacotherapy involves postsynaptic 5-HT_{1A}R. Chronic administration of antidepressant drugs with diverse primary pharmacological actions enhances postsynaptic 5-HT_{1A}R function. Postsynaptic 5-HT_{1A}R binding in the insula, cingulate, parieto-occipital, and orbital/ventrolateral prefrontal cortices is abnormally decreased in most studies of MDD and BD. Depressed individuals also show blunted thermic and endocrine responses to 5-HT_{1A}R agonist challenge, suggesting that 5-HT_{1A}R function also is reduced.

It remains unclear whether reduced 5-HT_{1A}R function and expression constitute a neurodevelopmental or acquired abnormality in mood disorders. This issue is of importance because interruption of 5-HT_{1A}R function during neurodevelopment persistently alters the function of emotion-modulating systems in genetically engineered mice. Nevertheless, the reduction in 5-HT_{1A}R binding and expression in depression may arise secondarily to cortisol hypersecretion, as 5-HT_{1A}R mRNA expression and density are under tonic inhibition by glucocorticoid receptor stimulation. In experimental animals, the increased corticosterone secretion during repeated stress reduces 5-HT_{1A}R mRNA expression and density. Moreover, mood and anxiety-disordered subgroups with reduced 5-HT_{1A}R binding appear limited to those with a diathesis to hypersecrete cortisol.

Altered serotonin transporter (5-HTT) function may also play a role in the pathophysiology of the MDE. Neuroimaging and postmortem studies of MDD or BD report abnormalities of 5-HTT binding that differ in direction across regions. Moreover, genetic polymorphisms involving 5-HTT regulatory sites increase the vulnerability for developing mood disorders. For example, the common 'short' (s) allele of the functional 5-HTT promoter region length polymorphism increases the vulnerability for developing MDD within the context of stress.

Catecholaminergic Systems

The central dopaminergic and noradrenergic systems are also implicated in the pathophysiology of depression and the mechanisms of antidepressant drugs. Administration of reserpine or α-methyl-*para*-tyrosine, which reduces the availability of catecholamines, induces depressive syndromes in vulnerable individuals. Conversely, selective norepinephrine reuptake inhibitors (e.g., reboxetine), dopamine reuptake inhibitors (e.g., nomifensine), and dopamine receptor agonists (e.g., pramipexole) exert antidepressant effects in placebo-controlled studies. In MDD, cerebrospinal fluid (CSF) and jugular vein plasma levels of the dopamine (DA) metabolite, homovanillic acid, are abnormally decreased, consistent with reduced DA turnover. In contrast, levels of norepinephrine metabolite concentrations are decreased in some, but increased in other studies. Neuroimaging studies of MDD show reduced striatal DA transporter binding and [^{11}C]L-DOPA uptake across the blood–brain barrier, consistent with reduced DA neurotransmission. Finally, degeneration of DA neurons in Parkinson's disease increases vulnerability for MDE.

The mesolimbic DA projections from the ventral tegmental area (VTA) to the nucleus accumbens shell and medial PFC play major roles in learning associations between operant behaviors or sensory stimuli and reward, and in mediating the reinforcing properties of drugs of abuse and natural rewards. Thus, reduced DA neurotransmission in depression is hypothesized to underlie the anhedonia, amotivation, and psychomotor slowing seen in MDEs.

Cholinergic System

The cholinergic system has also been implicated in the pathophysiology of mood disorders, with evidence generally suggesting that the muscarinic cholinergic system is hyperresponsive in depression. Increasing cholinergic activity using physostigmine (an acetylcholine esterase inhibitor) results in rapid induction of depressive symptoms in currently manic bipolar patients, and in a worsening of symptoms in MDD patients. Depressed individuals also show exaggerated polysomnographic, neuroendocrine, and pupillary responses to cholinomimetic agents or muscarinic receptor agonists relative to healthy controls, and aspects of sleep abnormalities observed in depression, including decreased rapid eye movement (REM) latency and increased REM density, are thought to reflect muscarinic receptor hypersensitivity. These data contribute to the hypothesis that a hyperresponsive cholinergic system partially accounts for mood symptoms associated with mood disorders.

The preclinical literature also implicates the muscarinic receptor system in mediating the cholinergic effects on emotional behavior. In rats genetically bred for increased sensitivity of muscarinic receptors, cholinergic agonists enhance the behavioral analogs of depression, while antimuscarinic drugs improve these behaviors. Consistently, the muscarinic cholinergic receptor antagonist, scopolamine, exerts rapid and robust antidepressant effects in depressed MDD and BD patients.

Several studies more specifically implicate the M_2 receptor (M_2R) in mood regulation and depression. Multiple M_2R gene polymorphisms have been associated with increased risk for developing an MDE. In humans, administration of the M_2R antagonist, procaine, elicits emotional responses ranging from sadness, fear, and severe anxiety to euphoria, and results in physiological activation of the cingulate cortex, which receives dense cholinergic projections. A PET neuroreceptor imaging study demonstrated decreased M_2R binding in the cingulate cortex in BD.

In experimental animals, excessive cortical cholinergic activity results in 'hyperattentive impairments', whereby overactivity of acetylcholine (ACh) reduces the threshold for signal detection and leads to overprocessing of stimuli. Given the central role of ACh in emotional and sensory processing (see later), the overactivity of the cholinergic system in mood disorders may result in the overrepresentation (through altered signal/noise processing) of emotionally laden information, conceivably producing the emotional processing bias and correlated cognitive deficits associated with MDD and BD.

Glutamatergic and GABAergic Systems

The major excitatory and inhibitory neurotransmitters, glutamate and γ-aminobutyric acid, respectively, are also implicated in mood disorders. Early studies reported abnormal reductions in plasma and CSF GABA concentrations in MDD. In contrast, postmortem studies of the NMDA receptor complex found evidence of increased glutamatergic transmission in the PFC, and of altered NMDA and metabotropic glutamatergic receptors in depression and suicide. Moreover, antidepressant and mood-stabilizing drugs which have diverse primary pharmacological actions generally reduce NMDA receptor sensitivity and/or transmission, and many of these agents also increase GABA levels or transmission.

Elevated glutamatergic function is thought to support the neurophysiological activation of visceromotor circuits in depression. Anatomical connections between the PFC, thalamus, and amygdala implicated in mood disorders are formed by predominantly excitatory neurons. Cerebral glucose metabolism predominately reflects the energetic requirements associated with glutamatergic transmission, so the elevated metabolism in limbic–thalamic–cortical circuits during MDEs implies that glutamatergic neurotransmission is increased in these circuits. During effective antidepressant drug or electroconvulsive therapy, metabolic activity decreases in these regions (Table 1), compatible with evidence that these treatments result in desensitization of NMDA receptors in the PFC. Elevated glutamatergic transmission within discrete anatomical circuits may explain the targeted nature of gray-matter changes within mood disorders (e.g., affecting left, but not right, sgACC), as the pathogenesis of dendritic atrophy during repeated stress depends partly on NMDA receptor stimulation.

Magnetic resonance spectroscopic (MRS) studies of MDD also demonstrate abnormalities of glutamate (measured together with glutamine as the combined 'Glx' peak in MRS spectra) and GABA concentrations in depressed patients. These MRS spectra reflect the combined intracellular and extracellular pools of glutamate, glutamine, and GABA, but are dominated overwhelmingly by intracellular pools. Depressed MDD patients show abnormally reduced GABA levels in the dorsomedial/dorsal anterolateral PFC. The majority of the GABA pool exists within GABAergic neurons, so the reduction in GABA in the dorsal anterolateral PFC appears compatible with reports of reduced GABAergic neurons in this region (BA9) in MDD. Similarly, the abnormally reduced Glx levels in the dorsomedial/dorsal anterolateral and ventromedial PFC in MDD are compatible with histopathological evidence of reduced glia in these regions, as glia play prominent roles in glutamate–glutamine cycling.

Glucocorticoid System

The hypothalamic–pituitary–adrenocortical (HPA) axis appears overactive in depression. Thus, severe depression is associated with hypersecretion of cortisol, with pituitary and adrenal gland enlargement, and with CSF–CRF levels that are increased to an extent that is inappropriate to plasma cortisol levels (i.e., implying negative feedback systems are impaired, and/or excessive central drive on release of CRF or other adrenocorticotropic hormone secretagogues). Depressed patients also show blunted adrenocorticotropic hormone (ACTH) responses to CRF *in vivo*, reduced CRF receptor density in the PFC, and increased corticotropic cell size and mRNA levels in the pituitary gland postmortem, indicating chronic HPA axis activation. Some depressives show reduced sensitivity to dexamethasone negative feedback and/or to glucocorticoid 'fast feedback.' During successful – but not unsuccessful – treatment, serum cortisol and CSF–CRF levels normalize, and cortisol secretion becomes suppressible by dexamethasone. The chronic elevation of cortisol secretion in depression is thought to contribute to mitochondrial dysfunction, neuropathological changes, elevated body temperature, premature osteoporosis and aging, and other medical morbidity.

Autonomic Nervous System Function in Mood Disorders

Relative to nondepressed controls matched for cardiac disease, depressed patients show a two- to fourfold increase in sudden death and a sevenfold increase in ventricular arrhythmia. This excess risk of cardiac events in MDD is hypothesized to result from elevated noradrenergic and sympathetic autonomic function, coupled with reduced parasympathetic tone on the heart rate.

Disturbances in Sleep Physiology

Clinical complaints of sleep regulation including insomnia, hypersomnia, and restless sleep are among the most common features of an MDE. Polysomnographic studies of sleep architecture during depression demonstrate reduced latency to the onset of rapid eye movement sleep, increased density of REM sleep, reduced time spent in slow-wave sleep, and decreased sleep efficiency (i.e., less time spent asleep due to increased nocturnal awakenings). Some of these abnormalities are evident early in the illness course, and also are evident in female children at high familial risk for mood disorders.

Alterations of Cognitive and Emotional Processing in Mood Disorders

Cognitive and neuropsychological impairments are characteristics of MDE, and were incorporated into the diagnostic criteria for MDD as "an impaired ability to think or concentrate." Nonetheless, behavioral studies designed to characterize these symptoms in mood disorders have produced discrepant results. Some studies reported wide-ranging deficits in mood disorders that include impairments in early information processing, attention, memory, and executive functions, although other studies failed to identify such deficits. Several factors may contribute to the discrepancies in the literature, including heterogeneous patient groups, medication status of patients, and differences in task paradigms that theoretically assess the same cognitive domain. Nonetheless, sufficient evidence points consistently to the presence of cognitive impairment in MDD and BD. Moreover, residual deficits in remitted MDD and BD patients demonstrate that some cognitive features occur independently of mood state.

Motor Function

The diagnostic criteria for MDEs also include psychomotor agitation or retardation, but these symptoms manifest as prominent clinical features in a minority of depressed cases. Most studies of unmedicated, depressed patients do not find increased response latency on most cognitive tasks. Some studies report psychomotor slowing on tasks such as pattern recognition and match-to-sample paradigms, and others report slowed response latency in unmedicated, remitted patients with a history of seasonal depression. While psychomotor slowing may affect a minority of depressed patients, the effects of motor function on performance measures must be considered when interpreting behavioral changes as cognitive effects in mood disorders.

Early Information Processing

Impairments in early information processing are evident in patients with mood disorders. Inspection time, measured as the minimum duration of stimulus presentation necessary for near-perfect performance on a two-choice visual discrimination task, assesses the speed of early information processing independent of motor speed or cognitive strategy. Inspection time is found to be longer in unmedicated MDD patients than in both medicated MDD and healthy controls. In a visual backward masking task, whereby a stimulus is shown briefly and then masked using a noninformative stimulus, medicated BD patients had deficits in the identification of masked stimuli consistent with an early information processing impairment. Thus, evidence suggests that early information processing is altered in mood disorders.

Emotional Processing Bias

A consistently reported finding in mood disorders is the presence of a mood-congruent processing bias, defined as a bias to process negative information as compared to positive or neutral information. In memory studies, depressed patients recall more negatively toned than positively toned information. In the context of attention paradigms, depression-related negative words produce more interference on emotional Stroop tasks than do happy or neutral words. In an affective attention-shifting task (i.e., affective go/no-go), medicated and unmedicated depressed patients are faster when responding to the presentation of sad word targets, as compared to happy word targets, consistent with the idea that sad words are processed more readily. In a face dot-probe task designed to assess the allocation of attention between a face with a neutral expression and one with an emotional expression, individuals with MDD consistently attend preferentially to faces with sad expressions. Finally, medicated depressed patients are more negative in their interpretation of ambiguous words and ambiguous situations than are healthy participants. Thus, the

literature suggests that a bias exists in stimulus processing that may result in a preferential representation of negatively toned information.

Results from functional neuroimaging studies are consistent with behavioral findings, showing altered neurophysiological responses in brain regions that process emotional information during tasks that utilize emotional stimuli. The amygdala, a brain region central to the processing of emotional stimuli, shows elevated levels of activity in MDD during exposure to sad faces. Similarly, the amygdala shows increased activity during the presentation of masked fearful and sad faces in MDD patients versus healthy controls; and lateral OFC shows higher activity to negative emotional stimuli in an affective go/no-go task. Similar increases in amygdala activity are observed in response to sad faces in remitted patients with MDD, suggesting that this abnormality is traitlike in MDD. In another study, healthy volunteers showed a linear increase in activity in fusiform visual cortex and ventral striatum as the intensity of a happy facial expression increased, while MDD patients showed a similar pattern as the intensity of a sad expression increased, but the pattern extended into hippocampus and amygdala in patients. This literature suggests that neural responses within regions underlying emotional processing are altered, and these altered responses may represent the neurophysiological correlates to the emotional processing bias observed in mood disorders.

Attention, Memory, and Learning

Subjective impairments of concentration and attention are among the most commonly reported symptoms and sources of functional impairment associated with MDEs. Although disagreement remains, traditional neuropsychological test batteries with standard measures of attention and memory have failed to identify clear, consistent patterns of deficits in MDD and BD, and this likely is due partially to the lack of tasks designed specifically for this clinical population. In set-shifting tasks, including Trail Making A and digit symbol substitution, medicated depressed patients reportedly perform more poorly than do controls, requiring more time to perform the tasks and making more errors; other studies report performance on set shifting to be spared in medicated depressed patients. The effect is more pronounced when using emotionally toned material, as in the aforementioned affective attention-shifting task. Selective attention and working memory also are reported to be impaired in depression, but again these findings are inconsistent, and the results are complicated further by medication status during study participation. Verbal memory deficits in currently depressed patients and in unaffected twin and nontwin siblings of BD patients have been shown, raising the possibility that impaired verbal memory may constitute an endophenotype for BD. Impairments of spatial recognition memory and delayed match-to-sample tasks have been reported in medicated MDD and BD patients, but not in unmedicated MDD or BD patients.

Executive Function

Studies assessing executive functions, which include domains such as decision making, planning, and problem solving, also produce conflicting findings in the literature. While complicated by diagnostic heterogeneity and medication status, most studies that utilize the Wisconsin Card Sorting Task and the Tower of London task, which require planning and problem solving, report deficits in MDD. Other tasks that assess executive function, such as Trail-Making Part B and Controlled Oral-Word Association tests, produce more variable results. However, these tasks are more attention based and potentially are less demanding tests of executive function, and thus may not be sufficiently sensitive to identify deficits in mood disorders.

Implications for Circuit-Based Models of Depression

The neuropathological, neurophysiological, and neurochemical abnormalities extant within the extended visceromotor network may impair this network's modulation of neuroendocrine, autonomic, neurotransmitter, behavioral, and cognitive responses to aversive and reward-related stimuli or contexts, potentially accounting for disturbances within these domains in mood disorders. For example, as depicted in Figure 2, the basolateral amygdala sends anatomical projections to the central nucleus of the amygdala (ACe) and the bed nucleus of the stria terminalis (BNST), and these structures send projections to the hypothalamus, PAG, nucleus basalis, locus coeruleus, raphe, and other diencephalic and brain stem nuclei, which together mediate the neuroendocrine, neurotransmitter, autonomic, and behavioral responses to stressors and emotional stimuli. The OMPFC sends to each of these structures, as well as to the amygdala, overlapping projections, which function to modulate each component of emotional expression. The neuropathological changes evident in the OMPFC in mood disorders may thus impair the PFC's modulatory role over emotional expression, disinhibiting or dysregulating limbic responses to stressors and emotional stimuli.

Reciprocal, functional relationships between structures that mediate emotional expression (e.g., amygdala) and those which modulate emotional expression (e.g.,

Figure 2 Anatomical circuits involving the orbitomedial prefrontal cortex (PFC) and amygdala, reviewed within the context of a model in which orbitomedial PFC dysfunction results in disinhibition of limbic activity through the amygdala, yielding the emotional, cognitive, endocrine, autonomic, and neurochemical manifestations of depression. The basolateral amygdala sends efferent projections to the central nucleus of the amygdala and the bed nucleus of the stria terminalis (BNST). The efferent projections from these structures to the hypothalamus, periaqueductal gray (PAG), nucleus basalis, locus coeruleus, raphe, and other diencencephalic and brain stem nuclei then organize the neuroendocrine, neurotransmitter, autonomic, and behavioral responses to stressors and emotional stimuli. The orbitomedial PFC shares reciprocal projections with all of these limbic, hypothalamic, and brain stem structures (although only the connections with the amygdala are shown), which function to modulate each component of emotional expression. Impaired orbitomedial PFC function may thus disinhibit or dysregulate the limbic outflow of the central nucleus of the amygdala and BNST. Solid white lines indicate some of the major anatomical connections between structures, with arrowheads indicating the direction of projecting axons. Solid yellow lines show efferent pathways of the central nucleus of the amygdala and BNST, which generally are monosynaptic, but in some cases are bisynaptic connections. 5-HT, 5-hydroxytryptamine (serotonin); ACh, acetylcholine; CORT, cortisol; CRF, corticotropin-releasing factor; DA, dopamine; DL, dorsolateral column of PAG; N, nucleus, NE, norepinephrine; PVN, paraventricular nucleus of the hypothalamus; VL, ventrolateral column of PAG; VTA, ventral tegmental area.

parts of OMPFC) are evidenced by electrophysiological and lesion analysis studies in experimental animals. In rats, stimulation of projections from the amygdala to the medial prefrontal cortex (mPFC) inhibits neuronal ensemble activity in mPFC, and stimulation of projections from the mPFC to the amygdala excites GABAergic projections, which inhibit neuronal activity in ACe. Moreover, rats exposed to fear-conditioned stimuli show reduced mPFC neuronal firing activity, and the magnitude of this decrement correlates inversely with the corresponding increase in amygdala neuron activity and fear behavior. Conversely, lesions of the right or bilateral mPFC enhance behavioral, sympathetic, and endocrine responses to stressors or fear-conditioned stimuli.

Reciprocal relationships between the effects of OMPFC and amygdala function on emotional behavior also are evident in humans. In MDD, depression severity correlates positively with amygdala and sgACC activity, but negatively with activity in the left VLPFC/lateral OFC. Lesions of the left OFC increase the risk for an MDE, whereas electrical stimulation of the amygdala can produce fear, anxiety, dysphoria, sympathetic autonomic arousal, social withdrawal, and cortisol release in humans and/or nonhuman primates. Drugs and deep brain stimulation, which reduce activity in the amygdala and/or sgACC, exert antidepressant effects, while interpersonal psychotherapy enhances activity in the VLPFC/anterior insula and can reduce depressive symptoms in MDD. Finally, higher activity in the pgACC holds positive prognostic significance in MDD, as depressives who improve during antidepressant treatment show higher pgACC metabolism and

electrophysiological activity than do treatment-nonresponsive cases and healthy controls. Taken together, these data suggest that during MDEs, activation of some OMPFC areas reflects a compensatory response which modulates depressive symptoms, and impaired function of these regions results in more severe and treatment-refractory illness.

Impairment of OMPFC function that disinhibits amygdala activity may also contribute to the neuroendocrine, autonomic, neurotransmitter, attention, and reward-seeking abnormalities associated with MDEs. The amygdala mediates the stressed component of glucocorticoid hormone secretion by disinhibiting CRF release from the hypothalamic paraventricular nucleus. Conversely, the glucocorticoid response to stress is inhibited by stimulation of glucocorticoid receptor concentrations in the ventral ACC, such that lesioning this cortex in rats increases ACTH and cortisol (CORT) secretion during restraint stress. Excessive amygdala activity combined with reduced sgACC gray matter may thus contribute to the excessive cortisol response to stress seen in depressed humans.

The autonomic imbalance associated with depression could also reflect OMPFC dysfunction coupled with excessive amygdala activity. Amygdala stimulation of the locus coeruleus, lateral hypothalamus, and PAG increases sympathetic autonomic arousal. In contrast, parasympathetic tone on the heart rate is partly regulated by projections from infralimbic cortex (a putative homolog of the human posterior sgACC) to the nucleus tractus solitarius of the vagus nerve, and lesions of this cortex reduce parasympathetic tone on the heart. The effects of increased amygdala activity and reduced infralimbic cortex function conceivably could account for the increased ratio of sympathetic-to-parasympathetic tone on the heart rate seen in depression.

Dysfunction of the OMPFC coupled with amygdala hyperactivity may also contribute to the anhedonia, amotivation, and inattention manifest in depression. Cognitive and behavioral response patterns supporting goal- or reward-directed activity are thought to depend upon PFC inputs to the ventral striatum, which are maintained or 'gated' by projections from the hippocampal subiculum to the ventral striatum. Stimulation of projections from the amygdala to the ventral striatum interrupts the maintenance of these cortically driven response patterns, providing an adaptive, limbic override that interrupts goal-directed thought or behavior in response to unexpected threats or novelty. Nevertheless, in MDEs, excessive amygdala activity conceivably may interfere with cognitive performance and goal-directed behavior to an extent that is maladaptive.

Summary

Convergent results from studies applying neuroimaging, lesion analysis, and postmortem techniques support models in which the signs and symptoms of MDEs emanate from dysfunction within an extended visceromotor network, which interferes with this system's modulatory role in emotional behavior. Antidepressant therapies may compensate for this dysfunction by attenuating the pathological limbic activity which putatively mediates depressive symptoms, and by increasing expression of neurotrophic/neuroprotective factors that preserve OMPFC function. Cognitive–behavioral strategies for managing depressive symptoms may instead rely upon enhancing the function of OMPFC corticolimbic circuits to facilitate their role in modulating emotional behavior.

Development of Behavior

K A French and A Marin-Burgin, University of California at San Diego, La Jolla, CA, USA

Anyone who watches the development of behavior in a human infant during his or her first 2 years of life must be struck by the enormous changes that take place during this time. Most newborn humans are capable of producing a number of behaviors: they can suck, they can cry, and they can move their arms and legs, albeit rather randomly. Then, during the first 2 years of life their behavioral repertoire greatly increases in breadth, skillfulness, and focus. However, the behavior of a human infant does not suddenly begin at birth. Embryonic and fetal animals are capable of a range of behaviors beginning well before birth. For example, human embryos make movements and respond to sounds when they are still *in utero*, chick embryos move and even make noises before they hatch out of the shell, and fly embryos wiggle and squirm before emerging from the egg case. In some species, these behaviors play a critical role in the individual's survival: to survive, a baby chick must actively break out of its shell, and components of hatching behavior arise many days before the chick would normally make its well-coordinated escape. In other cases, the ability to produce particular behaviors may not ever be used under ordinary conditions: For example, human infants who are born very prematurely respond behaviorally to light although a baby would never experience this stimulation *in utero*.

Factors That Shape the Development of Behavior

The progression of behavioral development depends on a number of different, but interacting, factors (Figure 1).

Behavior Depends on the Nervous System: As the Nervous System Develops, Behavior Changes

Behavior is the observable consequence of activity within the nervous system of an individual animal, regardless of the type of animal. The individual can produce only behaviors that are initiated, coordinated, or modulated by neurons, so behavioral development reflects the changing state of the nervous system. In many animals, including humans, the nervous system contains at birth most of the nerve cells it will ever have, yet many newborn animals produce a very small behavioral repertoire compared with adults of the same species. What is different between the two stages? It is the complexity of connections among the neurons. As a result, observing the progress of behavioral development is, in a very real sense, observing the progress of 'wiring up' the neurons in the nervous system. Once neurons have been generated, which typically happens quite early in development, synaptogenesis – the formation of the synapses that connect neurons with one another – is the major developmental focus, and executing this phase of development precisely and appropriately exerts an overwhelming effect on the future behavior of an animal. In humans, the first year of life is a period of active synaptogenesis and of refining synaptic connections, making a stimulating environment particularly important at this time.

As the nervous system develops, some behaviors arise and are then maintained into adulthood, although the detailed nature of the behavior may change (human babies usually crawl before they walk, and they walk before they run). Other behaviors appear at one stage of development and later disappear (human infants make sucking motions when they are touched on the cheek, but human children rarely exhibit this response). Perhaps the most dramatic examples of this second category of behaviors are seen in animals that metamorphose in their normal life cycle. In these animals, a single individual progresses through stages, each of which is so different from the others that they appear to be entirely different organisms with different methods of feeding, breathing, locomoting, and acquiring food. In such an individual, the nervous system undergoes major remodeling as the animal makes each transition: some neurons are retained in approximately the same form, some neurons die, some are retained but are strikingly modified, and some new neurons are added. The net effect is a single nervous system that is appropriately matched to very different lifestyles as the individual progresses through its life cycle. For example, a tobacco hornworm moth begins life as a leaf-eating caterpillar that crawls on plants, it then becomes a burrowing pupa, and finally, as an adult, it acquires wings and begins to fly. Similarly, a frog starts as an aquatic tadpole that swims and eats algae, but after metamorphosis it is a terrestrial animal that walks and hops and hunts the invertebrates that make up its carnivorous diet.

Synaptic Connections Are Established in General; Then Later They Are Refined Based on Neuronal Activity

Synapses can be divided into two major types: electrical synapses, in which the two neurons are connected

Figure 1 Behavior arises and matures as the nervous system develops. Development is affected by events within the nervous system and by signals from other parts of the body and in the environment.

via protein complexes called gap junctions, and chemical synapses, in which a signal between the two neurons is carried by specific molecules. Electrical synapses are nearly always excitatory; that is, when one of the neurons is excited, the other one becomes excited, too. Chemical synapses may be either excitatory or inhibitory, depending on the nature of the neurotransmitter and the receptors and channels in the postsynaptic cell. In many locations, it appears that neurons are initially connected by gap junctions, which form transiently. Subsequently, under the control of signals not yet understood, some of these electrical synapses are replaced by chemical synapses. Characteristic behavior may be generated during even the earliest stages when neurons are connected only through electrical synapses.

In many systems, construction of synapses begins with a stage in which connectivity is broader and more diffuse than the eventual adult pattern of the connections, and in many instances activity within the nervous system plays an important role in fine-tuning the connections. This increase in specificity among connections improves the skill, coordination, and precision of behavior. Some of these processes begin before birth; for example, in a newborn kitten, neurons in the retina of the eye are connected with neurons in the brain in an approximation of the eventual adult pattern, but once the kitten's eyes open and the circuitry is actively used, the connections are modified based on that activity until the final adult pattern is produced. During the process, the kitten's visually guided behavior becomes more precise; if the process is interrupted by occluding vision in one or both eyes, the adult pattern fails to develop and visually guided behavior remains compromised.

Hormones Modify Some Parts of the Developing Brain

Hormonal signals can exert very strong effects on the development of behavior, beginning as early as embryonic or fetal life. One particularly striking example is the development of sex and reproductive behavior in vertebrates. Sexually reproducing animals typically belong to one of two categories that are usually called 'male' and 'female,' and in many species the two sexes display a specific range of behaviors that are related to their reproductive roles. The sex of an individual is typically determined genetically, which might be thought of as sex at the cellular level. However, the development of reproductive behaviors, which might be thought of as sex at the organismic level, is subject to control by hormonal signals. For example, in birds that sing as part of courtship and territorial defense, it is typically the males that produce the song, whereas the females remain silent. In one species, the zebra finch, a genetically female bird can be induced to sing by treating her with exogenous gonadal hormone early in development and then again once she has reached adulthood. Both treatments are required; neither suffices alone, suggesting that the development of the brain is permanently shaped by the bird's hormonal status early in life.

Learning Changes Behavior

Behavior is shaped by the processes of learning; that is, behavior changes based on an individual's own experience. As it acquires feedback from its environment and from the effects of its own behavior, a human baby increases its skill in a vast array of

actions from focusing on objects within its visual field to reaching for an object, producing vocal sounds, or executing the movements of crawling or walking. The physiological basis of learning is thought to depend at least in part on modifications in the synaptic connections among neurons, so the modification of behavior based on experience is one subset of the larger collection of changes in connectivity that take place during the development of behavior. Interestingly, experiments in a variety of mammals suggest that the shaping of behavior based on learning begins well before birth. Many mammals, including humans, emerge from the uterus already able to recognize their mother based on her smell or the sound of her vocalizations. Thus, neuronal activity is subject to the guidance of experience from surprisingly early in development.

An Individual's Responsiveness to Specific Stimuli Varies during Development

In many instances, there are particular developmental stages during which the nervous system – and consequently developing behavior – is unusually and exquisitely sensitive to environmental conditions. Such a period is called a 'critical period' or 'sensitive period.' In many animals, including humans, exposure to ethanol (e.g., alcoholic beverages ingested by a pregnant woman) can produce babies with a constellation of physical and behavioral abnormalities called fetal alcohol syndrome. This condition is largely irreversible; exposure to ethanol before birth produces behavioral abnormalities that cannot be remedied after birth. However, critical periods are not just important in abnormal development. Many normal behaviors are also established during a critical period: young male zebra finches must be exposed to the song of an adult male during a particular window of time or they will never sing a normal song characteristic of the species. Also, young ducks and geese become attached to (i.e., imprinted on) the first moving object that they see after they hatch (normally their mother). This attachment lasts a lifetime: not only do these imprinted birds follow that object as chicks but also, in adulthood, males will court objects like the one on which they imprinted as chicks.

Behavior as a Window into the Developing Nervous System

Typically, behavior is produced in response to some kind of sensory input, so a simple reflex arc is frequently used to illustrate how behaviors arise: a sensory stimulus causes sensory neurons to become active; that activity is transmitted into the central nervous system, where it is processed by interneurons; interneurons cause activity in motor neurons, which control the contraction of muscles; and contractions of muscles cause parts of the body to move (i.e., cause behavior). A nervous system can execute this transmission of information along a chain of neurons only if during development sensory neurons found and constructed synapses onto interneurons, interneurons found and constructed synapses onto motor neurons, and motor neurons found and constructed synapses onto appropriate muscles.

Although in the definitive circuitry the transmission of information begins at sensory receptors and ends at motor neurons, which affect muscles, the process of constructing the pathway may follow a different logic. In several species, the first neurons to become connected are the motor neurons, and behavior begins as soon as these connections form. This developmental pattern is reflected in the onset and nature of the first observable behaviors, and thus it illustrates how observing changes in behavior during development can provide insight into underlying developmental processes in the nervous system.

Motor Behaviors

Several experiments in different species indicate that the earliest muscle contractions are driven by input from motor neurons before those neurons receive input from sensory receptors. Some of the first experiments addressing this question were carried out in chick embryos while they were still in the egg. Chicks produce movements of the head and legs prior to hatching, and these experiments were designed to reveal the source of embryonic movement. The dorsal spinal cord (which contains the sensory neurons) was surgically removed, leaving the ventral (motor) region of the spinal cord intact. Following this surgery, the embryos moved their legs normally, indicating that in chicks at that developmental stage, sensory input was unnecessary for generating these normal motor behaviors. Similarly, when all sensory neurons were genetically ablated from *Drosophila* (fruit fly) embryos and larvae, a similar result was obtained: embryonic or larval flies performed normal behavior – that is, peristaltic movements of the body – in the absence of any sensory input. These results, together with other observations, suggest that the neuronal circuitry responsible for the first spontaneous behaviors in a variety of species normally develops in the complete absence of sensory input.

However, in the long term, effective behavior must produce an appropriate response to environmental cues, and this matching of behavior to circumstances requires that information from sensory receptors must

be integrated into control of the motor system: synaptic connections must develop to connect sensory input with motor output. The number of connections that link sensory and motor neurons may be small and the arrangement relatively simple, as in simple vertebrate spinal reflexes, or they may be extremely complex, such as when a student reads an exam question and then writes an answer in the form of an essay.

The mechanisms and consequences of sequential development within the nervous system are illustrated by the genesis of a simple adult behavior, called local bending (LB), in an annelid worm, the medicinal leech. LB is a response to moderate touch: within the body segment that was touched, longitudinal muscles close to the touch contract while at the same time longitudinal muscles on the opposite side of the body relax. The net effect is a subtle response that moves the skin away from the site of the touch, and both the identities of neurons that produce LB and their synaptic connections have been characterized in detail.

This simple behavior goes through a developmental sequence that illustrates several of the principles listed previously (Figure 2). In fact, leech embryos produce two closely related behaviors using the same set of motor neurons. The first behavior to emerge is called circumferential indentation (CI); it consists of a ring of longitudinal contraction that encircles the body. This behavior is initially generated spontaneously; touching the body fails to elicit it. During this period, motor neurons are interconnected with one another only through electrical synapses, but they receive no synapses carrying sensory information. A few days later, touching the body wall elicits CI, and experiments have revealed that by this time sensory neurons have formed electrical connections onto interneurons, which have formed electrical connections onto motor neurons, but the behavior is still not adultlike because there is no relaxation on the side opposite the touch. (Similar observations have been obtained from zebra fish embryos and chicks: Initially, locomotory movements occur spontaneously when motor neurons are connected through electrical synapses, and later in development they are elicited by sensory input.) The final adult form of LB emerges when inhibitory chemical synapses form within the set of motor neurons (unlike the vertebrates, many invertebrates have inhibitory, as well as excitatory, motor neurons). The appearance of inhibitory chemical synapses modifies a response in which all longitudinal muscles within the segment are excited by touch into a response in which some of the muscles contract, whereas others relax.

Figure 2 Sequential development of local bending behavior in an embryonic leech. Neurons begin to develop before behavior is produced. During this period, there is neither spontaneous nor evoked behavior. Once electrical synapses form, behavior begins. Initially, only motor neurons are connected, and circumferential indentation (CI; an embryonic behavior) is produced spontaneously, but not in response to touch. Later, when sensory information is carried by way of electrical synapses to the motor neurons, touch elicits CI. Later still, inhibitory chemical synapses appear, permitting expression of adult local bending in which touching the skin elicits contraction of longitudinal muscles ipsilateral to the touch, while contralateral longitudinal muscles relax.

How Are Spontaneous Embryonic Behaviors Generated?

Spinal cords isolated from embryos of several different species have been used to identify the source of early, spontaneous behavior. Conceptually, the first movements might stem from myogenic contractions of muscle fibers, or they might arise only after motor neurons have made functional synapses onto the muscle fibers. Several experiments suggest that even the earliest behaviors are neurogenic. Recordings made from chick spinal cords reveal bursts of action potentials from extensor and flexor motor neurons. Similar bursts of activity have been observed in spinal cords from fetal mice and rats, and several properties appear to be critical for the expression of spontaneous activity by spinal networks. One important feature is that the embryonic motor neurons are hyperexcitable, which may result from one or more of the following:

- functional recurrent connectivity (i.e., the activity of a neuron feeds back to maintain or even heighten its excitation);
- all major neurotransmitters may be excitatory in early spinal development (even γ-aminobutyric acid, which is generally inhibitory in adult nervous

systems, is excitatory in vertebrate embryos due to cellular properties of embryonic neurons);
- overproduction of neuronal connections (which are later pruned back); or
- transient overexpression of some neurotransmitter receptors, which increases the response to released neurotransmitters.

In leech embryos, the transition from CI to LB depends on the appearance of inhibition in a circuit that is initially purely excitatory. Similar results have been observed in mouse embryos. Spinal cords isolated from mouse embryos produce bursts of spontaneous activity that are initially synchronized bilaterally across the cord, which might cause a mouse to hop like a rabbit if it were executing locomotion. However, as development continues, the timing of the bursts shifts until they alternate from side to side, which would correspond to a walking gait. This shift from synchrony to alternation takes place when glycinergic inhibitory synapses appear, and the alternating pattern is then maintained into adulthood.

Acquiring Complexity by Combining Behaviors

In some cases, behavior develops as individual modules become assembled. A striking example of this pattern is displayed in the development of swimming behavior in larval salamanders. A very early spontaneous behavior of salamander tadpoles is a bending of the head to one side or the other. Initially, only the head bends, but as development progresses, muscles further along the body join in, causing the bend to extend posteriorly. Eventually, the bend is so extreme that it produces a behavior called coiling. Even later, coiling can be elicited by a touch to the skin on the side opposite the contraction, presumably when connections are formed that deliver sensory information to the motor neurons. The timing of these unilateral bends then becomes modified to produce contractions that alternate along the body, generating swimming.

Some of the embryonic behaviors may not have an adaptative role; instead, they reflect function in a partially completed neuronal circuit. In other cases, embryonic behaviors can have a clear adaptive purpose. An example is the hatching movement of the bird embryo, which allows the embryo to break open and escape from the shell.

Development of Behaviors That Depend on Endocrine Function and Learning

Although development of the nervous system – that is, generation of neurons and production of synaptic connections – is necessary for the normal development of behaviors, in some cases it is not sufficient. Additional factors are required to make the nervous system capable of producing normal behavior. The acquisition in many bird species of the ability to produce normal, species-specific song provides an excellent example. Most of the research on this topic has focused on canaries and zebra finches, both of which are highly tractable in a laboratory. In both species, only male birds sing, and anatomical study reveals that several brain centers are much larger in male birds than they are in the female brain. These centers are intimately involved in the production of song, and their large size depends on the presence of gonadal hormones during a critical period early in the bird's life. Some of the enlarged structures are necessary for the production of song – that is, they are motor or premotor centers; ablating them from the brain of an adult male bird that could sing normally prior to the ablation renders him unable to sing. Other enlarged regions are unimportant for the production of adult song, at least in the short term, but they are critical for the development of normal singing behavior because these birds must learn to sing – much as a human child must learn to talk.

During early life, a male zebra finch goes through a phase during which he listens to the song of one or more conspecific males around him (in the natural world this 'tutor' is his father) and memorizes the song. At this time, the bird does not himself sing, so memorization does not require active practice, and this learning period is of limited duration. That is, there is a critical period for the learning of the song. Later in life, when environmental cues cause a surge in reproductive hormones, the bird begins to develop his own song, which will resemble – but not precisely reproduce – his tutor's song. During this time, he practices his song and must be able to hear himself; deafened birds sing poorly if at all. Male birds that are reared in isolation during the critical period eventually do sing, but the structure of the song is very simple and lacks the characteristics of normal zebra finch singing.

The development of language in human infants has many features in common with song development in zebra finches. Language learning begins early, and in the initial phase the human infant listens to and memorizes some features of the language he or she encounters, but does not speak. Later, the infant begins to practice sounds that eventually coalesce into language, followed by a period of rapid linguistic development. Around puberty, the critical period for learning language seems to close, and although adults are capable of learning new languages, the process

calls on different regions of the brain and operates differently from acquisition of language by children.

One Nervous System, Very Different Lifestyles: Metamorphosis

In animals in which the life cycle includes distinctly different life stages (e.g., insects and amphibia), the nervous system must be radically reconfigured during transitions to allow the individual to produce critically important behaviors during each stage, even though the lifestyle during each stage may require different sensory capabilities, locomotory behaviors, and central processing. The transitions between stages are typically associated with changes in the levels of one or more hormones, and variations in hormone levels act directly on the identified neuron, which then changes the behavioral output. For example, in the tobacco hornworm moth, during the larval stage the caterpillar crawls on the plants that provide its food using pro-legs, which are not precursors of the legs in the adult. The neurons that drive and coordinate the muscles of the pro-legs survive the transition from the caterpillar to the legless pupal stage, but the morphology and synaptic input changes. In fact, generally the motor neurons survive from the caterpillar stage, through pupation, and into the adult stage, changing their morphology and function with each transition. In contrast, sensory systems in adult insects may include new neurons.

Summary

The development of behavior depends on the intricate interaction between the cellular processes of development in the nervous system, other systems in the body (e.g., endocrine function), and the individual's environment. It begins well before hatching or birth (depending on the species) and continues throughout life. Many of the processes that underlie behavioral development have been studied in other contexts, such as the mechanisms of learning and the hormonal regulation of target organs. This complex web of developmental processes equips the individual to respond appropriately and effectively to the many challenges it will encounter.

Development of Drosophila Neuromuscular Junctions

Introduction

The *Drosophila* neuromuscular junction (NMJ) ranks as one of the best-understood genetic model-systems for examining synaptic development and function. Most research involves the motor neurons and muscle fibers of the embryonic and larval body wall. The connections are precise and relatively invariant, simplifying the analysis of mutant phenotypes. Furthermore, the NMJ's peripheral location aids experimental access. Developing motor neurons may be observed *in vivo,* and electrophysiological studies are possible at all developmental stages.

Drosophila generates its motor systems twice, first as an embryo and then again as a pupa. The adult motor system is more complex than the larval one, with segment-specific specializations for flight, walking, and reproductive behavior. Although many useful insights have emerged from studies of the developing pupa, most current research is focused on the more accessible embryonic and larval synapses.

General Features of the Neuromuscular Junction

The *Drosophila* larval body-wall muscles generate the movements involved in locomotion and postural control. Most research has examined the first seven abdominal segments (A1–A7). These share the same muscle pattern of 30 muscle fibers on each side, with only a minor difference in segment A1 (Figure 1(a)). The terminal (A8) segment has a distinct muscle pattern, as do the three thoracic segments (T1–T3).

The major source of innervation for the hemisegment is the ganglionic peripheral nerve (PN), which emerges laterally from each central nervous system (CNS) segment. In segments A1–A7, the PN contains between 80 and 90 axons, of which fewer than half are efferent. The PN elongates throughout development, reaching 3 mm by the end of larval life. At the body wall the PN divides into five branches. All dorsal and most mid-body-wall muscle fibers are innervated by the intersegmental nerve branch (ISN), whereas the remaining mid-body-wall muscles are innervated by the dorsal branch of the segmental nerve (SN)a. All ventral longitudinal muscle fibers are innervated by the SNb branch (also referred to as the ISNb), whereas the remaining oblique and superficial ventral muscles are innervated by the SNc and SNd (or, alternatively, ISNd) branches. A minor source of innervation is provided by the transverse nerve (TN), which exits from the dorsal midline of each abdominal CNS segment to innervate ventral and mid-body-wall targets.

All motor neurons are glutamatergic. A subset also expresses synaptic cotransmitters, including the neuropeptides proctolin and leukokinin I, and the neuromodulatory transmitter octopamine. Unlike many invertebrates, there are no inhibitory GABAergic motor neurons. The NMJ also responds to neuromodulatory molecules that circulate in the hemolymph, such as the FMRFamide peptides.

The neuromuscular junction consists of multiple branches bearing variously sized synaptic boutons. The NMJs lie on the muscle fiber side facing the animal's interior (Figure 2). Individual boutons contain multiple neurotransmitter release sites, characterized by T-bar ribbons with synaptic vesicles and soluble *N*-ethylmaleimide-sensitive factor attached protein receptor (SNARE) proteins. Surrounding each release site is a periactive region where vesicle endocytosis occurs. By the end of larval life, each bouton may contain up to 40 release sites. The postsynaptic membrane opposite the bouton is enriched for glutamate receptors (GluRs), adhesion proteins, and ion channels. The proteins are anchored by multiple adaptor proteins, including the postsynaptic density (PSD-)95 homolog Discs large (Dlg) and the 4.1 superfamily protein Coracle. The postsynaptic site has a highly folded membrane known as the subsynaptic reticulum (SSR).

There are two postsynaptic ionotropic GluRs at the NMJ. These multimeric receptors are assembled from the five receptor subunits expressed by muscles. The two receptors differ by whether they contain the GluR-IIA or GluR-IIB subunit, but both have GluR-IIC (also referred to as dGluR-III), GluR-IID, and GluR-IIE subunits. The GluR-IIA and GluR-IIB subunits form the channel pore and confer the single-channel conductance, antagonist sensitivity, and desensitization characteristics. On the presynaptic side, there is also a single GluR-A metabotropic GluR (also referred to as DmGluR-A) that contributes to synaptic augmentation and facilitation.

The Motor Neurons and Their Projections

There are approximately 35 motor neurons that innervate each abdominal hemisegment. Of these, some 30 type Ib motor neurons synapse with either a single muscle fiber or muscle fiber pair. The Ib neurons provide direct control of individual muscle fibers during locomotion. At the NMJ, the Ib motor

Figure 1 The motor neurons and muscle fibers of the abdominal body wall: (a) muscles of a single abdominal hemisegment displayed from the ventral midline (vm) to the dorsal midline (dm) (rhodamine phalloidin fluorescence; anterior at the top); (b) diagram of the central nervous system (CNS) (left) and muscle map showing the major nerve branches (right). In (a), each muscle fiber is designated by a number from 1 to 30 (several superficial muscle fibers are not visible in this dissection). In (b), left, the diagram shows the motor neurons that innervate a single abdominal hemisegment. The gray bars indicate the anterior commissures (ac), posterior commissures (pc), and the longitudinal connectives (lc). Each motor neuron's preferred muscle target is indicated by the number within the cell body. All the motor neurons shown are type Ib, except for two type Is cells. The color code indicates the nerve branch the axon takes. In (b), right, the muscle map is colored to indicate the transcription factor code that defines motor-neuron-targeting preference. Panel (b, left) on Chiba A (1999) Early development of the Drosophila neuromuscular junction: a model for studying neuronal networks in development. *International Review of Neurobiology* 43: 1–24.

neurons have large boutons with diameters ranging from 2 to 6 μm (Figure 2). There are, in addition, two type Is motor neurons that function as common excitors. These cells each innervate large subsets of dorsal and ventral muscles, respectively, and have medium-sized 1–4 μm round boutons. Bouton diameters for both classes remain fairly constant throughout larval development. The size differences between Ib and Is motor neuron boutons may be due to differences in action potential firing rates. Type Ib boutons become smaller and resemble Is boutons when action potential firing rates are experimentally reduced using either Na^+ channel mutations or sublethal doses of tetrodotoxin (TTX) during development.

There are also two type II efferent neurons that express octopamine and are probably neuromodulatory. They each innervate multiple dorsal and ventral muscle fibers, respectively, with boutons smaller than 1 μm. Finally, a single type III motor neuron with oblong boutons innervates muscle fiber 12 in four abdominal segments. A typical muscle fiber receives three inputs: from a type Ib, a type Is, and a type II motor neuron.

Each type Ib motor neuron synapses with its target muscle fibers with high fidelity. The motor neuron RP1 innervates the ventral longitudinal muscle fiber 13 with only a 3% error rate. The preference of a motor neuron for a specific muscle fiber is retained

Figure 2 The neuromuscular junctions of the ventral longitudinal muscle fibers 7, 6, 13, and 12 of a third instar larva, visualized with neuron-specific labeling (anti-HRP). The three major motor neuron types (Ib, Is, and II) are distinguishable by their characteristic bouton morphology. Scale bar = 50 μm. even when muscle patterning is altered. When muscle fiber 13 is duplicated, the RP1 motor neuron faithfully innervates both duplicated cells, whereas motor neurons to neighboring muscle fibers remain unaffected. This implies the presence in motor neurons of a cell-specific muscle-recognition mechanism.

Cellular Determination and Axon Guidance

Motor neuron growth cones make multiple guidance decisions during development. They must first take the correct neuropilar tracts to exit the CNS and then follow an appropriate nerve branch to either a dorsal or ventral muscle field. These choices require multiple receptors operating at specific times during development. The dorsal or ventral muscle field choice is governed by the combinatorial expression of several transcription factors, which, in turn, control the expression of specific receptors and signaling pathways. Significantly, some of the transcription factors involved in ventral muscle field preference are conserved evolutionarily between insects and mammals.

Factors Regulating Motor Neuronal Identity

Two transcription factors, Hb9 and Nkx6, contribute to ventral muscle targeting (Figure 1(b)). The proteins regulate the expression of at least two additional transcription factors, Islet and Lim3. Both Islet and Lim3 are expressed by motor neurons that take the SNb nerve branch to ventral longitudinal muscle fibers, whereas Islet alone is expressed by motor neurons projecting to the nearby ventral oblique muscle fibers innervated by the SNd branch. In *lim3* loss-of-function mutants, the SNb motor neurons behave like those of SNd. Conversely, overexpression of Lim3 in SNd motor neurons switches them to SNb targets. The homeodomain transcription factors Barh1/h2 play a similar essential role for SNa-projecting axons to the mid-body wall (Figure 1(b)).

Dorsally projecting motor neurons express the transcription factor Even skipped (Eve). Mutations of *eve* cause dorsal motor neurons to project to ventral regions. When Eve is expressed in ventral motor neurons, the neurons switch their identity and project to dorsal targets. Because Eve functions as a transcriptional repressor, it is probable that this guidance switch is due to the inhibition of factors required for ventral identity, such as Hb9 and Lim3.

The identity of the downstream effectors regulated by these transcription factors remains incompletely understood. For the ventrally projecting motor neurons, Islet and Lim3 positively regulate the expression of the Ig superfamily homophilic adhesion molecule Fasciclin III (FasIII). They also negatively regulate the IgSF protein beaten path (Beat1c), a molecule involved in axonal defasciculation at specific choice points along the body wall. Among the dorsal class of motor neurons, Eve indirectly regulates the expression of the Ig superfamily homophilic adhesion molecule Fasciclin II (FasII) and Unc5, one of the receptors for the Netrin chemotropic factors.

The Decision to Defasciculate

The next task faced by a motor neuron is to decide where to leave the axon fascicle. The decision to defasciculate depends on a balance between interaxonal adhesion and repulsion. All motor neuron axons express FasII, as well as the chemorepulsive molecule Semaphorin Ia (SemaIa) and its receptor PlexinA. Subsets of motor neuron axons also express additional cell adhesion molecules, such as Fasciclin I, FasIII, and Connectin (Con). Increased expression of FasII in motor neuron axons suppresses defasciculation, as does the reduction of either SemaIa or PlexinA. The *SemaIa* mutant phenotype can be suppressed by reducing levels of either FasII or Con. This is consistent with the idea that defasciculation is regulated by the relative levels of adhesion and repulsion between axons.

Defasciculation is also regulated by locally secreted molecules, such as Beaten path. *Beat* mutants fail to defasciculate, bypassing their muscle targets. Genetic interaction studies indicate that the Beat

protein tips the balance toward defasciculation by selectively interfering with FasII-mediated axonal adhesion, possibly by directly binding to the FasII ectodomain.

Additional insight into defasciculation has come from examining the neurally expressed receptor tyrosine phosphatases (RPTPs) dLAR, DPTP66D, and DPTP99A. In general, mutation of the RPTPs leads to a failure to defasciculate, although with mild phenotypic penetrance. The phenotype is more severe when multiple RPTPs are eliminated, suggesting redundancy or cooperative functions among the proteins. Although the identity of the ligands and intracellular targets of most RPTPs remains unresolved, dLAR is thought to interact with the extracellular heparin sulfate proteoglycans Syndecan and Dally-like. The intracellular targets of dLAR include the cytoplasmic tyrosine kinase Abelson (Abl), and its phosphorylation target Enabled (Ena). dLAR may contribute to a growth cone's chemotropic response by regulating actin cytoskeleton assembly.

Embryonic axons fail to defasciculate when muscle fibers are genetically eliminated from the body wall, suggesting that defasciculation also depends on muscle-derived cues. One candidate for a muscle-derived signal is Sidestep (*side*), a chemotropic ligand that is expressed by all muscle fibers. In *side* mutants, motor neurons bypass their muscle targets, but unlike *beat* mutants, the phenotype is not suppressed by reduced levels of FasII. This suggests that defasciculation depends on at least three mechanisms: (1) a local reduction in interaxonal adhesion, combined with (2) elevated interaxonal repulsion, and possibly (3) one or more chemotropic signals derived from the musculature.

Target Selection

As growth cones explore the body-wall musculature, they extend rapidly moving filopodia that sample cell surfaces. A filopodium may exist for as little as a few minutes and extend as far as two to three muscle fibers ahead of the growth cone. Time-lapse studies in *Drosophila* embryos show that the efferent growth cones direct themselves toward their destined targets by following trajectories pioneered by specific filopodial contacts. The earliest contacts between the motor neuron growth cone and the target muscle fiber occur at muscle protrusions known as myopodia. These processes resemble neuronal filopodia and increase the probability of interactions between the growth cone and muscle fiber. The myopodia may also present key cell-surface molecules to the motor neuron, promoting target recognition.

Molecular Recognition of Synaptic Targets

The molecular recognition of specific muscles by motor neurons involves both attractive and repulsive signaling (Figure 3). Some key molecules are expressed by all or large subsets of motor neurons and muscles, whereas others have narrower, cell-specific expression patterns. The molecules include secreted as well as cell-surface proteins. During embryonic synaptogenesis, all muscle fibers and motor neurons express FasII. In addition, all muscle fibers secrete the chemorepellant protein Semaphorin IIa (SemaIIa), and all motor neurons in turn express PlexinB, the SemaIIa receptor. Gain- and loss-of-function tests indicate that the

Figure 3 Multiple attractive (+) and chemorepulsive (–) molecules are expressed by individual muscle fibers and motor neurons at the time of innervation. A motor neuron's affinity for a specific muscle target depends on balancing multiple attractive and repulsive molecular cues. From Nicholson N and Keshishian H (2006). Metamorphosis and the formation of the adult musculature. In: Sink H (ed.) *Muscle Development in Drosophila,* pp. 113–120. New York: Springer.

affinity of motor neurons for muscle fibers is adjusted in part by balancing the relative levels of FasII, SemaIIa, and/or PlexinB. Although these broadly expressed proteins cannot define specific target preferences, their balance modulates the stability of neuromuscular contacts as synaptogenesis proceeds.

Specific targeting decisions depend on the expression of molecules within subsets of motor neurons and/or muscles (Figure 3). For example, the IgCAM FasIII is expressed by both motor neuron RP3 and its two synaptic targets, the muscle fibers 7 and 6. In loss-of-function *FasIII* mutants, RP3 shows low-frequency but statistically significant targeting errors. This indicates that other guidance molecules are available to guide RP3 to its targets with some accuracy. However, RP3 can be misdirected when adjacent muscles are made to express FasIII. Significantly, the ectopic expression does not degrade or alter the guidance of other motor neurons, indicating that muscle-expressed FasIII is a specific recognition cue for the RP3 motor neurons. Results similar to these have been obtained for several other proteins involved in target selection, including Connectin and Capricious. Probably every muscle fiber has a distinct and characteristic profile of molecules involved in recognition and targeting. For example, muscle fibers 7 and 6 express FasII, FasIII, NetrinB, Toll, and SemaIIa, whereas the nearby ventral longitudinal muscle fiber 12 expresses FasII, SemaIIa, and Capricious (Figure 3).

A combinatorial model involving attractive versus repulsive signaling has been tested by analyzing the phenotypes of *netrinB* (*netB*), *FasII*, and *SemaIIa* mutant embryos. In *netB* mutants, the RP3 motor neuron fails to reliably innervate muscle fibers 7 and 6, suggesting a role for NetrinB in guiding the growth cone to those muscles. The guidance defect is largely suppressed when *SemaIIa* mutations are combined with *netB*, suggesting that NetrinB-mediated attraction is in balance with repulsive signaling by SemaIIa. Because adjacent nontarget muscle fibers do not express NetrinB, this favors RP3's innervation of its NetrinB-positive target muscle fibers over neighboring ones. Similar scenarios exist for motor neurons projecting throughout the body wall, involving a balance between attractive and repulsive signals to define specific muscle targets against a generally repulsive nontarget background.

Synaptic Development and the Role of Activity

Although relatively little is known about how synaptogenesis is initiated, mutations of genes that delay this step have been informative. Tetraspanins are evolutionarily conserved proteins with widespread functions in cell signaling and motility. Three tetraspanin genes are transiently expressed by motor neurons as synapses form. In mutants of the tetraspanin gene Late bloomer, growth cones correctly identify and contact their target muscle fibers, but then delay synaptogenesis for hours. The phenotype is enhanced when all three tetraspanins are deleted, suggesting that the proteins function in a cooperative fashion to trigger synapse formation. How this happens remains unknown.

The transformation of an embryonic growth cone to an anatomically recognizable presynaptic terminal takes only 3–4 h. On the presynaptic side, the immature contact forms multiple round varicosities that prefigure synaptic boutons. Electron microscopy (EM) studies show that postsynaptic electron-dense regions arise exclusively at the contacts made between the growth cone and its preferred muscle fiber.

Early Roles for Activity at the Neuromuscular Junction

Both the localization of postsynaptic receptors and the refinement of synaptic connections depend on neural activity. Small glutamatergic potentials can be recorded from muscle as soon as the motor neuron growth cone arrives on site. GluRs are initially expressed throughout the muscle fiber. Following growth cone contact, the receptors accumulate at the site of the developing synapse. Although it is not known whether this early localization is due to the trapping of existing receptors (as occurs at larval synapses), the localization to the synapse is disrupted when motor neuron activity is suppressed.

From the time motor neurons first contact the musculature to the time of hatching, the embryo executes 1–2 strong peristaltic contractions/min. The contractions are driven by motor neuron action potentials activating NMJs throughout the body wall. The significance of this periodic, wavelike motor activity has been tested by suppressing motor neuron electrical activity. Normally, motor neurons withdraw contacts made with nontarget muscle fibers during the first few hours of synaptic development. The loss of evoked NMJ activity results in a failure to withdraw these incorrectly placed contacts throughout the body wall. The ectopic contacts are removed only if activity is restored during an early critical period that ends soon after the embryo hatches. The remaining contacts mature into functional but miswired NMJs. The mechanisms governing activity-dependent refinement remain largely unknown.

The Growth of the Neuromuscular Junction

After hatching, the larval NMJ undergoes dramatic growth. In hatchling larvae, the NMJs on muscle fibers 7 and 6 have fewer than 20 synaptic boutons, with each bouton averaging only two release sites. By the end of larval development 100 h later, the muscle fiber surface area has increased 100-fold and the NMJ contains 80–100 boutons, with up to 40 release sites per bouton.

Neurotransmission is also modified as the NMJ grows. Spontaneous miniature currents are initially small and infrequent, but become steadily larger and more regular as the embryo develops. By the time of hatching, these quantal events are skewed toward larger sizes. Quantal size (the postsynaptic response to a single vesicle) thereafter remains constant as the larval NMJ grows. The amplitude of the evoked excitatory junctional potential (EJP) also remains constant despite a fall in membrane resistance as the muscle grows. By contrast, quantal content (the average number of vesicles released per action potential) steadily increases as the NMJ enlarges. This is due to the large increase in the number of release sites at the NMJ and probably from increases in release efficiency.

In vivo imaging of NMJ development indicates that more than half of new boutons are added by intercalation within existing strings of boutons. In the remaining cases, the boutons are added at branch tips. The new boutons have the same density of vesicles, active zones, and T-bar ribbons as mature boutons and precede the development of postsynaptic specializations and SSR folding. Synaptic boutons are also eliminated from the NMJ. Because the SSR develops only after boutons have formed, isolated SSRs that lack boutons probably indicate elimination events. Nearly 18% of muscle fiber 7 and 6 NMJs in late first and early second instar larvae show these tell-tale bouton retraction footprints, compared to 5% in the third instar. Whereas bouton formation can occur anywhere along an NMJ branch, elimination is usually restricted to branch termini.

Time-lapse studies of green fluorescent protein (GFP)-tagged GluRs show that larval GluRs first appear in the muscle membrane as extrasynaptic hot spots. Fluorescence recovery studies of tagged GluR-IIA indicate that the extrasynaptic receptors are preferentially recruited into the expanding PSD that develops opposite the presynaptic boutons. After they enter the PSD, the receptors become immobilized, presumably by binding to adaptor proteins, with only a 20% turnover every 24 h.

The periactive zone surrounding the release site is enriched for the adhesion molecule FasII, a protein that plays an important role in NMJ growth. Newly budded boutons have lower levels of FasII than parental boutons. This is an intriguing observation because mutations that reduce FasII levels generally have enlarged NMJs. The actions of FasII on NMJ expansion depend in part on presynaptic signaling via the amyloid precursor protein (APPL) and through interactions with the PSD-95, Dlg and ZO1 (PDZ)-containing adaptor protein dX11/Mint/Lin-10. The periactive zone is also enriched for Bruchpilot (also referred to as NC82), a coiled-coiled domain protein with homology to the human active zone protein ELKS/CAST. Bruchpilot has a key role in defining the boundaries of the active zone and in the clustering of Ca^{2+} channels.

The Roles of Activity in Neuromuscular Junction Growth and Function

The NMJ's physical size is correlated to the level of neuromuscular activity. Mutations that increase membrane excitability, as well as treatments that increase locomotor activity, result in larger and more highly branched NMJs. These NMJs have up to twice as many boutons as controls and also have larger EJPs and more frequent spontaneous activity.

In genetically hyperactive larvae, there is a substantial reduction of the cell-adhesion molecule FasII at the NMJ. Hypomorphic *FasII* mutations, which directly reduce FasII to the levels observed in hyperactive larvae, have similarly enlarged NMJs. This implies that the activity-dependent downregulation of FasII is sufficient to account for the NMJ expansion seen with neuromuscular hyperactivity. Significantly, the expected NMJ expansion of hyperactive larvae is effectively blocked when FasII levels are held constant.

Cyclic adenosine monophosphate (cAMP) levels also influence NMJ growth. *dunce* mutants have elevated levels of cAMP and significantly expanded NMJs. When *dunce* is combined with hyperactivity mutations such as *Shaker,* there is a strong synergizing effect that further promotes NMJ expansion. Conversely, mutations that reduce cAMP levels suppress activity-dependent NMJ growth. Significantly, FasII levels at the NMJ are reduced in *dunce* mutants, and the overgrowth caused by increased cAMP levels is blocked when FasII levels are held constant. Thus, FasII is a common endpoint in multiple regulatory cascades affecting NMJ expansion.

Activity-dependent NMJ growth is also dependent on transcriptional regulation. The expression of the cAMP responsive element-binding protein (CREB) transcriptional activator enhances the NMJ expansion phenotype of FasII mutants, whereas the expression of

a negative repressor of CREB blocks the increase in presynaptic neurotransmission seen in *dunce* mutants. This indicates that presynaptic transmitter release and NMJ structural plasticity may be regulated in different ways. This idea is supported by the actions of AP-1, an immediate-early transcription factor composed of a Fos and Jun heterodimer. AP-1 functions through CREB to regulate NMJ growth but independently, via Jun kinase, to modulate synaptic function.

Activity influences the expression and localization of GluRs by increasing local subsynaptic translation during larval development. The NMJ expansion associated with elevated motor neuron activity is partially blocked by mutations that decrease the number of available receptors or suppress their translation. This indicates that receptor availability limits the formation of new boutons, which is supported by the finding that reducing GluRIIs to relatively low levels leads to smaller NMJs.

Finally, functional plasticity at the NMJ can arise soon after short bouts of hyperactivity; 40 min of vigorous locomotion is sufficient to cause long-term facilitation of evoked potentials at the NMJ. This is due to an increase in neurotransmitter release, surprisingly through the recruitment of physically larger vesicles to the release sites, resulting in increased quantal size. The effect depends on presynaptic protein kinase A activity and is independent of postsynaptic receptor activation. Similarly, when postsynaptic sensitivity is acutely decreased using GluR toxins, there is a rapid compensatory elevation of quantal release, possibly through the modulation of presynaptic Ca^{2+}-channel activity. The relationships between these acute forms of physiological plasticity and long-term growth changes at the NMJ are not yet known.

Transsynaptic Signals Involved in Neuromuscular Junction Development

Retrograde signaling, from muscle to motor neuron, plays several important roles during NMJ development. For example, GluR-II mutations lead to a compensatory increase in the number of release sites, elevating quantal release. This homeostatic mechanism holds the amplitude of postsynaptic potentials constant despite changes in muscle receptor sensitivity. Similarly, when muscle depolarization is suppressed by experimentally elevating the potassium leak, the motor neuron responds by increasing transmitter release. Elevating CREB transcriptional activity in muscle, achieved by expressing the CREB co-activator dCBP, also results in a retrograde inhibitory signal. The motor neuron responds by reducing both evoked neurotransmitter release and short-term facilitation.

The best-understood retrograde signaling system regulating NMJ growth involves the transforming growth factor (TGF)-β/bone morphogenetic protein (BMP) ligand Glass bottom boat (Gbb). Gbb is expressed in body wall muscle fibers and regulates presynaptic development through both canonical and noncanonical pathways (Figure 4). In the canonical mode, Gbb binds to a presynaptic TGF-β receptor complex containing the type II BMP receptor Wishful thinking (Wit) and at least one of two type I BMP receptors. These kinases stimulate transcription by activating the R-Smad transcription factor Mad and its co-Smad Medea. Disrupting any of these results in smaller NMJs with reduced neurotransmission. Presynaptic TGF-β/BMP signaling also depends on proteins in the early and late endosomal compartments, as well as on retrograde axonal transport, suggesting

Figure 4 Retrograde signaling at the *Drosophila* NMJ. The TGF-β/BMP growth factor Gbb is expressed by muscle and is required for normal NMJ growth and bouton formation. The ligand stimulates a motor-neuronal receptor complex composed of the type II BMP receptor Wit and the type I receptors Tkv and/or Sax. The activated complex phosphorylates the R-Smad transcription factor Mad. Phospho-Mad associates with the co-Smad Medea and stimulates transcription at the cell body. Regulation is, in part, by ubiquitination of Medea via the E3 ligase (Hiw) and by regulation within the signaling endosome. Hiw also negatively regulates a MAPK cascade that promotes bouton addition through its action on the MAPKKK Wallenda. Gbb binding also stimulates a noncanonical signaling pathway involving Limk, leading to the stabilization of new boutons. BMP, bone morphogenetic protein; MAPK, mitogen-activated protein kinase; MAPKKK, MAPK kinase kinase; NMJ, neuromuscular junction; TGF, transforming growth factor.

the physical transport of one or more proteins from the NMJ to the cell body.

The mechanisms that regulate Gbb release from muscle remain largely unknown. Inhibition of calmodulin-dependent protein kinase (CaMK)II in the muscle fiber stimulates a retrograde signal (possibly Gbb) that depends on the Wit receptor to increase the number of T-bar ribbons and the quantal content of motor neurons. Similarly, postsynaptic Dystrophin regulates a retrograde signal that influences presynaptic short-term facilitation, again through the activation of Wit in the motor neuron.

Finally, there is evidence that Wit can activate noncanonical signaling pathways independent of the Smads. For example, the C-terminus of Wit binds directly to presynaptic Lim kinase (Limk), leading to the stabilization of newly formed boutons. The loss of function mutation of *limk* results in a substantial expansion of the NMJ. Surprisingly, the increased number of NMJ boutons in *limk* mutants does not result in increased EJP amplitudes, as is the case when NMJs expand following elevated neuromuscular activity.

Mutations affecting Highwire *(Hiw)*, a large multifunctional protein with E3 ubiquitin ligase and scaffolding activities, reveal something of the complexity of presynaptic signaling during NMJ growth. Mutant larvae have significantly more boutons than normal, suggesting that Hiw functions to inhibit bouton addition. Hiw negatively regulates at least two signaling systems. It inhibits the TGF-β/BMP cascade involving Wit through a direct interaction with the transcriptional cofactor Medea, and it attenuates a mitogen-activated protein kinase (MAPK) cascade involving the MAPK kinase kinase (MAPKKK) protein Wallenda, the MAPK c-Jun N-terminal kinase (JNK), and the transcription factor Fos (**Figure 4**).

NMJ development also requires anterograde signaling from motor neuron to muscle. The Wnt family morphogen Wingless (Wg) is secreted by motor neurons, and its receptor is located on both pre- and postsynaptic membranes. In *wg* mutants, bouton formation is suppressed. The boutons have unbundled microtubules, as revealed by labeling the microtubule binding protein Futsch. In addition, the terminal NMJ branches do not elongate, resulting in less separation between boutons. *wg* larvae also have extensive postsynaptic phenotypes, including aberrant expression of the GluR-IIA, the Dlg adaptor protein, and overall reduced development of the SSR. Significantly, similar phenotypes are observed when a dominant negative Wg receptor is expressed in the body-wall muscles. These results suggest that Wg may function as both an anterograde as well as an autocrine signal to regulate NMJ growth and development.

Concluding Observations

Several areas of NMJ formation and maturation remain especially promising for further study. These include: (1) to decipher the combinatorial transcription factor codes that define motor neuronal identity, which control the receptors and signaling cascades involved in axon guidance; (2) to define the molecular signals that trigger synaptogenesis, transforming a growth cone into a synapse; and (3) to determine how multiple transsynaptic signals are integrated to control synaptic growth and function on time scales ranging from minutes to days. Finally, we need to acquire a deeper understanding of the motor system from a functional standpoint, including the roles that cotransmitters and circulating substances play in modulating motor output. Fortunately, the molecular-genetic and physiological tools are available to illuminate these areas of neuromuscular development and function in a highly accessible system of synapses.

Developmental Disability and Fragile X Syndrome: Clinical Overview

D Hessl, C Green, D Aguilar, L Cordeiro, C McCormick, and J Yuhas, University of California at Davis, Sacramento, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Fragile X syndrome (FXS) is the most common of many known X-linked mental retardation syndromes, and it is the most prevalent inherited form of mental retardation. (Down syndrome is more common but not inherited.) This article provides a clinical overview of FXS, including the distinctive physical features, cognitive profile, and behavioral and psychiatric characteristics that have been identified through empirical study. To set the stage for this overview, and to guide a better understanding of the genotype–phenotype association studies, a brief review of the genetic basis of the disorder is presented.

Genetics of FXS

FXS is caused by an expansion of a trinucleotide (cytosine–guanine–guanine or CGG) repeat in the 5′ untranslated region of the fragile X mental retardation 1 (*FMR1*) gene located on the X chromosome at Xq27.3. CGG expansions larger than 200 repeats typically cause hypermethylation and subsequent transcriptional silencing of the gene, thereby inhibiting the production of the *FMR1* protein (FMRP). The absence or reduction of FMRP production causes FXS, which has an estimated prevalence of 1 in 4000 to 1 in 6000 live births. Individuals with 55–200 CGG repeats have the fragile X premutation, characterized by instability in parent–offspring transmissions, with a bias to expansion related to maternal repeat size, as well as increased risk for premature ovarian failure in women and fragile X-associated tremor/ataxia syndrome (FXTAS), a recently described neurodegenerative condition in aging men and women. Normal individuals have between ~5 and 54 repeats, usually with stable transmission from parent to offspring.

Physical Features

Classic physical features of FXS include a long, narrow face and prominent ears (Figure 1); however, these features may not be present until after puberty. Additional facial features are prominent jaw, midface hypoplasia, narrow palpebral fissures, epicanthal folds, strabismus, a highly arched palate, and general macrocephaly. It is important to recognize that many females and some males, even after puberty, do not develop these features. Many males present with macroorchidism (large testicles), although this has no documented effect on reproduction ability. Other common features include flat feet, joint laxity, scoliosis, tall stature, and connective tissue dysplasia. Individuals with the premutation can present with the FXS physical (and behavioral) phenotype, presumably due to a reduction in FMRP (Figure 1).

Cognitive Profile

As described previously, *FMR1* refers to 'fragile X mental retardation 1,' and it is perhaps not surprising that a high proportion of males with the full mutation (approximately 80%) have cognitive deficits falling within the mental retardation range (IQ below 70). However, there is considerable variability, spanning from the profound mental retardation range to scores falling within, or even above, the average range. 'High functioning' males with FXS usually have some degree of FMRP expression due to repeat size or methylation mosaicism; alleles with an unmethylated *FMR1* site or alleles with fewer than 200 CGG repeats will typically express FMRP normally. More variability in level of functioning is found among females with FXS due to the presence of two X chromosomes (one X with full mutation and one X with normal CGG repeat size) and effects of X inactivation, whereby only one X in each cell is active. Females with a higher proportion of cells with the normal X active are typically less affected. Genotype–phenotype association studies have documented that cognitive ability as measured by IQ is associated with FMRP variation due to the genetic factors discussed above (Figure 2). These association estimates are imprecise because the currently available FMRP measure relies on immunocytochemistry which simply reports the percentage of blood lymphocytes expressing FMRP, which is only a proxy for FMRP levels present in brain tissue. IQ is not associated with CGG repeat size within the full mutation range.

Of course, other factors, such as background genetic and environmental effects, contribute to cognitive ability in FXS, and this has been demonstrated in large family studies. For example, mean parental IQ is correlated with the cognitive ability in children with FXS, suggesting that background genes contributing to

Figure 1 (a) A young boy with the fragile X full mutation demonstrating classic features of prominent ears and a long, narrow face with prominent jaw. (b, c) Two girls with the full mutation showing similar, but perhaps less prominent, features of FXS. (d) A boy with the fragile X premutation (66 CGG repeats, FMRP expression 77% of normal, and *FMR1* mRNA 3.5 times above normal). He has a full-scale IQ of 97 but presents with prominent ears, hyperextensible joints, learning difficulties, and symptoms of ADHD and autism spectrum disorder.

Figure 2 Scatterplots of full-scale IQ on FMRP expression for fragile X full mutation and premutation females. Reprinted from Loesch DZ, Huggins RM, and Hagerman RJ (2004) Phenotypic variation and FMRP levels in fragile X. *Mental Retardation and Developmental Disabilities Research Reviews* 10: 31–41, with permission from Wiley-Liss, Inc.

heritability of intelligence as well as family environmental factors appear to play a role in determining cognitive outcome. Family environmental factors are also related to adaptive and maladaptive behaviors in these children; for example, children living in higher quality family environments with frequent learning opportunities, enrichment, and increased organization tend to have higher adaptive levels and fewer autistic behaviors. These findings indicate that intervention at the level of the family environment, in addition to the typical behavioral and medication treatment strategies, may be effective.

Almost all studies examining the longitudinal trajectory of cognitive ability in FXS have demonstrated substantial IQ decreases across childhood and adolescence. This has been attributed to a slower

acquisition of skills relative to typical children over time rather than a loss of function. In addition, measurement of IQ in younger children appears to capture relative strengths in children with FXS, such as in visual matching and labeling, whereas tests designed for adolescents and adults tend to focus more on abstract reasoning, which is a known area of weakness.

Neuropsychological studies show that the fragile X mutation contributes to a cognitive profile of relative strengths and weaknesses, suggesting that particular brain regions are more affected than others, perhaps due to regional differences in *FMR1* expression during development. For example, it is well established that individuals with FXS show more profound impairment in mathematics computation, visual–spatial organization, and executive functions such as working memory, attention, and response inhibition. Functional magnetic resonance imaging (fMRI) studies have elucidated the brain basis for the math reasoning deficit; females with FXS demonstrate less brain activation in regions that are known to mediate math computation in typically developing individuals, and this reduction in activation is associated with FMRP expression (Figure 3). Individuals with

Figure 3 Brain areas that show significantly greater activation during two-operand arithmetic equations for (a) unaffected subjects and (b) females with FXS and during three-operand arithmetic equations for (c) unaffected subjects and (d) females with FXS. Reprinted from Rivera SM, Menon V, White CD, Glaser B, Glover G, and Reiss AL (2002) Functional brain activation during arithmetic processing in females with fragile X syndrome is related to FMR-1 protein expression. *Human Brain Mapping* 16(4): 206–218, with permission from Wiley-Liss, Inc.

FXS typically have speech and language difficulties, including articulation, rate, prosody, and tone problems. Speech is often rapid, cluttered, tangential, perseverative, and repetitive.

Executive functions include such processes as planning, initiation, inhibition, cognitive flexibility, behavioral and attentional regulation, working memory, and conceptual problem solving. Both males and females with FXS demonstrate deficits in executive functioning, and many studies have documented that problems in this domain are present even in comparison to IQ- and mental age-matched comparison groups. Furthermore, brain fMRI studies have been effective in demonstrating executive functioning deficits associated with FXS and, specifically, with *FMR1* gene expression. A notable example is a study of females with FXS that examined brain activation in response to a response inhibition, or 'go/no-go' task. The study found that subjects with FXS demonstrated less brain activation during the inhibition task as opposed to typical developing controls in several brain regions, including the supplementary motor area, anterior cingulate and midcingulate cortex, basal ganglia, and hippocampus. The most important finding demonstrated a strong association between FMRP expression and activation in the ventrolateral prefrontal cortex and the left and right striatum (**Figure 4**). Other fMRI studies have suggested that individuals with FXS have different neural processing organization but also posses the capacity to overcome executive functioning weaknesses by recruiting alternative brain regions to accomplish cognitive tasks in a compensatory fashion. These findings have been hopeful in terms of design of more targeted intervention to address deficit areas. These and other neurogenetic studies have been useful not only in understanding the brain basis of unique phenotypic features of FXS but also in shedding light on more common conditions such as attention-deficit/hyperactivity disorder (ADHD).

The Behavioral Phenotype

Although individuals with FXS may present with a wide range of behavioral and psychiatric difficulties, there are a number of symptoms that are very common and therefore are considered to be phenotypic of the disorder. These symptoms include inattention, hyperactivity, hand flapping, hand biting, poor eye contact, shyness, and other features of social anxiety, tactile defensiveness, aggression, and autistic behaviors such as social withdrawal, stereotypic speech, and gaze avoidance.

A number of studies have investigated the overlap between the behavioral symptoms of FXS and autism. An estimated 15% of females and 33% of males with FXS meet *DSM-IV* diagnostic criteria for autistic disorder, and the vast majority present with clinically significant symptoms on the autism spectrum – up to 67% of males and 23% of females. For example, many individuals have stereotypic behaviors such as hand flapping, whereas core social abilities are preserved and developmentally appropriate. These children are motivated to interact socially with others and recognize and respond to social and emotional cues from others. Obsessive–compulsive behaviors are also common and may co-occur with more significant autism symptoms. There is evidence that lower functioning individuals with FXS present with more significant autistic symptoms. Autism is not as common in females with FXS; however, social problems and anxiety are prominent. Screening studies show that approximately 2–6% of individuals with autism test positive for FXS; these studies have led to the recommendation that all males and females with autism be screened for the *FMR1* mutation with DNA testing. Interestingly, multiple studies have been unable to document an association between FMRP and autism in FXS, suggesting that environmental, modifying secondary genetic factors or function of genes regulated by FMRP might play a role. For example, work by our group documents that the serotonin transporter gene appears to modify behavioral phenotype expression in males with FXS. Furthermore, previous studies have shown that family environment effects are also associated with autism severity in males. Thus, although FXS is a single gene disorder with a well-described phenotype, it is becoming clear that considerable variability exists and that many environmental, genetic, and biological factors known to affect typically developing children also have a measurable impact on children with FXS.

Shyness and social anxiety are common features of FXS, and these symptoms can overlap with autism. Individuals often demonstrate signs of autonomic hyperarousal and panic symptoms when confronted by a change in usual routine, a novel social situation, or in larger social gatherings. Selective mutism is another manifestation of anxiety in FXS, and it seems to occur more often in girls. Classically, individuals with FXS, especially males, turn their heads and look away when introduced to others. Over time, the anxious responses to these stimuli often can lead to significant social withdrawal and isolation. There is also evidence that individuals with FXS demonstrate increased sympathetic nervous system responses to basic sensory stimuli. Aggression toward others and self-injury appear to occur following anxiety-provoking situations or in response to

Figure 4 Positive correlation between FMRP and go/no-go-related activation in females with FXS in the left dorsolateral prefrontal cortex (a), right ventrolateral prefrontal cortex (b), and basal ganglia (c). Negative correlation between FMRP and activation in the ventromedial prefrontal cortex (d). Reprinted from Menon V, Leroux J, White CD, and Reiss AL (2004) Frontostriatal deficits in fragile X syndrome: Relation to FMR1 gene expression. *Proceedings of the National Academy of Sciences of the United States of America* 101 (10): 3615–3620, with permission.

aversive sensory input. Some internalizing behaviors that are prominent in FXS are associated with elevated levels of the stress hormone cortisol. Interestingly, it was found that the glucocorticoid receptor mRNA is one of several mRNAs regulated by FMRP. Although multiple clinicians and investigators have emphasized the prominence of anxiety symptoms in FXS, the prevalence of full-blown anxiety disorders such as social phobia or obsessive–compulsive disorder among these individuals is unknown.

A number of empirical studies and clinical evidence suggest that hyperarousal and poor modulation of sensory input contribute to a number of behavioral difficulties in FXS, including aggression, social withdrawal, and some of the autistic symptoms. There are likely to be links between biological systems regulating stress, sensory processing, and hyperarousal and these social–emotional difficulties. For example, studies have shown that cortisol and sympathetic responses decrease following social gaze aversion in individuals with FXS. Males with FXS also have high and stable heart rates and poor vagal modulation of heart rate, further suggestive of autonomic dysfunction. One study showed that prepulse inhibition of startle, a measure of sensorimotor gating, was significantly impaired or completely abolished in males with FXS and highly correlated with IQ, adaptive behavior, autistic symptoms, and inattention (Figure 5).

Psychosis has not been carefully studied in FXS; however, general behavioral studies and clinical experience suggest that it is relatively uncommon. Schizotypal and paranoid features can develop in females and higher functioning males, for example, when social phobia and anxiety is especially pronounced. Identification of psychotic symptoms in FXS is especially difficult because of communicative problems and insight limitations, and classic behaviors related to FXS such as self-talk and unusual gesturing or hand mannerisms may be misinterpreted as evidence of hallucination.

Figure 5 Prepulse inhibition of startle (PPI) is disrupted in young males with FXS. (a) Mean PPI is shown for control (blue) and FXS (red) subjects. Scatterplot showing range of PPI scores in control (red) and FXS (blue) subjects. (b) Scatterplot of IQ vs. PPI magnitude for FXS subjects. Lower IQ scores were associated with reduced levels of PPI. (c) Scatterplot of attention scores vs. PPI magnitude for FXS subjects. Attention deficits were associated with reduced PPI. (d) Scatterplot of adaptive behavior scores vs. PPI magnitude for FXS subjects. Maladaptive behavior was associated with reduced PPI. (e) Scatterplot of autism scores vs. PPI magnitude for FXS subjects. Subjects scoring higher on the autism scale were more likely to have reduced PPI levels. (2004) Sensorimotor gating abnormalities in young males with fragile X syndrome and Fmr1-knockout mice. *Molecular Psychiatry* 9: 417–425, with permission.

Fragile X Premutation: Occasional Features of FXS

This article focuses on FXS who typically have the *FMR1* full mutation. Some clinical aspects of the fragile X premutation are reviewed here because an FMRP deficit, without methylation, can occur in individuals with high CGG repeats within the premutation range and because these individuals can present with features of FXS. The fragile X premutation is defined by CGG repeat expansions between 55 and 200. The premutation occurs more often than the full mutation, in an estimated 1/813 men and 1/259 women in the general population. Those with expansions approaching the full mutation range (upper 100s) may have decreased transcriptional efficiency leading to FMRP reduction without any methylation (Figure 6). In addition, increased *FMR1* mRNA, ranging from 2 to 10 times higher than normal, is present, which may lead to a toxic effect in the brain. Two conditions unique to the premutation population have been specifically attributed to the toxic effects of the premutation mRNA excess. A proportion of older

Figure 6 FMRP levels as a function of CGG repeat tract length. Molar ratio (mean and SE) of FMRP vs. number of repeats for 15 cell lines. The means and standard errors of each of the four groups are depicted on the left: normal (purple), intermediate (dark blue), premutation (light blue), and penetrant premutation (green) alleles. Reprinted from Kenneson A, Zhang F, Hagedorn CH, and Warren ST (2001) Reduced FMRP and increased FMR1 transcription is proportionally associated with CGG repeat number in intermediate-length and premutation carriers. *Human Molecular Genetics* 10(14): 1449–1454, with permission.

male and, less often, female carriers of the premutation develop the neurodegenerative disease FXTAS, a condition characterized by cerebellar ataxia, progressive intention tremor, and cognitive decline. A second condition thought to be caused by mRNA excess is premature ovarian failure, defined as the cessation of menses before the age of 40 years. This occurs in approximately 20% of female carriers, in contrast to 1% of the general population. The protein deficit found in some premutation carriers has been identified as the cause of clinical involvement similar to that in the full mutation, though less severe (Figure 1(c)). Most fundamentally, some of the same prototypical dysmorphology and behavioral features found in individuals with FXS full are found in an unknown proportion of premutation carriers with protein deficits. Finally, there are reports of children with the premutation having autism spectrum disorder (ASD), although the cause may be a combination of factors rather than a protein deficit alone. A study of non-clinic-referred children showed that 14% of males and 5% of females with the premutation were classified as having clinically significant symptoms on the autism spectrum. Indeed, recruitment bias problems in some of these studies have made it difficult to conclude with certainty that the premutation actually contributes to expression of autism. Carefully controlled studies are needed in this area to document the prevalence and molecular–biological mechanisms involved in expression of ASD symptoms in those with the premutation.

Summary

This article has summarized the primary physical, cognitive, and behavioral clinical features of. Because the brain and molecular genetic basis of FXS is relatively well understood through numerous human studies and animal models, it provides a useful model for understanding links between genes, brain, and behavior; specific conditions such as autism, ADHD, and anxiety disorders; and for testing pharmacological, behavioral, and gene therapies. For example, the discovery that *FMR1* knockout mice (the animal model for FXS) have enhanced long-term depression (LTD; weakening of synapses) in the hippocampus has led to a treatment model involving the role of a drug to block the metabotropic glutamate receptor that is critical in LTD and thereby mitigate symptoms of FXS. Some of the behavioral and physiological measures shown to be abnormal in patients with FXS may be useful in future clinical trials.

Developmental Synaptic Plasticity: LTP, LTD, and Synapse Formation and Elimination

D E Feldman, University of California at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Neural activity, in the form of spontaneously generated or sensory-evoked spiking, is required for early postnatal development of synapses and brain circuits. Neural activity drives two types of changes in developing glutamatergic synapses: physiological changes that alter the function of existing synapses, and morphological changes that alter synapse structure. Physiological changes include long-term potentiation (LTP) and long-term depression (LTD), which strengthen and weaken synapses, respectively. Structural changes include synapse formation and elimination, which change the physical wiring of developing circuits. Structural plasticity can also include changes in dendritic spines and axonal boutons, and large-scale changes in axonal and dendritic branch patterns.

Functional and structural plasticity are thought to be highly coordinated, so that activity drives physiological strengthening and anatomical stabilization of a subset of synapses, and weakening and physical removal of others. By selecting appropriate synapses to strengthen and retain, developmental synaptic plasticity leads to the emergence of optimized neural circuits. In mature animals, some of these developmental plasticity mechanisms are downregulated, but others are retained, and are thought to contribute to information storage and learning in adults.

Activity-Dependent Maturation of Glutamate Receptor Content

Immature glutamate synapses contain a different mixture of α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA), *N*-methyl-D-aspartate (NMDA), and kainate (KA) subtypes of ionotropic glutamate receptors than mature synapses. Glutamate receptor composition gradually matures during early postnatal development, as a result of activity-dependent synaptic plasticity, and this maturation contributes to developmental strengthening of synapses.

Three aspects of glutamate receptor maturation have been studied in detail:

- progression from 'silent' synapses to 'functional' synapses,
- insertion of AMPA receptors to strengthen synapses, and
- developmental maturation of NMDA and AMPA receptor subtypes.

'Silent' Synapses Containing Only NMDA Receptors

Many immature glutamate synapses exhibit NMDA receptor-mediated currents without any detectable AMPA receptor currents. These are termed 'silent' synapses, because they do not generate synaptic current when the postsynaptic neuron is at rest, as a result of the voltage dependence of NMDA receptors. Silent synapses are proposed to represent synapses that contain surface NMDA receptors, but no surface AMPA receptors, although alternate interpretations exist. Silent synapses are highly prevalent early in postnatal development, and are downregulated the first few postnatal weeks in many brain areas, as AMPA currents become more widely expressed (Figure 1).

Insertion of AMPA Receptors Converts Silent Synapses into Functional Synapses, and Is a Basic Mechanism for Strengthening Synapses

Strong, correlated firing drives LTP at silent synapses, which is manifest by the rapid appearance of AMPA receptor currents. This appearance of AMPA receptor currents renders silent synapses functional (nonsilent), and is due to activity-dependent insertion of AMPA receptors. Thus, the developmental loss of silent synapses is thought to reflect the gradual accrual of LTP by endogenous activity, which converts early, silent synapses into functional, nonsilent synapses by adding AMPA receptors. The trigger for LTP is calcium entry through NMDA receptors, which detect correlated pre- and postsynaptic firing. Silent synapses have therefore been proposed to represent 'test synapses' that remain nonfunctional unless correlated activity between pre- and postsynaptic neurons renders them functional. At many nonsilent synapses, LTP is also thought to involve insertion of AMPA receptors, which increases AMPA content of synapses and enhances the postsynaptic response to released glutamate. This process has been observed directly in developing cortical synapses, and can be driven by sensory experience. Thus, AMPA receptor insertion is a major means of synaptic strengthening during development.

Developmental Maturation of NMDA Receptor Subunits

NMDA receptors are heteromultimers of NR1 and NR2 subunits, of which four types exist (NR2A-D).

Figure 1 'Silent' synapses. (a) Newly formed glutamate synapses are a mixture of silent synapses, which contain NMDA receptors but not surface AMPA receptors, and standard functional synapses, which contain both receptor types. (b) Correlated activity drives LTP via insertion of AMPA receptors into silent synapses, either from subsurface stores (red) or extrasynaptic locations (blue). This causes silent synapses to become functional. Similar mechanisms act to strengthen previously functional synapses. (c) The proportion of silent synapses decreases during early development. Data are from dorsal horn of spinal cord, CA1 hippocampus, S1 cortex, and V1 cortex.

Immature synapses in neocortex and hippocampus express primarily NR1 and NR2B subunits, which produce long-lasting NMDA receptor currents. During the first few postnatal weeks, NR2A expression increases, resulting in NR2A-containing NMDA receptors that exhibit much shorter-duration currents. This developmental subunit switch is activity dependent, since sensory deprivation and activity blockade prevent the switch, while sensory experience hastens it. The functional importance of this subunit switch remains unclear, but one possibility is that faster NMDA receptor current kinetics enable faster temporal resolution for synaptic plasticity and information processing in mature versus developing circuits.

Changes in AMPA Receptor Subunits during Development

Developmental changes also occur in AMPA receptor subunits. AMPA receptors are composed of subunits GluR1–4, with GluR2 controlling calcium permeability of the AMPA receptor. Mature AMPA receptors contain GluR2 that has undergone RNA editing to make AMPA receptors calcium impermeable. In embryonic development, AMPA receptors lack GluR2, or contain an unedited version of GluR2, both of which render AMPA receptors calcium permeable. During the first two postnatal weeks, edited GluR2 becomes plentiful, and nearly all AMPA receptors on excitatory cells become calcium impermeable. This may serve to restrict calcium-dependent synaptic plasticity and alter information processing in mature networks.

LTP and LTD at Developing Excitatory Synapses

Developing synapses are capable of rapid, activity-driven changes in synaptic strength, including LTP and LTD. LTP and LTD are defined as a rapid, long-lasting increase or decrease, respectively, in strength of an existing synapse. LTP and LTD implement Hebbian plasticity, and are widely hypothesized to help mediate activity-dependent refinement of developing circuits.

The dominant theory is that initial synapses are generated relatively imprecisely, and that appropriate synapses are then strengthened by LTP, while inappropriate synapses are weakened by LTD, and ultimately eliminated. In support of this theory, initial glutamatergic synapses innervating a single postsynaptic neuron are often many and weak, and become fewer and stronger with maturation. This developmental refinement of connectivity occurs not only at glutamate synapses, but also at some inhibitory synapses, and at the neuromuscular junction. This synapse strengthening is hypothesized to reflect LTP at a subset of initially weak synapses, while the reduction in synapse number is thought to represent activity-dependent, anatomical withdrawal of selected synapses, perhaps following LTD (Figure 2).

LTP and LTD Occur Robustly at Developing Synapses

LTP and LTD appear to be near-universal properties of developing glutamate synapses (at least for synapses on excitatory neurons). LTP and LTD have been observed in developing neocortex, hippocampus, amygdala, striatum, spinal cord, nucleus accumbens, cerebellum, and other structures. LTP and LTD are often most robust during early critical periods of postnatal development. However, they can often still be induced, albeit sometimes with more difficulty, in adults. At many developing synapses, LTP is triggered by calcium entry via NMDA receptors, and involves

Figure 2 Synaptic refinement in developing networks. Immature networks are composed of weak, imprecisely targeted synapses. Many more presynaptic neurons synapse on each postsynaptic neuron than in mature circuits. During maturation, some synapses are eliminated, while others are strengthened and stabilized. This leads to the maintenance of fewer (sometimes only one), stronger inputs on each postsynaptic cell. Adapted from Hooks BM and Chen C (2006) A model for synaptic refinement in visual thalamus. In: Guido W, Erzurumlu R, and Molnar Z (eds.) *Development and Plasticity in Sensory Thalamus and Cortex*, pp. 226–244. New York: Kluwer/Plenum.

activity-dependent insertion of AMPA receptors, though other mechanisms also exist. LTD is more heterogeneous, existing in NMDA receptor-dependent and independent forms, and can involve either internalization of AMPA receptors or decreases in presynaptic release probability. The intracellular signaling mechanisms for LTP and LTD can be distinct in developing versus mature synapses.

Critical Periods for LTP and LTD during Development

LTP and LTD are often most robust, or entirely restricted to, specific critical periods of development. In sensory cortex, these critical periods for NMDA receptor-dependent LTP and LTD occur in the first postnatal weeks, and overlap with critical periods for experience-dependent plasticity of visual and somatosensory maps, suggesting that LTP and LTD may contribute to map plasticity (Figure 3). Why LTP and LTD are restricted to these early critical periods is not known. The developmental switch in NMDA receptor subunits, which coincides with the end of critical periods in some systems, does not seem to be the causative factor, because interference with this subunit switch in transgenic mice does not alter the critical period for LTP or experience-dependent plasticity. Another hypothesis, still unproven, is that GABAergic inhibition, which increases strongly during this same developmental period, prevents effective LTP induction.

Experience Drives LTP and LTD *In Vivo*

Studies have shown not only that developing synapses are capable of LTP and LTD, but also that sensory experience drives LTP and LTD at these synapses *in vivo*. For example, pharmacological or genetic blockade of LTP and LTD can interfere with experience-dependent map plasticity in developing somatosensory and visual cortex, suggesting that sensory map plasticity involves LTP and LTD. In addition,

Figure 3 LTP and LTD at developing synapses. (a, b) Examples of LTP and LTD in developing somatosensory cortex *in vitro*. LTP and LTD are apparent as rapid, long-lasting changes in the amplitude of excitatory postsynaptic current (EPSC) evoked by a single presynaptic spike. LTP and LTD were induced after a stable baseline period by correlated activation of pre- and postsynaptic neurons (black bars). (c) Critical period for LTP and LTD at thalamocortical synapses in somatosensory cortex. The critical period for LTP and LTD overlaps with the critical period for somatosensory cortex plasticity *in vivo*, measured by experience-dependent changes in whisker map anatomy or receptive fields. After Feldman DE, Nicoll RA, and Malenka RC (1999) Synaptic plasticity at thalamocortical synapses in developing rat somatosensory cortex: LTP, LTD and silent synapses. *Journal of Neurobiology* 41: 92–101.

sensory deprivation-induced LTD has been directly measured at specific cortical synapses, and sensory use has been shown to drive LTP by AMPA receptor insertion into synapses in somatosensory cortex. It is therefore widely assumed that during normal development, network activity drives LTP and LTD and that this contributes to developmental refinement of circuits and response properties.

Other Forms of Synaptic Plasticity during Development

Developing synapses also exhibit other forms of plasticity, besides LTP and LTD. One example is homeostatic synaptic scaling. Synaptic scaling acts on a slower timescale than LTP or LTD to maintain neural activity at a stable, set-point level. Thus, increased network activity drives slow, cell-wide decreases in excitatory synapse strength, and decreased network activity drives increases in excitatory synapse strength. Synaptic scaling occurs in developing sensory cortex *in vivo*, and has been proposed to function to maintain stable network activity in the face of developmentally changing input levels. Scaling has also been proposed to prevent instabilities inherent in Hebbian plasticity. Developing synapses also exhibit another form of slow plasticity, termed metaplasticity, in which activity patterns change the future ability of cells to undergo LTP and LTD.

Experience-Dependent Structural Plasticity at Developing Synapses: Synapse Formation, Elimination, and Morphological Change

Sensory experience and neural activity also alter the structure of developing synapses. Such structural plasticity includes synaptogenesis, synapse elimination, changes in the morphology of existing synapses and dendritic spines, and larger-scale changes in axonal and dendritic branch morphology. Structural plasticity can be quite rapid (on the timescale of minutes), and has been proposed as a major basis for experience-dependent developmental plasticity and information storage. A key question, currently unanswered, is how structural plasticity is related to functional plasticity like LTP and LTD.

During normal development, synapses are continuously formed, altered, and eliminated, as demonstrated by live, time-lapse imaging of axons, dendrites, and dendritic spines. This ongoing structural remodeling is strongly regulated by sensory experience and neural activity, suggesting that it represents experience-dependent synapse formation and elimination, and decreases markedly in the adult. Recent studies have begun to reveal how activity drives structural plasticity and how this guides development of functional connectivity in developing networks.

Three major features of structural plasticity have been investigated in detail:

- developmental changes in morphology of dendritic spines,
- relationship between structural plasticity of spines and LTP and LTD, and
- structural plasticity of axonal arbors.

Developmental Changes in Morphology of Dendritic Spines

Dendritic spines are the site of most excitatory synapses on excitatory neurons. The earliest dendritic spines are thin and highly motile filopodia, and carry synapses which are thought to dynamically sample the nearby neuropil for appropriate synaptic partners. As development proceeds, filopodia are replaced by less motile spines with large bulbous heads, that are thought to receive mature, stable synapses. Because filopodia and small spines often contain detectable NMDA receptors but not AMPA receptors, it has been proposed that these structures represent newly formed, 'silent' synapses, while larger spines represent mature functional synapses. During postnatal critical periods of plasticity, spine motility persists, and is likely to reflect ongoing synapse elimination and formation. Spine motility decreases with age, in parallel with the decreased capacity for plasticity in older animals (Figure 4).

Relationship between Structural Plasticity of Spines and LTP and LTD

LTP and LTD are not unitary processes, but consist of distinct early and late temporal components. Early theories proposed that rapid components of LTP and LTD represented purely functional synaptic changes (e.g., AMPA receptor insertion), without macroscropic structural correlates. Slower, long-lasting components (which were known to be dependent on protein synthesis) were proposed to reflect synapse formation or elimination. Time-lapse imaging of living spines has recently provided qualified support for this hypothesis. LTP causes a rapid increase in spine head size, particularly for small spines, followed later by formation of new spines, while LTD causes a rapid shrinkage of spine heads. These rapid changes in spine head size may be structural correlates of the earliest changes in synaptic strength, perhaps AMPA receptor insertion or removal, while new spine formation may be related to later components of plasticity. These findings support an emerging model that immature synapses on small spines (with few or no AMPA

Figure 4 Development of spine morphology. The earliest dendritic protrusions are highly motile, thin filopodia, which are thought to carry weak or silent synapses. During postnatal development, many filopodia are lost, and are replaced by spines. In juveniles, spines dynamically appear and disappear, perhaps reflecting activity-dependent synaptogenesis and synapse elimination. In mature animals, spines become morphologically stable and carry mature synapses. Dashed outlines indicate transient filopodia or spines.

receptors) are converted by LTP into functional synapses with a full complement of AMPA receptors, carried on larger spines. However, additional experiments are needed to test this model fully. In particular, direct evidence that synaptogenesis and synapse elimination contribute to late phases of LTP and LTD remains elusive.

Structural Plasticity of Axonal Arbors

A final question is how activity-dependent synaptic plasticity shapes larger-scale structure of neurons, including axonal and dendritic branch patterns. Studies of the developing retinotectal projection in *Xenopus laevis* have shed light on this issue. Retinal ganglion cells (RGCs) from each eye innervate the opposite optic tectum of *Xenopus* to form a retinotopic map. During retinotectal development, RGC axons and tectal cell dendrites are highly dynamic, adding and retracting small synapse-bearing branches continously. To determine how activity guides axonal development, a surgical manipulation has been used that forces both eyes to innervate a single tectum. This causes activity-dependent segregation of RGC axons into eye-specific territories within the tectum, reminiscent of ocular dominance columns in V1. Time-lapse imaging reveals that RGC axons from one eye form new synapse-bearing branches uniformly in both eye-specific territories, but that branches are preferentially stabilized in the territory dominated by the same eye, and are preferentially eliminated in the territory dominated by the other eye. This differential stabilization/elimination requires NMDA receptor signaling, suggesting that it is guided by Hebbian synaptic plasticity.

These findings indicate that during development, new synapses are formed everywhere, but are selectively retained only when NMDA receptor-dependent Hebbian processes determine that they are appropriate. This supports the common model that activity strengthens and stabilizes some synapses and their associated spines and axonal/dendritic branches, while others are weakened and eliminated, causing their spines and axonal/dendritic branches to be removed.

Summary: Toward a Comprehensive Model of Functional and Structural Synapse Development

Many questions remain to be answered about how activity guides development of glutamate synapses and networks. However, the existing literature, summarized above, suggests a unified model for development of synapse function and structure. In this emerging model, many initial glutamate synapses are weak or silent, and contain an immature complement of glutamate receptors including NMDA receptors but few or no AMPA receptors. These immature synapses are carried on highly motile small spines or filopodia, which sample surrounding neuropil searching for appropriate synaptic partners. During development, activity causes glutamate receptor subtypes to mature. A subset of synapses will experience correlated pre- and postsynaptic firing, which activates NMDA receptors and drives synapse strengthening via Hebbian LTP, due in part to insertion of AMPA receptors. Synapse strengthening also causes structural maturation of spines, making them larger and less motile, and stabilizes the axonal and dendritic branches bearing these 'effective' synapses. Unreinforced, 'ineffective' synapses may be weakened by LTD, structurally destabilized, and removed.

In this model, activity engages Hebbian synaptic plasticity rules to both regulate synapse strength and to guide the formation of mature synaptic morphology and circuit-level connectivity. This allows initial networks comprised of many weak, imprecisely targeted synapses to be refined into

networks built from a smaller number of strong, appropriately targeted synapses.

Introduction

The aim of this article is to present our understanding of how the abnormalities in peripheral glucose control and elevations in cortisol levels associated with type 2 diabetes mellitus (T2DM) may give rise to medial temporal lobe (MTL) pathology and dysfunction. The article falls into four main sections: Memory and aging, effects of glucocorticoid functioning on the brain, impact of diabetes on the brain, and, finally, an integrative model that attempts to explain how the specific MTL dysfunction may come about. First, we give a brief introduction on normal and pathological changes in the aging brain before we explain how hypothalamic–pituitary–adrenal (HPA) axis functioning, that is, cortisol secretion and control, can affect brain and cognition. Next, we summarize evidence that insulin resistance and type 2 diabetes can contribute to a reduced integrity of the MTL memory system. In this context we highlight the multiple interactions between the glucoregulatory system and the neuroendocrine stress system. The last section presents an explanatory model of how we conceptualize the above-mentioned processes give rise to the MTL impairments, and provides a framework for the generation of specific hypotheses for future research in this area.

Memory in Aging: Normal Changes, Mild Cognitive Impairment, and Dementia

Cross-sectional studies of human aging have consistently reported that, relative to younger individuals, normal elderly show performance reductions in memory, attention, visual–spatial function, abstraction, and problem solving. Longitudinal studies provide a refinement by demonstrating that over time the most salient declines are in tests sensitive to frontal lobe function, namely working memory (requiring the short-term storage and manipulation of information prior to responding), psychomotor efficiency, word knowledge, attention, learning, and problem solving. Although the majority of this literature suggests that most cognitive deficits are related to frontal dysfunction, some research suggests that MTL, which includes structures such as the hippocampus, amygdala, and entorhinal cortex, may also be involved. In normal aging cognitive deficits do not generally result in impairments in everyday functioning.

Memory impairments have been recognized for many years as the most reliable early clinical symptom in dementia of the Alzheimer's type, and both the pathology – namely the distribution of neurofibrillary tangles (one of the two types of brain pathology that are necessary for a brain diagnosis of Alzheimer's disease (AD)) – and the *in vivo* imaging literature indicate that the earliest lesions are in the MTL. In addition, among elderly individuals who demonstrate subtle impairments in functioning and who may be considered at higher risk for significant cognitive decline and AD, those who have so-called mild cognitive impairment (MCI), demonstrate predominantly MTL pathology in the earliest stages of cognitive deterioration. With that being said, most middle age and elderly individuals who present with memory and other cognitive impairments, but with no impairments in overall functioning, will not go on to develop dementia.

Links between Diabetes and Dementia

There is evidence from longitudinal population-based studies that the risk of dementia is higher among individuals with diabetes than among those without it. The risk seems to be higher for individuals with the Apo E ε 4 genotype or receiving insulin treatment. The Apo E gene, which has a polymorphic distribution in the population, codes for a protein that is important in lipid transport and metabolism. Individuals with one or two copies of the Apo E ε 4 allele have a higher risk for cardiovascular disease. However, findings have been inconsistent as to whether this increased risk is specific for AD, multi-infarct dementia (MID), or dementia in general. Although the associations between diabetes and dementia are intriguing, none of these studies has directly assessed the impact of T2DM-related factors. For example, the impacts of hypertension and cardiovascular disease, conditions associated with T2DM, cognitive decline, and dementia, have not been evaluated. Although diabetes is often associated with vascular pathology ranging from micro-vessel disease to hypertension and stroke, studies to date have not provided sufficiently detailed data on those diabetes-associated factors to better ascertain how they may mediate or modulate the risk for dementia associated with diabetes.

The magnitude of the risk for AD related to diabetes is only modest and smaller than that of some nonspecific risk factors, such as low education or history of head trauma. It is possible that the impact of diabetes, analogous to that of low education and head trauma, is to reduce the brain reserve of affected individuals, and thus the associations observed between diabetes and AD may also be nonspecific. This position is supported by the extant pathology literature. Out of the autopsy series available, most fail to find increased Alzheimer's pathology in those individuals with diabetes (with some studies actually finding reduced AD pathology among diabetics), and only one series found a nonsignificant increase among Apo E ε 4 diabetics. However, based on indirect evidence some investigators have speculated that diabetes may be 'mechanistically' linked to AD. This hypothesis is based on observations that insulin acutely enhances memory in healthy older subjects, but is less able to do so in AD patients. In addition, insulin might increase levels of inflammatory cytokines and amyloid beta in the brain. Future research will test these hypotheses.

The Impact of Cortisol on Cognition and the Brain

Stress is conceptualized as a perceived challenge to the organism's balance or homeostasis, and the resulting processes intended to return the organism to equilibrium are termed 'allostasis.' The most prominent of these processes is the activation of the HPA axis. This activation results in the release of glucocorticoids (GCs) and the activation of the sympathetic nervous system (SNS), leading to the release of catecholamines (epinephrine and norepinephrine). In the presence of an acute stress these responses protect and allow the organism to adapt to its changed internal or external environment. However, when the stress becomes chronic or the organism responds inappropriately (e.g., poor habituation or a failure of negative feedback), multiple systems, including the brain, are negatively impacted. This state has been called 'allostatic load.'

GCs, depending on their timing, can have positive or negative acute effects on memory. For example, stress (or an acute increase in GCs) during learning, or immediately thereafter, leads to enhanced memory consolidation. In contrast, an equivalent rise in GCs shortly before delayed retrieval causes impaired retrieval. Animal and human studies suggest that both the positive and negative GC effects are mediated by interactions between amygdala and hippocampus, two limbic structures central in emotional processing and memory formation.

Chronic stress leads to negative consequences in both animals and humans. In animals, chronic stress causes structural alterations of neurons (dendritic atrophy or dendritic remodeling) in hippocampus and prefrontal regions. In addition, stress negatively impacts neurogenesis and alters cholinergic, serotonergic, and dopaminergic systems. These changes are associated with impaired memory performance, although the mediating mechanisms remain unclear. For example, both rats and tree shrews subjected to repeated stress develop impairments in hippocampal-based memory tasks. In contrast, amygdala-mediated tasks, such as fear conditioning, are enhanced. Age affects the organism's response to stress. Although there is large individual variability, aged individuals have increased GC levels as well as impairments in HPA axis negative feedback, both of which have been associated with cognitive impairments. For example, rodents with age-associated increases in HPA activity had impairments in memory performance, whereas those with normal levels did not. Moreover, pharmacological or behavioral interventions that stabilized HPA activity throughout life offered protection from those age-associated memory problems.

In the human, conditions leading to substantially elevated cortisol levels are characterized by impairments in memory, attention, and mood. For example, the hypercortisolemia present in Cushing's disease is associated with reductions in memory performance and hippocampal atrophy, deficits that are at least partly reversible upon successful reduction of the supraphysiological cortisol levels. Elevations in basal GC levels within the normal range have also been associated with cognitive dysfunction; older individuals with higher cortisol levels show poorer memory and faster cognitive decline. However, the causal order of these associations remains unsettled. The behavioral impairments may be secondary to cortisol-induced hippocampal atrophy. However, given the importance of the hippocampus on cortisol feedback inhibition, the cortisol elevations may be the result rather than the cause of hippocampal atrophy. Nevertheless, some recent studies offer indirect support for primacy of cortisol elevations leading to hippocampal damage. For example, self-reported stress proneness is associated with an increased risk for dementia, a disease that involves hippocampus and other MTL structures in its initial stages. Further indirect support is offered by the finding that individuals with genetically determined increases in tissue GC bioavailability have a higher risk for AD.

HPA axis dysregulation, in addition to possible direct effects on the hippocampus, may affect memory through its impact on other related systems also known to affect memory. For example, GCs can

impair insulin sensitivity or lead to enhanced visceral fat deposition and altered food intake, which in turn can lead to problems with glucose control, conditions known to be associated with reductions in memory performance. Interestingly, the adverse consequences of stress on the hippocampus occur faster in diabetic animals, suggesting an increased vulnerability of the diabetic brain. The interactions between the HPA axis and the glucoregulatory system will be illustrated in the following section.

Interactions between Cortisol, Insulin Function, and Type 2 Diabetes

Research conducted during the past decade has demonstrated that the HPA axis and the glucoregulatory system interact at multiple levels. Examples can be found for interactions at the behavioral and system level as well as on particular aspects of neuronal or transporter functioning.

Cortisol secretion and peripheral glucose regulation are closely linked. For example, we know that physiologically increased cortisol acutely inhibits insulin release, and that pharmacological doses of GCs cause reductions in glucose disposal (insulin resistance). In addition, in animal models GCs reduce the amount of insulin transported across the blood–brain barrier (BBB), and in large doses inhibit neuronal and glial glucose uptake in the hippocampus but not in other brain regions (e.g., hypothalamus, cerebellum, or cortex). Similar effects have been noted in the human; we have shown that acute cortisol administration leads to a specific *in vivo* hippocampal reduction in glucose utilization as seen with positron emission tomography. It is noteworthy that the hippocampus is the brain area with greatest co-localization of cortisol and insulin receptors. It is possible that the GC-mediated reductions in memory performance are due to their impact on hippocampal energy status.

Chronic stress in animals leads to effects at a behavioral level. Investigators have documented that chronic stress, through a facilitating effect on the HPA axis, leads to changes in eating habits. These animals seek more 'comfort' food and the GC elevations promote visceral fat deposition. In the human, chronic stress, with the associated hyperactivity of the SNS and HPA systems, can lead to the metabolic syndrome, which is characterized by central obesity, impairments in glucose regulation, hypertension, and abnormal lipid profiles.

Problems with peripheral glucose control may potentiate the deleterious effects that cortisol exerts on the brain. For example, when diabetic rats are stressed, they develop extensive hippocampal damage in one-third the time it takes nondiabetic animals to develop equivalent stress-mediated damage. It has also been shown that diabetic rats have chronic elevations of basal GCs and have greater and more prolonged responses to stress. We also know that reduced hippocampal integrity may lead to impaired cortisol feedback inhibition, and thus to elevated cortisol secretion. Adding support to the notion that the stress and the glucoregulatory systems interact in their influence of cognition during aging are observations from the MacArthur Study on Successful Aging. These investigators reported that summary measures of allostatic load, consisting of a combination of stress hormone measures and metabolic syndrome measures, were a superior predictor of cognitive and functional decline in older individuals.

Although it is difficult to ascertain cause and effect, it may be that abnormal glucose tolerance causes hippocampal dysfunction, which then affects cortisol feedback control, which in turn may result in elevated cortisol levels, thus contributing to a vicious cycle of further hippocampal damage.

Impact of Diabetes on the Brain

Neurons neither synthesize nor store glucose and are hence dependent on external sources to meet their energy demands. For a long time it was thought that the brain sat in a privileged position and that its glucose supply was independent of what was happening in the periphery. Only in recent years has this view changed, and it has become apparent that glucose transport into the brain is affected by the peripheral environment and that insulin, insulin receptors, and insulin-sensitive glucose transporters (GLUTs) are all present in brain, although their function remains unclear.

Under normal physiological circumstances the metabolism of glucose borne by the blood accounts for 99% of the brain energy needs. Although glia and astrocytes contain glycogen, the contributions of this glycogen to the overall energy demands of the brain are not known. (Note: It is our opinion that understanding the role of glycogen in brain will be an area of great interest in the near future. This opinion is based on the fact that upon restoration of euglycemia after an episode of hypoglycemia, glycogen deposition in brain goes up markedly, perhaps protecting the brain from subsequent hypoglycemic episodes. In addition, experimental animals subjected to weekly episodes of significant hypoglycemia perform better than sham animals on memory tests during euglycemia, and this improved memory performance is preserved in these animals in old age. Whether these memory-enhancing and protective effects are due to hypoglycemia-based improved transport of glucose

across the BBB or to increased deposition of brain glycogen, or both, has yet to be established.)

Despite the fact that the brain depends on peripheral glucose, up until 10 years or so ago, it was commonly believed that the brain was able to obtain all the metabolic substrate it needed, irrespective of what was happening in the periphery. Although the transport of glucose across the BBB remains poorly understood, we now know that the peripheral environment can exert significant influences on BBB transport. For example, the BBB glucose transporter can be up- or downregulated, dependent on the sustained peripheral glucose levels. Additional potential links between systemic and brain glucose control and metabolism are offered by the presence of insulin and insulin-sensitive glucose transporters (GLUT4) in the brain. In peripheral tissues insulin regulates glucose homeostasis through effects on GLUT4, the glucose transporter highly expressed in fat and muscle. GLUT4 is also expressed in brain, including the hippocampus. However, it is not known if insulin affects glucose uptake into the hippocampus. Moreover, it remains to be seen how brain GLUT4 behaves in a state of peripheral insulin resistance. Regardless, it is clear is that glucose uptake and utilization in the brain are complex and that their regulation is yet to be understood.

Because impaired insulin function (or absence of sufficient insulin) and the resulting hyperglycemia are at the core of diabetes, it is likely that these fluctuations will have an impact on the brain and its functioning. There is mounting evidence that diabetes, whether it is type 1 or type 2, has a negative impact on both cognition and brain. However, the resultant adverse effects may vary by the type of diabetes. A straightforward assessment of the differential impact of type 1 and type 2 diabetes on cognition and brain is complicated by the fact that most studies only contrast one type of diabetic patient against controls and do not control for comorbid conditions or possible mediating factors such as hypertension, vascular disease, and depression, which are often associated with diabetes.

Adults with type 1 diabetes mellitus (T1DM), when contrasted to nondiabetic controls, show reduced performance on several cognitive domains, including psychomotor efficiency, intelligence, visual and sustained attention, and speed of information processing. The majority of studies of adults with T1DM demonstrate that the presence of macrovascular disease, but not glycemic control or the number of hypoglycemic episodes, contributed to the lower cognitive performance described. Cognitive deficits are also observed in children and adolescents with T1DM, but there's no consensus in the literature as to whether age of onset or disease duration affects the severity of those cognitive deficits. Furthermore, it remains unclear whether the cognitive impairments worsen with age. In addition, the nature of the impact on cognitive functioning of episodes of either hypoglycemia or hyperglycemia remains unclear. Different studies have evaluated study participants of various ages and have used different test batteries, which do not permit a straightforward comparison across studies.

In contrast to the findings in T1DM, studies of T2DM show mostly impairments in verbal memory and processing speed, whereas other cognitive domains, such as visuospatial function and attention, remain preserved. There is also evidence that in T2DM, glycemic control might influence the cognitive deficits; improvements in glucose control by either pharmacological or behavioral interventions have been associated with attenuation of the cognitive deficits. Additionally, cognitive deficits seem to be augmented by factors associated with T2DM, such as hypertension, depression, and vascular disease. Some studies suggest that severe memory impairments are only seen in older T2DM populations and that the cognitive deficits seen in T2DM represent an acceleration of normal brain aging.

There are only a few *in-vivo* imaging studies in diabetes, and existent studies have not contrasted T1DM and T2DM. The overall findings are that type 1 diabetes leads to general brain atrophy, whereas T2DM seems to preferentially involve MTL structures, and that these findings may be independent of vascular complications. In our own work we have demonstrated that among relatively young individuals with well-controlled T2DM, only reductions in memory, performance, and hippocampal volume separate them from age-, gender-, and education-matched normal controls. In addition, we have described very similar cognitive and imaging findings among normal middle-aged and elderly nondiabetic individuals with impairments in glucose tolerance. Few studies evaluate the brain in T1DM, and there is only one study of adults with T1DM that looked at both cognition and brain with magnetic resonance imaging (MRI). One small pilot study in adults with longstanding T1DM observed reductions in psychomotor speed and selective attention which was accompanied by global cerebral atrophy (increase in cerebrospinal fluid and decrease in total brain volume). However, no evidence for hippocampal volume reductions and memory impairments were detected.

In recent years, paralleling the obesity epidemic, the prevalence of T2DM within the population has risen even among children and adolescents. To date there are no reports in the literature evaluating cognition and brain status among children with

T2DM. Preliminary pilot data from our group shows widespread cognitive impairments among obese adolescents with T2DM when contrasted with age-, gender-, and education-matched obese controls.

The precise mechanisms by which diabetes and impaired glucose regulation affect memory are not clear, but the risk factors that are often associated with insulin resistance and that are part of the metabolic syndrome, namely hypertension and dyslipidemia, might play a role. In the next section we outline a model of how diabetes directly affects brain structures that are central for memory process, that is, the hippocampus.

Possible Mechanisms for the Cognitive Impairments Seen in T2DM

Glucose is transported across the BBB by GLUT1, a glucose transporter highly expressed in the vascular endothelial cells of the BBB. Although the regulation of glucose transport into the brain is not well understood, GLUT1 has very high affinity for glucose and is saturated at normal blood glucose levels. Previous work in animal models has established that long-term elevations in peripheral glucose result in decreased transport of glucose across the BBB, whereas the opposite is true for chronic hypoglycemia, in which there is an increase in transport across the BBB. In both these circumstances it is believed that the amount of GLUT1 expressed at the BBB is responsible for the changes in glucose transport.

During brain activation, there are measurable shifts in the local concentrations of available glucose. For example, visual stimulation reduces visual cortex glucose concentrations as seen with MRI-based spectroscopy. Brain glucose levels can be measured directly with microdialysis probes in free-moving rats. Using these techniques there is evidence that glucose is compartmentalized in brain, and that different brain areas control their glucose levels locally. For example, glucose drops are restricted to the hippocampus when the animal is performing a memory test, and are present despite constant peripheral glucose levels.

The BBB glucose transporter, GLUT1, is saturated at normal physiological glucose concentrations. Therefore, to acutely increase net glucose flux across the BBB, the number of GLUT1 proteins exposed to the blood must be increased. Dilatation of the capillary bed will expose more endothelial cells, with their corresponding GLUT1, to the blood, and thus increase the acute transport of glucose into the brain. However, the mechanisms responsible for regulating the rapid changes in local blood flow that are associated with brain activation are not yet well characterized. What is currently well described is that both individuals with T2DM and individuals with insulin resistance short of diabetes show impairments in endothelial-dependent vasodilatation. Consequently, given that cognitive testing leads to activation (and drops in the interstitial glucose levels in the areas activated), this endothelial dysfunction may lead to a 'functional hypoglycemia' and contribute, at least in part, to the cognitive deficits associated with diabetes and insulin resistance.

It is not known whether elevated cortisol levels affect glucose transport at the BBB (Figure 1). However, we know from animal studies that glucocorticoid exposure inhibits glucose transport into hippocampal neurons and glia. We also know that individuals with T2DM (and insulin resistance) have abnormalities in the HPA axis, particularly in feedback control. Consequently, we propose that, analogous to the reduced ability to locally increase glucose flux across the BBB with activation due to the reduced vascular reactivity in T2DM and insulin

Figure 1 Representation of the blood and the brain compartments separated by the BBB. The green trapezoids represent the GLUTs. Reduced glucose transport across the BBB (step 1) and/or into the cells in the hippocampus (step 2), particularly during activation, may result in functional hypoglycemia and impaired memory performance. The sections of the bidirectional arrows pointing to the down red arrows represent known negative influences on glucose transport, and those pointing to the question marks represent a proposed negative influence that remains to be shown.

resistance, among individuals with elevated cortisol levels, there may also be a 'functional hypoglycemia,' this time at the neuronal level, also contributing to the cognitive deficits.

We propose that although this aggregate 'functional hypoglycemia' may be widespread in the brain, its damaging consequences may be at first more apparent in the hippocampus because of its high vulnerability to damage from hypoglycemia or other noxious influences. This hypothesized chronic low-grade 'functional hypoglycemia' may, in the long run, lead to hippocampal damage and volume loss.

It is also possible that chronic hyperglycemia is toxic to the microvascular endothelial cells, thus impairing transport of glucose across the BBB. Also, chronic hyperglycemia may be toxic to hippocampal cells directly by the increased production of damaging oxidative species resulting from increased metabolism based on increased intracellular glucose. However, this model, proposed by Brownlee to explain the tissue damage resulting from diabetes, does not offer an explanation for the damage associated with milder forms of insulin resistance, when glucose levels are still normal and there is only an elevation in fasting insulin levels. Future research will need to approach the problem more comprehensively, by evaluating multiple systems in the same individuals so as to better determine the relative contribution of each in the phenomenology expressed.

Summary

Americans are living longer, which has contributed to the rising rate of age-associated diseases such as type 2 diabetes and dementia. This, coupled with the epidemic of obesity in industrialized nations, which will further add to an increasing number of T2DM cases within the overall population, makes improving our understanding of how type 2 diabetes affects the aging brain indispensable. In this article, we have reviewed the existing literature on brain aging, diabetes, and the stress regulatory system. There is increasing evidence that dysregulation of the stress and glucoregulatory systems interacts at multiple levels to exert a negative impact on human health in general, and on the aging brain in particular. Although a consensus has not yet gelled within the literature on the exact brain areas affected by the dysregulation of those systems, it is now clear that the MTL is likely the major brain region affected. Within the MTL, the hippocampus, a structure crucially involved in recent memory, appears to be particularly sensitive to these neuroendocrine abnormalities. Since MTL atrophy is also of relevance for MCI and AD, this might explain some of the recently reported associations between dementia and type 2 diabetes. An enhanced understanding of the underlying pathological processes will allow the development of behavioral and pharmacological approaches targeted to protect the integrity of the hippocampus in older individuals. But there is much work to be done and additional progress in this research area is clearly warranted.

Diabetic Neuropathy

H C Powell and A P Mizisin, University of California at San Diego, La Jolla, CA, USA

© 2009 Published by Elsevier Ltd.

Although conventional medical treatment of diabetes mellitus markedly prolongs life, chronic long-term complications involving blood vessels, kidneys, eyes, and nerves affect a large proportion of the more than 10 million people believed to have diabetes in the United States. The frequent occurrence of neurological complications in diabetic patients likely contributed to the erroneous belief held by nineteenth-century physicians that diabetes was a primary disorder of the nervous system. Although peripheral neuropathy remains the major neurological complication of diabetes mellitus, the impact of this endocrine disturbance affects all parts of the nervous system and findings involving the central nervous system have become the focus of increased attention. Mild cognitive impairment and increased susceptibility to Alzheimer's disease are increasingly recognized manifestations of neurological dysfunction in diabetes mellitus. Furthermore, vascular disorders historically linked to kidney, retinal, and nerve complications are now implicated in cerebrovascular disease and stroke etiology in diabetes mellitus. Similar to renal and ocular complications, central and peripheral neural deficits represent major complications of both insulin-dependent (type 1) and noninsulin-dependent (type 2) diabetes mellitus, as well as in diabetes associated with nonalcoholic pancreatic disease, hemochromatosis, and pancreatectomy.

Clinical Overview

Epidemiology

Estimates of the prevalence of neuropathy in the diabetic population are varied and range from 5% to nearly 60%. A lack of agreement as to what constitutes diabetic neuropathy has no doubt contributed to the varied estimates of its prevalence. Indeed, subclinical features of neuropathy can be demonstrated by electrophysiologic tests in nearly every diabetic patient. Both the prevalence and the incidence of neuropathy increase with the duration of diabetes, suggesting a relationship to hyperglycemia or metabolic consequences of hyperglycemia. Information about the geographic distribution of diabetic neuropathy is incomplete and available only from areas where epidemiologic surveys have been conducted, namely North America, Western Europe, Scandinavia, and Nigeria.

Classification

Attempts to classify the types of diabetic neuropathy have been hampered by an incomplete knowledge of pathogenic mechanisms, the diverse neuropathic manifestations observed, and the fact that mixed forms of neuropathy are often encountered. Nevertheless, classifications are clinically useful because individual syndromes occur with sufficient frequency and because classification may help to better predict the natural history and outcome of diabetic neuropathy and, therefore, guide treatment. Although various classifications have been proposed, a simple scheme based on the symmetry of the neuropathy and the type of nerves involved is shown in Table 1.

Somatic and autonomic peripheral nervous system manifestations The most common diabetic neuropathy is a symmetric, predominately sensory, neuropathy that affects the distal regions of the lower limbs first, gradually spreads proximally, and later similarly affects the upper limbs. Symptoms include paresthesias, numbness, and, in some patients, burning and lancinating pain in the lower limbs. Once established, sensory diabetic neuropathy is persistent even if hyperglycemia is controlled.

Acute painful diabetic neuropathy is an infrequent syndrome that often follows precipitous weight loss. Patients with this neuropathy experience unremitting, burning pain in the lower limbs. Cutaneous hyperesthesia that results from contact with clothing or sheets is especially troublesome to these patients. Their symptoms often resolve over the course of a few months, after weight gain accompanying diabetic control.

Severe autonomic neuropathy is rare in diabetic patients, and symptoms usually occur in conjunction with a distal symmetric sensory neuropathy in insulin-dependent diabetes mellitus. A wide variety of symptoms affecting all aspects of autonomic function can be present, including heart rate abnormalities and postural hypotension; distal anhidrosis and gustatory sweating; diabetic diarrhea and gastric, duodenal, and colonic atony; bladder atony and impotence; disturbances of respiratory control; and unawareness of hypoglycemia. Once established, autonomic neuropathy is usually irreversible.

A poorly reversible symmetric lower limb motor neuropathy is sometimes present in older diabetic patients, often accompanied by a distal sensory neuropathy. Proximal lower limb neuropathy can have the natural history of an acute or chronic inflammatory polyradiculoneuropathy. The disorder tends to be
